#### INTRODUCTION

Osteoarthritis (OA) is a highly prevalent joint disease and a leading cause of disability. Diagnosis and monitoring of OA progression is usually determined using radiographs, computer tomography and magnetic resonance (MR) imaging. Among these modalities, MRI has shown excellent capability in imaging soft tissues and has been used to quantify cartilage morphology [1]. Three-dimensional (3D) cartilage models reconstructed from plain MR images can provide important quantitative information on articular cartilage surface area, thickness and volume. However, there remains a need to evaluate the factors influencing the *in vivo* accuracy of MRI derived geometry. The purpose of this study was to test the accuracy of articular cartilage thickness measurement from MR images by using a 3D laser scanner.

#### METHODS

Data was obtained from two total knee replacement (TKR) patients (age 79 and 82, both male) after IRB approval and informed consent were obtained. Prior to TKR surgery, MR images of the knee were acquired using a 1.5T GE Signa Scanner (GE Healthcare, Milwaukee, WI). We used a 3D spoiled gradient echo sequence in the sagittal plane with fat-saturation, TR=60ms, TE=5ms, flip angle=40°, matrix 256x256, rectangular field of view 140x140mm, slice thickness 1.5mm, 60 slices. Tibial articular cartilage in the MR images was segmented and reconstructed into 3D surface models using custom software [2].

After TKR surgery, the entire resected tibial plateau was immediately taken into the laboratory to measure the actual shape of the cartilage using a 3D laser scanner (Model-15, Cyberware, Monterey, CA). This scanner has an average accuracy of 50-200  $\mu\text{m}$  [3]. The cartilage surface was properly coated using a powder spray of negligible thickness to prevent laser scan error due to optical properties of the cartilage before acquiring the 3D surface shape of the cartilage [4]. After laser

**Figure 1:** Tibial cartilage thickness maps of the first subject calculated using (a) MRI and (b) 3D laser scan.

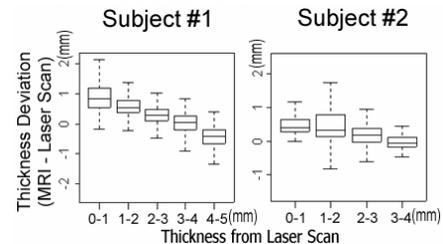

scanning, the articular cartilage on the tibial plateau was removed using a 6.0% sodium hypochlorite solution. A second laser scan was then performed to obtain the 3D surface of the subchondral bone.

Data from the laser scans obtained before and after articular cartilage removal were then aligned and combined to estimate the true articular cartilage thickness.

Thickness maps were calculated for both 3D cartilage models, one from MR images and the other from 3D laser scans, by calculating the Euclidean distance between cartilage surface and bone-cartilage interface surface, and encoded on the

surfaces of the models. The two models were aligned and projected onto a plane as shown in Fig. 1 to compare thickness measurements across the entire surface.

#### RESULTS AND DISCUSSION

**Figure 2:** Comparison of thickness measurements for the tibial cartilage between 3D models from MR images and laser scan data. The graphs in the lower rows show the deviation of the MR-based cartilage thickness measurement from the laser scan-based measurement.

The correlation coefficients ( $R^2$ ) between the thickness measurements from the MR images and the 3D laser scan were 0.7463 ( $p < 0.001$ ) and 0.7068 ( $p < 0.001$ ) for the first subject and the second subject, respectively. The deviation graphs show that MR will overestimate the true thickness of articular cartilage for thin cartilage (<3mm).

This result is consistent with other studies [4]. The high voxel anisotropy caused by a through plane resolution of 1.5mm vs. in-plane resolution of 0.6 mm has the effect of over-estimating cartilage thickness in regions of thin cartilage.

#### CONCLUSIONS

Cartilage thickness measurements from MR images have a good correlation with the measurements from laser scan data that best estimate the actual thickness. Thin cartilage less than 3mm has an inclination to be overestimated in MR images with high voxel anisotropy. This result has important implications for protocol design in longitudinal studies that follow cartilage volume and thickness with MRI.

### INTRODUCTION

The human foot is a complex, multifunctional system that serves as the primary physical interaction between the body and the environment during gait and understanding the impact mechanics during human motion is important for research in motion analysis and footwear design. Many fundamental and applied human motions are influenced by complex deformations, internal stresses and shock waves of the foot skeletal system but it is difficult to directly examine the relationship between foot structure and function *in vivo*.

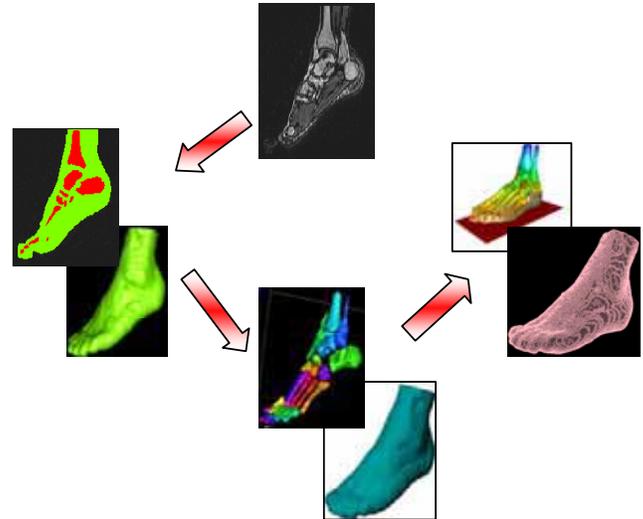

A new technique is emerging in the advancement of motion analysis and image processing. The ability to automatically convert any 3D image dataset into high quality meshes, is becoming the new *modus operandi* for studying the mechanical loading of complex structures. Novel proprietary techniques have been developed for the automatic generation of volumetric meshes from 3D image data including image datasets of complex structures composed of two or more distinct materials at resolutions down to the sub-micron level. The techniques guarantee the generation of robust, low distortion meshes from 3D data sets for use in finite element analysis (FEA). Such a model could generate simulations of normal and pathological foot behaviour.

The purpose of this study was to develop a complex skeletal model for finite element analysis of physical exercise, sports injury and footwear design.

### METHODS

Magnetic Resonance Image (MRI) scan data was obtained from the Medical Physics department of the University of Exeter. The original scan had a plane resolution of 0.75mm and a slice-to-slice separation of 0.75mm. A first generation finite element (FE) model of the foot, that had been preliminarily validated against cadaveric data, was developed (Figure 1) using an in-house software package, Scan IP™ [1]. The model consisted of 26 foot bones (including the distal tibia and fibula), 51 ligaments (including the plantar aponeurosis) and the plantar soft tissue (flesh).

Material properties of each tissue structure were assigned to the model and appropriate loading conditions according to the mass of a 70kg human, were introduced thus imitating the impact of the weight on the articulations.

**Figure 1:** Development of the model from MRI scan to numerical (FE) model

### RESULTS AND DISCUSSION

The aim of the study was successfully achieved in the development a high quality, complex mesh of unprecedented sophistication for use in FE analysis. The model is true to form and patient specific which opens the door to a vast array of applications in biomechanics. Parametric analyses can be performed to explore the function of different regions of the foot. Various treatment strategies could be simulated to quantify their efficacy in treating foot pathology. In addition to the obvious potential for sports injury and physical exercise analysis, it leads the way to mass customization of subject specific products such as running shoes or football boots.

## THE ACCURACY OF SURFACE MEASUREMENT FOR OSTEOPOROTIC SPINE MOTION ANALYSIS

ZY Yang, LW Sun, JF Griffith, PC Leung, <sup>1</sup>Raymond YW Lee  
 Department of Rehabilitation Sciences,

The Hong Kong Polytechnic University, HKSAR, China

<sup>1</sup>Corresponding author, email: rsllee@polyu.edu.hk, web: <http://www.rs.polyu.edu.hk/rlee>

### INTRODUCTION

The surface method of measuring lower thoracic and lumbar spine motion with Fastrak<sup>®</sup> was examined for validity. There is an increasing awareness of the health risks of exposure to radiation associated with repeated radiographic assessment of spinal curvature and spinal movements. As a skin-surface measurement device, Fastrak<sup>®</sup> was employed to study the effect of low bone mineral density on spine motion. However, the reliability and validity of data recorded has not been established. The purpose of this study was to develop a methodology to determine the accuracy of the surface measurement device when it is applied on osteoporotic spine motion analysis.

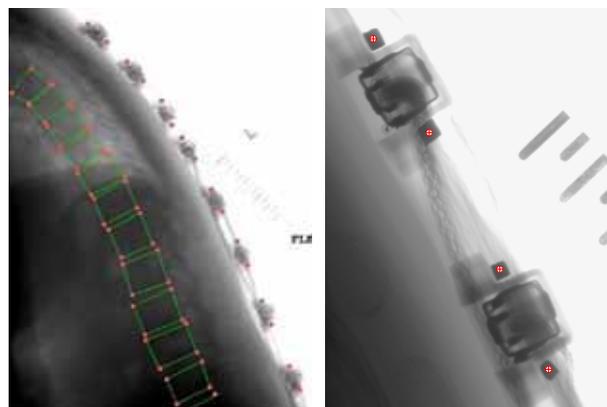

### METHODS

The Fastrak<sup>®</sup> system consists of a source of pulsed electromagnetic waves and four sensors of signals. The source was placed in fixed positions close to the subject. The sensors of signals were attached to the skin overlying spinous processes. The angle and distance between each sensor and the source were then sampled at 30 Hz and input to computers for calculation.

Nine volunteers (3 men, 6 women, 73±4 yrs old) with different level of bone mineral density (2 normal, 5 osteopenia, 2 osteoporosis) agreed to participate. In this study, the region of interest is lower thoracic spine and lumbar spine. The tips of the spinous processes of the seventh thoracic (T7), the first lumbar (L1), and first sacral (S1) vertebrae were identified by palpation and three sensors were placed over them. Three more sensors were evenly distributed on the spine between T7 and L1 and two more between L1 and S1 to reconstruct the spine curvature. Two sets of Fastrak<sup>®</sup> systems were used in this study.

With sensors attached, the subjects were requested to take lateral radiographs in three postures: neutral upright, full flexion, and full extension. In order to facilitate the image processing, two radiopaque lead markers were fixed on each sensor as shown in Figure 1.

The sagittal rotation and translation of vertebrae and sensors were then calculated from the radiographs. The vertebral body corners of T7, L1, and S1 were marked out on the three radiographs using the method presented by Frobin [1]. The translation and rotation of the overall lower thoracic spine and lumbar spine were calculated from the corners points of T7, L1 and that of L1, S1, respectively. As for the sensors, the lead markers were easily identified on the radiographs and two lead markers on one sensor could determine the orientation and location of that sensor. Therefore, the movement of sensors on T7, L1, and S1 could be calculated.

**Figure 1:** Manual 4 points quadrangles and sensors with radiopaque markers mounted on skin.

### RESULTS AND DISCUSSION

Table 1 shows the differences of rotation angle and translation distances in two orthogonal directions calculated from vertebrae corners and lead markers on the sensors. The differences are relative differences in percentage, i.e., the calculated differences are divided by the motion range calculated from vertebrae corners. These differences were regarded as the error of the surface measures with respect to radiographic measures. It can be observed the accuracy is poor. It might be caused by the fatty bagged back of the aged subjects and the inaccurate palpation of osteoporotic spines.

	T7-L1		L1-S1	
	F / N	E / N	F / N	E / N
<b>Rotation Angle</b>	5.62%	12.3%	8.31%	10.85%
<b>Translation X</b>	16.30%	8.56.3%	9.47%	4.59%
<b>Translation Y</b>	9.34%	11.40%	2.41%	7.83%

**Table 1:** The accuracy of surface measures and radiographic measures. (F/N: Flexion-Neutral, E/N: Extension-Neutral)

### CONCLUSIONS

Radiographs taken with 3D sensors are demonstrated as a method of accuracy estimation of surface measurement. It is expected that the relationship between the measured data obtained with the two methods can be established when sufficient subjects are examined and the surface measured data can be compensated. Therefore, more accurate data could be collected and radiographic risk eliminated. Although the accuracy calculation method is applied on elderly people with osteoporotic spine in this study, it is obvious that the method is applicable to normal healthy person as well.

## AN ORGANOTYPIC MODEL OF TRAUMATIC BRAIN INJURY CAUSED BY ACCELERATION-INDUCED SHEAR STRAIN

<sup>1</sup>Mark B. Sommers, <sup>1</sup>Katrin Weidner, <sup>2</sup>Theresa A. Lusardi and <sup>1</sup>Michael Bottlang

<sup>2</sup>Robert S. Dow Neurobiology Laboratories, Legacy Research & Technology Center, Portland, OR;  
email: [mbottlang@biomechresearch.org](mailto:mbottlang@biomechresearch.org)

### INTRODUCTION

Traumatic Brain Injury (TBI) in form of diffuse axonal injury is commonly inflicted by head acceleration, which subjects brain tissue to shear strain. This tissue level injury cascade can be simulated by *in vitro* TBI models based on organotypic brain cultures, which closely replicate the *in vivo* apparent cell heterogeneity and spatial cell architecture. However, these models typically subject cultures to stretch and fall short to employ defined shear strain as the primary mechanical insult.[1,2] This abstract presents an organotypic TBI model, which inflicts controlled, graded neuronal injury to organotypic hippocampal cultures by means of acceleration-induced shear strain.

### METHODS

Hippocampi from 8-day old rat pups were harvested and sliced into 400 $\mu$ m thick coronal cross-sections using a tissue slicer. Hippocampal slices were plated onto Millicell culture inserts (Millipore, Bedford, MA) in a 6-well dish containing 1.1 ml of culture medium (50% MEM, 25% horse serum, 25% HBSS, 5 mg/ml glucose, and 1mM glutamine). Slices were maintained in a 37°C humidified incubator with a 5% CO enriched atmosphere for 12 days before the TBI experiment. A custom-designed linear acceleration device was utilized to produce controlled, inertia-induced shear strain in organotypic cultures (Figure 1). An electromechanical actuator impacted the acceleration module, which contained up to six Millicell culture inserts. The acceleration magnitude could be adjusted up to 12,000g. The acceleration history was measured with a piezo-resistive accelerometer (350B03, PCB Piezotronics, Depew, NY) attached to the acceleration module, and was stored with a digital oscilloscope (54603B, HP, Palo Alto, CA) at a sampling rate of 60 MHz. Following rapid linear acceleration, the acceleration module was decelerated with a constant breaking force along a 400 mm long chute with a viscoelastic foam end stop.

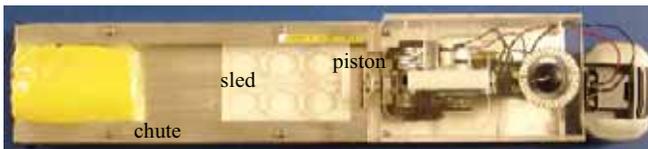

Fig. 1: TBI device with 6-well culture module.

Nine cultures each were subjected to an acceleration magnitude of 450g, 9,000g and 11,500g. Nine additional slices served as sham cultures, which were removed from the incubator, placed onto the TBI device, but were not accelerated. 21 cultures were used as control and remained in the incubator. Cellular response was measured in terms of cell death determined by propidium iodide (PI) which labels the nucleus of dead cells. Subsequently, cultures were treated with

1 mM NDMA, which caused 100% death of the neuronal cell population. This allowed expression of the initial PI labeling results as a percentage of maximum neuronal cell death. Statistical analysis was conducted using ANOVA with a Fisher's posthoc test using a confidence level of  $\alpha=0.05$ .

### RESULTS AND DISCUSSION

Viability of hippocampal cultures was not affected by placing slices onto the TBI device as shown by comparison between cell death rates in the control group (7.1 $\pm$ 2.3%) and sham group (7.3 $\pm$ 1.4%) (Fig. 2). Acceleration of 450g did not produce significantly elevated death of neuronal cells. Acceleration of 9,000g produced 33.6 $\pm$ 21.9% cell death, which was significantly higher compared to sham cultures ( $p<0.01$ ). Cell death was observed mainly in the CA1-CA3 regions and in the dentate gyrus, which are densely populated with neuronal cells (Fig. 3). 11,500g acceleration resulted in over 100% cell death, which suggests that cell death had been inflicted not only in the neuronal cell population, but extended to other cell phenotypes in the hippocampus.

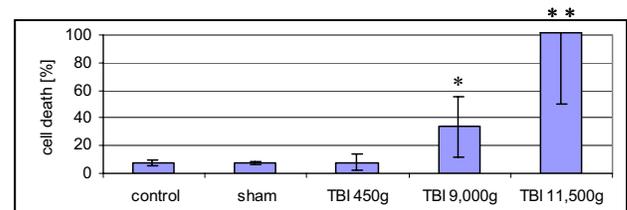

Fig. 2: Cell death response (mean +/- SD)

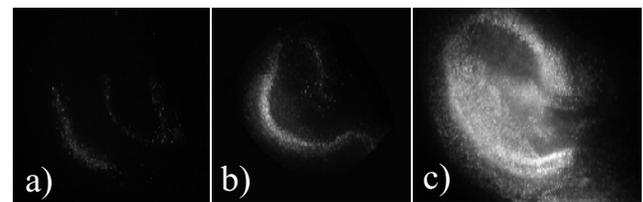

Fig. 3: PI results: a) sham; b) after 9,000 g; and c) 11,500 g.

### Conclusion

The presented TBI model was able to induce acceleration-induced shear strain injury in organotypic brain slices in a graded, reproducible manner. Further characterization of this model will include measurement of the tissue-level shear strain during acceleration, a more accurate predictor of TBI.

## AN ANALYTICALLY TRACTABLE MODEL FOR A COMPLETE GAIT CYCLE

Sujatha Srinivasan and Eric R. Westervelt  
 Department of Mechanical Engineering, The Ohio State University  
 email: {srinivasan.54, westervelt.4}@osu.edu

### INTRODUCTION

Human walking is complex due to a human's many degrees of freedom (DOF) and the periodic impacts that occur at leg exchange. This has resulted in models of walking that either deal with only limited aspects of the gait, for example, models of only the swing phase, or models that attempt to be all-inclusive that include, for example, all of a human's DOF and musculature [1]. As a result, these models have limited use for clinical judgments, which are usually based upon gait analysis heuristics or statistical comparisons. The work described here deals with the development of an analytically tractable hybrid model to model an entire gait cycle of human walking (a forward-dynamic model). The model is validated using experimental data for normal gait reported by Winter [2].

This analytical model, in turn, will lead to a low-dimensional model that captures the essential dynamics of human walking. Such a *template* dynamical model is considered possible because of the observed parsimony of human gait (Figure 1). Having such a model has important implications for clinical applications and could lead to the development of analytical tools that, for example, predict the effect of anthropometric changes, or enable analysis of systematic changes to prosthetic alignment instead of relying on heuristics.

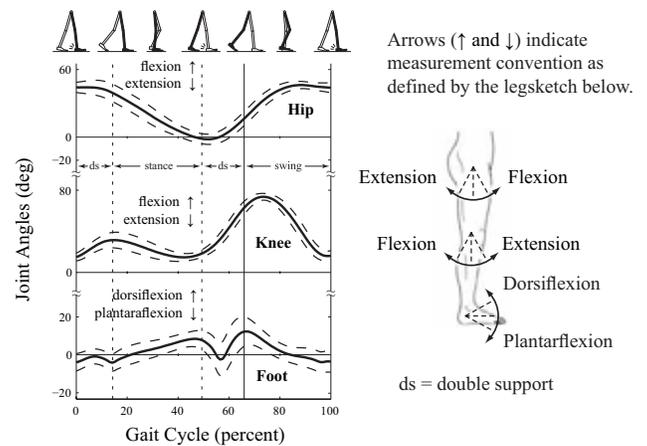

### METHODS

Since the gross motions during human walking take place in the sagittal plane, a 2D model is developed. (Extension of the model to three dimensions is planned.) The hybrid dynamic model consists of three parts, the single support phase, a leg-ground contact event, and a double support phase. The analysis of the continuous phases (single and double support) is developed using standard robotics analysis: Kinematics are obtained via the Denavit-Hartenberg convention and then Lagrange's method is used to derive the equations of motion [3]. The discrete phase, (leg-ground contact event) is modeled as a rigid impact. We term this approach "robomimetic" in that the inspiration for this approach is from a framework developed for the systematic design and analysis of controllers to induce stable walking in planar biped robots [4].

The single support phase model is of five rigid links: two shanks, two thighs and a HAT segment. The weight-bearing leg has a rocker foot, the shape of which is determined using the roll-over shape model of Hansen [5]. The single support model is valid from heel contact to opposite heel contact.

A rigid impact model, which acts instantaneously, is used to model the transition from single support to double support. The model captures the energy loss associated with this event.

The model for double support (DS) is of six rigid links, with the trailing limb's ankle joint being actuated. This additional DOF is to enable the model to capture the impulse at toe-off.

**Figure 1:** Average joint angles for five subjects using five trials each. Note strikingly small variation in the joint trajectories, which indicates that humans use their DOF parsimoniously, and with uniformity, while walking. Data courtesy of J. Linskill, Limb Fitting Centre, Dundee, Scotland.

To validate the model, the energies of the segments are computed using the hybrid model and compared with the data for a single normal gait cycle reported by Winter [2].

### RESULTS AND DISCUSSION

The analytical model described is a first step in the development of a low-dimension model of human gait. Preliminary comparisons of the data generated from this analytical model show that the model is able to capture well the energetics in the single support phase. Note that, in a first analysis, the DS model's trailing limb ankle was not actuated. This model was not able to accurately capture the energetics of the DS phase. With the addition of an actuated ankle, the energy burst that appears at toe-off is captured.

The parsimony of human gait and the successful use of an analytically tractable low-dimension model to implement stable walking in a biped robot [4] suggest that a template dynamical system for human walking is possible. The model developed here provides the foundation for this approach.

## INFLUENCE OF SEAT HEIGHT ON PITCH ANGLE AND PUSHRIM KINETICS DURING A WHEELIE ACTIVITY

<sup>1,2</sup>Po-Chou Lin, <sup>1</sup>Fong-Chin Su, Kenton R Kaufman<sup>2</sup> and Kai-Nan An<sup>2</sup>

<sup>1</sup>Institute of Biomedical Engineering, National Cheng Kung University, Tainan, TAIWAN; email: fcsu@mail.ncku.edu.tw

<sup>2</sup>Biomechanics and Motion Lab, Div. of Orthopedic Research, Mayo Clinic, Rochester, MN, USA

### INTRODUCTION

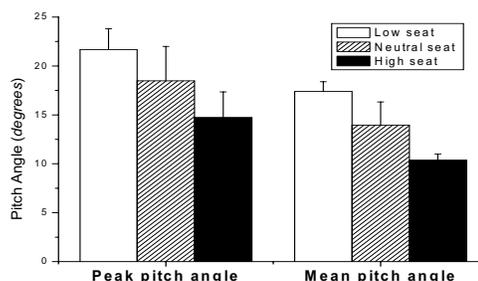

A wheelie is a high level skill performed when the user pops the front casters off the ground and keeps balance on the rear wheel. The pitch angle is the tilt angle of the rear wheel axle when maintaining the wheelie. Bonaparte et al. suggested wheelie performers appear to use a proactive balance strategy in maintaining a stationary wheelie<sup>1</sup>. The seat height affects manual wheelchair propulsion<sup>2, 3</sup>. Pushrim kinetics plays a very important role in wheelie activity, but the influence of seat height has not been studied. Therefore, the purpose of this study was to compare the pushrim kinetics of individuals in different seat height when performing a wheelie.

### METHODS

Five experience spinal cord injury males (age 26.6±1.5 years old, weight 64.7±6.3kg, and height 171.3±5.2cm) participated in this study. A six-camera Expert Vision™ motion analysis system (Motion Analysis Corp, CA, USA) was used to collect the three-dimensional trajectory data of 8 markers placed on the wheelchair. A standard type manual wheelchair instrumented with a six-component load cell was used to collect the forces and moments applied on the hand-rim by users. Subjects were requested to keep their balance as stable as possible during tests which lasted 10 seconds at each of three different seat heights. The standardized seat height adjusted by a suitable seat cushion, were defined as 80, 60 and 40 degrees of elbow flexion for low, neutral and high seat positions, respectively, when the hands were placed on top-dead-center of the rim. We defined the time after 3 minutes as the balance phase when maintaining wheelie balance. Statistical analysis using ANOVA with repeated measurement was used to compare the pitch angles and pushrim kinetics among the different seat heights.

### RESULTS AND DISCUSSION

Increased seat height decreased the peak pitch angle which occurred during popping the wheelchair up and the mean pitch angle during the balance phase (Figure 1). Because the center of mass (COM) of the whole user-wheelchair system was moved from the front of the axle to the top, the angle between the vertical through the rear axle and a line connecting the rear axle and the system COM is less in the high seat which will cause a lower pitch angle. The maximum peak tangential and axial components of applied handrim

**Figure 1:** Mean pitch angle when keeping wheelie balance and peak pitch angle.

contact forces occurred at the neutral seat position (Table 1). At this position, bodyweight compensation helped to keep the wheelie balanced and may increase more than other seat positions. The peak radial force on the pushrim was largest at the high seat position, because less elbow flexion resulted in a larger radial force to push on the hand rim. In contrast, the mean tangential and axial forces were significantly smaller at the high seat position. The high seat position results in not only a lower effective biomechanical mechanism in wheelchair propulsion but also lower effective (tangential) force in peak force and mean force during the balance phase of a wheelie activity. We suggest that the effective force is used to against the stability of the wheelchair.

### CONCLUSIONS

The results indicate that the seat height significantly affects the pushrim kinetics in during a wheelie activity. Our findings show that the effective force may be compensated by the body weight to maintain the wheelie balance force.

### INTRODUCTION

Stress-strain data obtained from animal and human tissue have several applications including medical diagnosis, assisting in surgical instrument design and the production of realistic computer-based simulators for training in minimal access surgery. Up to the present time, about gastrointestinal organs, some researchers have reported the extensive investigations. The common problem of the methods employed in these works, however, has been the extirpation of the organs from the experimental animals or human, so-called in vitro experiment. The object of this study is to determine the passive mechanical properties of large intestine under the condition in vivo. Experiments to determine the mechanical properties are to be performed on intact living organs.

### METHODS

#### 1. In vivo indentation experiments

Experiments were performed in the descending colons of a female goat under general anesthesia. Through an incision in the skin the large intestine were laterally exposed. A supporting plate of the indentation test was inserted into it through the incision on the intestinal wall, preserving the neurovascular supply. The indenter was cylindrical and flat-ended in  $\phi 1$  mm, and applied to the tissue perpendicularly. Three indentation rate were chosen; 0.02, 0.5, and 5 mm/s. Load values and indent depth were measured at each experiment. The thicknesses of layers were also measured.

#### 2. Finite element analysis

The biomechanics of compression behavior of descending colon was analyzed using a 3-dimensional finite element (FE) model. FE model consists of 3861 hexahedral and wedge shaped iso-parametric elements (Figure 1). The indenter was assumed to be a rigid body. The dimensions of the model and boundary conditions were assumed to be one of the representative model of the in vivo experiment. Descending colon was assumed to be incompressibility and homogeneous. Mechanical properties of descending colon were calculated as a inverse problem. The commercial FE software package ANSYS (Cybernet Systems, Co., LTD) was applied for analysis.

### RESULTS AND DISCUSSION

The relation between indentation depths and load values is shown in Figure 2. These curves are results of in vivo experiment. The influence of the heartbeat and the respiration

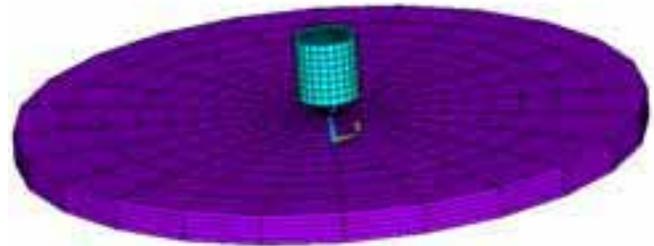

Figure 1: FE model of intestinal wall and rigid indenter

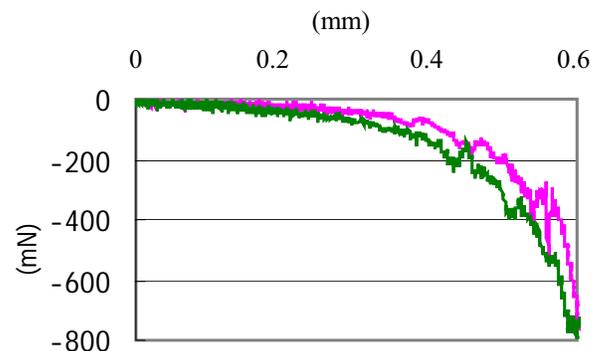

Figure 2: Results of in vivo experiments

is apparent. Values of elastic modulus were derived from these curves using Heyes' formula [1]. Average value of elastic modulus was 99.93 kPa. This value was same as the elastic modulus of the spleen [2] approximately. Elastic modulus derived from FE analysis was nearly consistent with the result of in vivo experiment. As a conclusion, the elastic modulus of descending colon was measured by in vivo indentation tests and the results of experiments were validated by FE analysis.

#### INTRODUCTION

Novel techniques have been developed to convert 3D image data as obtained from a range of imaging modalities (MRI, CT, Ultrasound) into numerical meshes suitable for finite element or computational fluid dynamics analyses. These new meshing techniques provide a significant qualitative and quantitative improvement compared to currently available methods.

A number of example cases will be shown to illustrate the use of these techniques in a wide range of fields including Finite Element models of a hip implant and CFD models of cooling of a thanksgiving turkey in a light breeze.

#### METHODS

The steps involved in the generation and processing of finite element models based on medical imaging data are listed below.

##### (1) Scan and Image Processing

ScanIP is Simpleware's Image processing software tool. It offers a user friendly environment and a wide range of image processing tools to assist the user in visualizing and segmenting regions of interest from 3D data.

##### (2) Finite Element Model Generation

ScanFE, Simpleware's meshing software tool automatically generates the mesh from the parts (masks) generated by ScanIP. The proposed automated mesh generation from scan data simplifies has several important advantages:

- 1) finite element mesh sub-voxel geometry accuracy;
- 2) automatic multiple part structures meshing;
- 3) variations in material properties throughout the medium can be reflected in the finite element model
- 4) interfacial contacts can be modelled;
- 5) both scan and experiments can be performed simultaneously within the imaging modality.

##### (3) Export to FE mesher

Nodes, elements, material properties, contact surfaces for any or all meshed parts may be exported to input-format files for a variety of FE and CFD packages.

##### (4) Export to RP facility

Mesh surfaces for any or all parts may also be exported in STL file format. It allows the generation of an exact physical replica of any part for which a volumetric mesh has been generated and can, for example, be used to provide experimental corroboration of FE simulations.

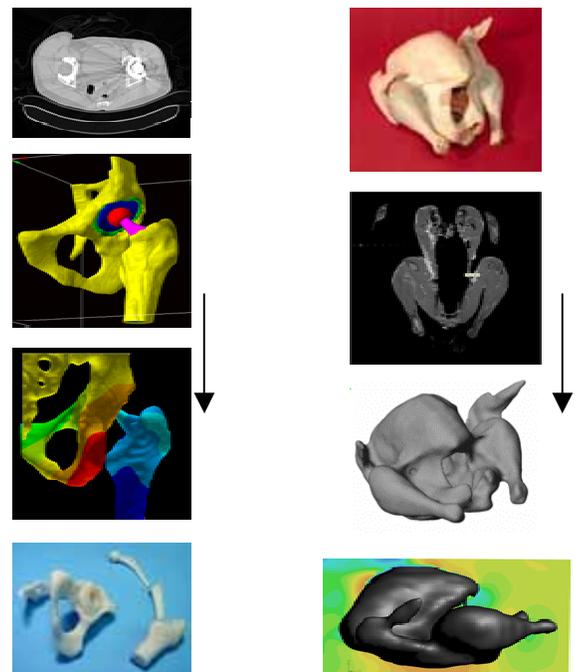

#### RESULTS AND DISCUSSION

##### (1) Hip Implant

A male patient with a Total Hip Replacement (THR) was CT scanned (cf. Figure 1-a). The data was then segmented in 6 different parts and meshed. RP models were generated and an FE analysis was conducted with different mesh density models, taking into account material properties derived from the original greyscale, boundary conditions and loads were applied. Excellent qualitative and quantitative agreement was obtained for predicted stresses using both low and high element density models.

##### (2) Thanksgiving Turkey

A frozen turkey was scanned in an MRI scanner (cf. Figure 1-b). The segmentation was carried out based on grayscale intensities and the mesh was created in minutes. Airflow past the turkey was modelled to obtain effective lift and drag coefficients. The lift /drag ratio = 0.09 - frankly, it won't fly!

**Figure 1:** a) Total Hip replacement: from CT scan to FE analysis and RP model. b) Turkey: from actual turkey to CFD analysis.

#### CONCLUSIONS

These studies have clear implications for the future of Biomechanical modelling. Models of unmatched sophistication can now be generated with ease which opens up a wide range of previously difficult or intractable problems to numerical analysis.

## A NOVEL ROBOTIC DEVICE WITH HAPTIC FEEDBACK FOR LOWER LIMB REHABILITATION

<sup>1</sup>Ann M. Barkowitz, <sup>1,2</sup>Daniel P. Ferris

<sup>1</sup>Dept. of Biomedical Engineering & <sup>2</sup>Dept. of Movement Science, University of Michigan, Ann Arbor  
email: [abarko@umich.edu](mailto:abarko@umich.edu)

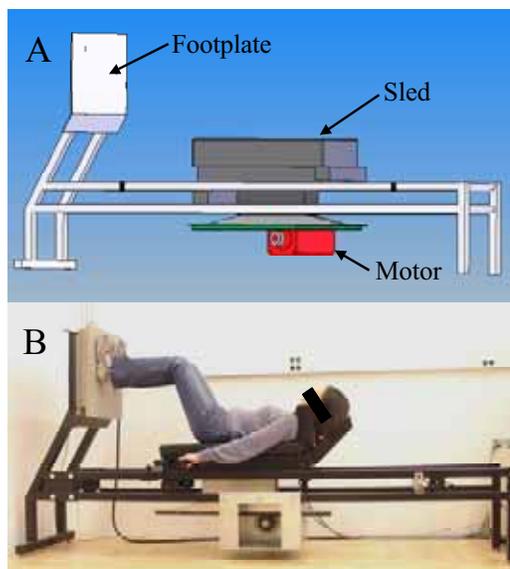

### INTRODUCTION

After a stroke, many individuals have difficulty producing symmetric forces with their limbs. Several rehabilitation devices currently use visual biofeedback in attempts to increase this symmetry, but studies have shown only small changes in function when compared to no feedback controls [1]. A novel alternative is to use force-sensing feedback, or haptics, for rehabilitation. This technique uses computer controlled force feedback and has been suggested as a means to improve coordinated bilateral movements in the upper limbs of stroke subjects [2]. We developed a lower limb robotic device that uses haptics to investigate motor learning after stroke. In haptic feedback mode, subjects perform lower limb extensions while computer control increases resistance proportional to lower limb force asymmetry. We propose that practice with this form of direct haptic feedback will promote improved lower limb symmetry during leg extensions.

### METHODS

We modified a commercially available exercise machine (Plyo-Sled, Lifestyle Sports) by adding a computer controlled electrical motor for providing resistance (Kollmorgen MT706C1-R1C1 Goldline XT Servomotor) (Figure 1). Subjects lie supine on a sled with rollers and place their feet on a vertical footplate to perform lower limb extensions. The motor affects sled movement through a rack and pinion attachment. Computer software (RT-Lab Solo, Opal-RT Technologies) controls the real-time processor to determine motor resistance. We attached a force platform (Model OR6-7MA, AMTI) to the footplate to capture center of pressure during lower limb extensions. From center of pressure data we can discern the relative symmetry between the right and left foot forces. Safety measures include an emergency stop button and electrical and mechanical stops.

In haptic feedback mode the computer controls resistance based on center of pressure from the force platform. If foot forces are equal (i.e., the subject's center of pressure remains directly in between his/her feet), the motor resistance will stay at baseline levels. If foot forces are unequal (i.e., the subject's center of pressure moves away from the center line and towards one of the feet), the computer will increase the motor resistance above baseline levels. This controller provides immediate force feedback of the amount of relative symmetry in the lower limbs. The resistance is proportional to the amount of asymmetry of the subject's foot forces. Feedback in this mode includes person-in-the-loop, where the subject can perceive increases and decreases in resistance and adjust their foot forces accordingly. If stroke subjects rely more on their non-paretic limb, they will perceive the increase in resistance and presumably increase force in their paretic limb (or decrease force in their non-paretic limb).

**Figure 1.** (a) Computer renderings of the robotic device. (b) Robotic device in use on a healthy subject.

Three healthy subjects performed leg extensions on the robotic device. Each subject performed 20 repetitions at a frequency of 0.5 Hz under two conditions; a) against baseline resistance of ~50% body weight, and b) in haptic feedback mode where the resistance was increased above baseline in proportion to the asymmetry in lower limb forces. We measured root mean square (RMS) of center of pressure excursion over the last 10 repetitions. We hypothesized that the center of pressure excursion (measure of symmetry between lower limbs) would decrease in haptic feedback mode compared to the condition with constant resistance.

### RESULTS AND DISCUSSION

While providing haptic feedback to subjects, we are able to produce variable resistances up to 1200 N. Our results showed that while performing leg extensions against a constant resistance, the center of pressure excursion RMS was  $3.1 \pm 0.4$  cm. While subjects performed leg extensions in haptic feedback mode, their center of pressure excursion RMS was  $2.2 \pm 0.4$  cm. These results support our hypothesis and provide a basis for further testing on the robotic device in stroke subjects.

## CHILDREN'S POSTURAL CHANGES AT ADULT COMPUTER WORKSTATIONS

Carol Murphy and Joan Stevenson.

Biomechanics/Ergonomics Laboratory, 148PEC, Queen's University, Kingston, Canada, dcmurph@cogeco.ca

### INTRODUCTION

The increasing incidence and disability associated with RSI and MSD and their frequency among computer users has led to concern. (Gerr, 2002) This concern has been extended to young children who are potentially also at risk for these injuries. Jacobs (2002) has shown that children are reporting moderate amounts of musculoskeletal discomfort and this discomfort can be related to computer use. This risk is increased by the fact that children are often required to play and work on computer workstations which are designed for adult anthropometrics. The purpose of this research study was to examine the quality and quantity of postural movements exhibited by five and six year olds when using an adult workstation to play a computer game. The quantitative measures children's postures and joint and segmental angles and the qualitative analysis was examined by time-motion analysis.

### METHODS

Six physically active 5 and 6 year old boys and girls were asked to participate in the study. After ethics approval by parents, children were asked to give verbal assent. Each child was asked to wear a dark shirt. Joint markers were placed on the shoulder, elbow, wrist, and third knuckle for upper limb joint angles. For head orientation, the earlobe and two sweat-band markers were used. For back orientation, bilateral extended markers were placed at the level of T1, T7, and L5. Although not always visible at all times, the hip, knee and ankle were marked for lower limb kinematics.

Once outfitted, each child was asked to play a pre-selected computer game for 20 minutes. The game set-up involved use of the keyboard initially, but thereafter it was primarily mousing. Digital images were taken perpendicular and posterior to the subject for the total time. After 20 minutes, each child was asked to complete a series of shoulder shrugs and head flexion, extension, lateral bending and rotation to determine their full range of motion. Neutral resting posture was also recorded.

Using Pinnacle Studio DV software, the time that subjects spent in static postures and the frequency and nature of their postural changes were recorded from the time counter. Then, individual images were extracted from each segment in order to evaluate the posture that the child was assuming. The specific postures of interest from the side camera were: 1) joint angles of the a) upper trunk, b) elbow c) lower trunk, and segment angles of a) upper trunk, b) lower trunk, c) elbow, d) forearm and e) wrist. From the rear camera, the points of interest were angles from the horizontal of a) T1, b) T7, c) L5, d) shoulder abduction, e) elbow and f) wrist. Data were

analyzed using descriptive statistics and comparing their postures to recommended postures for office ergonomics.

### RESULTS AND DISCUSSION

In analyzing children's postures it was observed that all children show the same postural movement patterns with a greater number of postural shifts occurring in the feet and legs. Children show little change in their upwardly tilted head position throughout the 20 minutes. Joint and segment angles were surprisingly similar between subjects. The children chose one of three arm and hand positions when using the mouse. All involved abduction of the shoulder averaging 67° and elbow displacement of 9.2 cm which exceeded the limit recommended as 0° abduction and minimal displacement. The forearm segment angle was 20°, above the recommended horizontal position. The spinal posture was also rounded from their natural upright sitting posture.

Analysis of children's postures at adult workstations show four main areas of concern: 1) spinal curves were compromised from their neutral positions; 2) their heads were upwardly inclined; 3) their arm postures were compromised in that: a) the forearm of their mouse hand rested on the desk; b) their arms were held in 90° of abduction; and, c) their wrist of the mouse hand rested on the edge of the desk; and, 4) children's frequent postural shifts indicate discomfort.

### CONCLUSION

Based on these results it would be advisable to devise recommendations and guidelines for children's workstation design. This need is deemed to be imperative based on the increasing use of computers both in school and at play and the increasing amount of time spent at the computer on a daily basis. (Jacobs, 2002)

## MEDIAL LONGITUDINAL ARCH MOTION AND THE WINDLASS EFFECT DURING GAIT USING A MULTI-SEGMENT FOOT MODEL

<sup>1</sup>K Anas and <sup>1,2</sup>TR Jenkyn

<sup>1</sup>Department of Biomedical Engineering, <sup>2</sup>Wolf Orthopaedic Biomechanics Laboratory, University of Western Ontario  
London Ontario, Canada  
email: tjenkyn@eng.uwo.ca

### INTRODUCTION

Current gait analysis practice treats the foot as a single rigid segment and is therefore unable to measure clinically important motion of the joints of the foot. Several multi-segment foot models have been developed to address this deficiency [1,2]. This study uses a multi-segment foot model to examine the behaviour of the medial longitudinal arch and the hallux during normal level walking. The movement of these structures has had limited study [3] due to the difficulties in tracking six degree of freedom motion of the required segments in vivo. However, there has been much speculation on the role of the medial longitudinal arch and the windlass effect of the dorsiflexing hallux, and how these structures allow the foot to transition from a flexible and compliant structure in early stance to a rigid lever in late stance. However, this has yet to be clearly demonstrated in a large population in vivo.

Since much of the clinical practice in podiatrics and pedorthics presumes this behaviour, it seems important that this assumption be validated. Proper characterization of normal arch function and its disruption due to pathology would improve clinical understanding and treatment.

### METHODS

One subject (age 26, weight 85.5 kg, height 82.5 cm) with no prior history of foot or ankle problems performed level barefoot walking at self-selected pace. 3D kinetic and kinematic data were collected with a Helen Hayes full body marker set and a multi-segment right foot marker set (Motion Analysis Corp). The foot was functionally divided into six rigid segments: talus, hindfoot, midfoot, medial and lateral forefoot and the hallux. Each segment (except for the talus) was tracked in six degrees of freedom with a three marker cluster (marker diameter 8mm, separation 24mm, carbon-fiber stalks, 16mm delrin base).

11 bony landmarks were digitized during an initial static trial and tracked during walking. Three are used in this study: lateral distal calcaneus (CL), navicular tuberosity (NT) and lateral eminence of the 1<sup>st</sup> metatarsal head (M1). The length (L) of the medial longitudinal arch is defined as the distance from CL to M1. The height (h) of the arch is the perpendicular distance from NT to the arch length vector. The ratio h/L was found and normalized to 1.0 in quiet standing. Dorsiflexion/plantarflexion of the hallux was defined as the angle of the long axis of the hallux segment with respect to the shaft of the 1<sup>st</sup> metatarsal. This approximately to 180° in quiet standing. Decreasing angle represents dorsiflexing motion.

### RESULTS

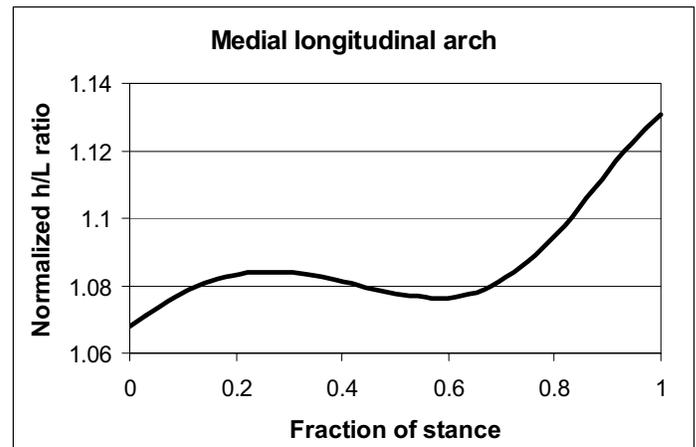

The medial longitudinal arch was shown to be flatter and longer in early stance and higher and shorter in late stance (Figure 1). An unexpected small rise in the arch was seen between 10% and 40% stance. The hallux was found to be equally dorsiflexed early and late in stance and more neutral from 20% to 70% stance (Figure 2).

### DISCUSSION

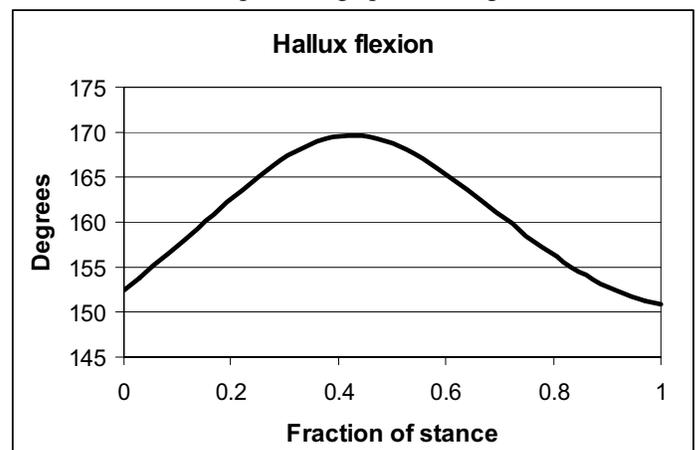

Early in stance, the arch was low and long but the hallux was dorsiflexed as much as in late stance. This likely represents the activity of the extensor hallucis longus acting to dorsiflex the ankle between heel strike and foot flat. In terminal stance during toe-off, the arch was found to be high and short with the hallux dorsiflexed. The hallux is likely acting as a windlass to tighten the plantar fascia and stabilize the arch as has been previously speculated. The lower peak in the h/L ratio of the arch between 10% and 40% stance was unexpected and deserves further study to determine its clinical significance.

**Figure 1:** Normalized h/L ratio of the medial longitudinal arch shows the arch is raised higher and shorter than quiet standing. The arch showed an unexpected low peak in height early in stance and then the expected high peak in height in late stance.

**Figure 2:** Hallux flexion angle in the sagittal plane where 180° defines the hallux in line with the 1<sup>st</sup> metatarsal and smaller angles represent dorsiflexion. Note the equal amounts of dorsiflexion early and late in stance, with more neutral positioning in midstance.

## THE INFLUENCE OF AGING ON THE MATERIAL PROPERTIES OF TENDON

<sup>1</sup> Sarah Calve, <sup>2</sup> Keith Baar, <sup>1</sup>Kevin Mundy and <sup>1</sup> Ellen M. Arruda

<sup>1</sup>University of Michigan,

<sup>2</sup>University of Dundee; email: scalve@umich.edu

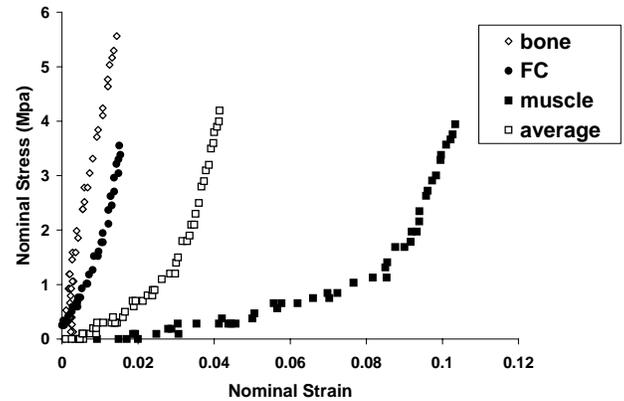

### INTRODUCTION

Our lab studies the effect cyclic and static mechanical loads have on soft tissue. Specifically, we are interested in quantifying how material properties of tendon change during development and aging. We have shown that the tibialis anterior (TA) tendons of rats have varying material properties along their length, and when loading was removed by functional denervation, the entire tendon stiffened up and displayed homogeneous material properties [1]. It has previously been shown that there are age related changes in the musculoskeletal system, but very little data exist specifically on tendon. In order to examine the effects of aging on both the average end-to-end response and the heterogeneity of the response of old tendon, we compared local and average  $\sigma$ - $\epsilon$  responses of young and old rat TA tendon.

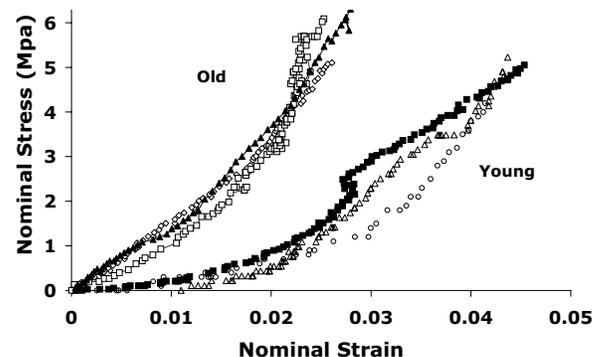

### METHODS

The TA tendon unit (TA muscle, TA tendon, and the 5<sup>th</sup> metatarsal) was removed from young (8 months) and old (38 months) Fisher x Brown Norway F-1 Hybrid rats and stored in sterile PBS prior to determination of the stress vs. strain response curve. The cross-sectional area (CSA) of the tendon was determined by placing the specimen in DPBS and measuring the diameter at three 60° orientations and calculating the area of the ellipse described by these data. The optical stress-strain device consisted of an optical force transducer of our own design with a force resolution of 0.2 to 200 mN, two uniaxial servomotors controlled using LabVIEW, and a Basler digital video camera connected to a Nikon (SMZ800) dissecting microscope. Spots of tissue marking dye were placed at equal intervals along the length of the tendon to allow optical measurement of tissue displacement. The samples were loaded at a constant strain rate until failure and the synchronized force and image recordings were compiled using LabVIEW. The raw load vs. optical displacement data were converted to nominal stress (load/CSA) vs. nominal strain (change in separation of ink marks/initial separation). The (maximum) tangent stiffness was determined by calculating the secondary slope of the nominal stress vs. nominal strain data.

Hydroxyproline concentration was determined following the method of Woessner [2]. Constructs were dried at 110°C, weighed immediately then placed in 6 N HCl and hydrolyzed for 3 hours 130°C. After neutralizing to pH = 7 with NaOH, Chloramine T was then added, and the tubes were incubated for 20 minutes at room temperature. The chloramine T was inactivated by the addition of perchloric acid before adding an equal volume of Ehrlich's reagent. The tubes were incubated at 60°C for 20 minutes, cooled, and absorbance measured at 560 nm. Results were converted to collagen concentration by assuming hydroxyproline accounts for 13.8% of the dry weight of collagen.

**Figure 1:** The young TA tendon displays heterogeneous material properties across the different regions of tendon. Bone = region closest to osteotendinous junction, FC= fibrocartilage region, Muscle = region closest to myotendinous junction.

**Figure 2:** The stress-optical strain response reveals that the TA tendon becomes stiffer and less compliant in old rats.

### RESULTS AND DISCUSSION

The old tendons maintained the graded mechanical response previously recorded for young adult TA tendon (Figure 1), but there was a significant reduction in the length of the toe region and an increase in tendon stiffness (Figure 2). The maximum tangent modulus increased from 195 +/- 36 MPa at 8 months to 461 +/- 193 MPa at 38 months. Interestingly, the collagen concentration did not change as the animal aged (data not shown). This pronounced extensibility of the tendon region nearest the muscle is presumed to protect the muscle fibers from injury. The loss in tendon extensibility with aging may partially explain the increased incidence of both muscle and tendon injury with aging [3].

## DIFFERENCES IN JOINT KINETICS IN GIRLS DUE TO CHOICE OF BODY SEGMENT PARAMETERS

<sup>1,2</sup>Michelle Sabick, <sup>1,3</sup>Kristof Kipp and <sup>1,3</sup>Ron Pfeiffer

<sup>1</sup>Center for Orthopaedic & Biomechanics Research, <sup>2</sup>Department of Mechanical Engineering,  
<sup>3</sup>Department of Kinesiology, Boise State University, Boise, ID USA; email: [MSabick@boisestate.edu](mailto:MSabick@boisestate.edu)  
web: [coen.boisestate.edu/cobr](http://coen.boisestate.edu/cobr)

### INTRODUCTION

The effects of gender on lower extremity mechanics during landing have been studied extensively in adults, but little is known about landing mechanics in preadolescent populations. By studying landing strategies in preadolescent children, body morphology differences between the genders are essentially eliminated. However, joint kinetics calculated during landing using inverse dynamics are affected by the method used to estimate body segment parameters (BSPs) [1]. Some BSP data sets contain primarily elderly specimens, and many contain primarily males [1].

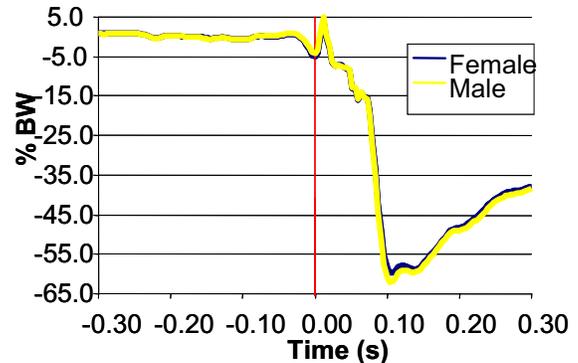

For preadolescents and young adults, not many studies have provided equations to estimate BSPs. According to Zatsiorsky et al [2], BSPs for girls from 9 to 10 years old (28 to 30 kg) can be calculated with little error using the equations for boys the same age. BSPs for boys, in turn, are calculated using equations for men as long as the boys have normal tissue composition (body fat between 15% and 20%). Our subject group, girls between the ages of 9 and 12, spans the suggested age dividing line for using male or female data. Therefore, it was not clear whether their BSPs should be calculated using the equations for men or women. The purpose of this study was to compare the joint kinetics from the same landing trials when calculated with male and female BSP data. To our knowledge, this is the first study to examine the effect of body segment parameters on joint kinetics during landing.

### METHODS

From a larger study of gender effects on landing mechanics, a subset of five female subjects (10 to 12 years of age) were randomly selected for this study. In the larger study, subjects dropped from a horizontal bar (net drop 30.5cm) landing barefoot on one leg. The test leg was randomized. The landing surface was a force platform sampling at 1250 Hz. Each subject performed 5 to 10 trials and the first five successful trials were analyzed.

Pelvis and lower extremity kinematic data were collected at 250 Hz. The 3-D marker coordinate data were smoothed using a 4<sup>th</sup> order Butterworth filter with a cutoff frequency of 17 Hz. Kinematics of the pelvis, hip, knee, and ankle were calculated using Euler angles.

Internal joint resultant forces and moments for the instrumented lower extremity were calculated using inverse dynamics. Body segment parameters for all subjects were computed using data from de Leva [1] referencing Zatsiorsky [2], first using data from female subjects and then using data from male subjects [1]. Comparisons of joint kinetic variables between the data processed using male and female BSPs were made using two tailed Student's t-tests with an  $\alpha$  level of 0.05.

**Figure 1:** Hip anterior-posterior shear force computed using male and female BSP values.

### RESULTS AND DISCUSSION

In most cases the joint force and moment components were not significantly different when computed with different BSP data. Differences between variables calculated with male and female BSPs ranged from -8.8 to 7.3%, and were usually more pronounced for components in which the ground reaction force had little effect (Fig 1). Peak knee distraction force was significantly greater for trials in which female BSPs were used ( $5.51 \pm 0.20$  %BW vs.  $5.15 \pm 0.19$  %BW,  $p=0.018$ ), although peak knee compression was the dominant force in the superior-inferior direction and its at values were not significantly different between groups ( $235 \pm 43$  %BW vs  $237 \pm 44$  %BW,  $p=0.939$ ).

Although not necessarily statistically significant, differences in joint kinetic values of 5-8% might be clinically significant. Many studies comparing landing mechanics data between genders do not specify how BSPs were calculated. Differences in joint kinetics between groups could be either positive or negative, so group differences may be either minimized or inflated by the use of BSPs from a data set that does not adjust for gender.

### CONCLUSIONS

For most variables of interest, use of male or female BSPs did not significantly affect our results. However, differences of as much as 8.8% in certain joint force components were due solely to differences in BSPs, even with the same ground reaction forces and joint kinematics. The use of inappropriate BSPs may influence the results of a gender comparison either positively or negatively.

## CONTROLLED ENERGY STORAGE AND RETURN PROSTHESIS REDUCES METABOLIC COST OF WALKING

Steven H. Collins and Arthur D. Kuo

Dept. Mechanical Engineering, University of Michigan, Ann Arbor, MI USA

email: [shc@umich.edu](mailto:shc@umich.edu), web: [www.umich.edu/~shc](http://www.umich.edu/~shc)

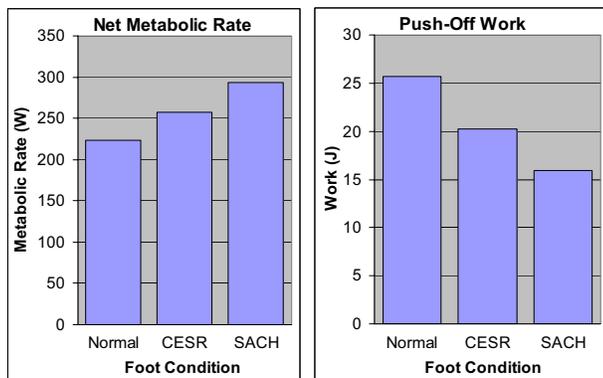

### INTRODUCTION

Humans actively push off with the trailing leg just before and during the double support phase of walking. Push-off compensates for the energy lost as the leading leg performs negative work during the transition between steps [1]. Simple models predict that the energy used in walking is strongly linked to the mechanics of this step-to-step transition; pushing off just before double support can theoretically reduce the step-to-step transition work by a factor of four [2].

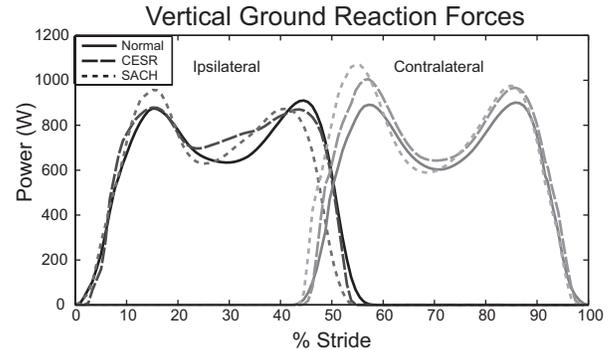

Lower-limb amputees have a reduced capacity for ankle push-off during walking [3] contributing to a 20-30% greater energy demand than intact individuals [4]. A variety of prosthetic feet have been designed with elastic properties to compensate for lost ankle function, but none have significantly reduced the metabolic cost of walking compared to the conventional Solid Ankle Cushion Heel (SACH) foot [4]. We hypothesized that mechanical energy should optimally be stored during load acceptance and released during push-off, as opposed to being spontaneously returned as in existing elastic prostheses. We tested this hypothesis by constructing a prototype prosthetic foot with *Controlled Energy Storage and Return* (CESR), and by measuring the resulting metabolic cost of walking.

### METHODS

We tested intact individuals using a foot prosthesis simulator, a boot that securely constrains the ankle and has a foot prosthesis attachment at its base. Each subject wore the prosthesis unilaterally (ipsilateral foot) with a rocker-bottomed lift on the contralateral foot to compensate for the 10 cm height of the prosthesis attachment. We tested 5 male subjects (ages 20-25 yrs, mass 73-90 kg), walking on a treadmill at 1.3 m/s. Metabolic rate ( $\text{VO}_2$ , Physio-Dyne Max-II) was averaged over the last 3 minutes of each 7 minute walking trial to allow subjects to approach steady state. We also recorded ground reaction forces in 6 identical over-ground trials, and computed

**Figure 1:** Left: Net metabolic power consumed while walking with different foot prostheses: Controlled Energy Storage and Return (CESR) prototype and conventional Solid Ankle Cushion Heel (SACH) foot. Right: Push-off work performed on body center of mass. The CESR significantly reduced metabolic rate and increased push-off work compared to The SACH foot.

**Figure 2:** Average vertical ground reaction forces over one stride. Prototype CESR prosthesis yielded more normal forces (greater push-off and lower collision) than the SACH foot, for the ipsi- to contralateral transition (about 50-60% stride).

work performed on the body center of mass by each leg [1]. We defined push-off as positive work by the trailing leg during double support, and collision as simultaneous negative work by the leading leg. Experimental conditions included normal walking, CESR prosthesis, and SACH prosthesis.

### RESULTS AND DISCUSSION

Walking with the SACH foot resulted in a 69 W increase in metabolic rate over normal walking, or about 31% ( $p < 0.005$ , Fig. 1). This increase is consistent with results for amputees, though simulator mass and height may also have contributed to metabolic cost. With the CESR foot, subjects used 36 W less metabolic power than with the SACH foot ( $p < 0.005$ ).

The CESR foot appears to partially compensate for the loss of push-off (Fig. 1). Work produced by the trailing leg with the CESR during push-off was 27% greater than that with the SACH foot ( $p < 0.02$ ). Both prostheses produced lower push-off and greater collision or load acceptance forces than in normal walking (Fig. 2). The mechanical power capacity of the CESR foot was about 14 W, not all of which was successfully returned at push-off. Newer prototypes have been constructed that may improve on energy return.

### CONCLUSIONS

We have developed a prototype prosthetic foot that stores and returns mechanical energy during successive step-to-step transitions, significantly reducing metabolic energy consumption compared to a conventional prosthesis. Simultaneous positive and negative work during the step-to-step transition seems to be a significant determinant of the metabolic cost of walking, a determinant with clinical applications.

## DENERVATION IMPAIRS ACHILLES TENDON HEALING IN RAT MODEL

<sup>1</sup> Chi Keung Yeung BSc, <sup>1</sup>Xia Guo MD and <sup>1</sup>Gabriel Yin Fat Ng PhD

<sup>1</sup>Department of Rehabilitation Sciences, The Hong Kong Polytechnic University

### INTRODUCTION

With the advance of immunohistochemical techniques, the role of nervous system in successful repair of injured tissue has been recognized. Evidences have shown the importance of innervation in promoting wound, bone and ligament healing. [1,2] How peripheral nervous system contributes to repair of tendon remains unknown. In this study, we investigated the effect of denervation on healing of rats using biomechanical and histological methods.

### METHODS

Hemi-transection of the right Achilles tendon was performed on 28 adult male Sprague-Dawley rats. An additional sciatic neurectomy (SN) (n=14) or patella tenotomy (PT) (n=14) was also performed on the limb with AT injury. At 4 weeks after surgery, all rats were sacrificed and their bilateral Achilles tendons were subject to biomechanical test/histological analysis.

The medial portion of Achilles tendon, with the intramuscular tendinous fibers and the calcaneal bone were dissected out, and was attached to the MTS Synergie 200 machine (MTS Systems Corporation, Minnesota). The tendon was subjected to ultimate tensile testing at an elongation rate of 500mm per minute until failure. [2] The load-displacement curve was plotted with the peak of the curve representing the ultimate tensile strength (UTS) and the gradient in the linear portion representing the stiffness. (Figure one) Finally, all the above values of right leg were normalized against the left leg of the same animal for further analysis.

Statistical tests were used for the result of biomechanical test. Student t-test was used to compare the difference between the means of biomechanical test parameters (UTS, Stiffness and load relaxation) of injured legs between PT and SN groups, as well as the normalized UTS, stiffness and load relaxation.  $\alpha$  was set at 0.05 for all tests.

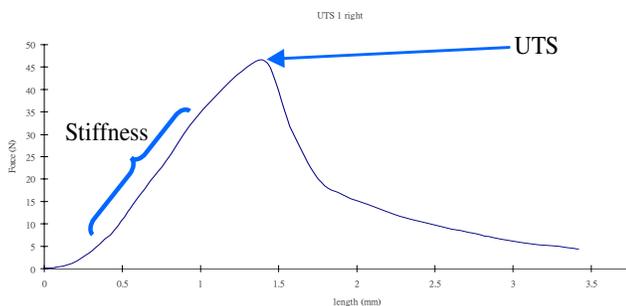

Figure one: Load-displacement curve of tendon

### RESULTS AND DISCUSSION

The mean ultimate tensile strength (UTS) of the injured tendon in SN group was significantly lower than of the PT group. (\*:p<0.05, Figure two) However, no significant difference in stiffness and load relaxation was found between these two groups. After normalizing the right leg values (UTS,

stiffness and load relaxation) with that of the left leg, no significant difference in all normalized values was found among three groups. (Figure three) Denervation result in scar tissue with irregular collagen alignment and higher cell to matrix ratio. Whereas immobilization with patella tenotomy revealed a relatively mature scar tissue with more mature fibroblasts and better alignment of collagen matrix. (Figure four)

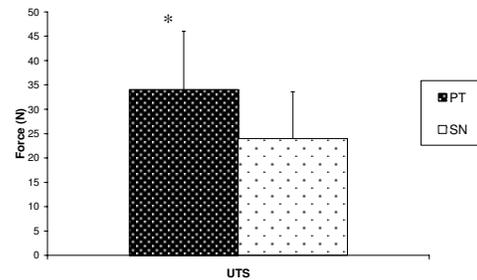

Figure two: Mechanical test result: Right leg UTS

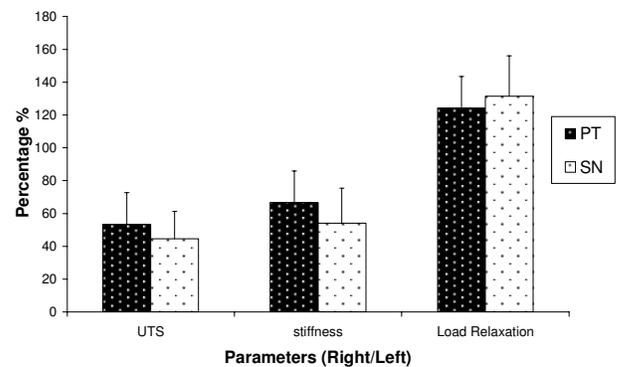

Figure three: Mechanical test result: Right/leg %UTS, stiffness and load relaxation

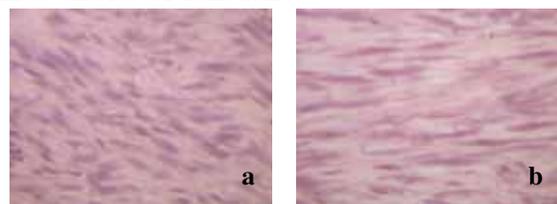

Figure four: Histology of scar tissue in SN (a) and PT (b) group

### CONCLUSIONS

Denervation affects tendon healing, during which the scar tissue is biomechanically and morphologically inferior to that of innervated tendon. An intact nervous system is vital for normal healing of tendon.

**INTRODUCTION**

C57BL/6J and DBA/2 inbred mouse strains have been shown to differ in their skeletal response to aging. This study was designed to increase our understanding of the genetic architecture responsible for the maintenance of bone quality across the lifespan. Our primary aim was to identify quantitative trait loci (QTL) linked to bone quality in young (200 day) and old (800 day) C57BL/6J X DBA/2 (BXD) recombinant inbred (RI) mice. Identifying QTLs in both cohorts adds confirmation of the locus while the identification of QTLs in either the 200 or 800 day old cohort suggests that these loci are operating on bone quality at specific ages.

**METHODS**

Skeletal measures of strength and architecture were assessed in C57BL/6J X DBA/2 recombinant inbred (RI) mouse strains at both 200 and 800 days of age. The young adult (200 day) population included 23 RI strains with 10 male and 10 female mice per strain. A second population was bred to achieve similar numbers of mice at old age (800 days of age). The original study was designed to target 10 male and 10 female mice per 23 strains at 800 days of age taking into account known attrition rates. Despite these precautions, adequate numbers of mice per strain were unable to be maintained to 800 days of age. Those strains that did not have at least 3 mice for each male and female strain were not included in the QTL analyses. This resulted in 15 strains in the female analysis and 18 strains in the male analysis. The average number of 800 day old mice included in the QTL analyses was 6 per strain. Strain means were used in quantitative trait loci analysis to search for chromosomal regions influencing skeletal phenotypes at 200 and 800 days of age.

A three-point bending test was used to assess the mechanical integrity of the mid-shaft of femora and tibiae and a shear test was performed on the femoral neck to assess the mechanical integrity of this functionally significant skeletal site. Gross morphological measurements were made on both bones. Percent water, organic, ash, and mineralization were also measured. Separate sex-specific QTL analyses were performed using QTL Cartographer. Genotypes for the RI lines consisted of 672 microsatellite markers in each BXD strain. LOD scores of 3.3 or greater were considered significant while scores between 1.9 and 3.3 were considered suggestive.

**RESULTS AND DISCUSSION**

The QTL results from the sex-specific interval mapping analyses are presented in Table 1 (cM corresponds to peak centimorgan position of the maximum LOD score or logarithm of the odds that linkage between a marker and a trait did not occur by chance). Significant LOD scores are

highlighted with grey shading. Numerous QTLs for skeletal phenotypes mapped throughout the mouse genome. Table 1 summarizes the QTL results for those traits that had a LOD score of 3.3 or greater in either the 200 or 800 day old analyses.

**Table 1:** Interval mapping results from QTL analyses of 200 and 800 day BXD RI mice. R indicates QTLs detected using data adjusted for animal size.

## CAT HINDLIMB MUSCLE RESPONSE TO SLOW MOVEMENT SHOWS POOR RELATIONSHIP TO LENGTH-TENSION PROPERTIES

<sup>1</sup> Thomas G Sandercock, <sup>1</sup> Aaron Daub, and <sup>2</sup> Eric J. Perreault

<sup>1</sup>Dept. Physiology and <sup>2</sup>Biomedical Engineering; Northwestern University; email: [t-sandercock@northwestern.edu](mailto:t-sandercock@northwestern.edu)

### INTRODUCTION

The ultimate goal of our research is to determine the contributions of individual muscles and muscle combinations to whole limb endpoint stiffness in 3 dimensional space. Initially we are examining the intrinsic muscle properties without reflex contributions. For this particular task, i.e. characterizing endpoint stiffness, a central consideration is how a muscle's force changes when a small change in joint angle is imposed on it. This particular study examines tetanic activation with relatively slow movement (short range stiffness properties are ignored). Several well known contractile properties play a role in the total response. They include: length-tension-frequency, force-velocity, and persistent tension excess or deficit properties. Muscle models often use the tetanic length-tension and force-velocity curves but the results here show this leads to substantial errors, and false estimates of endpoint stability.

The purpose of this study is to test the hypothesis that within the physiological range of a muscle, slow stretch of a tetanically active muscle will always result in more force, and slow shortening of a muscle will always result in less force, irregardless of the position on the length tension curve.

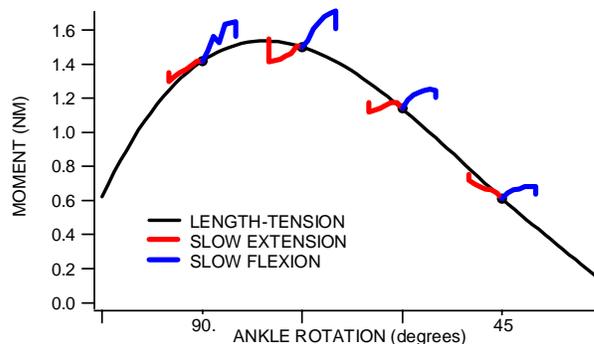

### METHODS

Data were collected from 3 cats (2-3kg) under deep anesthesia (pentobarbital). Three muscle groups, accessible with minimal disruption of the surrounding connective tissue, were examined: the medial gastrocnemius (MG), the lateral gastrocnemius and soleus (LG/S), and the Tibialis Anterior and Extensor Digitorum Longus muscles (TA/EDL). Muscles were stimulated in pairs when nerve separation would have caused an undesired level of connective tissue disruption. During all measurements, muscles were maximally stimulated (100Hz) using peripheral nerve cuff electrodes. Reflex activation was eliminated by cutting the ipsilateral dorsal roots.

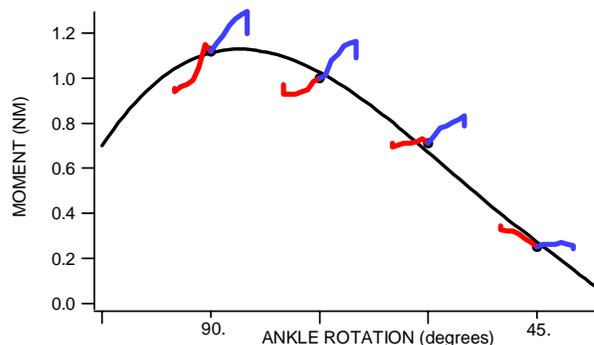

The cat foot was rigidly attached to a 6 degree-of-freedom load cell (JR3) coupled to a 6 degree-of-freedom robotic manipulator (Staubli RX60). Each trial (Fig. 1) consisted of an initial isometric stimulation period (0.25 sec), followed by a robot-controlled joint rotation (5 degrees in 0.37 or 0.75 s) around the ankle. Isometric muscle force was measured immediately prior to the imposed movement and fit with a polynomial to determine the static length-tension properties.

### RESULTS AND DISCUSSION

Figure 1 shows typical results from the combined LG/S muscles. The cat's knee was extended allowing the LG to be studied on the descending limb of the length-tension curve. The dark line shows the static moment-angle properties. The superimposed traces show moments measured during

**Figure 1:** Torque-Rotation (flexion-extension) curve for combined LG and SOL muscles.

**Figure 2:** Torque-Rotation (flexion-extension) curve for MG.

extension (blue) and flexion (red) movements (5 degree rotations over .75s) followed by a .25 isometric hold. The movement is slow so force-velocity properties play a trivial role. Note that the hypothesis is supported at all but the longest muscle length.

Figure 2 shows typical results from the MG. Similar results were obtained for the TA/EDL which was primarily on the ascending limb of the length-tension curve for the same leg position. The results shown here were supported by data from the other 2 cats.

### CONCLUSIONS

The hypothesis was disproved at the longest muscle lengths. However, over a wide range of muscle lengths, muscle force increased during slow stretch and decreased during slow shortening, irregardless of the position on the static length-tension curve. This suggests muscle is intrinsically stable, even in the absence of reflex mechanisms.

## DOES WARMING UP WITH A WEIGHTED BAT HELP OR HURT BAT SPEED IN BASEBALL?

Young-Kwan Kim and Richard N. Hinrichs  
Department of Kinesiology, Arizona State University, Tempe, AZ, USA  
email: [Young-Kwan.Kim@asu.edu](mailto:Young-Kwan.Kim@asu.edu)

### INTRODUCTION

Although baseball players may believe that by warming up with a heavy bat they will increase their swing speed, past research indicates that following warm-up with heavy bats, swing patterns are significantly altered resulting in lower velocities than warm-ups with a standard bat [1]. Further, it was demonstrated that prior to impact with a ball on the first swing following a weighted warm-up there is a 3.3% reduction in linear bat velocity at the trial right after weighted bat swing [2]. The purpose of the current study was to identify if warm-ups with different weighted bats prior to bat swing alter the bat speed and determine whether bat speed agrees with kinesthetic feeling from subjects.

### METHODS

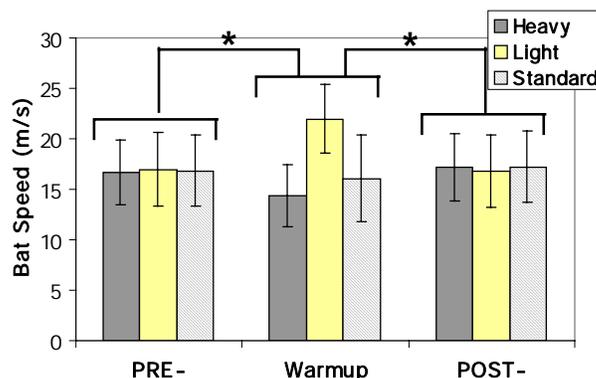

Thirteen subjects ranged from 22 to 28 years (eight males and five females) participated in this study. They came in three different days for three different bat warm-ups. Three different weighted bats, such as a lighter bat (wiffle bat, 113g), a standard bat (909g), and a heavier bat (standard bat + 568g donut weight), were used for each warm-up condition. Subjects were asked to perform total 15 trials of swing as fast as they could per day. The first five trials were PRE-warm-up swings with a standard bat. Following two minutes break, the next five trials were warm-up swings with a randomly selected bat. The last five trials following two minutes break were POST-warm-up swings with a standard bat again. Subjects were asked to rate the kinesthetic feeling of each swing on a scale from -5 (very slow) to +5 (very fast) after each trial during POST-warm-up swings.

A seven-camera VICON system (sampling rate: 120 Hz) was used to collect kinematic data of the bat. Seven reflective markers on a bat and upper arms were attached to measure the trajectories and to determine pattern changes. Peak tangential velocity and time-to-peak velocity at each landmark were dependent measures for the analysis.

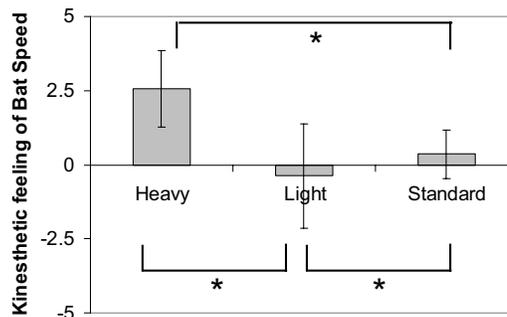

### RESULTS AND DISCUSSION

Repeated measures ANOVA on bat speed indicated that there were significant differences between PRE-warm-up and warm-up conditions and between warm-up and POST-warm-up ones, while there was no significant difference between PRE- and POST-warm-up conditions. Bat speed of the lighter bat at warm-up (22.0 m/s) was significantly faster than the heavier bat (14.4 m/s) and the standard bat (16.0 m/s) (see Figure 1). One-way ANOVA on kinesthetic feeling at POST-warm-up swing indicated significant main effect of different weighted bat warm-up (see Figure 2). Subjects felt significantly faster bat speed following a heavier bat warm-up ( $2.55 \pm 1.29$ ) than any other bat warm-ups ( $-.38 \pm 1.75$  and  $.35 \pm .82$ ) regardless of non-difference on bat speed. No pattern change was found following warm-ups. However, there were changes of the differences on time-to-peak

velocities between bat and wrists and between wrists and elbows in leading and trailing arm, respectively.

**Figure 1:** Changes in bat speed among PRE-Warm-up, Warm-up, and POST-Warm-up with different weighted bats. Significant differences are shown with an asterisk.

**Figure 2:** Kinesthetic feeling of bat speed at POST-Warm-up swings following different weighted bat warm-ups. Scale ranged from -5 (very slow) to +5 (very fast) with indication of 0 (no difference). Significant differences are shown at each different POST-Warm-up swing.

### CONCLUSIONS

Warm-up with different weighted bats provides no significant differences on bat speed following warm-ups, while it provides significant different kinesthetic feelings of bat speed. The kinesthetic feeling during POST-warm-up swing may result from the shortened differences on time-to-peak velocity between wrists and elbows. Finally, there is no benefit on bat speed with a heavier bat warm-up.

## IN VIVO FASCICLE VELOCITY OF CAT GASTROCNEMIUS AND SOLEUS MUSCLES DURING THE PAW-SHAKE

Boris I. Prilutsky, Huub Maas and Robert J. Gregor

Center for Human Movement Studies, School of Applied Physiology, Georgia Institute of Technology, Atlanta, GA, USA  
Email: boris.prilutsky@ap.gatech.edu

### INTRODUCTION

During the paw-shake (PS) in the cat a differential activation of ankle extensor synergists, the two-joint gastrocnemius (GA) and the one-joint soleus (SO), occurs: the GA demonstrates very high activation, whereas SO is either inactive or its activation is substantially reduced [1,5]. The two muscles are activated during the lengthening phase of the muscle-tendon complex (MTC) [1,4], in which substantial activation of SO and GA Ia- and Ib-afferents has been reported [4]. Thus, both velocity-dependent (Ia) and force-dependent (Ib) feedback might be used to regulate the differential activation of the two muscles.

The velocity-dependent feedback is related among other factors to muscle fascicle velocity rather than to MTC velocity. Therefore, the role of MTC and fascicle velocity in the regulation of muscle activity in the PS remains unclear. High shortening velocity in muscle fascicles during PS can also be a limiting factor in muscle force production. The aim of this study was to determine fascicle and MTC velocities of the cat medial gastrocnemius (MG) and SO during the PS.

### METHODS

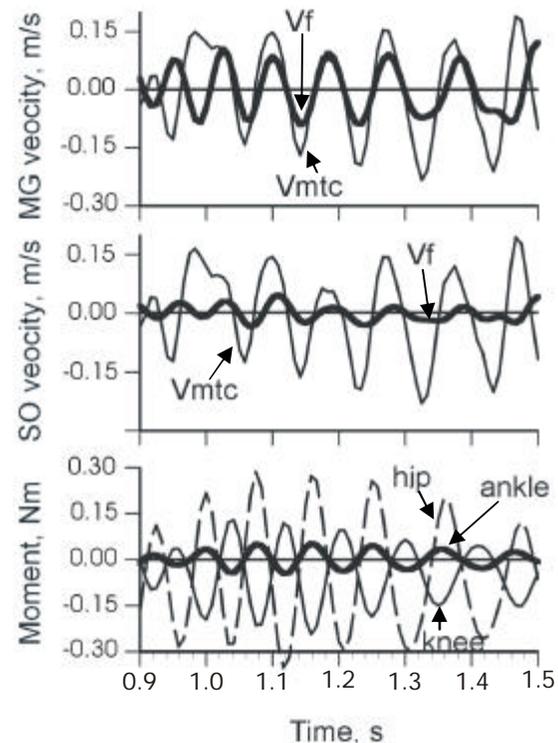

Four cats were surgically instrumented with EMG electrodes in SO and MG [2]. Selected cats were also instrumented with sonomicrometry crystals to measure fascicle length [3]. After recovery, the PS was elicited by attaching a sticking tape to the paw and allowing the animal to walk on a walkway. Reflective markers on the animals were video-filmed using high-speed (120 Hz) motion capture system (Vicon, UK) with simultaneous recordings of EMG or sonomicrometry signals. The recorded kinematics and a geometric model of the hindlimb were used to calculate the origin-to-insertion (MTC) lengths of MG and SO. Joint velocities, moments and powers were also calculated for the major hindlimb joints.

### RESULTS AND DISCUSSION

During the PS, MTC shortening velocity peaks of MG and SO were up to 0.2 m/s (Fig.1) or 80 and 120% of their in-situ MTC  $V_{max}$  [6], respectively. Fascicle shortening velocity peaks reached much smaller values of 0.1 and 0.05 m/s for MG and SO, respectively, (Fig. 1) which corresponded to 40 and 27% of  $V_{max}$  expressed in fiber lengths of each muscle [6]. The above results may be explained, in part, by in-series compliance of the tendons and aponeuroses of MG and SO.

MG fascicle and MTC velocities changed in phase during steady state PS cycles (Fig.1), whereas SO fascicle velocity changes were delayed with respect to the MTC velocity (Fig. 1). These results suggest that velocity-dependent feedback from the two muscles during the PS might be different and thus could contribute to their differential activation.

Stretch velocity peaks of MG fascicles typically coincided with the switch of joint moment directions: from ankle flexion/knee extension/hip flexion to ankle extension/knee flexion/hip extension (Fig. 1). Thus, signals from MG velocity-sensitive afferents might be involved in phase regulation between the flexors and extensors during the PS.

**Figure 1:** Velocity of muscle fascicle and MTC of MG (top panel) and SO (middle panel) and moments at the hindlimb joints (bottom panel) during a paw-shake. Positive velocities correspond to muscle shortening, positive joint moments correspond to extension.

**VALIDATION OF THE VICON 460 MOTION CAPTURE SYSTEM™ FOR  
 WHOLE-BODY VIBRATION ACCELERATION DETERMINATION**

<sup>1</sup> Robert J. Jack, <sup>1,2</sup> Michele Oliver, <sup>2</sup> Gordon L. Hayward

<sup>1</sup> Department of Biophysics, University of Guelph, Guelph ON; email: [rjack@uoguelph.ca](mailto:rjack@uoguelph.ca)

<sup>2</sup> School of Engineering, University of Guelph, Guelph ON

**INTRODUCTION**

With mobile equipment operators experiencing root mean square (RMS) average accelerations ( $A_{ms}$ ) ranging from 0.1g to 0.3g [3], the ultimate goal of this research program is to recreate and monitor in a laboratory environment the whole-body vibration (WBV) exposure levels experienced by forestry equipment operators in a field setting. Since the research questions being asked are concerned with investigating the transmission of WBV for frequencies up to 20Hz, coupled with the fact that the body can have transfer functions approaching 2 [2], the ability to measure an  $A_{ms}$  of 0.6g up to a frequency of 20Hz is required.

To better understand the body’s response to WBV more detailed studies need to be conducted, where vibration levels are monitored at many levels of the spine in concert with muscle activation and posture measurements. This requires many markers, accelerometers, and electrodes to be placed on the subject. If multiple measurement systems are used, subject preparation is time intensive, large amounts of memory for data storage and processing are required, and results can be affected by skin artifacts and the encumbrance of the subject. Using a high sample rate/high resolution camera system to determine accelerations can reduce some of these problems. Thus, the purpose of this study was to determine if a VICON camera system could measure WBV acceleration levels within the range established above, eliminating the need for accelerometers.

**METHODS**

A Bruel and Kjaer™ 4810 electromechanical shaker was used to produce RMS accelerations of 1.09±0.11g, 0.74±0.06g, 0.33±0.06g, and 0.13±0.01g at each of 30Hz, 25Hz, 20Hz, 15Hz, 10Hz, 5Hz, and 3Hz frequency levels. A VICON™ 460 motion capture system (with six M<sup>2</sup>mcam cameras) recorded a reflective marker vibrated at each amplitude and frequency combination while a Crossbow™ CXL04LP3 accelerometer recorded the acceleration. Each amplitude and frequency combination was recorded for a 5 second duration at a sampling rate of 250Hz.

The raw digitized VICON and accelerometer data were fourth order zero lag Butterworth filtered (cutoff frequency of 45Hz [1]). The VICON data were then double differentiated using a three point method to provide acceleration values. A 1/3-octave band-pass filter was then applied to the VICON and accelerometer data and the overall  $A_{ms}$  acceleration levels were calculated for each combination of the input acceleration and frequency levels using the 3.15Hz to 31.5Hz 1/3 octave bands. The percent difference between the VICON and accelerometer overall  $A_{ms}$  acceleration values were compared for all acceleration and frequency combinations.

**RESULTS AND DISCUSSION**

When comparing the overall  $A_{ms}$  acceleration values it was found that the percent difference between the VICON 460 motion capture system and the accelerometer was 4.43±8.23% for frequency and acceleration combinations ranging from 5Hz to 25Hz, and 0.33g to 1.09g (Table 1). Larger errors were observed at the 3Hz and 30Hz frequencies, as well as the 0.74g accelerations (Table 1). While errors were greater than 10% for some acceleration frequency combinations, for the most part, these errors resulted from the shaker having small displacements (<1mm) which are probably within the error of the VICON system. Field measurements indicate that displacements at all frequencies of interest are in excess of 1 mm suggesting that the VICON system can be used to predict acceleration in laboratory studies which simulate field vibration profiles.

Results are promising and further validation studies will be conducted using acceleration profiles from actual field data.

### INTRODUCTION

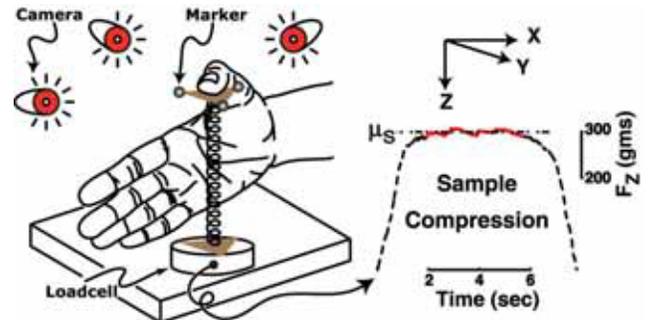

Characterizing the roles of feedback and feedforward control, during any motor behavior is essential, albeit challenging, to further our understanding of the human sensorimotor system. The repertoire of control methodologies used by the sensorimotor system to accomplish any task can be classified as (i) passive mechanics (e.g., soft contact of finger pulp, etc) (ii) feedforward control (e.g., high stiffness, internal model, etc.), or (iii) feedback control (e.g., visual, tactile, etc.). The sensorimotor system may use any control strategy chosen from a continuum of mixtures of the above methodologies. Additionally, activities of daily living often necessitate active and dynamic regulation of fingertip position and forces to stabilize objects (e.g., rolling a pen)[1]. Our past studies [2] have suggested that nonlinear dynamical analysis of a neuromuscular system at the boundary of instability is a powerful paradigm for understanding complex dynamical sensorimotor behavior. In this study, we extend our past work to explore the continuum of control strategies used by the sensorimotor system during dynamical dexterous manipulation by exploiting the dependence of its behavior at the boundary of instability on the specific composition of the control strategy.

### METHODS

As in our previous work [2], 13 consenting unimpaired subjects ( $25 \pm 2$  yrs, 8 males) used their thumbpad to compress and hold at maximum possible compression, a slender spring ( $D=8.7\text{mm}, d=0.787\text{mm}, N=24, L_0=76\text{mm}$ ) prone to buckling while we recorded 3D position/orientation of the spring's endcap and vertical compressive spring force (Fig 1). Audio feedback was provided as a tone of diminishing volume for increasing vertical load. The goal was to maximize vertical compressive load, i.e., minimize the volume of the audio feedback. The protocol consisted of 2 days: Day1 – "testing" before and after 110 trials of practice; Day2 – "testing" before and after a digital nerve block of the thumb (1% Lidocaine at the base of proximal phalanx, blocking the digital nerve branches of the median and radial nerves). A "test" is defined as at least 3 satisfactory compressions (a steady hold within 90% of the maximal load ever reached by the subject). The response variable used for all analyses presented here is  $\mu_s$  (Fig 1). Mixed-model ANOVA using contrasts for post-hoc tests were used to test for differences in  $\mu_s$  with changes in tactile feedback and learning. Maximal static key and opposition pinch strength were also recorded in all subjects.

### RESULTS AND DISCUSSION

The value of  $\mu_s$  after practice on Day 1 was  $305\text{gm} \pm 4.8\%$ . The mixed-model ANOVA results show a significant drop due to loss of tactile feedback ( $23\text{gm}$ ,  $p < 0.0001$ ) and a significant, but smaller rise due to learning ( $11\text{gm}$ ,  $p = 0.0086$ ) in  $\mu_s$  that carried over to the next day. The deficit in  $\mu_s$  after the nerve

**Figure 1:** Schematic of the experiment. The unused digits were restrained against a vertical post and the arm using a vacuum pillow (not shown).  $\mu_s$  is the mean sustained vertical load ( $F_z$ ).

block quantifies and characterizes the role of tactile feedback. The performance after the nerve block by itself, characterizes the combined contribution of other sensory feedback (e.g. visual), feedforward control and passive mechanics.

With tactile feedback,  $\mu_s$  was strength independent ( $R^2=0.01, p=0.81$ ;[2]), but without tactile feedback,  $\mu_s$  was not strength independent ( $R^2=0.64, p=0.02$ ). Together with the previous result, this strongly indicates that without tactile feedback, a high stiffness strategy (feedforward) dominates, with little contribution from vision or passive mechanics. Interestingly, we observe that stiffening is not the best strategy when tactile (short latency) feedback is available.

### CONCLUSIONS

The sensorimotor system has a different behavior at the boundary of instability for every distinct condition of sensory feedback or quality of feedforward control used (i.e., learning), as seen above. Hence, we can quantify and characterize the contributions of the feedback, feedforward and passive components at the boundary of instability. The set of control strategies available to the sensorimotor system is a continuum of mixtures of feedback and feedforward strategies. Each member of this continuum of control strategies causes a different type of instability. This feature of our paradigm that maps different controller compositions to different behavior at the boundary of instability facilitates the exploration of the continuum of control strategies used during dynamical dexterous manipulation. This can be extended to sensorimotor behavior in general using an appropriate dynamical task.

### INTRODUCTION

The performance of an elite archer can be affected by effective control of muscle in the upper extremities. Moreover, archery can be described as a comparatively static sport requiring strength and endurance of the upper body, in particular of the forearm and shoulder girdle [1]. Thus, EMG provides useful information to investigate the static skill of archery. So far, a contraction and relaxation strategy with regard to forearm muscles during the release of the bowstring has been observed and studied through EMG for different skill levels of players [2,3]. These studies showed that archers released the bowstring by active contraction of the forearm extensors, whereas a clear relaxation characterized the forearm after release. Improper contraction may lead to the incorrect movement and hasten fatigue of the muscle, as seen in beginner archers. However, most studies of the relaxation of release only focus on either the forearm or certain shoulder muscles (e.g., the right trapezius). There is no study that investigates how different contraction and release strategies might apply from the distal to proximal segments of the upper extremities, especially in world rank elite archers. Thus, the purpose of this study was to (1) investigate this strategy in the limb extremities from distal to proximal segments using Olympic Female Archery Players, (2) quantify relaxation strategy which was indicated by reduction in muscle activation before and after the release, and (3) determine the characteristic of reduction level of muscle activities in supplemental studies of anchoring and aiming. These studies can provide archers and coaches with the possible assessments of optimal skill patterns.

### METHODS

The Chinese Taipei 2004 Athens Olympic archery team was used in this study. The national rankings of team members were Archer A: fourth position, Archer B: sixth position, and Archer C: fiftieth position. Measurements were made under simulated Olympics conditions on the outdoor court of the Taiwan National Training Center. Biovision surface electrodes were placed on the central portion of each muscle. Electromyography activity of the M. extensor digitorum, trapezius muscle, and deltoid muscle were recorded at a sampling frequency of 1000Hz using synchronized electronic signals for 24 shots by each participant. The mean amplitude of EMG activity during (1) one second of pre- and post-anchoring start point, (2) pre- and post-release timing, and, (3) the first second and last second of the aiming phase were obtained using standard processing. Reduction in the level of muscle activity at anchoring and release were calculated to evaluate release skill in the 0.1 s duration prior to (X) and after specific timing (Y) using the following equation:

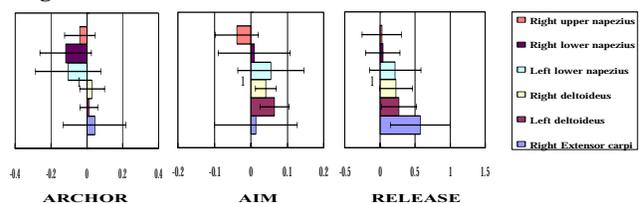

$$\text{Reduction in muscle activity} = 1 - Y/X \quad (1)$$

A higher positive reduction ratio represented a higher reduction in muscle activation, whereas a negative value represented an increase in muscle activation.

### RESULTS AND DISCUSSION

The reduction ratio is shown in Figure 1 from proximal to distal segments for three phases. A greater reduction of muscle activation was seen in the more distal of muscle groups at release. However, anchor and aiming phases did not exhibit such a tendency. During the aiming phase, the extensor carpi of the draw arm increased, unlike other muscle groups. During the anchor phase, proximal muscle groups increase activation whereas distal muscle groups tend to reduce activation. On the other hand, reduction levels and variation in activation were compared among players using One-way ANOVA and post-comparisons (LSD). There were no significant differences between the three archers in reduction of muscle activation during anchoring and release phases. However, during the anchor phase, player A exhibited a significantly greater reduction level relative to other players for the distal muscle groups (right extensor carpi, left deltoid, and right deltoid). This may imply that player A with a better performance may be due to a better relaxation strategy that yields more consistent performance.

**Figure 1:** Reduction level in muscle activation for three archers

in three phases. (n=72)

### CONCLUSIONS

This study indicates that the proximal muscles exhibit a lower reduction level of muscle activation than do distal muscles for three archers after release. Archer A with a better Olympics ranking had the more coherent reducing muscle activation for all muscle groups at release phase, and reduced with distal muscle group during aiming phase. This may imply such relaxation strategy leads to better performance.

## A NEW FRONTAL PLANE FOOT MODEL SHOWS THE EFFECT OF NARROWED BASE OF SUPPORT ON UNIPEDAL BALANCE

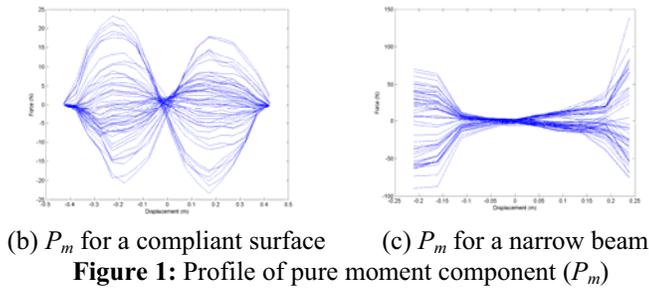

<sup>1</sup> Jaebum Son and <sup>1</sup> James A. Ashton-Miller  
<sup>1</sup> The University of Michigan, Ann Arbor  
 email: [jaebum@engin.umich.edu](mailto:jaebum@engin.umich.edu)

### INTRODUCTION

Despite balancing on one leg being widely used as a clinical test of frontal plane balance, comparatively little is known about the biomechanics of this task. The foot is generally described as a ground-attached pivot that transfers the ankle torque to the ground ‘transparently’ and this assumption forms the basis for using an inverted pendulum to model balancing on one foot. Two common ways to increase the difficulty of balancing tasks are to ask the subject to stand on a compliant surface or on a narrowed base of support. In the latter case, balancing on a narrow beam limits the transmission of ankle torque to the support surface. In this paper we will show that a narrowed base of support also changes the effective compliance of the foot-ground interface, an effect that is often neglected in the simple inverted pendulum model.

### METHODS

Let us first posit that the compliance of the foot-ground interface changes the passive dynamics of balancing on one foot. To prove this, we developed an analysis method called *ground pressure decomposition (GPD)* whereby the ground pressure profile is decomposed into pure force ( $P_f$ ) and pure moment ( $P_m$ ) components.

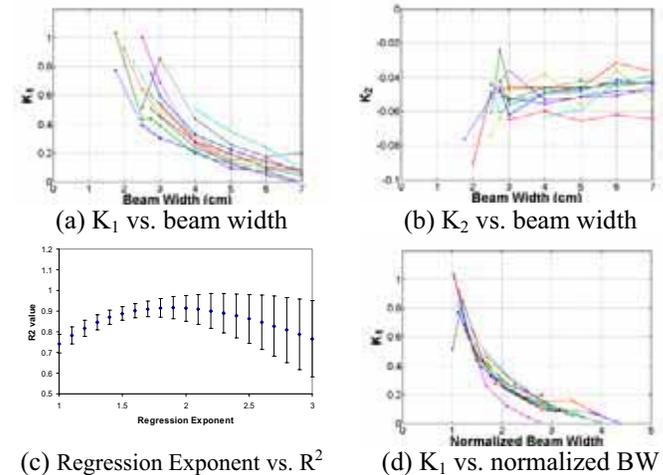

We assume that the frontal plane motion of the foot can be modeled as the sum of a deflection and a rolling component ( $\Delta X_{\text{ankle}} = K_1 \Delta \text{COP} + K_2 \Delta \phi_{\text{limb}}$ ) [where COP denotes center-of-pressure]. In this we hypothesize that the deflection coefficient (or effective stiffness)  $K_1$  is inversely proportional to the square of beam width (**H1**). The existence of the deflection suggests that there exists a critical beam width (CBW) at which it is no longer possible to balance upon: a base of support narrower than CBW (**H2**).

To test above hypotheses (**H1** & **2**), 11 healthy young adults (ages 23-32 yrs., 5 females) were recruited. They were asked to balance for 30s on one foot placed on one of six beams of increasing widths (1.75 cm to 7 cm) presented in a randomized order (total 15 trials for each subject). The kinematics and the

ground reaction force were measured at 100 Hz using three Optotrak® markers and two AMTI® force plates and filtered with a 4<sup>th</sup>-order bidirectional low-pass (7-Hz cut-off) Butterworth filter.

### RESULTS AND DISCUSSION

Of a total of 165 trials from the 11 subjects, 141 trials exceeded 20 s and analyzed. In Figure 1a & b we see that the deflection component gain,  $K_1$ , increased while the rolling component gain,  $K_2$ , remained constant. Figure 1c shows that the change of  $K_1$  has an optimal regression exponent,  $n=1.9$ , close to our expected value of  $n=2.0$ , thereby supporting **H1**. Figure 1(d) shows the change of  $K_1$  against beam width normalized about CBW. No subject could stand on beams narrower than CBW, supporting **H2**.

**Figure 1:** Least square regression result result using  $\Delta X_{\text{ankle}} = K_1 \Delta \text{COP} + K_2 \Delta \phi_{\text{limb}}$ .

So, balancing on a narrow beam has two characteristics: COP saturation and a compliant interface. As the compliance increases, the axis of the torque source (i.e., ankle jt.) is translated laterally causing relative system instability.

### CONCLUSIONS

- 1) The foot has both compliance and rolling characteristics in the frontal plane.
- 2) This compliance reduces the transmission of the ankle torque to the ground, and defines a critical beam width (CBW) that limits balancing in a pure ankle mode.

## FACTORS AFFECTING THE JAVELIN'S ATTITUDE ANGLE IN AMERICAN JAVELIN THROWERS

Michele LeBlanc and Rachael G. Mooney  
 California Lutheran University  
 email: mleblanc@clunet.edu

### INTRODUCTION

The distance a javelin travels is affected not only by its release velocity and angle, but the javelin's orientation with the horizontal plane (its attitude angle). Several authors have reported optimal values for these release angles [1,2]. Recent work has found that during the final release phase, American female javelin throwers exhibit much larger attitude angles while having similar release angles to their male counterparts [3]. These large attitude angles are detrimental for the javelin's flight and can lead to shorter throw distances [1,2]. The American females' trunk forward/backward lean angles also differed from the males' during the early part of the release phase. However, a significant relationship between the trunk's lean angle and the javelin's attitude angle did not exist and so other differences should be investigated.

The purpose of this study was to further examine the differences in the javelin's attitude angle between American female and male elite-level javelin throwers. In particular, to determine how the throwing arm's wrist position relative to the shoulder position may contribute to the attitude angle differences observed.

### METHODS

The nine finalists for the men's and for the women's javelin throw competition at the 2003 US National Championships were filmed at 60 Hz with two cameras. Standard DLT methods were used to obtain 3D coordinates for 21 body landmarks and 3 javelin landmarks. The 3D coordinates were expressed in an orthogonal reference frame in which the X axis pointed toward the right, the Y axis pointed forward, and the Z axis pointed upward (see Fig. 1).

For each athlete, the two best analyzable throws were used. At the end of the run-up, the right-handed javelin thrower performed a crossover step onto their right foot (RTD), planted their left foot (LTD), and released the javelin (REL). Each throw was digitized from before RTD past REL. The relatively low frame rate was adequate for this study as the parameters investigated exhibited small changes during the time frame studied.

The javelin's attitude angle (ATT) was defined as the angle between the projection of the javelin's long axis on the YZ plane and the +Y axis. The arm angle (ARM) was defined as the angle between the projection of the vector pointing from the right wrist to the right shoulder onto the YZ plane and the +Y axis. These angles were computed at RTD and at LTD.

The difference between these two angles created with the horizontal (DIFF) was also computed.

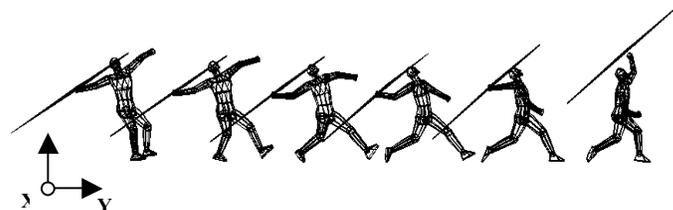

Figure 1: Sequence of the release phase of the javelin throw.

Mean and standard deviation values were computed for the male and female groups. Student's t-tests were used to determine if differences existed between the male and female values. An experiment-wise  $\alpha = 0.05$  was used with a correction made for multiple comparisons. Correlation coefficients were computed between ATT and ARM values at RTD and LTD for each gender and for the pooled data.

### RESULTS AND DISCUSSION

Table 1 gives the mean and standard deviation values for the male and female groups. There was a statistically significant positive correlation between ATT and ARM at RTD for the pooled data as well as each gender separately. At LTD, none of these correlation coefficients were statistically significant. DIFF values were significantly different at both RTD and LTD indicating that there are differences in the angle between the thrower's arm and the javelin's long axis which are presumably due to differences in wrist angles.

Results suggest that by raising their throwing wrist, females may be able to decrease their attitude angle at RTD. There is a strong relationship between the javelin's attitude angle at RTD with its value at LTD and REL. Thus, having a smaller value at RTD may be enough to create a more favorable attitude angle at REL. Wrist flexion/extension angles should also be considered.

## OPTIMIZATION OF FEEDFORWARD AND FEEDBACK CONTROL DURING WALKING

Shawn M. O'Connor, Arthur D. Kuo  
 Department of Mechanical Engineering and Biomedical Engineering  
 University of Michigan Ann Arbor, MI USA  
 Email: smoconno@umich.edu

### INTRODUCTION

We used a simple walking model to study how feedforward (FF) and feedback (FB) control can be optimally combined to produce steady walking motions. We interpret combined FF and FB control in terms of an internal model that is updated by sensory information. The theory of state estimation suggests there is an optimal balance of FF and FB control for improved performance in the presence of noise.

Biological systems function despite imperfect sensors and the presence of disturbances. Neural oscillators are thought to act as Central Pattern Generators (CPGs) of rhythmic motor commands, producing FF commands even in the absence of sensory FB. But this FB is also thought to play an important role in normal behavior, and FF compensates poorly for disturbances. How can the apparent feedforward behavior of CPGs be reconciled with FB? We previously proposed [1] that the neural oscillators could be interpreted as an internal model of limb dynamics. In control theory, internal models can estimate the system state and associated sensory output. Errors in sensory prediction are used to refine the state estimate, which is then used for FB control. In this interpretation, the internal model produces FF commands even when error FB is removed. The optimal motor combination of FF and FB is determined by the presence of two types of noise: *process noise* refers to unpredictable disturbances that are detrimental to pure FF control, and *sensor noise* refers to sensor imperfections that are detrimental to high gain FB. To demonstrate this interpretation, we applied a controller with state estimation to a simple walking model under the presence of both types of noise. We tested whether step variability would be minimized with a predicted optimum combination of FF and FB, as opposed to using either control strategy alone.

### METHODS

We employed a simple passive dynamic model of two-dimensional, straight legged biped walking [2], but with added actuation of the hips. The hip torque had two components: a torque applied in proportion to the angle between the legs, as estimated by the internal model, and a constant torque to add energy lost in collisions during double support.

The control system (Figure 1) uses a CPG to model the dynamics of limbs, producing an estimate of the system state used to drive hip torque. The error signal, from model stretch sensors, was used to refine the state estimate via an estimator feedback gain,  $L$ , which scales the relative influences of FF and FB on the controller (i.e. small  $L$  produces pure FF and large  $L$  produces pure FB control). State estimation theory predicts an optimal value of  $L$  given characteristics of process and sensor noise.

Walking simulations were conducted over many steps for a range of  $L$  between pure FF and pure FB. Process and sensor

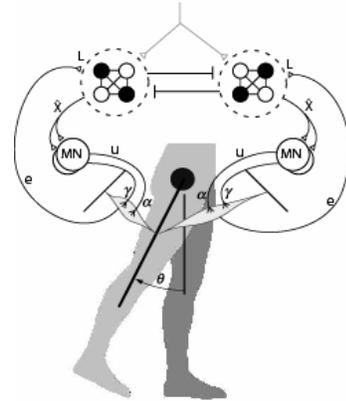

Figure 1: Model of CPG control of hip torque

noise were applied to the system with equal weight such that both had the equivalent strength of 10% of the maximum hip torque produced by the walker. Step-to-step variability was calculated from the standard deviation of leg angles and velocities at the end of each double support period.

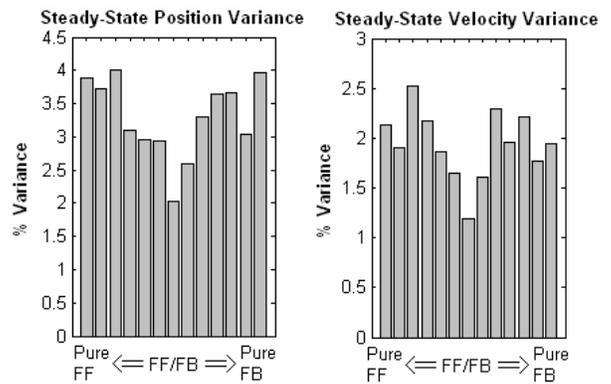

Figure 2: Percent variation of leg angle and velocity over a range of values of the estimator feedback gain.

### RESULTS AND DISCUSSION

The model demonstrates (Figure 2) that step-to-step variability is minimized when the relative roles of FF and FB are appropriately balanced. In the presence of noise, there is an optimal combination that produces better performance over either FF or FB alone. CPGs may be interpreted to act as local internal models of limb dynamics. In this sense, CPGs are not seen to simply produce motor commands for muscle activation, but also to process sensory information. Further application of state estimation theory may provide insight into the role of CPGs in biological movement.

## BIOMECHANICS OF THE FLEXRIM LOW IMPACT WHEELCHAIR HANDRIM

W Mark Richter, Russell Rodriguez, Kevin Woods, and Peter Axelson  
 Beneficial Designs BioMobility Lab, Nashville TN  
 mark@beneficialdesigns.com      www.beneficialdesigns.com

### INTRODUCTION

Handrims are the primary interface by which a wheelchair user controls the wheelchair. The standard handrim is anodized aluminum and relatively slippery. As a result, the user must grip it tight to keep their hand from slipping. A vinyl-coated handrim provides increased friction so the user does not have to grip as much. Because the vinyl coating is a heat insulator, it can burn the hand when braking downhill. However, its benefits to propulsion are important to take advantage of, since decreasing physical demand on the wheelchair user may serve to delay or prevent the development of upper extremity repetitive stress injuries.

In a study of 9 wheelchair users pushing on a treadmill set to a range of grade conditions, we found the use of a vinyl-coated handrim resulted in a 9% average decrease in metabolic demand during propulsion [1]. In a similar study of 25 wheelchair users, we found subjects tended to push with an average of 10% more power during the push [2]. As a result users spent less time pushing and more time coasting. However, this increased push intensity also resulted in a higher rate of loading in the radial direction, which has been associated with incidence of repetitive stress injuries. Use of a compliant handrim has been shown to reduce the rate of loading during propulsion [3]. The FlexRim is a new handrim that incorporates a high friction grip surface with a compliant interface to reduce impact loading (Figure 1). The outer rim is uncoated, so the FlexRim preserves the ability to brake downhill. The purpose of this study was to assess the biomechanics of the FlexRim during propulsion.

**Figure 1:** The FlexRim has a high friction compliant interface for the hand that is designed to improve grip and reduce impact loading during propulsion.

### METHODS

Full-time manual wheelchair users were recruited to participate in this study. Subjects were asked to propel their wheelchair (with instrumented wheels) on a treadmill using

one of either the FlexRim handrim or the standard handrim. Handrim order was randomized. Subjects propelled at predetermined self-selected (comfortable) speeds for 35 pushes on level, 30 pushes at 3 degrees, and finally 25 pushes at 6 degrees. Kinetic and kinematic measures were made continuously over each handrim trial. The last 20 pushes from each grade condition were used in the analysis. For each push analyzed, target temporal and kinetic characteristics were determined and averaged over the entire 60-push set. Biomechanical metrics were then compared between the handrim conditions using a paired samples t-test and determined to be statistically significant for  $p < 0.05$ .

### RESULTS AND DISCUSSION

Twenty-five (25) subjects, with an average of 17 years of wheelchair experience ( $sd=11$ ) participated in the study. The resulting temporal and kinetic biomechanical measures are given in Table 1. The magnitude and rate of loading radially into the handrim ( $Fr$ ,  $dFr/dt$ ) were maintained due to the compliance of the FlexRim. The axial moment ( $Ma$ ) and moment generated by the hand ( $Mh$ ) were both found to be significantly higher, by 15.5% and 27.8% respectively for the FlexRim. The FlexRim did not affect push frequency. Similar to the vinyl-coated handrim, use of the FlexRim resulted in improvements in the ratio of time spent pushing to coasting, as well as in the amount of power generated during the push. The FlexRim resulted in a 13.2% increase in the average power generated, even greater than that found for the vinyl-coated handrim in an earlier study [2].

### CONCLUSIONS

Improving the ergonomics of wheelchair propulsion is important as it may serve to delay or prevent the development of repetitive stress injuries. The FlexRim low impact handrim was found to result in dramatically improved power generation during the push without the adverse effects found for the vinyl-coated handrim. Longitudinal studies of injury development will be necessary to evaluate the long-term injury prevention potential of the FlexRim.

## HIP- SPINE INTERACTION DURING SIT-TO-STAND IN HEALTHY YOUNG SUBJECTS

Fotoohabadi MR, Tully EA, and Galea MP.

School of Physiotherapy, The University of Melbourne, Parkville, Victoria 3010.  
email: [m.fotoohabadi@pgrad.unimelb.edu.au](mailto:m.fotoohabadi@pgrad.unimelb.edu.au), web: [www.physioth.unimelb.edu.au/](http://www.physioth.unimelb.edu.au/)

### INTRODUCTION

Standing up from sitting (STS) is essential for walking and therefore independent function. However, little is known about the contribution of the thoracolumbar spine during STS. It has been suggested that minimal movement occurs in the spine during STS, with trunk forward lean prior to buttock's lift off (LO) being produced solely by flexion of the hips[1,2]. The aim of this study was to use computer-aided video analysis to determine the sagittal contribution of lumbar and thoracic spine, hip and knee joints during STS in a group of healthy young adults.

### METHODS

Forty-seven healthy young adults with reflective markers attached over the mid-line thoracolumbar spine, right lateral pelvis and lower limb were videotaped (i) performing STS at their preferred speed from a chair set at 100% knee height, and (ii) undertaking tests for maximal available thoracic, lumbar and hip joint flexion. The automatic digitization mode of the 2D Peak Motus was used to track the marker movement on the videotape at 50Hz. Following (Butterworth) filtering of the data sagittal thoracic, lumbar, hip, and knee angles were calculated. All angular data were normalized to 100% movement duration to accommodate speed variations between subjects.

### RESULTS AND DISCUSSION

Forward trunk lean prior to LO was accomplished by concurrent lumbar and hip flexion; 1° lumbar flexion for every 2.7° hip flexion. As the lumbar spine flexed the thoracic spine extended resulting in a LO trunk angle of 45.7°(±5.8°). Following LO, the hip(s) and lumbar spine extended and the thoracic spine flexed, with the standing thoracic angle approximating the initial thoracic flexion posture in sitting. During STS subjects used 95.5%, 65.9%, and 57.7% of their maximal available hip, lumbar and thoracic spine flexion respectively.

### CONCLUSION

Improved knowledge of sagittal thoracolumbar and hip-spine movement patterns in healthy subjects will facilitate rehabilitation of dysfunctional STS.

## KINETIC CHARACTERISTICS OF MIDDLE-AGED AND OLDER ADULTS DURING WALKING

<sup>1</sup> Hidetaka Okada, <sup>2</sup>Shinya Kuno, <sup>2</sup>Mitsuo Matsuda and <sup>2</sup>Michiyoshi Ae  
<sup>1</sup>The University of Electro-Communications, Japan; e-mail: hidetaka@e-one.uec.ac.jp  
<sup>2</sup>University of Tsukuba, Japan

### INTRODUCTION

The ability to walk is one of the most important factors for us to live actively. It may be a strong determinant for independent daily living, especially for elderly people. Unfortunately, the ability of the elderly to walk seems to deteriorate with aging. However, we can find the biomechanical causes of that deterioration and show how the elderly can maintain the ability to walk from the results of kinetic analyses of their motion.

The purpose of this study is to clarify the kinetic characteristics for middle-aged and older adults during walking and to present findings useful for maintaining or enhancing their ability to walk.

### METHODS

The subjects were 326 healthy Japanese adults, including 49 middle-aged, 265 elderly and 12 young adults (Table 1). They were instructed to walk about 10m as they usually did in their daily lives. In order to analyze the motion in the sagittal plane, we videotaped them during walking with a digital VTR camera at 60fps. The ground reaction forces on the right foot were measured by a force platform installed below the walkway. Two-dimensional coordinates of the eight body landmarks were obtained by using a video digitizing system (Frame-DIAS, DKH Co., Ltd.). The coordinates were smoothed by a fourth-order, zero-phase-shift Butterworth digital filter at the optimal cut-off frequencies that were derived from residual analysis (Winter, 1990). After synchronizing the smoothed coordinate data and ground reaction forces, we calculated joint torques at the ankle, knee and hip using a link-segment model based on the inverse dynamics method. Joint torque powers were next calculated by multiplying the joint torque by the joint angular velocity. Finally, joint mechanical work was calculated by integrating the joint torque power over time.

### RESULTS AND DISCUSSION

Figure 1 depicts the joint mechanical work of the ankle, knee and hip during normal walking for each age group. From these results, it appeared that positive work of ankle and knee and negative work of each joint for M, E1, E2 and E3 were smaller than those for Y. The positive ankle work was remarkably smaller in older groups. In contrast, the positive hip work was larger in older groups than the younger group.

Table 1 Subjects and age groups

Group	Abbr.	n	Age (yr.)	
			Mean±SD	Range
Young	Y	12	24.5±1.8	22.02-27.54
Middle-aged	M	49	59.7±4.8	45.30-64.97
Elderly 1	E1	97	67.6±1.3	65.14-69.99
Elderly 2	E2	109	72.5±1.4	70.05-74.98
Elderly 3	E3	59	77.7±2.2	75.31-86.32

Positive ankle power is exerted only in the second half of the stance phase (push-off phase) in walking. In this phase, positive power is generated by concentric contraction of the ankle plantar flexors, in which plantar flexion torque is exerted as the joint moves in the direction of plantar flexion. We therefore believe that the function of plantar flexors during walking deteriorates with aging and the hip joint must then exert more power to compensate for the decline in ankle function.

### CONCLUSIONS

The most remarkable characteristic of walking kinetics for middle-aged and older people is the decrease in positive ankle work. Therefore, preventing the decline in ankle plantar flexor function during walking may be the key for maintaining or enhancing the ability of the elderly to walk.

## DYNAMIC STABILITY IN A ROUGH ENVIRONMENT: THE INFLUENCE OF INITIAL LIMB POSTURE ON BODY DYNAMICS DURING AN UNEXPECTED PERTURBATION.

Monica A. Daley and Andrew A. Biewener  
Concord Field Station, Harvard University; mdaley@oeb.harvard.edu

### INTRODUCTION

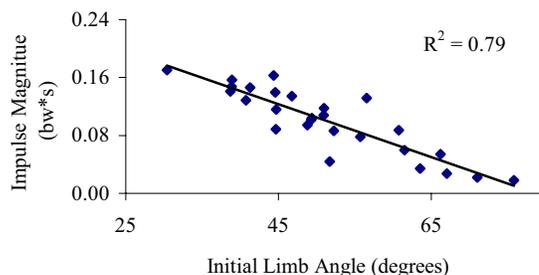

Little is currently known about the capability, mechanics and time-course of recovery from the types of perturbations that animals face while running in the natural world. Work on humans reveals that changes in  $k_{leg}$  help maintain similar CoM motions over surfaces of varying compliance [e.g., 1, 2], and these changes in  $k_{leg}$  can occur through intrinsic changes in limb mechanics [3]. Furthermore, stability of running can be improved by adjusting leg contact angle, which can be accomplished automatically if the leg retracts during late swing phase [4]. Thus, proper tuning of limb parameters in the face of a changing external environment is required to maintain locomotor stability. However, the relative importance of different control mechanisms during real-world perturbations is not yet clear. In this study, we perturb the running of guinea fowl by subjecting them to an unexpected drop in substrate height ( $\Delta H$ ). The goal of this study is to investigate how body centre of mass (CoM) mechanics deviate from steady running dynamics in response to an unexpected  $\Delta H$ , and how limb dynamics mediate the response.

### METHODS

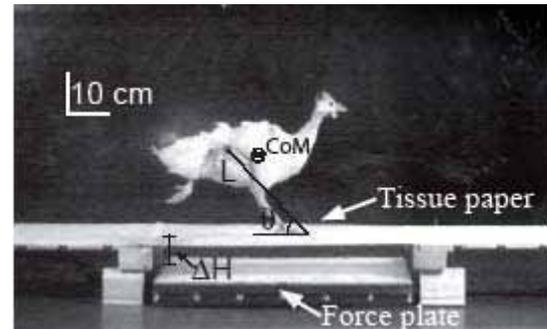

The drop in substrate height is camouflaged to remove any visual cue about the upcoming change in terrain (Figure 1). Ground reaction forces (GRF), measured in the vertical and fore-aft directions, were recorded at 5000Hz and used to calculate instantaneous kinetic and potential energies of the CoM. Limb kinematics during the response were obtained from synchronized high-speed digital video recorded in lateral view at 250 frames  $s^{-1}$ .

### RESULTS AND DISCUSSION

The birds stumbled or fell in fewer than 6% of the unexpected perturbations. In contrast, during visible substrate drops, they stumbled or fell in 20% of the cases, and came to a complete stop in an additional 25%. Due to altered timing between limb retraction and limb loading, an exchange between potential

**Figure 2:** The relationship between limb contact angle and GRF impulse magnitude.

**Figure 1:** Still frame of a guinea fowl as it encounters a hidden drop in terrain, illustrating the experimental setup.

and kinetic energy occurs during the perturbed step, unlike during steady running. The birds exhibited three CoM energy exchange patterns in response to the unexpected  $\Delta H$ , each characterized by a distinct combination of altered magnitude and direction of the ground reaction force (GRF) impulse.

Overall, the results suggest that decoupling of limb retraction from limb loading plays a primary role in determining the dynamics of the response. Limb angle at the time of ground contact explains much of the variation in CoM dynamics during the response (Figure 2). In contrast,  $k_{leg}$  during the unexpected  $\Delta H$  varies dramatically but does not predict the CoM dynamics. Therefore, it appears that limb posture at ground contact plays a larger role in the response to the perturbation than does  $k_{leg}$  alone. The variation in stance phase CoM dynamics during the perturbation likely relates to altered intrinsic mechanics when the leg contacts the ground with a different posture.

### CONCLUSIONS

Despite large changes in CoM dynamics and a great deal of variability in the response to an unexpected  $\Delta H$ , guinea fowl are quite successful in maintaining dynamic stability, as they rarely stumble or fall. Further investigation of the joint and muscle dynamics underlying this variation could yield further insight into the control mechanisms that allow such robust dynamic stability during running in the face of large, unexpected perturbations.

## SHORT AND LONG-TERM INFLUENCE OF A CUSTOM FOOT ORTHOTIC INTERVENTION ON LOWER EXTREMITY DYNAMICS IN INJURED RUNNERS

Christopher L. MacLean and Joseph Hamill

Biomechanics Laboratory, University of Massachusetts-Amherst, Amherst, Massachusetts, USA

E-mail: [cmaclean@excsci.umass.edu](mailto:cmaclean@excsci.umass.edu)

### INTRODUCTION

Prior research on the influence of custom foot orthotic (CFO) intervention has primarily focused on the short-term dynamical influences at the ankle and knee in healthy runners. That is, subjects in the study were dispensed custom foot orthoses and tested immediately with no controlled period of wear. In addition, for the most part, subjects included in these studies have been healthy subjects who are not typically candidates for this intervention (Mundermann et al., 2003). Therefore, the purpose of this study was to analyze the short and long-term influence of a CFO intervention on the lower extremity dynamics in a sample of runners who had a history of running related knee injury.

### METHODS

Eight female runners (at least 10+ miles per week) with a history of a knee-related running injury were selected for participation in the study. Each subject performed 5 acceptable over-ground running trials with a CFO and without a CFO (SHOD) (Paris Orthotics Lab, Vancouver, BC, Canada). Subjects were tested at the time of orthotic dispense and following 6 weeks of orthotic wear during all running activity.

Kinematic data were collected using Qualisys® software (Gothenburg, Sweden) at 240Hz and kinetic data were collected using an AMTI® force platform (Watertown, MA, USA) at 1920Hz. Data were processed using Visual 3D® (C-Motion, Inc. Rockville, MD, USA) for the calculation of ankle and knee angles and internal joint moments. Data were statistically analyzed using a Condition X Time X Subjects repeated measures ANOVA. Significant main effects and interactions were indicated with a criterion alpha level of 0.05.

### RESULTS AND DISCUSSION

CFO intervention resulted in significant main effects for Condition (CFO vrs Shod) but not for Time (0 vrs 6 weeks). Short and long-term intervention led to significant decreases in maximum values for rearfoot eversion angle (Figure 1), rearfoot eversion velocity (Figure 2) and internal ankle inversion moment (Figure 3).

The results of this study reveal that 3-D frontal plane dynamics of the ankle were affected by CFO intervention in subjects with a history of running-related knee injury. Results from this sample of runners indicate that the influence of CFO intervention might be realized immediately and that changes in dynamical variables were not significantly influenced by prolonged wear following dispense.

## PATELLAR LIGAMENT INSERTION ANGLE INFLUENCES QUADRICEPS USE DURING STAIR CLIMBING: EFFECT OF AN ANTERIOR CRUCIATE LIGAMENT DEFICIT

<sup>1</sup>Ajit Chaudhari, <sup>1</sup>Choongsoo Shin, <sup>1,2</sup>Chris Dyrby and <sup>1,2</sup>Thomas Andriacchi

<sup>1</sup>Dept. of Mechanical Engineering, Stanford University,

<sup>2</sup>Bone & Joint Center, VA Palo Alto Health Center; email: ajit.chaudhari@stanford.edu, web: biomotion.stanford.edu

### INTRODUCTION

The patellar ligament transfers the force of quadriceps muscle contraction to the tibia. The orientation of the force transferred to the tibia is influenced by the patellar ligament insertion angle (PLIA), defined as the angle between the patellar ligament and the tibial shaft, since the PLIA determines how quadriceps force is decomposed into the anterior and superior directions. In individuals with an anterior cruciate ligament deficit (ACL-D), this anterior component of the force may cause anterior tibial translation. One of the explanations for why ACL-D individuals often reduce quadriceps force gait during walking is to prevent excessive anterior tibial translation [1]. Based on this explanation one would expect that anatomical variation in the PLIA would influence the tendency of patients to reduce quadriceps contraction. While it has been observed that ACL-D knees have a reduced PLIA relative to the contralateral knee or control knees [2], the relationship between this reduced PLIA and the reduction or avoidance of quadriceps usage has not been explored.

This study tested the hypothesis that in ACL-D knees, the peak external knee flexion moment during stair climbing would be negatively correlated to the PLIA, while in the contralateral or control limbs no such correlation would occur.

### METHODS

Seventeen subjects were studied after giving IRB-approved informed consent – nine unilateral ACL deficient (age=40.1±12.7 years, 7 male, 2 female, average 178 months past injury) and eight controls with no history of musculoskeletal injury (age=34.3±9.9 years, 6 male, 2 female). Sagittal-plane magnetic resonance images (3DSPGR) were taken of each subject's knees in a fully extended, non-

weight-bearing position. PLIA was defined as the angle in the sagittal plane between the patellar ligament and the tibial shaft, as described previously [2].

All subjects climbed a set of 21-cm steps while being recorded using an opto-electronic motion capture system with six markers on each lower limb. A force plate under the first step recorded the ground reaction force. A previously-described link model was used to estimate the net external forces and moments acting at the joints [3]. Three trials were captured for each leg, and the peak external knee flexion moments for the three trials were averaged together for subsequent analysis.

Linear regressions were performed to examine the strength of the correlations between the PLIA and the peak knee flexion moment, with a significance level of  $\alpha=0.05$ .

### RESULTS AND DISCUSSION

The significant negative (slope=-0.41,  $p=0.04$ ,  $R^2=0.48$ ) relationship between PLIA and knee flexion moment (Figure 1) for the ACL-D knees suggests that individuals with a smaller PLIA experience less of an anterior pull on the tibia when the knee extensors are active, and therefore they show less of a tendency to avoid using these muscles.

Although it fell short of statistical significance, the positive slope observed in the contralateral knees (slope=0.39,  $p=0.05$ ,  $R^2=0.43$ ) appears to be different from the control knees and deserves further study. For the control knees, no relationship was observed ( $p=0.19$ ,  $R^2=0.26$ ).

### CONCLUSIONS

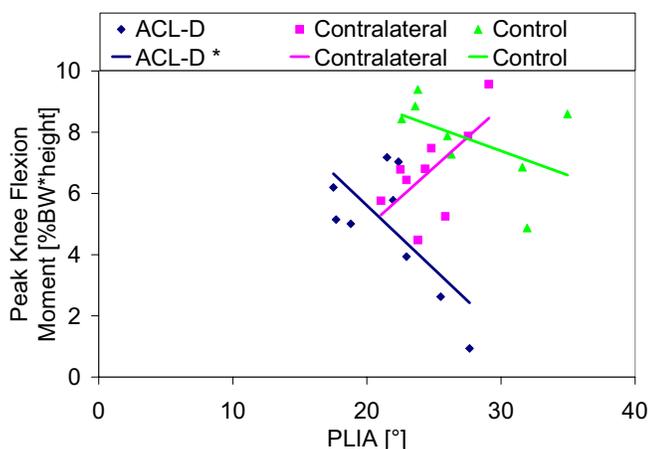

The results of this study indicate that differences in the orientation of the patellar ligament can influence the tendency of ACL-D patients to reduce quadriceps contraction. Moreover, this study may help to explain why some researchers have reported observing quadriceps avoidance [1] while others have not [4], since the PLIA variability between ACL-D subjects can be considered as a confounding factor in those earlier studies.

**INTRODUCTION**

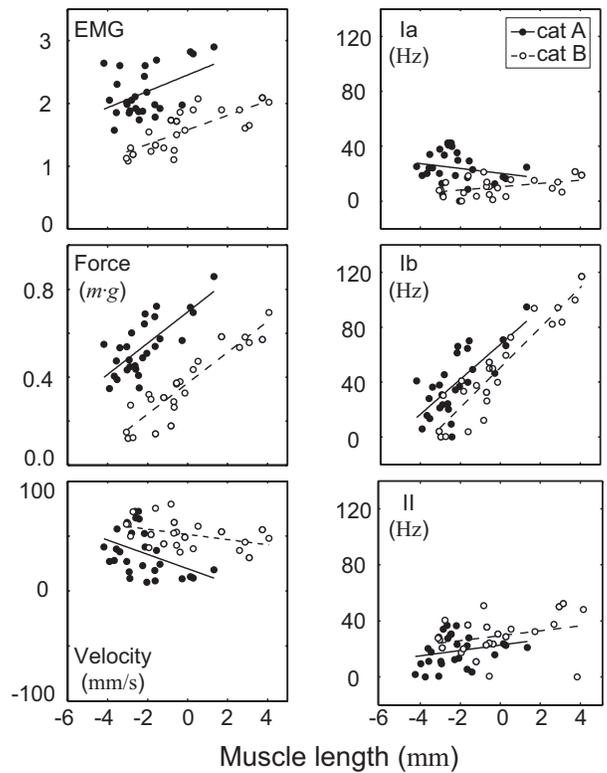

Our previous work on decerebrate cats suggested that force feedback, originating from Golgi tendon organs (GTOs), makes a substantial contribution to ankle extensor activity accounting for approximately 50% of suprathreshold activity at longer muscle lengths [1]. To test the functional significance, we determined the contribution of force feedback to muscle activity during walking in conscious cats with intact central nervous systems.

**METHODS**

We trained 2 cats to walk on a pegway that could be adjusted to different slopes (Figure 1; +25, +10, 0, -10, -25 degrees). One peg measured ground reaction force. Video analysis yielded joint kinematics. To isolate the MG muscle, other major ankle extensors (LG, Sol, and Pl) were denervated 4 days prior to data collection. Implanted EMG electrodes measured muscle activity. Using inverse dynamics and moment-arm measurements, we estimated MG force, length, and velocity. The estimates allowed the use of mathematical models [2] to predict muscle spindle (Ia and II afferents) and GTO activity (Ib afferents).

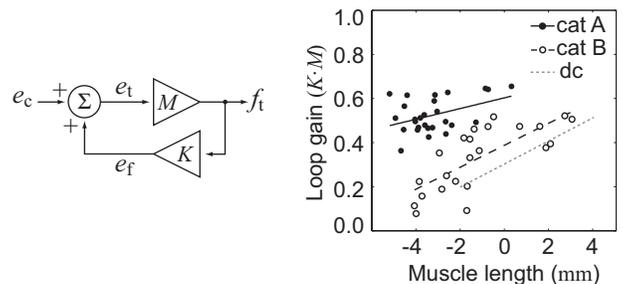

**Figure 1:**

**Figure 2:** Relationship between muscle length and muscle activity, force, velocity, and predicted proprioceptor activity during stance. A positive velocity denotes a lengthening muscle. Symbols represent the average value over 50 ms beginning 50 ms after ground contact. Lines are best-fit linear regression lines.

**RESULTS AND DISCUSSION**

As expected, greater slopes resulted in increased muscle activity and force at longer muscle lengths during stance (Figure 2). Due to this increase in force, predicted Ib activity increased strongly with length. Predicted Ia and II activity, however, was nearly independent of length because muscle velocity decreased at longer muscle lengths. This suggested that changes in muscle activity were due primarily to force feedback allowing the use of a simple model of the neuromuscular system to estimate the pathway loop gain ( $K \cdot M$ ; Figure 3). This gain ranged from  $\sim 0.2$  at short muscle lengths to  $\sim 0.6$  at longer muscle lengths demonstrating that force feedback was of modest importance downhill, accounting for 20% of total activity and force, and of substantial importance uphill, accounting for 60%. This length dependence was due to the intrinsic force-length property of muscle,  $M$ . The gain of the pathway that converts muscle force to motoneuron depolarization,  $K$ , was independent of length. These findings emphasize the general importance of feedback in generating ankle extensor activity during walking in the cat and suggest the intriguing possibility that feedback automatically compensates for changes in slope without requiring different descending commands.

**Figure 3:** Left: Force feedback model. Total muscle activity,  $e_t$ , and force,  $f_t$ , are measured variables.  $e_c$ , the central contribution to  $e_t$ , was estimated as the y-intercept of the regression line for the relationship between  $e_t$  and  $f_t$ . We solved for the remaining variables. Right: Relationship between loop gain and muscle length. Symbols represent the average values and lines represent linear regressions. The dotted line shows that previous decerebrate experiments yielded similar results to current findings.

## APPROACH VELOCITY PROFILES OF ELITE MALE AND FEMALE LOWER-LIMB AMPUTEE LONG JUMPERS

### INTRODUCTION

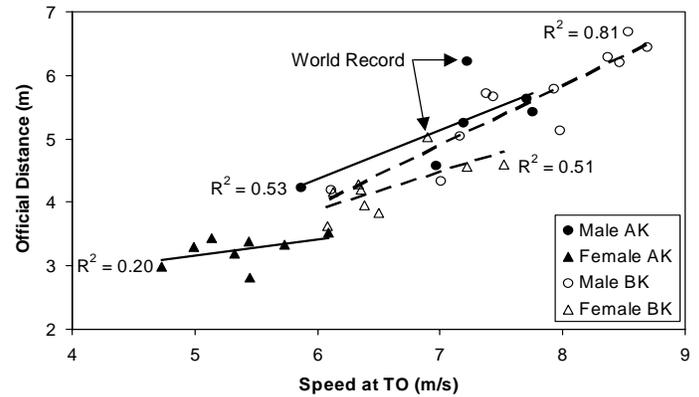

The approach velocity is accepted as a key determinant of successful long jump performance for elite able-bodied athletes [1,2]. Whether a similar relationship underlies the performance of disabled athletes, such as lower-limb amputees, is not well known. There is evidence that greater approach speed at take-off (TO) contributes positively to distance jumped for male below-knee amputees (BKA) and also for male above-knee amputees (AKA) with some slight adjustments in technique [3]. However, compensatory kinematics due to a prosthetic knee joint likely influences the regulation of velocity on the long jump approach [4]. The aim of this study was to compare approach velocity profiles of elite AKA and BKA, and the relationship between approach velocity and distance jumped.

### METHODS

The velocity profiles of the approach runs of 14 AKA (male = 6, female = 8) and 20 BKA (male = 11, female = 9) were investigated during the long jump finals at the 2004 Paralympic Games. Approach velocities were sampled (100 Hz) using a laser Doppler device (Laveg, Jenoptik, Germany) positioned behind the long jump pit and targeted on the torso of each athlete during the run up. Velocity for the entire run up was recorded for each successful jump, corrected for perspective error and smoothed using Laveg Sport<sup>®</sup> software. Mean ( $\pm$  SD) data of selected velocity variables for positions 0m (take-off (TO) board), 1m, 6m, and 11m before the take-off board were calculated for each group using the greatest official distance jump of each athlete (Table 1). Differences between classification (AKA vs BKA) for each gender were determined using Students t-test. Relationships between variables were analysed using Pearson correlation and linear regression. Significance was set at  $p < 0.05$ .

### RESULTS AND DISCUSSION

Female AKA approach velocity and distance jumped were lower than female BKA (Table 1), and lower than those reported for skilled able-bodied jumpers [1]. Likewise, the male athletes ran slower and jumped less far with increasing level of amputation, supporting previous research [3]. The positive relationship between approach velocity and distance

**Figure 1:** Relationships between approach velocity and distance jumped for male and female AKA and BKA athletes.

jumped was strongest for male BKA athletes (Figure 1). Male AKA and female BKA athletes showed a slightly weaker relationship, partly conforming to the accepted long jump model [2,3]. Female AKA, however, exhibited a weak relationship indicating that for a given increase in approach velocity, the gain in distance jumped is minimal. Female AKA had a greater increase in approach velocity between 11-6m compared to the other athletes (Table 1). They also were the only group to have a relationship ( $r = -0.77$ ) between this variable and distance jumped, and the only group to exhibit a weak relationship ( $r = 0.25$ ) between average velocity at 11-6m and distance jumped. Thus, female AKA may be compensating for their slow approach velocity by continuing to accelerate between 11-6m from the TO board. This has a negative effect on their jump performance. The mechanisms which prevent female AKA from performing long jump technique in the same manner as female BKA or male AKA are not known and warrant detailed kinematic analysis.

## WHAT FACTORS EFFECT THE ACCURACY OF SOLID MODELS MADE FROM CT DATA?

Heidi-Lynn Ploeg<sup>1</sup>, Nick Byrne<sup>1</sup>, Sylvana Garcia<sup>1</sup>, Mariana Kersh<sup>1</sup>, Andrew Van de Weghe<sup>1</sup>  
<sup>1</sup>Departments of Mechanical and Biomedical Engineering, University of Wisconsin, Madison, WI, USA  
 email: [ploeg@engr.wisc.edu](mailto:ploeg@engr.wisc.edu), web: [http://www.engr.wisc.edu/me/faculty/ploeg\\_heidi-lynn.html](http://www.engr.wisc.edu/me/faculty/ploeg_heidi-lynn.html)

### INTRODUCTION

Computer models of bones are essential tools for research in orthopaedics, preclinical analysis of orthopaedic implant designs, and in computer-aided surgery. In these applications, solid models of bones are routinely created from computed tomography (CT) scan data; however, there are few studies [1-3] that have quantified the effects of the process parameters, on the error of the resulting geometry. The purpose of this study was to determine the magnitude of the error in solid models generated from CT-scan data and to which factors the error was most sensitive.

### METHODS

This study compared the volumes of simple shapes derived from their measured dimensions and their segmented CT data. Cubes and cylinders were constructed from aluminum 6063 and polyurethane (PU) foam and their geometric dimensions were measured. Solid models based on the measured dimensions of the pieces were constructed with Unigraphics NX 2.02 from EDS, Plano, TX. In addition, the pieces were CT scanned (120 kV, 30 mA ,GE Litespeed<sup>16</sup> CT scanner from GE Medical Systems, Waukesha, WI at the University of Wisconsin Hospital), and their geometry was reconstructed by segmenting (Mimics 8.11 from Materialise, Ann Arbor, MI) the grey values of CT data that represented the density of the shapes.

The volumes of the shapes reconstructed from the CT data were normalized to the volumes of the solid models constructed from the measured dimensions. The effect of 7 factors at 2 levels each on the normalized volume of the segmented models was investigated using a one quarter fractional factorial design. 32 ( $2^{7-2}$ ) treatments were run without replication in random order. The 7 factors and each of their high and low levels were:

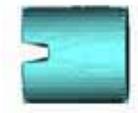

1. CT-scan axis orientation: parallel and perpendicular to sample axis;
2. CT-scan slice thickness: high (1.25 mm) and low (0.625 mm);
3. CT-scan slice spacing: high (1.25 mm) and low (1.625 mm);
4. Density: high (aluminum 6063, 2700 kg/m<sup>3</sup>) and low (solid rigid PU foam, 320 kg/m<sup>3</sup>);
5. Fill: full and hollow (wall thickness 3.18 mm);
6. Feature: with and without a 3.3 mm wide by 6.6 mm deep, centered slot; and,
7. Shape: cube (25.4 mm<sup>3</sup>) and cylinder (25.4 mm diameter x 25.4 mm height).

### RESULTS

The mean of the normalized volumes of all the segmented shapes was 96% (79%-115%). A normal probability plot of the effect estimates from the fractional factorial analysis found that density was the only main effect that was likely to be important. The normalized volume of the aluminum and PU samples were 105% (93-115%) and 88% (79-96%) respectively. In contrast, all the highs and lows of the other main effects differed by less 2% (95-97%). In Table 1, the qualitative effects of the scanning parameters on the segmented models are demonstrated.

**Table 1. The Effects of Scanning Parameters**

**a) Scan Axis Perpendicular to the Sample Axis.**

	Fine Spacing	Coarse Spacing
Fine Thickness		
Coarse Thickness		

**b) Scan Axis Parallel to the Sample Axis.**

	Fine Spacing	Coarse Spacing
Fine Thickness		
Coarse Thickness		

### DISCUSSION

Even though, normalized volume is a relatively insensitive result, density was found to be an important main effect. Volumes were under and over-estimated for low and high density pieces respectively. The scanning parameters had a qualitative effect on the models; however, it remains to be investigated, if a more sensitive result would find quantitative effects.

## EFFECTS OF SHORT-TERM WALKING EXERCISE IN ELDERLY

Sukhoon Yoon, Jeff Casebolt, Sunghoon Shin, Jaewoong Kim, and Young-Hoo Kwon  
 Biomechanics Laboratory, Texas Woman's University, Denton, TX 76205-5647  
 email: [g\\_2yoon@mail.twu.edu](mailto:g_2yoon@mail.twu.edu), web: <http://www.twu.edu/biom>

### INTRODUCTION

Falls among the elderly are quickly becoming an enormous concern for the United States in the 65-plus age group population. Tripping is one of the main causes for concern and is usually attributed to decreased lower extremity strength, stability, and range of motion. Minimizing the potential for tripping when maneuvering around or over an obstacle requires body control and working within a safe distance of the obstacle in question. Furthermore, if an obstacle is of a different height, then additional strength and coordination are needed from the lower extremity to perform the appropriate action.

The purpose of this study was to determine the effectiveness of: 1) a three month regular walking program, and 2) three different walking groups to improve an elderly individual's ability to interact with a series of obstacles in a safe and effective manner.

### METHODS

Subjects were medically screened and cleared by a doctor to participate in the study. Thirty-three subjects volunteered and met all the criteria for participation (mean age:  $73.2 \pm 5.5$  yrs). Thirteen males and twenty females were randomly assigned to one of three walking groups: 1) walking without equipment (C), 2) walking with ski-poles (T1), and 3) walking with equipment where the poles attached to a vest and were allowed to swing freely by the participants side (T2). The walking program lasted for twelve weeks and included three sessions per week at forty-five minutes per session.

Each participant was asked to perform three distinct tasks at a self selected pace using both their Preferred (P) and Non-Preferred (N) leg: 1) Step-Over (SO), 2) Step-Up (SU), and 3) Step-Down (SD). The SO consisted of an obstacle placed in the path of the participant at a height of 30% of leg length. During SU and SD the subjects were asked to step on to or down from a platform at a self-selected pace. The height of the platform was set at 30% of leg length.

Participants' motions were recorded in both right and left sagittal planes at 60-Hz video cameras (Panasonic AG450) and digitized with Kwon3D motion analysis software (Visol, Inc., Seoul, Korea). Ground reaction forces were collected using two force plate (AMTI OR6-5).

The 3 x 2 (groups x periods) factorial ANOVAs were performed to see significance in dependent variables ( $\alpha < .05$ ).

### RESULTS AND DISCUSSION

During SO, Maximum Vertical Heel Clearance (MVHC) was calculated as the vertical distance between top of the obstacle and heel of the lead leg at the instant of the leg crossing the obstacle. Toe Clearance (TC) was defined as the horizontal distance between the toe of the lead leg and the obstacle prior to crossing the obstacle. Heel Clearance (HC) is the horizontal distance between the heel and the obstacle at post crossing obstacle. The significant crossing clearance differences in step over among groups were shown (Table 1). SU elicited different GRF loading times among groups ( $p < 0.05$ ). Longer propulsive force loading time were demonstrated in T2 versus T1 in both SU\_N and SU\_P, while T2 showed longer pulling force loading time compare with T1 in SU\_P.

Pulling force loading time may indicate the index of confidence for falling. If an elderly walker has confidence to step up onto an obstacle in a safe manner, the trail foot will remain in contact with ground until leading foot is fully secure on the top of the platform.

While we expected a training effect, none was noted. This is probably due to the relatively short training period (12 weeks) coupled with the relatively low intensity training (walking). One possible reason for lack of significant data may be the duration of the training period. O' Neill et al. reported positive resistance training effects within 3 months [1], but the current study may have been hindered due to the low-intensity activity of walking given the time frame [2].

### CONCLUSIONS

The current study revealed obstacle clearance and loading time differences among groups. At the present time, we cannot attribute these differences to the relatively short training period and low-intensity activity. A longer training period seems warranted, and further studies with longer training periods are in progress.

### INTRODUCTION

Osteoporosis is a systemic skeletal disease which increases bone fragility and susceptibility to fracture. Osteoporosis afflicts about 200 million people around the world [1] and osteoporotic fractures are estimated to be several millions annually in the US alone and cost tens of billions of dollars [1]. Characterization of bone quality in osteoporotic patients is very important with respect to monitoring treatment efficacy, however, currently quite limited. While some technical hurdles in developing a diagnostic tool using low frequency vibration have been overcome, many questions still remain including data interpretation and analysis. In particular, changes in the frequency response signal of bone have not been investigated at the various bone organizational levels. Our principal hypothesis is that the vibrational modes of bone tissue changes significantly with the deterioration of bone micro-architecture and that these modes can be captured by sensors to infer a structural compromise.

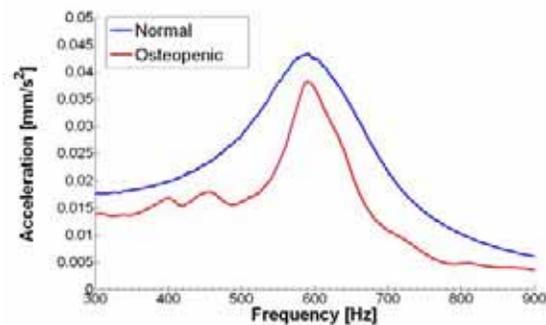

### METHODS

**Bone Models:** Rapid prototyped duplicates of trabecular bone samples were fabricated based on digital scans of a lumbar vertebra excised from a female cadaver and obtained on a  $\mu$ CT80 (Scanco Medical) with an isotropic resolution of 30  $\mu$ m. Through image manipulation, triangulated surfaces of a randomly selected bone cube taken from the lateral aspect of the vertebra were generated using the thresholded  $\mu$ CT scans. This bone cube measured a bone mineral density (BMD) of 127 mg/cm<sup>3</sup>, with is within the normal range [2]. An available custom algorithm was used to reduce the overall bone mass of the normal bone cube to an osteopenic stage (BMD of 86 mg/cm<sup>3</sup>). After scaling both models, digital files were exported to a rapid prototyping system, which fabricated a scaled up duplicate of both bone cubes with 20 cm edge length (Figure 1).

**Vibrational Analysis [3, 4]:** Dynamical responses were carried out by attaching the bone cubes to an active electro-dynamic shaker while simultaneously recording acceleration and dynamic force. Frequency Response Function (FRF) measurements were made using random broad band excitation signal. A sample rate of 2000 S/s with a Hanning time domain window allowed for a frequency resolution of 0.1 [Hz]. The experiments on the cubes were repeated three times in alternative order to ensure accuracy of the results. The power spectrums of the force and acceleration signals were computed. Acceleration signals were processed to derive velocity and displacement signals. Dynamic stiffness, half-peak bandwidth, and damping ratio ( $\zeta$ ) for both bone cubes were calculated using FRF measurements, and other techniques.

**Figure 1:** Scaled version of a normal (right) and osteopenic (left) bone cubes were made using rapid prototyping system.

**Figure 2:** Power spectrums of acceleration signals from normal and osteopenic bone models (peak at 595 [Hz]).

### RESULTS AND DISCUSSION

The normal bone model showed a light modal coupling in power spectrum, whereas the osteopenic bone model showed a heavy modal coupling with both models exhibiting a strong peak at 595 [Hz] (Figure 2). The half-peak bandwidths for the normal and the osteopenic bone were determined to be 265 ( $\zeta = 0.10$ ) and 130 ( $\zeta = 0.08$ ) [Hz], respectively. The dynamic stiffness of the osteopenic bone model was about one third of the normal bone model.

### CONCLUSIONS

The results of the experimental modal analysis of the bone cube models representing the normal and osteopenic stages of trabecular bone have been discussed here. Although at a preliminary stage, the results have showed a clear difference between these two architectures. Current and further studies are underway to ensure the feasibility and reliability of a structural dynamics approach to detect early stages of bone loss.

web: <http://pt.umaryland.edu>

**INTRODUCTION**

Stroke is the leading cause of disability in the US, leaving two-thirds of survivors with abnormal motor function, including hemiparetic gait. Gait velocity is commonly used to assess locomotor function in this population, though velocity alone provides only a general index of function (1). A more detailed description of hemiparetic gait can be derived from center of pressure (CoP) time series measurements taken at each foot during the gait cycle. These measures may reflect aspects of the underlying motor control for walking and have been used to characterize asymmetries in hemiparetic gait (2). The goal of this study was to identify paretic and nonparetic foot CoP characteristics that may have a predictive relationship with the global functional measure of gait velocity.

**METHODS**

Thirty-three chronic stroke survivors > than 6 months post-stroke (10 female; 22 with left hemiparesis; mean age 67±10 yrs) were evaluated during walking at a self-selected speed on an instrumented gait mat (GaitRite®, CIR Systems, Clifton, NJ, USA). Patients wore pressure sensitive shoe insoles (Pedar®, Novel, Munich, Germany) and completed 15 steady-state gait cycles (five from each of three trials). Walking velocity and center of pressure parameters were measured during each cycle. Multiple regression analyses were used to model 58 CoP and symmetry parameters as predictor variables of gait velocity in all possible combinations. For the final model, parameters were evaluated using an adjusted regression model with  $\alpha \leq 0.05$  and independence defined as a Variance Inflation Factor <10.

**RESULTS**

Table 1 shows the intercept and 11 parameters used to construct the final model, including bilateral variability of CoP mean location and displacement in anteroposterior (A-P) and mediolateral (M-L) directions, bilateral peak force, variability in stance time symmetry, and variability in CoP path length symmetry index. All parameters in the resulting final model contributed significantly and independently to the prediction

of gait velocity. CoP and symmetry parameters in this model accounted for a large portion of the variance in hemiparetic gait velocity ( $R^2_{adj} = .90$ ), showing strong predictive ability in this group of patients with chronic stroke.

**DISCUSSION AND CONCLUSIONS**

In the present study, 8 of the 11 variables used to predict hemiparetic gait velocity were derived from CoP time series. In addition, the relationships between the variability of the CoP parameters to gait velocity suggest a connection to motor control deficits at the foot and ankle during hemiparetic stance in both limbs. For example, velocity is positively related to variability of the nonparetic mean M-L CoP location, but is negatively related to the variability of A-P CoP location. Thus increased walking velocity may improve consistency of loading related to nonparetic dorsi-plantar flexor control, but it simultaneously introduces less predictable loading through the range of inversion-eversion. This latter effect is underscored by increasing ranges and variability on M-L loading of the paretic foot. The notion of improved motor control with higher velocities is also supported by the decreased variability in the symmetry ratio of paretic-to-nonparetic stance times, an indication of more consistent interlimb patterning. The significance of these results is that foot CoP measures not only successfully index functional locomotor status, but they may also be useful in determining adaptive mechanisms of recovery associated with specific therapeutic interventions.

## IMPACT OF RESTRICTED PIP JOINTS ON MCP JOINT MOTION IN THE HUMAN HAND

Jessica Woodworth\*, Matthew McCullough\*, Nicole Grosland<sup>†\*</sup> and Brian Adams<sup>†\*</sup>  
Departments of Orthopaedic Surgery<sup>†</sup> and Biomedical Engineering\*, University of Iowa, Iowa City, IA

### INTRODUCTION

Loss of motion of the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints caused by trauma or degenerative processes impairs hand function. Patients with arthritis often have involvement of multiple finger joints, which further decreases function. Surgical alternatives for severe PIP arthritis are arthrodesis and implant arthroplasty. Arthrodesis provides a pain-free and stable joint, but sacrifices motion, resulting in a need for compensatory increased motions at neighboring joints. Arthroplasty is an attractive option, but its risks should be weighed against the impairment caused by fusion. The impact of stiff finger joints on the performance of activities of daily living is unclear. In this study we aim to determine the affect of restricting PIP motion on the range of MCP motion while performing several manual tasks.

### METHODS

After obtaining IRB approval, 15 subjects (5 male/9 female) without upper extremity compromise were recruited from the local community. Subsequently, informed consent was obtained from each subject. The goal was to evaluate the motions used by the MCP joints of the dominant hand for a series of thirteen activities of daily living (ADL) with the PIP joints free and splinted. Tasks included: tying a shoe, buttoning a shirt, turning a doorknob, drinking, opening a jar, answering a phone, pouring milk, stirring rice, picking up small objects, eating soup, typing, wringing out a washcloth and signing ones name.

Motion of each finger was monitored using an Optotrak (Northern Digital, Inc., Waterloo, Ontario) motion analysis system with two position sensors. Each task was evaluated under two conditions: 1) unrestricted PIP and MCP motion (i.e. without the use of splints), and 2) fully restricted PIP motion of each finger (excluding the thumb) with unrestricted MCP motion.

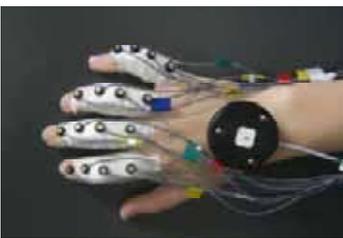

Figure 1. Splinted Finger Setup

For the first condition, four LEDs were affixed to each finger and the respective MCP joint was digitized with respect to a sensor placed on the back of the hand. Subjects were instructed to begin and end each task in the

neutral position (i.e. with their fingers in line with the long axis of the third metacarpal). For the second condition, all four of the PIP joints were splinted at 40 degrees of flexion using small aluminum splints covered with self-adherent

Coban (3M) and secured to the fingers with tape. The position sensor remained on the back of the hand and markers were applied directly to each splint (Figure 1). Each task was performed at a self-selected pace, while finger motions were recorded.

Data was processed using a Motion Monitor System (Innovative Sports Training, Chicago, IL) and then exported to a custom written Matlab program that used Euler angle transformation to compute the three-dimensional positions of the markers with respect to a local hand coordinate system. Differences in the maximum range of motion measurements were measured between the splinted and non-splinted trials for each task.

### RESULTS AND DISCUSSION

A significant increase occurred in the amount of MCP flexion used to perform some of the tasks during the splinted trials. Tasks normally involving substantial PIP motion typically produced an increase in MCP flexion when the PIP joints were restricted. For example, buttoning a shirt showed a significant increase in MCP flexion ROM at all four fingers ( $p < 0.05$ ) when splinted (Figure 2). Although recorded, increases in the amount of MCP flexion for most tasks were small and did not display great changes statistically due to high standard deviations.

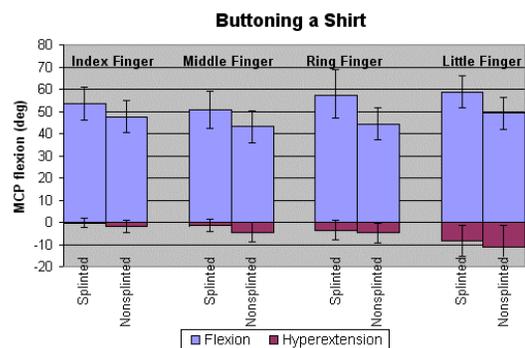

Figure 2. MCP flexion/hyperextension while buttoning

This investigation lends insight into the amount of compensatory motion used by the MCP joints when PIP joint motion is restricted at 40° of flexion. A wide range of required flexion was used by each subject indicating individuals accommodate well when PIP joints are splinted in this position. Since the finger DIP joints and thumb were neither monitored nor restricted, the affects of PIP restriction may have been underestimated in arthritic patients who often have multiple joint involvement. In fact, we observed that subjects altered thumb use to compensate for the restricted PIP joints in tasks such as tying a shoe and stirring rice.

## ENERGETICS OF LEGGED LOCOMOTION: WHY IS TOTAL METABOLIC COST PROPORTIONAL TO THE COST OF STANCE WORK?

Manoj Srinivasan

Cornell Bio-robotics and Locomotion Lab, Theoretical and Applied Mechanics  
Cornell University, email: [ms285@cornell.edu](mailto:ms285@cornell.edu), web: <http://www.tam.cornell.edu/~ms285>

### INTRODUCTION

What are the major contributors to the metabolic cost of legged locomotion? During the stance phase of a gait, energy is required to periodically redirect the velocity of the center of mass from down to up. This “**cost of stance**”, typically approximated by external work calculations, is a substantial fraction of the total metabolic cost. Another large fraction is the “**cost of swinging**”, relating to the energy required to swing the legs and other body parts faster than they would move passively.

In treadmill experiments [1], where an animal or a human runs at a number of speeds, researchers have found that the stance work (estimated by external work on the body) is approximately proportional to the total metabolic cost. And in a recent study, Marsh *et al* [2] showed that in running turkeys, over a range of speeds, the metabolic cost of swinging the leg is proportional to the metabolic cost of stance. While these two experimental results are consistent with each other, how can the proportionality be simply explained? We show that it can be explained by metabolic cost optimization.

### METHODS

The total cost of locomotion, minus the resting metabolic cost, is modeled as the sum of the two terms – the cost of swing and the cost of stance. The magnitude of these terms will depend both on the speed  $v$  of locomotion and on the stride rate  $f$ , or equivalently, the step-length  $d$ . For example, keeping the speed constant and varying the stride rate, or vice versa, changes the magnitudes of the terms. In particular, while swing cost and stance cost do depend on the details of the muscular coordination, for simplicity, they can be assumed to be functions of only the speed and the stride rate. This assumption might be also interpreted as using the costs for the optimal muscular coordination for a given speed and stride rate.

For simple models of the animal's mechanics, and in experiments, the individual cost terms are relatively well-approximated by power laws (e.g., [2]). Typically, the stance cost per unit distance is of the form:  $E_{\text{stance}} = c_1 v^m f^n$ .

Assuming a metabolic cost proportional to work, maximum force, integral of force, or any other reasonable quantity, results in such a power law, in walking [3] and in running [5]. For much of the following discussion, however, how exactly the power law is derived is not important, but only that it be a power law.

The swing cost per unit distance is assumed to have the same functional form,  $E_{\text{swing}} = c_2 v^p f^q$ . This has also been verified by systematic experiments (e.g., [3]). In experiments and in

models, for a given speed,  $E_{\text{stance}}$  decreases with increasing  $f$ , so  $n < 0$ .  $E_{\text{swing}}$  increases with increasing  $f$ , so  $q > 0$ . Other than these two conditions, the actual values of the various coefficients and exponents in these formulas are not important for obtaining the main result of the paper.

The total cost of locomotion is given by:

$$E_{\text{total}} = E_{\text{stance}} + E_{\text{swing}} = c_1 v^m f^n + c_2 v^p f^q. \quad (1)$$

### RESULTS AND DISCUSSION

It is well-established that, for a given velocity  $v$ , humans and animals pick the stride rate  $f_{\text{opt}}$  that minimizes their cost of locomotion (e.g., [6]). The optimal stride rate  $f_{\text{opt}}$  might be obtained by differentiating Eq.1 with respect to  $f$ , and setting it equal to zero. Substituting this expression for  $f_{\text{opt}}$  in the respective formulas for the costs, we get:

$$E_{\text{stance}} / E_{\text{swing}} = -q / n \quad (2)$$

Thus, as experimentally determined by Marsh *et al* [2], our simple theory predicts that the ratio of the cost components is independent of the speed. Eq.2 also suggests that  $E_{\text{stance}}$  is proportional to the total metabolic cost, independent of speed. Assuming that the cost of stance  $E_{\text{stance}}$  is proportional to muscle work and that the elastic recovery is a constant fraction of the stance work, we predict that the metabolic cost is proportional to stance work alone, as observed by early investigators [1].

### CONCLUSIONS

We have presented a simple way of understanding the apparently constant partitioning of the metabolic cost of legged locomotion observed in experiments, both old and new. More generally, the result provides a justification for the use of force plates as approximate ergometers [7], to estimate the total metabolic cost. The result is general in that it is independent of many details of the actual cost laws assumed. And it is likely to be applicable whenever the total metabolic cost of locomotion is modeled by sum of two terms, both of which are well-approximated by power laws.

## Aerodynamic Characteristics of Baseballs Delivered from a Pitching Machines

Tsutomu Jinji and Shinji Sakurai  
 School of Health and Sport Sciences, Chukyo University

### INTRODUCTION

The purpose of this study was to compare aerodynamic characteristics of baseballs delivered by actual pitchers and by pitching machines. The results of this study would suggest useful ideas for the usage of a pitching machine in batting practice.

Although many studies using the wind-tunnel experiment have clarified aerodynamic forces on a pitched baseball, the spin characteristics, such as spin rate and spin axis directions, during the actual ball flight have been hardly quantified. To elucidate the aerodynamics of a baseball more closely, we obtained three-dimensional trajectory, angle of spin axis and the spin rate of the actual pitched baseball.

### METHODS

All experiments were conducted indoors in order to minimize wind influence. Nine collegiate pitchers pitched 10 fastballs of 4-seam (FB) and 10 curve balls (CB), respectively. A pitching machine with a propulsion system of spinning wheels was used to fire 10 FBs of 4-seam and 10 CBs.

Trajectories of these balls were filmed with four synchronized video cameras (60Hz) and were analyzed using DLT procedures. The global coordinate system was set as follows; the Z-axis was defined as vertical, the Y-axis was defined as horizontal and pointing toward home plate and X-axis was then defined as the cross product of the Y- and Z-axes, with the origin at the center of the front edge of the pitching rubber. Polynomial function using the least square method was used to derive time-displacement relationships of ball coordinates during flight for each pitch.

To obtain the ball rotation axis and spin rate, the baseball was filmed just after the delivery with a high-speed video camera (250Hz) set with the lens axis along the Y-axis of the global coordinate system. The direction of spin axis and the spin rate were calculated using positional changes of drawn marks on the ball surface. The direction of the spin axis was defined by two angles,  $\theta$  (azimuth) and  $\phi$  (elevation), an angle between spin axis and y axis ( $\alpha$ ) was also obtained. The spin parameter ( $r\omega/V$ ;  $V$  is the free-stream velocity,  $r$  is radius of the ball and  $\omega$  is the ball angular velocity) was obtained, following previous studies.

### RESULTS AND DISCUSSION

Initial velocity and spin rate of the balls from pitching machine were within the ranges of those for the actual pitchers. However, there was a significant difference in the mean values of total break (composition  $\Delta X$  and  $\Delta Z$ ) between the balls from a pitching machine and the balls pitched by actual

pitchers for both FB and CB pitches ( $p < 0.001$ ). FB pitches tended to break in the opposite direction to the CBs. The mean value for the break of CBs by pitching machine was approximately 1.9 times larger compared to those for actual pitchers.

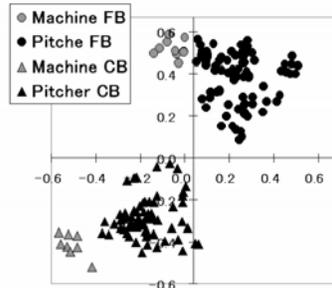

Figure 2: Deflections of trajectory due to the aerodynamic force. The two components of break, X and Z direction, are the differences between the fitted and spin-free trajectories at 18.44m.

Watts and Ferrer (1987) suggested that lift coefficient was proportional to  $r\omega/V$  in the wind tunnel. However, in this study, the lift coefficient did not depend on  $r\omega/V$  ( $r = 0.429$ ), but had a close relationship with  $\omega \sin \alpha$  ( $r = 0.860$ ). This parameter,  $\omega \sin \alpha$ , represents the actual effect of spin on lift force.

Magnus effect occurs from rotation of the ball, and act perpendicular to the axis of spin. Magnus effect is largest when the angular and translational velocity vectors are perpendicular to each other, and it indicates that the break of the pitched baseball is decreased when the angle between the two vectors comes closer to  $0^\circ$ . To adapt the features of the balls by a pitching machine to the actual pitchers' balls, it would be necessary to set the propulsion condition of a "screwball" for a fastball, and reduce the spin rate for curve ball.

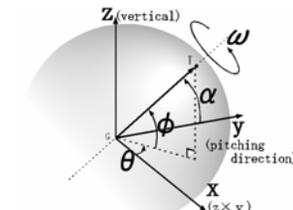

Figure 1: Definition of spin axis. The orientation of the angular velocity vector  $\omega$  is specified by two angles  $\theta$  and  $\phi$ .  $\alpha$  is angle between spin axis and y-axis.

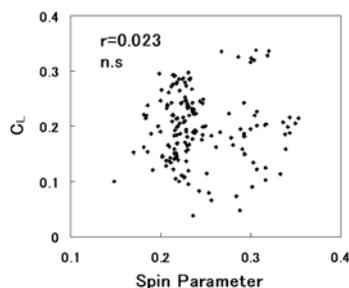

Figure 3: The relation between lift coefficient and Spin Parameter ( $r\omega/V$ )

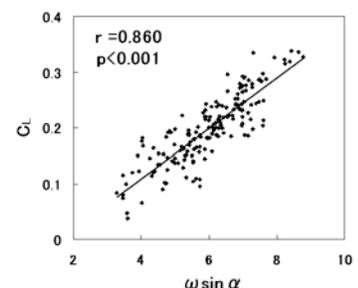

Figure 4: The relation between lift coefficient and  $\omega \sin \alpha$

### CONCLUSIONS

Balls delivered from a pitching machine whose axis was close to vertical to the pitching direction broke more largely than actual pitcher's balls.

## A 3-DIMENSIONAL CAMERA CALIBRATION ALGORITHM FOR UNDERWATER MOTION ANALYSIS WITH REFRACTION CORRECTION CAPABILITY

Young-Hoo Kwon  
 Biomechanics Laboratory, Texas Woman's University, Denton, TX, USA  
 email: [ykwon@mail.twu.edu](mailto:ykwon@mail.twu.edu)

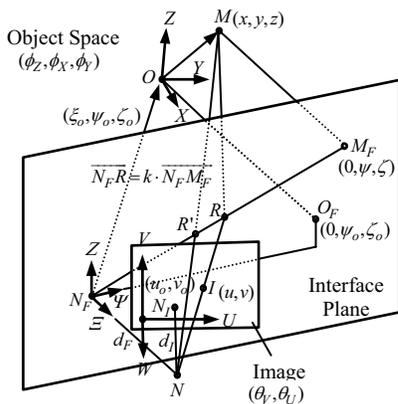

### INTRODUCTION

The DLT (Direct Linear Transformation) algorithm, the most frequently used calibration algorithm, is based on the so-called collinearity condition; i.e. the object, image, and projection center form a straight line. This condition, however, does not hold in an underwater analysis setting due to the nonlinear image deformation caused by refraction at the water-air interface (Figure 1) [1]. The immediate outcome of the image deformation is an increased calibration/reconstruction error when compared to its above-water counterpart.

Reconstruction accuracy can be improved to a certain extent by maintaining large interface-object distance and/or camera-interface distance [1], by using localized sub-volumes (localized DLT) [2], or by manipulating the characteristics of the calibration frame [1]. Although these methods are useful, the ultimate solution is to use a calibration algorithm that has the refraction correction capability. The purposes of this study are (a) to develop a calibration algorithm that allows refraction correction, and (b) to test its applicability through a simulation.

### METHODS

A comprehensive refraction model was developed with 12 experimental factors incorporated (Figure 1): position and orientation of the calibration frame with respect to the interface plane (6), camera position and orientation with respect to the interface plane (3), and the internal factors of the camera (3). Due to the complexity imposed by the nonlinear refraction equation, no simple direct solution is available and a special optimization strategy must be developed.

**Figure 1.** Refraction Model with 12 Experimental Factors

The new method proposed in this study is mainly based on the collinearity among the refraction point ( $R$  in Figure 1; not the object), image point ( $I$ ), and the projection center ( $N$ ). The coordinates of the refraction point were described as a fraction of the coordinates of point  $M_F$  by a ratio  $k$  (Figure 1).

Although  $k$  is a high-order function of the position and angle factors, it was considered as a constant in the cost function for simplicity. As a result, the interface-to-calibration-frame distance was optimized separately from the others since this factor is involved only in the computation of ratio  $k$ . All other factors are present in the cost function and can be computed through an iterative approach using the Newton method. The interface-frame distance was optimized based on the calibration error. A converged set of experimental factors were obtained for every level of interface-to-frame distance. The distance that shows the smallest calibration error was selected as the optimal interface-frame distance.

A simulation was performed to assess the performance of the new algorithm. A 3 m x 1 m x 1m calibration frame with 56 control points was used. An arbitrary set of experimental condition was used (interface-frame distance = 4.0 m, camera-interface distance = 0.8 m, etc.) to generate the image coordinates of the control points. A series of calibrations were performed based on the real-life coordinates and the simulated image coordinates.

### RESULTS AND DISCUSSION

Only 7 distance and internal camera factors were subject to optimization in this paper. Calibrations were repeated with various initial values. In all cases the distance and camera factors fell within 2 cm of the actual values used in the simulation. In terms of calibration error, the new algorithm outperformed the DLT algorithm considerably. Moreover, the calibration error showed a quadratic pattern with the minimum value coming from the optimized interface-frame distance. The calibration error increased when random errors were introduced to both the real-life coordinates and the image coordinates. However, the algorithm consistently generated stable (converged) solutions.

### CONCLUSIONS

The new algorithm was deemed applicable in the underwater analysis. Due to its refraction correction capability, the algorithm will be useful especially in situations with poor experimental conditions, such as short camera-interface distance and interface-frame distance. Distortion correction also means considerably less extrapolation error outside the control volume.

## QUADRICEPS-HAMSTRING MUSCLE SYNCHRONY DURING LANDING MOVEMENTS: IS IT AFFECTED BY MOVEMENT DIRECTION?

Bridget Munro and Julie Steele

Biomechanics Research Laboratory, Department of Biomedical Science, University of Wollongong, NSW, Australia, 2522  
email: [bmunro@uow.edu.au](mailto:bmunro@uow.edu.au), web: [www.uow.edu.au](http://www.uow.edu.au)

### INTRODUCTION

One of the most frequent non-contact mechanisms of isolated injury to the anterior cruciate ligament (ACL) occurs when landing from a jump, particularly when players land and rapidly decelerate their forward progression [1]. Past research has suggested that to protect the ACL from injury, athletes should land with more vertical rather than horizontal momentum and use run-on steps where possible [1]. Although appropriate muscle activation patterns that control the lower limb at initial contact (IC) have been suggested to protect the ACL, little is known as to how or whether these patterns change with different movement types and with different post-landing strategies. Therefore, the purpose of this study was to assess whether quadriceps-hamstring muscle synchrony are affected by different landing movements and/or the need to decelerate abruptly or not.

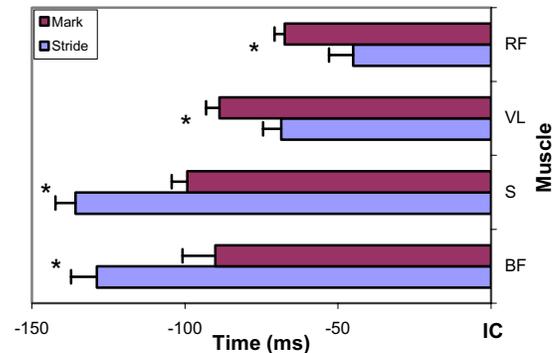

### METHODS

Thirty-six athletes (mean 23.6 years, range 19-30) involved in landing sports and with no history of knee joint injury volunteered to participate in the present study. All subjects underwent laboratory-based assessment of their landing technique when performing two landing movements (vertical mark, horizontal stride) and two post-landing strategies (rapid deceleration at IC, run-on after IC).

During the five trials per condition, electromyographic (EMG) data were sampled (1000 Hz; bandwidth, 0-340 Hz) for the rectus femoris (RF), vastus lateralis (VL), biceps femoris (BF) and semitendinosus (S) muscles of each subject's dominant lower limb using a Noraxon Telemyo system. Following zero offset removal, raw EMG signals were filtered using a fourth order zero-phase-shift Butterworth high pass filter ( $f_c = 15$  Hz). The filtered muscle activity data were then full-wave rectified and low pass filtered ( $f_c = 20$  Hz) and the resultant linear envelopes were screened with a threshold detector (7% of maximum amplitude) to determine the temporal aspects of each muscle burst with respect to IC. IC was confirmed against ground reaction force data collected (1000 Hz) using a Kistler force platform.

### RESULTS AND DISCUSSION

Two-way repeated measures ANOVA results indicated that, although there was no main effect of post-landing strategy on muscle activity, there was a significant main effect of movement type on quadriceps-hamstring muscle synchrony (Figure 1). That is, RF and VL were activated significantly earlier and S and BF were activated significantly later when subjects performed the vertical mark compared to the horizontal stride (Figure 1). When striding, a horizontally directed movement, subjects appeared to follow the typical sequential recruitment pattern of hamstrings followed by

**Figure 1:** Quadriceps and hamstring muscle synchrony when subjects performed the mark and stride movements (IC = initial contact; \* indicates  $p < 0.05$ ).

quadriceps activation. This pattern is suggested to protect the ACL by maximizing the efficacy of the hamstring muscles to produce posterior tibial drawer [2]. In comparison, when subjects performed the vertical mark, the thigh muscles showed a more simultaneous activation pattern, indicating greater co-contraction and preparation of the lower limb to absorb a more vertically directed ground reaction force and prevent collapse of the lower limb during landing. Interestingly, these two muscle activation strategies used during the two different movement types were unchanged regardless of the post-landing strategy to be performed.

### CONCLUSIONS

It was concluded that, although the direction of landing movement may alter quadriceps-hamstring muscle synchrony at IC, the movement to be performed after landing did not influence this muscle synchrony. However, research is warranted to determine whether the quadriceps-hamstring muscle synchrony noted for the vertical mark was more advantageous in terms of preventing ACL injury relative to the strategy used during the horizontal landing. Furthermore, whether unanticipated post-landing strategies, relative to anticipated strategies, could alter the quadriceps-hamstring muscle synchrony in a way that could predispose the athlete to ACL injury requires investigation.

## Gait Affects Tibial Component Migration in Unicondylar Knee Arthroplasty

<sup>1&2</sup> Brendan Joss, <sup>2</sup>Ming Guo Li, <sup>2</sup>David Wood and <sup>1</sup>David Lloyd

<sup>1</sup>School of Human Movement and Exercise Science, University of Western Australia

bjoss@cyllene.uwa.edu.au

### INTRODUCTION

The processes behind tibial component migration in Unicondylar knee arthroplasty (UKA) have been relatively unstudied. The force applied to the prostheses during walking increases the shear stress at the bone cement interface, which may lead to aseptic loosening<sup>1</sup>. Knee compressive forces in gait may also cause prosthesis migration<sup>1</sup>. By participating in a large amount of walking, the UKA prosthesis may be highly exposed to these knee loads, exacerbating the migration thus loosening. Roentgen stereophotogrammetric analysis (RSA) can accurately measure component migration<sup>2</sup>. In addition, by using three-dimensional (3D) gait analysis and wearing daily activity monitors, respectively we examined if knee joint loading during gait and exposure to this loading is related to UKA tibial component migration.

### METHODS

11 patients who received a Millar Glante (Zimmer) UKA for medial compartment Osteoarthritis with suitable RSA films for analysis at 2 years post surgery were studied with 3D gait analysis. The sample is part of a larger sample still to be collected and analyzed. The Vicon 370 (Oxford Metrics, Oxford UK) motion analysis system with 7 infra red camera at 50 hertz and two ATMI force plates were utilised to measure the lower limb joint kinematics and kinetic with the cluster marker model and optimized joint axes and centres<sup>3</sup>. Kinematic variables were normalized to bodyweight x height and expressed as external joint moments. Patients were instructed to walk at their self-selected, normal walking speed for analysis. Prior to the gait analysis session, each subject also wore an activity monitor. Nine age matched control subjects were also tested using the same procedures for comparison.

### RESULTS AND DISCUSSION

The UKA group walking with higher peak knee adduction and flexion moments during the stance phase compared to the control group. There was no correlation between peak knee adduction moment and tibial component migration. However peak knee flexion moments showed moderate correlations with distal subsidence ( $r=0.48$ ) and posterior tilt ( $r=0.43$ ) of the tibial component. Higher correlations were found between average number of steps per day and lateral ( $r=0.57$ ) and posterior subsidence ( $r=0.52$ ) and varus tilt ( $r=0.62$ ).

High peak knee flexion moments in total knee arthroplasty patients have also been associated with increased tibial

component migration, leading to the potential early onset of aseptic loosening<sup>1</sup>. High peak flexion moments also predict the presence and severity of anterior knee pain following total knee arthroplasty<sup>4</sup>.

The preliminary results are also the first to show an association with physical activity and component migration in knee replacement, supporting a long held belief by orthopaedic surgeons. When the peak knee flexion moments were multiplied by the average number of steps taken per day the correlations with components migration were strengthened ( $r=0.68$  for distal subsidence and  $r=0.61$  for varus tilt of the tibial component). These stronger correlations suggest the amount and frequency of knee joint loading has the greatest affect on potential tibial component loosening.

### CONCLUSIONS

The results from this small sample of a larger study group to be tested suggests that high flexion moments have a negative effect on the tibial component in UKA, similar to that seen in total knee replacement<sup>1</sup>. This sample is the first reported evidence of the frequency of joint loading having larger affect on migration, which is further strengthening when combined with high joint moments.

## PARAMETRIC FINITE ELEMENT MODEL OF FEMUR FROM CT DATA

<sup>1</sup>Mehran Armand and <sup>1</sup>Liming Voo

<sup>1</sup>Johns Hopkins University Applied Physics Laboratory, Laurel, MD. 21044

### INTRODUCTION

The investigation of the individual effects of structural and geometrical parameters on the bone strength can lead to a better understanding of the mechanisms and risk factors associated with a range of bone problems including fracture, aging, osteoporosis, and bone loss in microgravity. A semi-automatic technique is used to develop a finite element model of the femur bone from the CT data. The major difference between this technique and other FE models of the femur is that it is based on the parameterization of the bone; therefore, it directly lends itself to a sensitivity analysis of the femur's structural and geometrical factors. This work is the extension to the elliptical model reported previously [1], and generates a more accurate geometry.

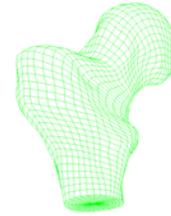

### METHODS

A proximal femur of an average male cadaver was scanned using a CT scanner. The steps towards developing FE mesh were as follows: 1) Semi-automatic custom algorithms were applied to extract the bone's outer contours and density information from the CT data; 2) A piecewise continuous cubic spline fit was applied to parameterize the outer contours; 3) The inner contours were calculated such that the constraint equations for cross-sectional mass and moment of inertia along femoral shaft and neck axes were satisfied; 4) Scaling was performed on the regions of interest; 5) An automated algorithm generated the volumetric model including outline of the bone and the inner cortex boundaries. 5) The bone volume was meshed automatically with 20-node brick elements, as needed for finite element simulations.

Semi-automatic custom algorithms were applied to extract the bone's outer contours and density information from the CT data. The algorithm re-sliced images along the axis of the shaft and neck of the femur (the transition from shaft axis to neck axis was defined by a hyperbolic fit). Edge extractions were performed for the outer boundaries of the femur using the re-sliced sections along the femur's neck and shaft axes [2].

The algorithm performed a piecewise continuous cubic spline fit on the new reformatted slices along shaft and neck axis. A minimum number of control points that would adequately approximate the true geometry were found for each cross-section. The cross-sections were also visually inspected for the any potential imperfection.

The main challenge in creating accurate parametric bone geometry is the extraction of the contours of the inner cortex. we derived a theoretical and algorithmic technique for analytical calculation of the inner contour from the outer cortical boundary geometry. These calculations satisfy the mechanical properties of each cross section of the bone while producing a comparable geometry to the original bone. We

**Figure 2:** A finite element mesh of a proximal femur with neck-shaft angle reduced by 15°

calculated the cortical/cancellous and cortical/marrow boundary such that the cross-sectional moment of inertia (CSMI) and cross-sectional area (CSA) of the model and the original bone remained equal (note that both are calculated from the mass of the cross-section based on one voxel thickness). We used the density map data for each cross-section plus the CSMI and CSA equations to calculate the appropriate spline fit to the cortical/cancellous or cortical/marrow boundaries. This enabled us to define the bone geometry and its material distribution with a finite number of control points for each cross-section. Thus, a full parametric model of the femur was created.

The regions of interest (e.g. neck angle, neck length) and cortical thickness was scaled using the cross-sectional geometries. An automated algorithm was developed to create surfaces on these cross-sections and mesh the generated volumes with 20-node hexahedral elements.

### A TYPICAL EXAMPLE

The simulations were performed using SDRC-IDEAS finite element software. A typical example of the scaled bone is shown in Figure 1. The neck-shaft angle in this model was reduced by 15° from the original CT data. The model had approximately 12000 hexahedral elements. Both cortical and cancellous layers had quality elements with maximum distortion less than 30%. In summary, the model from CT data included more accurate geometry than the previously reported elliptical model [1]. Additional user interaction, however, was required to verify the quality of the spline fits.

## THERAPIST CONTROLLED POWERED LOWER LIMB ORTHOSES TO ASSIST LOCOMOTOR TRAINING

<sup>1,2</sup>Gregory S. Sawicki, <sup>1</sup>Antoinette Domingo and <sup>1,3</sup>Daniel P. Ferris

Departments of <sup>1</sup>Movement Science, <sup>2</sup>Mechanical Engineering, & <sup>3</sup>Biomedical Engineering,  
University of Michigan, Ann Arbor, MI; email: [gsawicki@umich.edu](mailto:gsawicki@umich.edu)

### INTRODUCTION

Locomotor training with manual assistance can greatly improve walking ability after neurological injury. However, manual assistance is labor intensive and variable from trainer to trainer. Robotic assistive devices are currently being developed to assist locomotor training, but no current device can assist ankle plantar flexion, the major source of work during normal walking. Therapist-controlled, powered lower limb orthoses for locomotor training could decrease therapist labor requirements, increase walking speed during training and lead to increased muscle activation and improved gait kinematics. However, because sensorimotor feedback contributes to muscle activation, plantar flexor assistance could decrease muscle activation of the triceps surae. The purpose of this study was to test therapist-controlled, powered ankle-foot orthoses (AFOs) to facilitate gait rehabilitation after spinal cord injury. We assessed the impact of localized powered assistance at the ankle on muscle activation patterns and joint kinematics during walking with partial bodyweight support in individuals with incomplete spinal cord injury.

### METHODS

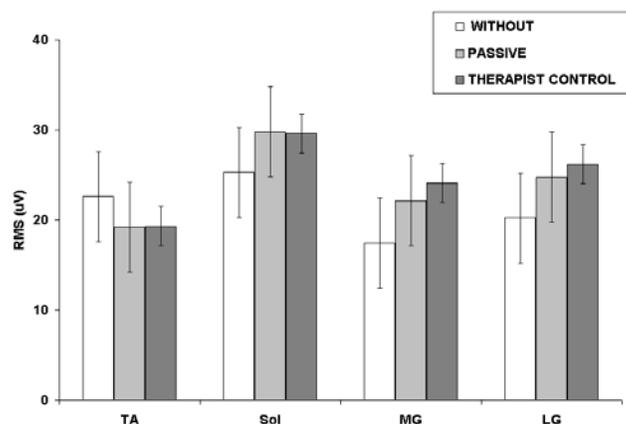

Four subjects (ASIA C or D) with chronic incomplete spinal cord injuries walked at 0.54 m/s under three different conditions: (1) without the AFOs, **WO**; (2) with passive bilateral AFOs, **PA**; and (3) with active bilateral AFOs under push-button control by a therapist, **TC**. Body weight support was provided at either 30% or 50% depending on the weight-bearing ability of the subject. When necessary, elastic cords provided lateral stability.

**Figure 1: (a) Powered Ankle-Foot Orthosis (AFO).** A lightweight carbon fiber orthosis (~1.5 kg) fit with an artificial pneumatic plantarflexor muscle. **(b) Therapist Control.** A therapist uses push-buttons to control the timing of active AFO assistance at the ankle as an ASIA D 24 yr. old male trains with partial body weight support.

### RESULTS AND DISCUSSION

The passive condition and therapist control condition produced higher stance phase RMS EMG muscle activation in all three triceps surae muscles (SOL, MG, LG) than the without condition (Figure 2). The tibialis anterior demonstrated decreased stance phase activity in the passive condition and therapist control condition compared to the without condition.

**Figure 2:** Stance phase averaged rectified RMS EMG for tibialis anterior (TA), soleus (Sol), medial gastrocnemius (MG) and lateral gastrocnemius (LG). Bars are mean and standard error of the mean.

### CONCLUSIONS

These findings suggest that powered plantar flexion assistance does not decrease plantar flexor muscle recruitment during gait in incomplete spinal cord injury subjects. Thus powered lower limb orthoses may be a viable aid to assist therapist during locomotor training.

Our powered AFO comfortably delivered ~50% of normal ankle plantar flexor torque. Therapist labor intensity was reduced considerably, allowing the therapist to focus more on gait quality. Another possibility is that the push button control could come directly from the patient during gait rehabilitation.

## MOTOR ADAPTATION TO A POWERED ANKLE-FOOT ORTHOSIS UNDER FOOT SWITCH CONTROL

<sup>1</sup>Stephen M. Cain, <sup>2</sup>Keith E. Gordon, and <sup>2,3</sup>Daniel P. Ferris  
Departments of <sup>1</sup>Mechanical Engineering, <sup>2</sup>Movement Science, & <sup>3</sup>Biomedical Engineering  
University of Michigan, Ann Arbor, MI; email: smcain@umich.edu

### INTRODUCTION

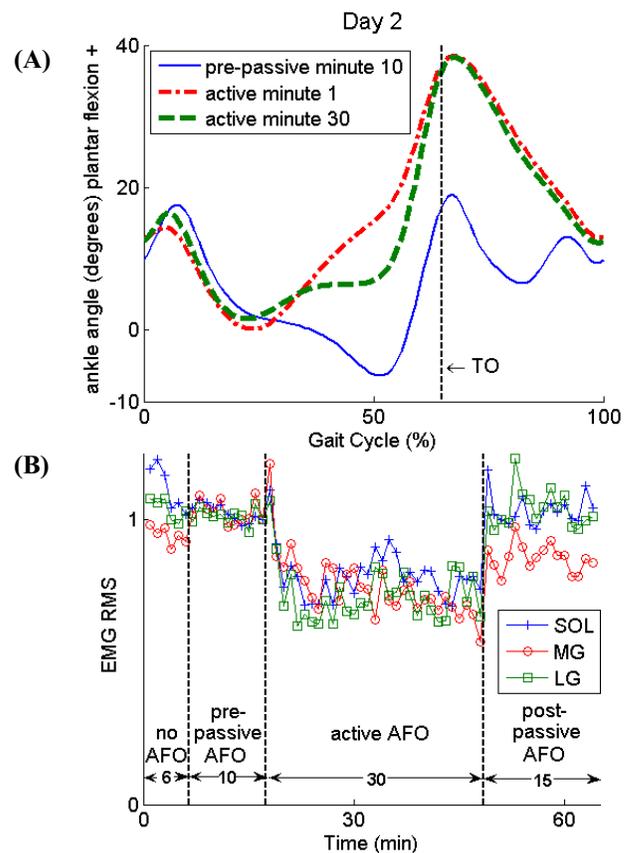

Powered orthoses are an innovative way to study how humans adapt and change control strategies during walking. A previous study [1] using a powered ankle-foot orthosis (AFO) under proportional myoelectrical control (soleus EMG) to provide plantar flexion assistance found a decrease in soleus EMG amplitude without concomitant decreases in gastrocnemius EMG amplitude. We hypothesized that using foot switch control, in which the nervous system has no direct control over plantar flexion assistance, would result in simultaneous decreases in soleus, medial gastrocnemius, and lateral gastrocnemius EMG.

### METHODS

Two healthy subjects (ages 23 and 24) participated in this study. The University of Michigan Institutional Review Board approved the study protocol and each subject gave informed consent. Each subject walked without an orthosis at a speed of 1.25 m/s on a treadmill and also while wearing a powered AFO as described by Gordon et al. [2] on the left leg. The powered AFOs used artificial plantar flexors (pneumatic muscles) that were controlled using an on/off (i.e., bang-bang) controller. The forefoot portion of a footswitch provided the signal to the controller to activate the artificial muscle. Each subject had two training sessions three days apart. A session consisted of walking without an AFO (no AFO) for 5 minutes, with a passive AFO (pre-passive AFO) for 10 minutes, with an active AFO (active AFO) for 30 minutes, and with a passive AFO (post-passive AFO) for 15 minutes. We collected and analyzed lower limb kinematics and electromyography (EMG) for 9 muscles (Motion Analysis system & Visual3D). We calculated average EMG RMS values normalized to the final minute of the pre-passive condition.

### RESULTS AND DISCUSSION

The powered orthosis produced a peak plantar flexion torque of ~55 Nm, which resulted in increased plantar flexion from mid-stance through swing phase when wearing the powered AFO (Figure 1A). The subjects decreased soleus (SOL), medial gastrocnemius (MG), and lateral gastrocnemius (LG) muscle activation when the AFO was active (Figure 1B). During the last 10 minutes of the active AFO condition, EMG was reduced to ~77, 68, and 72% of pre-passive values for SOL, MG, and LG, respectively. When the powered AFO was turned off, SOL, MG, and LG EMG returned to ~100, 87, and 100% of pre-passive values. Both subjects were able to adapt to the powered AFO more quickly on the second day of training. As hypothesized, both subjects decreased muscle activity in all three triceps surae muscles (SOL, MG, LG) when walking with the powered AFO. However, even after two days of training, ankle kinematics were substantially different from passive AFO walking.

**Figure 1:** **A)** Ankle flexion versus gait cycle (left heel strike to left heel strike). Subjects walked with increased plantar flexion with the artificial plantar flexor powered ankle-foot orthosis (AFO). **B)** EMG RMS normalized to the last pre-passive minute versus time for soleus (SOL), medial gastrocnemius (MG), and lateral gastrocnemius (LG). With the powered AFO, subjects decreased muscle activity in SOL, MG, and LG simultaneously.

### CONCLUSIONS

When a foot switch was used to control a plantar flexor-assist AFO instead of soleus EMG, muscle activity in all three triceps surae muscles (SOL, MG, LG) decreased synergistically. This study emphasizes that neural adaptations to a powered orthosis during gait depend on the type of controller used. Proportional myoelectric control [1] resulted in faster kinematic adaptation than foot switch control.

## POSTURAL SWAY ADAPTATION DURING INITIAL EXPOSURE TO PERIODIC AND NON-PERIODIC OPTIC FLOW

### INTRODUCTION

Previous work in our laboratory showed that postural sway power in a group of six healthy adults was significantly larger in response to a periodic sum-of-sinusoids (SOS), compared to a spectrally similar non-periodic SOS [1], but only at the highest component frequency of the stimulus (0.5Hz). The objective of the current study was to determine whether this behavior could be reproduced in a larger group of subjects, and for a wider variety of SOS optic flow stimuli.

### METHODS

Postural sway was examined in twenty healthy young adults during exposure to 90-second trials of various periodic and non-periodic optic flows, in a virtual reality setting [2] (Fig. 1b). Visual scene motion for each trial was driven by one of ten signals (Fig. 1a). Scene movements were presented only once, and in random order. Postural responses were examined through center-of-pressure (COP) excursions in the sagittal plane, measured via a force platform beneath the feet. Sway power at each stimulus component frequency was used as the means of comparison among PSUM and NPSUM groups. Differences were tested for statistical significance using a full-factorial repeated measures ANOVA ( $\alpha=0.05$ ).

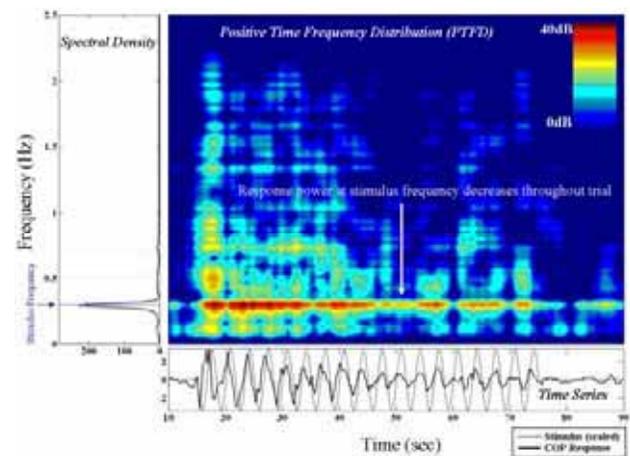

**Figure 1:** (a) Time-series of signals used to generate optic flow (60-seconds of motion, bounded at beginning and end by 15 seconds of stationary scene); (b) Subject standing on force platform, viewing the optic-flow pattern.

### RESULTS AND DISCUSSION

Postural responses to PSUM and NPSUM optic flow were not significantly different at any of the stimulus frequencies, contrary to previous observations. However, sway power was

again largest at the highest stimulus frequency (0.7Hz), suggesting that subjects were influenced by stimulus velocity, as others have reported [3]. In addition, an unusually strong trial effect was observed in 16 subjects, in which sway power for trial 1 was significantly larger than that for trials 2 through 10. Time-frequency analysis revealed *adaptation* (i.e. a within-trial decline in sway amplitude at the stimulus frequency [4]) in trial 1 (Fig. 2). That is, subjects responded strongly during initial exposure to optic flow, but the amplitude of this response decreased substantially during trial 1, and remained at an attenuated level for subsequent trials.

**Figure 2:** PTFD (see [4] for details) showing adaptation of sway response to 0.3Hz sinusoidal stimulus (subject 216).

This trial effect could not be completely addressed in the statistical analysis (due to insufficient power), so it is unclear whether or not this effect contributed to the current finding that responses to PSUM and NPSUM optic flow were not significantly different, which is contrary to prior observations.

### CONCLUSION

Previous results were not entirely reproduced, perhaps due to the confounding influence of a strong trial effect. Further study is required to better understand these findings.

## GENERATION OF FORWARD ANGULAR IMPULSE IN TASKS WITH BACKWARD TRANSLATION IS ACHIEVED BY REDIRECTING THE REACTION FORCE RELATIVE TO CENTER OF MASS

<sup>1</sup> Witaya Mathiyakom and <sup>2</sup> Jill L McNitt-Gray

<sup>1</sup>Andrus Gerontology Center and <sup>2</sup>Department of Kinesiology, Biomedical Engineering, Biological Sciences, and University of Southern California; e-mail: mathiyak@usc.edu

### INTRODUCTION

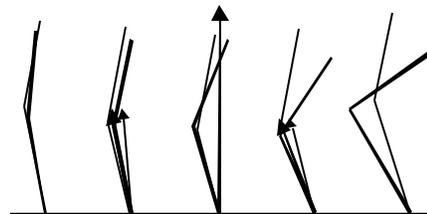

Successful performance of whole body movements is dependent on the ability of the performer to satisfy both linear and angular impulse requirements of the task during contact with the environment [1]. Previous research indicates that mechanisms of generating linear and angular impulse vary with tasks [2]. While linear impulse in both forward and backward translating tasks is affected by the orientation of the hips relative to the feet (leg angle) and lower extremity muscle activation patterns, angular impulse is affected by the moment arm between the reaction force and the center of mass (CoM) and the magnitude of the reaction force. During forward translating somersaults (e.g. reverse somersault), modification in CoM position relative to the center of pressure (CoP) is limited by anatomical constraints (e.g. dorsiflexion). As a result, the magnitude of the moment arm is regulated by redirecting the reaction force. In contrast, during backward translating somersaults (e.g. back somersault), the moment arm is regulated by reorienting the CoM relative to the CoP prior to rapid joint extension during the push phase. During the take-off phase of the inward somersault (backward translation, forward rotation), the foot contact duration is approximately half of the back and reverse somersaults and the reaction force passes posterior relative to the CoM. This time limitation for generation of linear and angular impulse led us to hypothesize that magnitude of the moment arm during the take-off phase of the inward somersault would be regulated by redirecting the reaction force rather than altering the CoM position relative to the CoP. Redirecting the reaction force was expected to be achieved by redistributing the lower extremity NJMs.

### METHODS

Six (2 females and 4 males) highly skilled divers performed a series of the inward somersault (IS) and inward timer (IT) take-offs from a force platform onto a landing pit using their competitive style. Sagittal plane kinematics and reaction force data were simultaneously collected and synchronized at the time of plate departure. Newtonian mechanics were used to compute the lower extremity NJMs.

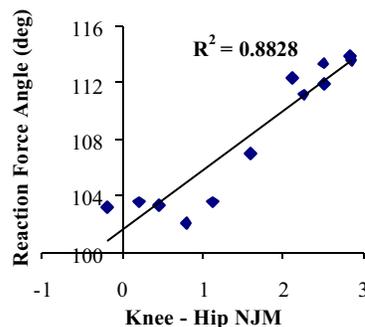

### RESULTS AND DISCUSSION

Between-task differences in reaction force direction and trunk-leg coordination indicated that angular impulse is generated by redirecting the reaction force relative to the CoM (Figure 1). Redirection of the reaction force was achieved by a redistribution of the knee and hip NJMs during the take-off phase. These results support the hypothesis that angular impulse is regulated by redirecting the reaction force. As expected, more posterior directed reaction forces were associated with trials with large knee NJMs in relation to hip NJMs (Figure 2).

**Figure 1.** Orientation of the trunk, leg, and reaction force (arrow) from initiation (left) to plate departure (right) during the take-off phase of the inward timer (thin line) and inward somersault (thick line).

Redistribution of the lower extremity NJMs and a more posterior oriented hip relative to the CoP (leg angle greater than 90 degrees) affected the orientation of the reaction force. At the time of peak horizontal reaction force, leg orientation and magnitude of the horizontal reaction force were significantly larger during the take-off phase of the IS as compared to the IT. The leg orientation explained only 55% of the variance in the reaction force direction, whereas the difference in the knee and hip NJMs explained 88% of the variance in the reaction force direction (Figure 2). These results further substantiate the role of redistribution of NJMs on reaction force redirection relative to the CoM in whole body movements [3].

**Figure 2.** Correlation between the differences in knee and hip NJMs and reaction force direction at the time of peak horizontal reaction force.

### CONCLUSIONS

Generation of the forward angular impulse and backward linear impulse during take-off phases with limited foot contact duration is primarily achieved by redirecting the reaction force relative to the CoM. Backward leg orientation facilitates generation of backward directed reaction force in global space. In addition, redistribution of the lower extremity NJMs redirects the reaction force relative to the leg and CoM.

### INTRODUCTION

Previous study of goal-directed whole body movements requiring the generation of reaction forces during interaction with the environment indicates that the nervous system organizes the human body using a structure that enables the performer to satisfy a variety of task objectives with minimal modification in control [1, 2]. In this study, we hypothesized that the redistribution of the knee and hip net joint moments (NJM) serves as a mechanism for altering the direction of the reaction force and magnitude of the angular impulse generated during the take-off phase of jumping-related tasks. We expected that relative magnitude of knee and hip NJMs would be regulated via reciprocal activation of bi-articular muscles crossing the knee and hip as previously observed during seated tasks [1]. We tested this hypothesis by comparing reaction forces, center of mass trajectories, lower extremity joint kinetics, muscle activation patterns of seven lower extremity muscles during the performance of forward (reverse, R) and backward (back, B) translating jumps performed with (BS, RS) and without rotation (BT,RT) about the somersaulting axis of the body and by determining the sensitivity of trunk and leg motion to redistributions of knee and hip NJMs using an experimentally validated dynamic model[3, 4].

### METHODS

Seven national level divers performed each task from a force plate onto a foam landing pit in accordance with the Institutional Review Board. Reaction forces (2000 Hz, Kistler, Amhurst, MA), sagittal plane kinematics (200Hz, NAC C<sup>2</sup>S), and muscle activation patterns (2000 Hz, Konigsberg, Pasadena, CA) were collected simultaneously[2]. Body landmarks (deLeva, 1996) were digitized (Motus, Peak Performance, Inc.) and filtered using a fifth-order spline (Woltring, 1986).

A dynamic model was used to determine the sensitivity of leg and trunk motion to alternations in the relative magnitude of the knee and hip NJMs [3, 4].

### RESULTS and DISCUSSION

The leg angle during the push phase and the redistribution of NJMs via reciprocal bi-articular muscle activation affected reaction force direction and angular impulse generation. The direction of the reaction force was affected by the orientation of the hip relative to the center of pressure (leg angle) during the tip phase and muscle activation patterns during the push phase. The relative magnitudes of knee and hip NJMs were affected by the orientation of the reaction force relative to the lower extremity segments resulting from reciprocal activation of the biarticular muscles (hamstrings and rectus femoris). No significant differences in NJMs or biarticular muscle activation patterns were observed between the BS and RS tasks and the BT and RT tasks (Figure 1A). The redistribution of knee and hip NJMs were shown to affect both leg and trunk angles during the push phase (Figure 1B) and affected the magnitude of the moment arm between the reaction force and center of mass. These results suggest multiple and diverse task objectives can be satisfied with minimal modifications in control.

## THEORETICAL BASIS FOR A LOAD CARRIAGE LIMIT EQUATION

<sup>1</sup>Joan Stevenson, <sup>2</sup>Timothy Bryant, <sup>3</sup>Evelyn L. Morin, <sup>1</sup>Susan A. Reid

<sup>1</sup>Physical & Health Education, <sup>2</sup>Mechanical Engineering, <sup>3</sup>Electrical & Computing Engineering and

<sup>4</sup>Ergonomics Research Group, Room #148 PEC, Queen's University, Kingston, Canada, [stevensj@post.queensu.ca](mailto:stevensj@post.queensu.ca)

### INTRODUCTION

Carrying heavy loads has always been the bane of existence for military soldiers, explorers and weekend trekkers. As a result, under certain conditions, people become 'beasts of burden'. In a recent military report entitled *Modern Warrior's Combat Load* about Afghanistan dismounted operations, U.S. rifle squads carried average approach loads of 43 kg (95 lbs) which was 35% BW and emergency approach marches of 63 kg (138.4 lbs) an amount that was 73.6% BW. The authors argued that this plight would not be solved until sufficient resources were put in place to lighten and reduce the size of combat items, increase the versatility of load carriage items and rethink the logistics and doctrine of operations and supply.

One difficulty for operations personnel is to appreciate the impact that various loads will have on foot soldiers. Even though payload items and their weights are known, there are only a few strategies to calculate the impact of these weights on the soldiers. For example, physiological regression equations were developed by (Pandolf et al., 1977; Holewijn and Meeuwsen, 2001) help determine the metabolic cost of various loads and load carrying conditions. However, the equations output information in percent maximal energy cost, units that most operations personnel would not understand. It is important to develop a predictive equation that encompasses more of the major variables that limit performance in the field.

### OBJECTIVE

The objective of the study was to use empirical data to develop a Load Carriage Limit equation that would provide backpackers and military with a simple guideline to assess the loads they could reasonably carry on a backpack.

### THEORETICAL MODEL

The concept to be investigated is whether a multi-dimensional load carriage limit (LCL) could be developed similar to the National Institute of Occupational Safety and Health's (NIOSH) guideline for lifting in industry. This NIOSH lifting guideline is structure around a load constant of 23 kg. (50 lbs). Then multipliers less than 1 are used to discount for non-ideal factors such as load horizontal distance or frequency of lifts. For the LCL, a similar concept would be used. The proposed equation is:

$$\text{LCL} = (\text{Load Constant} * \text{PF} * \text{BF} * \text{DF} * \text{RF}) * \text{Time}$$

Where:

PF is derived from physiological demands

BF includes shoulder and hip reaction forces, pack motions, contact pressures

DF includes body size, gender, and age

RF includes soldier readiness, fitness and injury factors

Time represents the mission expectations in terms of time/distance to be traveled.

### METHODOLOGY

The methodology for this model is based on a series of separate data collections over a period of eight years. Physiological data have been extracted from a data set by Morin et al. (2004) combined with findings of Pandolf et al. (1997) and Holewijn and Meeuwsen,( 2001). Maximum aerobic capacities were taken from 10 ft male subjects. On separate days subjects completed one of four test batteries, (either 0 kg and 38.7 kg at different speeds or inclines or 16.6kg and 25.9 kg at different speeds or inclines) while wearing a common backpack. A TEEM 100 metabolic cart was used to collect oxygen consumption in 20 sec intervals.

Biomechanical data were collected an objective load carriage simulator (Stevenson et al., 2004a,b) which has been validated by soldiers' opinions. Additional biomechanical data have been collected during a human trial fatigue tests where subjects were asked to provide feedback on discomfort as they completed a 45 minute treadmill march with loads of 0, 15, 25, 35 and 50 kg. These results have been distilled into important factors, such as: lumbar shear force, shoulder reaction forces, pack-person motion and other variables.

The demographic factor (DF) and readiness factor (RF) have been determined from the scientific literature. The load constant (LC) will be a high number that is discounted based on the conditions. Based on previous combat situations, loads of 63 kg and 68 kg were carried by soldiers in Afghanistan and the Falkland Islands respectively (McGaig and Gooderson, 1986). Based on injury data, these weights are too high thus a 50 kg (110 lbs) load was recommended as the starting point. At these extreme loads, the duration of load carriage will be minimal (under 1 hour) but humanly possible.

### DISCUSSION AND CONCLUSION

A discussion of results will be presented based on the empirical data for various examples of load conditions. This theoretical model remains to be validated by military field trials across a number of operational conditions.

## MUSCLE ACTIVATION DURING MANUALLY ASSISTED TREADMILL TRAINING AFTER INCOMPLETE SPINAL CORD INJURY

<sup>1</sup>Antoinette Domingo, <sup>1,2</sup>Gregory Sawicki and <sup>1,3</sup>Daniel P. Ferris  
Departments of <sup>1</sup>Movement Science, <sup>2</sup>Mechanical Engineering, & <sup>3</sup>Biomedical Engineering  
University of Michigan, Ann Arbor, MI; email: [adomingo@umich.edu](mailto:adomingo@umich.edu)

### INTRODUCTION

**Figure 1:** Manually assisted locomotor training

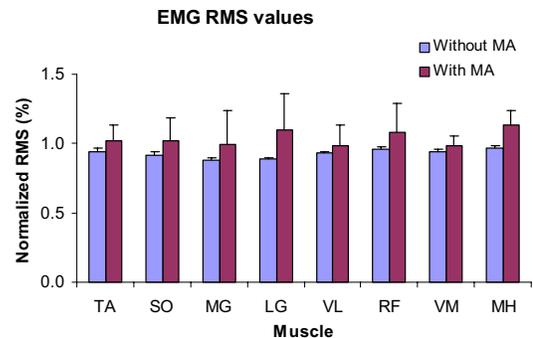

Partial body weight supported training (BWST) is effective in improving the gait of those with incomplete spinal cord injury [1,2]. In this treatment, the patient is suspended above a treadmill with a harness so that the patient bears only a portion of her weight on her legs (Figure 1). A therapist on each side of the patient manually assists the patient's legs through the motions of walking. Although this treatment is effective in improving walking ability, the neural mechanisms of locomotor recovery are not clear.

There are two competing hypotheses on how electromyographic (EMG) activity might be affected by BWST. One possibility is that manual assistance decreases the patient's effort, reducing EMG amplitudes. An alternative possibility is that manual assistance provides more normal kinematic patterns, thus resulting in more appropriate sensory feedback and increasing EMG amplitudes. The purpose of this study was to determine how manual assistance at the lower limbs specifically modifies EMG activity.

### METHODS

Four subjects with incomplete spinal cord injury (ASIA Impairment Scale Classification of C or D) at the cervical or thoracic level participated in the study. Subjects were at least 12 months post-injury and free of any conditions that would limit their ability to safely complete testing. Subjects were community ambulators with preferred overground walking speeds of 0.41-0.95 m/s. Three of the four subjects used canes. All subjects gave informed consent prior to participating.

Subjects stepped with and without manual assistance at 0.36 m/s with body weight support (30% or 50%, depending on the subject's tolerance). The same trainers manually assisted all subjects following the procedures described by Behrman and Harkema for locomotor training with partial bodyweight support [1]. While walking under the two experimental conditions, we collected kinematic and EMG data (tibialis anterior, TA; soleus, SO; medial gastrocnemius, MG; lateral gastrocnemius, LG; vastus lateralis, VL; vastus medialis, VM; rectus femoris, RF; and medial hamstring, MH). After averaging EMG RMS for each muscle, we normalized to the highest RMS that occurred without manual assistance. We also found separate RMS values for the stance and swing

**Figure 2:** Averaged and normalized EMG RMS values with standard error bars. EMG amplitudes were greater in all muscles with manual assistance, but not significantly ( $p > 0.3$ ).

phases of gait. We used a two-way ANOVA to test for significant differences.

### RESULTS AND DISCUSSION

EMG RMS values for the complete gait cycle were greater with manual assistance, but the differences were not significant (Figure 2). Stance phase and swing phase EMG RMS were similar to the overall gait cycle EMG RMS. Power analyses revealed that effect sizes for EMG amplitudes were all less than 0.11, indicating any real difference between conditions would be very small. To have at least a 50% chance of detecting a significant difference would require ~245 subjects [3].

### CONCLUSIONS

The two competing hypotheses are based on valid neural control principles. It is likely that both ideas are at least partially correct in explaining how manual assistance affects muscle activation during BWST. The overall result, however, is that EMG amplitudes change little with manual assistance for subjects with this level of incomplete spinal cord injury. Thus, therapists' fears that manual assistance will promote passivity by subjects are unfounded.

## FORWARD SOLUTION SIMULATION OF THE MIXED ACTION IN CRICKET FAST BOWLING

<sup>1</sup>René Ferdinands and <sup>2</sup>Uwe Kersting

<sup>1</sup>Department of Physics & Electronic Engineering, University of Waikato; email: [rene@waikato.ac.nz](mailto:rene@waikato.ac.nz)

<sup>2</sup>Department of Sport & Exercise Science, University of Auckland; email: [u.kersting@auckland.ac.nz](mailto:u.kersting@auckland.ac.nz)

### INTRODUCTION

The objective of fast bowling in cricket is to deliver the ball with a straight arm so that it reaches the batter at high speed after having first bounced once off the ground. The faster the ball, the less time the batter has to respond. However, fast bowlers require high run-up speeds, generate large ground reaction forces, and produce high joint torques [3]. With the loading placed on the body, it is not surprising that fast bowling is associated with a high incidence of lower lumbar injury. The susceptibility to such injury is correlated with shoulder counter-rotation during delivery stride [2]. The purpose of this study was to develop a forward solution model to predict the causal factors associated with the counter-rotation of fast bowlers. This approach potentially gives the cricket coach a scientific means of modifying the technique of mixed action bowlers to reduce their susceptibility to lower lumbar injury.

### METHODS

A three-dimensional (3D) forward solution dynamics model of the human body was used to simulate the motion of fast bowling in cricket. This model provides a mechanical basis for the remediation of fast bowling techniques that are correlated with an increased injury risk. Thirty-four fast bowlers were selected for study and divided into four groups according to ball release speed. An 8-camera 240 Hz motion analysis system (Motion Analysis Corp.) tracked markers placed on the bowler delivering a series of balls at a target approximately on a 'good length' in line with the wickets, and a Bertec force plate was used to measure ground reaction forces. The marker arrangement allowed for the 3D motion tracking of all major body segments. Kinematic alignment factors were calculated to classify bowlers according to bowling type: side-on, front-on, and mixed.

A forward solution model of the bowler was developed using *Mathematica's Mechanical Systems Pack*. This is a set of packages designed for the analysis of spatial rigid body mechanisms by implementing a dynamics formulation with Lagrangian multipliers. The computer model gives a 3D representation of the human body as a system of fifteen rigid body segments with mass and inertia properties. The forward solution model was used to test the effectiveness of technical hypotheses to correct a mixed action.

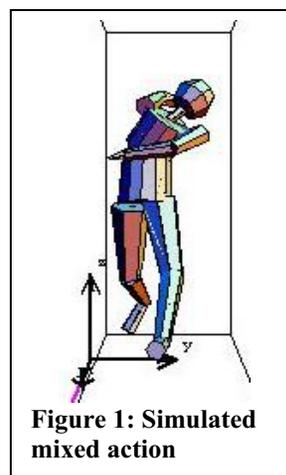

### RESULTS AND DISCUSSION

According to a modified classification for action type [3] only 11.8% were side-on, 27.5% front-on, and 61.7% mixed. The

**Table 1:** Shoulder and hip alignment characteristics show that mixed bowlers tend to have higher separation angles.

ACTION TYPE	Shoulder Angle BFC(°)	Shoulder/Hip Separation BFC (°)	Shoulder Counter Rotation (°)
Side-on	21.7 ± 1.8	10.2 ± 3.3	11.0 ± 5.4
Front-on	41.6 ± 3.4	9.07 ± 3.1	21.5 ± 2.4
Mixed	61.1 ± 2.7	28.4 ± 2.8	36.6 ± 2.3

mixed action bowlers had higher shoulder-hip separation angles than the side-on and front-on bowlers (Table 1). Mixed action bowlers also have more lateral flexion and hyperextension of the lumbar spine during delivery stride [1].

**Figure 1:** Simulated mixed action

The forward solution was run to test the effects of increasing the shoulder-hip separation angle of a front-on bowler. This was performed by increasing the anticlockwise upper trunk torque about the longitudinal axis and decreasing the corresponding torque of the lower trunk. This was represented by the shoulder to hip torque differential factor ( $\gamma$ ) in the forward solution.

The simulation of the bowler under these modified torque inputs ( $\gamma = 1.3$ ) increased the amount of lateral lean (15.3°),

hyperextension (10.2°), and shoulder counter-rotation (8.0°) at front foot contact. Increasing  $\gamma$  from 1 to 1.3 increases the severity of those factors that constitute a mixed action. As  $\gamma$  was increased more than 1.3 the solution become unstable. The kinematic data and the forward solution simulation suggest that a strong torquing between the shoulders and hips can promote shoulder-counter-rotation in bowling.

### CONCLUSIONS

This study showed that the mixed technique can be produced by changing the trunk torques in a forward solution. Despite their inherent stability problems, the further development of forward solutions should be pursued to give biomechanists a tool that not only achieves the objective of reducing shoulder counter-rotation, but that can also be used to improve other areas of performance.

## A NUMERICAL METHOD FOR DETERMINING IDEAL CAMERA PLACEMENT

<sup>1</sup> Joseph D Gardinier, <sup>1</sup>Kurt Manal

<sup>1</sup>Center for Biomedical Engineering Research, University of Delaware

### INTRODUCTION

Data piloting is important to ensure accurate coordinate data and to minimize camera drop-out. Camera drop-out occurs when a marker fails to be imaged by a camera; often due to marker merging and occlusion. In this paper, we present the conceptual framework of a numerical method for determining where video cameras, if placed, would have an occluded or a merged view of the markers. Experimental data are used to demonstrate the efficacy of the method as an effective tool to complement existing data piloting procedures.

### METHODS

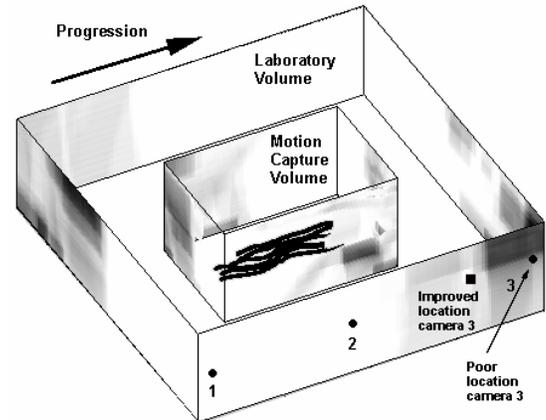

The method is best described by considering two markers within a motion capture volume. The motion capture volume is a subspace of a larger laboratory volume, both of which are defined by 4 walls, a floor and a ceiling (Figure 1). The apex of a cone is set at the midpoint between the markers, opening in the direction of one of the markers, and encircling its perimeter exactly. The cone continues outward, intersecting the walls, floor or ceiling of both volumes. A camera placed within this cone will have an occluded or merged view of the markers. This process is expanded to every possible marker pairing and at every point in time. Regions of intersection are displayed graphically to portray problematic camera locations. An exemplar graphical display is shown in Figure 1. The darker the shade of gray, the more frequently a camera in that location will drop-out. The method was tested using 3 video cameras positioned symmetrically as depicted by the circles in Figure 1 (Experiment 1). Markers were placed on the right leg and shoe of a subject using a modified Helen Hayes marker set. The distance between select markers was determined from data collected during a standing reference trial, and subtracted from distances measured during walking as an estimate of error due to camera drop-out. Note that camera 3 was initially positioned in a problematic location. In a second experiment, camera 3 was moved to a more favorable location (square in Figure 1) and the distance between the markers was computed once again.

### RESULTS AND DISCUSSION

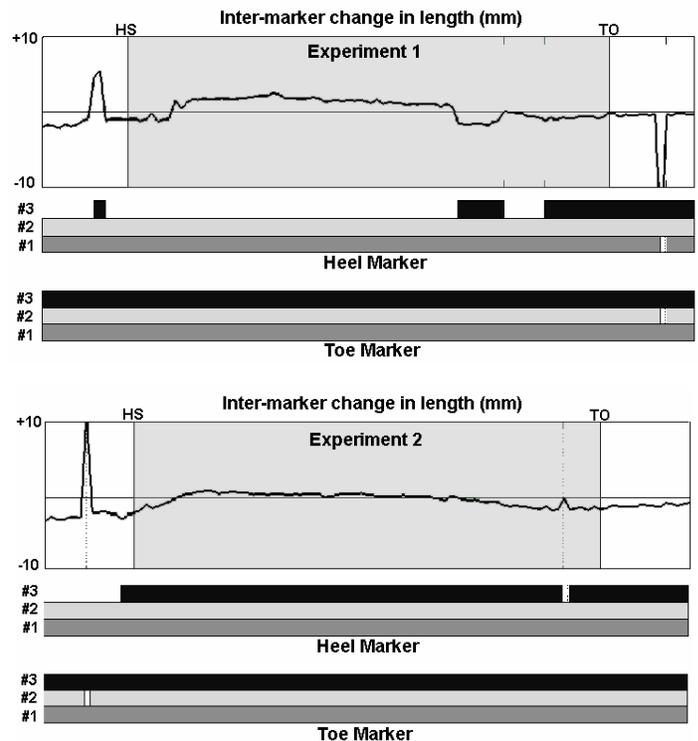

Only results for markers over the heel and toe are reported. The change in the distance represents errors due to camera drop-out since markers on the shoe are not subject to soft tissue error. Notice the large interval during stance in Experiment 1 when only cameras #1 & #2 contributed to the spatial determination of the heel marker. In contrast, camera 3 exhibited minimal drop-out and only small errors were noted during experiment 2.

### CONCLUSIONS

The method can be used to assist data piloting. It affords an objective and practical solution to minimizing errors associated with camera placement.

**Figure 1:** Gray regions depict problematic camera locations. The numbers identify the cameras. The black lines within the motion volume are marker trajectories.

**Figure 2:** Errors due to camera drop-out when camera #3 was located in a bad region (Experiment 1). The bar graphs indicate which cameras contributed to the spatial location of the markers. Cameras are identified as #1 - #3. HS = heel strike, TO = toe off. In contrast, the errors are smaller in experiment 2 when camera 3 was moved to a better location. Notice how camera 3 contributed to the location of the heel marker in all but 1 video frame.

### INTRODUCTION

New methods for the capture of human movement motivated by technological advances aiming to use non-intrusive or markerless motion capture [1] offer the potential to address some of the limitations of current methods for human gait analysis and open the door for new opportunities for the study of normal and pathological motion. While theoretical studies [2,3] showed that human kinematics can be accurately estimated in a virtual environment, these methods have not been tested with laboratory data. The purpose of this study was to evaluate the accuracy of human body kinematics extracted from experimental data using a visual hull markerless motion capture system.

### METHODS

Full body movement was captured using a marker-based and a markerless motion capture system simultaneously. The marker-based system consisted of an 8 Qualisys camera optoelectronic system monitoring 3D marker positions for the hip, knees and ankles at 120 Hz. The markerless motion capture system consisted of 7 Basler CCD color cameras capturing synchronously images at 76.9 fps. Movement was determined by first constructing visual hulls [2] and subsequently tracking an articulated body using an iterative closest point (ICP) tracking algorithm for articulated bodies [3]. The subject was separated from the background in the image sequence of all cameras using intensity and color thresholding compared to background images (Figure 1). The separated image information was projected into 3D and a visual hull (bounding surface) was constructed for each frame (Figure 2). The articulated body was created from a detailed full body laser scan with markers affixed to the subject's joints (Figure 1). The articulated body consisted of 15 body segments (hip, upper trunk, head, and left and right shoulder, forearm, hand, thigh, shin and foot) and 14 joints connecting these segments. Virtual markers were used to define segment coordinate axes. The joint angles (sagittal and frontal plane) for the knee calculated as angles between corresponding axes of neighboring segments, were used as preliminary basis of comparison between the two systems.

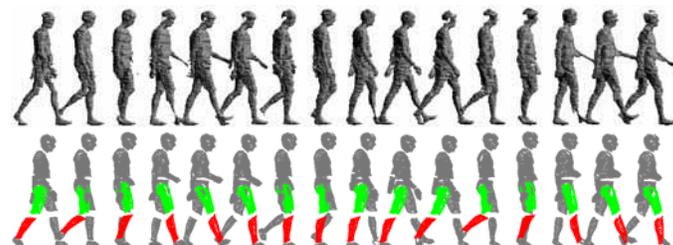

**Figure 1:** a) Background image. b) Image. c) Separated subject data. d) Laser scan. e) Body segments. f) Joint centers.

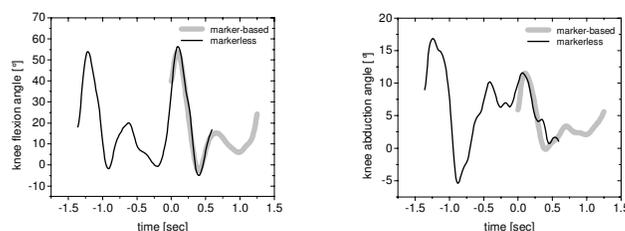

### RESULTS

The 15 articulated body segments defined from the laser scan were tracked through a gait cycle for both the markerless and

marker system (Figure 2). The kinematics from the markerless and marked system produced comparable results (Figure 3) for knee joint angles in the sagittal and frontal plane.

**Figure 2:** Visual hulls constructed using 7 cameras (top). Articulated body matched to visual hulls (bottom).

**Figure 3:** Motion graphs for knee flexion and knee abduction angles (gray = marker-based; black = markerless).

### DISCUSSION

The image processing modules used in this study including background separation, visual hull and iterative closest point methods yielded results that were comparable to a marker based system for motion at the knee. While additional evaluation of the system is needed, the results demonstrate the feasibility of calculating meaningful joint kinematics from subjects walking without any markers attached to the limb.

The markerless framework established in this study can serve as a basis for developing the broader application of markerless motion capture. Each of the modules can be independently evaluated and modified as newer methods, cameras and processors become available, thus making markerless tracking a feasible and practical alternative to marker based systems.

## FOREFOOT PLANTAR PRESSURE IS RELATED TO 3-D CT DERIVED MEASURES

<sup>1</sup> William R. Ledoux, <sup>1</sup> Eric S. Rohr, <sup>1</sup> Jane B. Shofer, <sup>1</sup> Randal P. Ching and <sup>1</sup> Bruce J. Sangeorzan  
<sup>1</sup> VA RR&D Center, Seattle, WA; email: [wyledoux@u.washington.edu](mailto:wyledoux@u.washington.edu) web: [www.seattlerehabresearch.org](http://www.seattlerehabresearch.org)

### INTRODUCTION

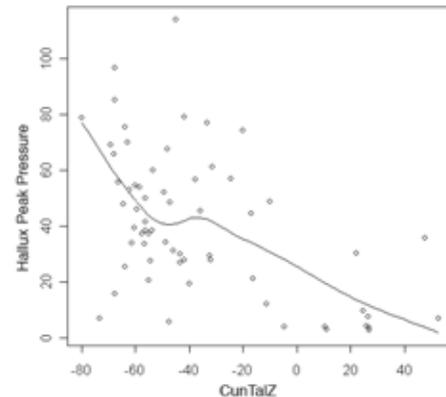

The relationship between foot structure and foot function is complex and not completely understood. Previous research has employed static X-ray parameters<sup>1</sup> or static X-ray parameters in conjunction with additional measures of foot structure and function,<sup>2</sup> including, among others, joint range of motion, tissue parameters, EMG, etc., to explain 35% and 50% of the variability of the plantar pressure, respectively. Our group has recently completed a study of the 3-D structure of feet ranging from flat to high arched feet.<sup>3</sup> Additionally, we compared plantar pressure data between these subjects.<sup>4</sup> In both studies, we found significant differences between foot types. The purpose of this study was to combine the work of the previous two studies to determine if 3-D measures of foot shape were related to forefoot plantar pressure.

### METHODS

A total of 40 subjects were enrolled with ten in each of four foot type groups: pes cavus (high arch), neutrally aligned, asymptomatic pes planus (low arch) and symptomatic pes planus. If the foot type was bilateral both feet were included (n=64 feet). Foot type was determined via clinical examination by an orthopaedic surgeon. Each foot was X-rayed (AP and lateral) and a weight-bearing CT scan was performed. Age, weight, height and gender were recorded. Ten trials of barefoot plantar pressure data were collected with an EMED-SF system and velocity was recorded. Peak pressure was determined over the entire foot as well as 6 subdivisions: the hallux and the 1<sup>st</sup> through 5<sup>th</sup> metatarsal heads. These subdivisions were obtained by overlaying the AP X-ray on top of an actual-size composite peak plantar pressure print out. Simulated weight bearing CT scans of the subject's foot were generated. Using techniques defined elsewhere, local coordinate systems (inertial matrices) were determined based on the bone morphometry.<sup>5</sup> These axes were then used to describe bone to bone orientation using the Z, Y', X'' Euler angles. Euler angles were calculated between the 1<sup>st</sup> Metatarsal-Talus (M1Tal), 5<sup>th</sup> Metatarsal-Talus (M5Tal), Calcaneus-Talus (CalTal), 2<sup>nd</sup> Metatarsal-1<sup>st</sup> Metatarsal (M2M1), Calcaneus-Fibula (CalFib), Cuneiforms-Talus (CunTal), Cuneiforms-Navicular (CunNav), and Navicular-Talus (NavTal), resulting in 24 total angles. Linear regression models of mean pressures (per subject) on Euler angles were calculated; age, BMI and mean velocity were adjusted for.

### RESULTS

To visualize trends for each location, a plot of the data with a loess-smoothed curve was generated (Figure 1). The regression for each location required only 3 or 4 of the 24 possible angles; additional angles made no improvement. For the hallux, the CunTalZ, M1TtalZ, and the M2M1Y' angles explained 46.4% of the variability in peak plantar pressure. The 1<sup>st</sup> metatarsal data indicated that the CalFibX'', M2M1Z, M1TalY', and CalTalX'' angles were significant and could

**Figure 1:** The hallux peak pressure vs. the CunTalZ angle.

account for 47.7% of the variability in peak plantar pressure. The 2<sup>nd</sup> and 3<sup>rd</sup> metatarsals only showed significance with one angle, the NavTalX'' and M2M1Z, respectively, and only 21.5% and 3% of the variability could be explained. The 4<sup>th</sup> metatarsal showed that the CunTalZ, M2M1Z, CalFibX'', CalTalZ angles were significant and able to describe 51.2% of the variability in peak plantar pressure. And finally for the 5<sup>th</sup> metatarsal we found that 44.7% of the pressure variability over this region could be accounted for when the M5TalX'', M1TalX'', CalFibX'', and CunNavX'' angles were analyzed.

### DISCUSSION

This study indicates that for several locations on the forefoot (hallux, and the 1<sup>st</sup>, 4<sup>th</sup> and 5<sup>th</sup> metatarsals) the 3-D static angles describe more of the variability of the plantar pressure than just X-ray parameters.<sup>1</sup> In fact, for these areas the 3-D static angles were as predictive as the range of foot structure and functional parameters used elsewhere.<sup>2</sup> However, for other locations, our analysis was a very poor predictor (2<sup>nd</sup> and 3<sup>rd</sup> metatarsal). It is not clear why these locations did not perform well; they were not emphasized in the selection of bony relationships to study, but neither was the 4<sup>th</sup> metatarsal and it had the highest percentage. Nevertheless, areas such as the hallux and the 1<sup>st</sup> and 5<sup>th</sup> metatarsals are important areas for ulcer occurrence. The data present here demonstrate that 3-D CT angles useful for predicting peak plantar pressure.

## STEPPING-OVER GAIT CHARACTERISTICS IN CHILDREN WITH DOWN SYNDROME

<sup>1</sup>Bee-Oh Lim, <sup>1</sup>Joong-Hyun Ryu, <sup>2</sup>Dong-Ki Han, <sup>1</sup>Gary Christopher and <sup>1</sup>Young-Hoo Kwon  
<sup>1</sup>Biomechanics Laboratory, Texas Woman's University, Denton, TX, USA  
<sup>2</sup>Dept. of Physical Education, Seoul National University, Seoul, Korea  
 email: [imabo@korea.com](mailto:imabo@korea.com), web: [www.twu.edu/biom](http://www.twu.edu/biom)

### INTRODUCTION

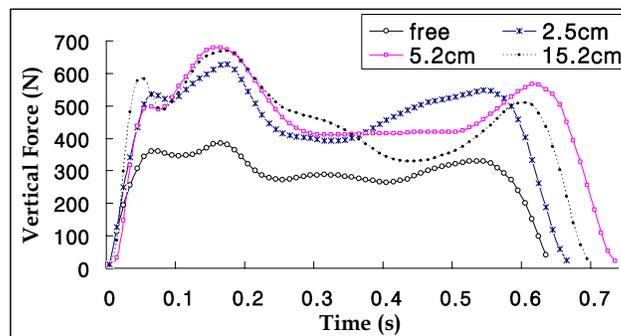

Approximately 80% of children with DS exhibit difficulty in walking [1]. Most studies on gait characteristics in children with DS have concentrated on level walking. We are not aware of any study dealing with stepping over obstacles, despite the frequency with which this must be done in everyday life and the potential consequences of falls [2]. The purpose of this study was to investigate the step-over gait characteristics of children with Down syndrome (DS) as they approached and stepped over obstacles of different heights. We tested the null hypothesis that no differences exist in dependant variables when stepping over obstacles of different heights.

### METHODS

Thirteen boys with DS initially participated in this study but analysis has been completed for only five (age:  $12.0 \pm 0.9$  yrs; height:  $134.9 \pm 9.7$  cm; mass:  $34.4 \pm 8.4$  kg) of them due to difficulties in obstacle clearance. A 10.0 m x 1.3 m walkway with a firm dark surface was used for data collection. An AMTI force plate was embedded in the walkway such that the first footfall after obstacle clearance occurred on the force plate. Three-dimensional motion analyses and ground reaction force analyses were performed to obtain dependant variables. One-way repeated-measure ANOVA was performed to determine whether obstacle height had a significant effect on the dependant variables. Four levels of obstacle height were used: 0, 2.5, 5.2, and 15.2 cm [1].

### RESULTS AND DISCUSSION

As obstacle height increased, the subjects exhibited greater vertical foot clearance, obstacle to heel horizontal distance, hip sway angle, joint ROM (knee & hip), impulse, 1<sup>st</sup> peak force (Figure 1), and support time compared to obstacle free

**Figure 1:** Vertical ground reaction force (subject 5). The ground reaction force pattern was characterized by a wide spectrum of individual differences. In some participants (subject 5), however, vertical force patterns similar to the normal pattern were observed.

gait. Hip ROM at swing phase, impulse and support time increased and knee angle at step over decreased as obstacle height increased (Table 1). The results of this study show that obstacle height gait differ in some ways from obstacle free gait. The fact that subjects had similar toe to obstacle horizontal distance, obstacle to heel horizontal distance and vertical foot clearance for each obstacle suggests a commonality in the strategy used for negotiating obstacles. The results suggest that this strategy places great emphasis on avoiding toe contact with the obstacles.

## ELBOW ANGLE EXCURSION SLOPE AS A DETERMINANT OF BOWLING LEGALITY

<sup>1</sup> René Ferdinands and <sup>2</sup>Uwe Kersting

<sup>1</sup>Department of Physics & Electronic Engineering, University of Waikato, Hamilton, New Zealand,

<sup>2</sup>Department of Sport & Exercise Science, University of Auckland, Auckland New Zealand

### INTRODUCTION

The legality of a bowler's action in cricket has been established in accordance with Law 24.3 of the International Cricket Council (ICC) rules, which state that "once the bowler's arm has reached the level of the shoulder in the delivery swing, the elbow joint is not straightened partially or completely from that point until the ball has left the hand" (MCC, 2002). However, fast bowlers seldom use a rigid straight arm, and the elbow angle generally increases after reaching shoulder height [1,3].

The ICC in keeping with these facts set a range of allowable elbow extension angles: 10° for fast bowlers, 7.5° for medium-pace bowlers, and 5° for spin bowlers. However, in a laboratory study of 42 subjects Ferdinands and Kersting [1] showed that there was no correlation between elbow extension angle and bowling type, and recommended a 15° flat tolerance level. The aim of this study was to further examine bowling action legality by measuring the elbow extension angle, and the elbow excursion angle slope through ball release of a sample of 67 bowlers using an 8-camera three-dimensional (3D) motion analysis system (240 Hz). The results suggest that elbow excursion angle is an important determinant of bowling action legality.

### METHODS

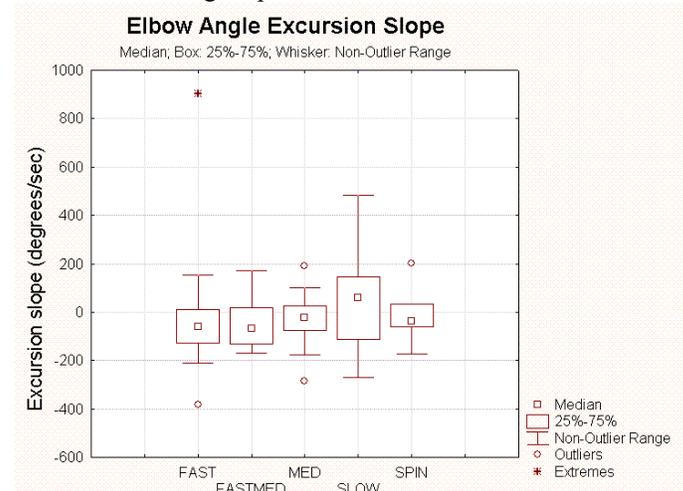

Sixty-seven bowlers were selected for the study, and grouped into fast, med-fast, medium, slow, and finger-spin categories. Also, 8 bowlers in this sample were observed as possibly having a throwing-type action. Each subject was filmed by an 8-camera marker-based 240 Hz motion analysis system. A 10-marker static calibration marker system was used. This was reduced to a 7-marker bowling set, which is the minimum required to carry out a 3D analysis of the arm based on an anatomically based joint coordinate system (JCS). The 3D elbow angles were calculated from the relative orientation of the forearm to the upper arm based on a joint coordinate system [2]. Six trials per subject were recorded. Elbow excursion angle slope was calculated as the rate of elbow angle change from two frames before to two frames after ball release.

### RESULTS AND DISCUSSION

The mean elbow extension angles for the groups were fast: 6.23±0.65°, med-fast: 4.79±0.63°, medium: 7.27±0.93°, and slow: 6.74±1.59°. There was no correlation found between elbow extension angle and ball release speed. Also, there was some variability in the mean elbow extension angles per subject. Eight bowlers had elbow extension angles in excess of 10°, and rare individual trials could have up to 15° extension. However, only one of these bowlers was suspected of throwing.

The elbow excursion angle slope was negative for 70.1% of the bowlers, which means that after an initial elbow extension,

the elbow flexed through release (Figure 1). For the remaining bowlers, the elbow excursion angle slope was positive, indicating that the elbow extended through release. This is partially consistent with the 4<sup>th</sup> edition of the MCC 1947 code (1970) which defined a legal bowl when the "process of straightening the bowling arm, whether it be partial or complete, takes place during that part of the delivery swing which directly precedes the ball leaving the hand." However, according to this law there would still be too many illegal bowlers. However, above an elbow excursion angle slope of a 100 %/sec, only 11.9% of the bowlers would be considered illegal, including all eight bowlers who had been previously observed as having suspect actions.

**Figure 1: Elbow excursion angle slope for all bowling groups. Positive means extension through release.**

### CONCLUSIONS

The findings suggest that a new bowling law should not only specify a flat tolerance level for elbow extension angle, but examine the new concept of elbow excursion angle slope through ball release. It is also possible that elbow excursion angle slope has a better correlation with a visual determination of bowling legality. From a biomechanical perspective, an extending arm through release is able to use both humerus internal rotation and elbow extension as a contribution to ball speed, as in a throw. More research is needed to determine the legal level of excursion angle slope. Also, the mean elbow extension data indicates that a 15° tolerance level may be excessive, particularly if there is no consideration of elbow excursion angle slope.

**ESTIMATION FOR DYNAMIC MEASUREMENT OF SCAPULA KINEMATICS  
 USING ELECTROMAGNETIC TRACKING DEVICE**

Koh Inoue and Shuji Suzuki  
 Graduate School of Human Sciences, Waseda University, Tokorozawa, Japan,  
 e-mail: k.inoue@ruri.waseda.jp

**INTRODUCTION**

Scapula motion is an important element of upper limb movement, and therefore several investigators have developed methods for measuring three-dimensional and dynamic scapula kinematics. Recently, *acromial method* [1] using electromagnetic sensor was investigated. Although this method is three-dimensional, dynamic, noninvasive and practical, sliding of scapula under skin prevents accurate measurement [2]. The purpose of this study was to examine the error pattern in *acromial method* during humerus elevation.

**METHODS**

Six adult subjects with functionally normal shoulder girdles participated. Kinematic data were collected with electromagnetic tracking device (Plhemus, LIVERTY). Sensors were attached to the skin on acromion, sternum and a three-pin device according to Johnson [3], which was scapula locator by palpating landmark. Scapula orientations from thorax coordinate system were recorded during humerus elevation, and expressed in Euler angle, which are comprised of three angles. These angles represented external rotation (ER), upward rotation (UR) and tilting (TI). Humerus elevations were performed in 76 positions: 19 humerus elevations per 10° and 4 elevation planes per 30°. The error of bone and skin based measurement was computed for each angle. Each rotation error was separately compared with a 19 (humerus elevation: HE) × 4 (elevation plane: EP) repeated measures ANOVA.

After examining the error pattern, estimation was tested. Estimation models were developed for each subject. The models were made by multiple linear regression: predictor was skin orientation and estimator was Scapula orientation. For practical application, samples were required to be small and easy to obtain. Therefore, 25 positions, 6 humerus elevations × 4 elevation planes in steps of 30° + 1 rest position, were selected. As the number of samples decreased from 25 to 2 samples, root mean squared error on average in all subjects (ARMSE) was observed and evaluated.

**Table 1:** The error of scapula and skin orientation.

Rotation	Factor	DOF	f-value	p-value
ER	HE	18	19.827	.000 **
	EP	3	0.417	.743
	HE×EP	54	2.280	.000 **
UR	HE	18	14.828	.000 **
	EP	3	12.315	.000 **
	HE×EP	54	2.370	.000 **
TI	HE	18	9.996	.000 **
	EP	3	5.990	.007 **
	HE×EP	54	1.952	.000 **

\*\* p<.01

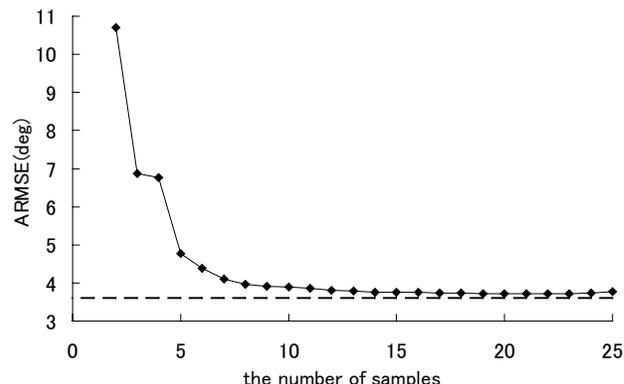

Figure 1: The change of ARMSE for the number of samples. Broken line expressed ARMSE by regression using all samples.

**RESULTS AND DISCUSSION**

All errors had HE × EP interaction (Table 1), therefore HE differently affected to error patterns in each EP. These complex errors were caused by slack of skin. During humerus elevation, the distance between scapula and humerus was partly contracted then the skin on acromion was slacked. Though the amount of the errors was individually different, the error patterns across all subjects were identified.

Systematic error pattern allowed estimation of regression. ARMSE was decreased from 20.3° (no regression) to 3.6° (using all samples). Focusing the number of samples (Figure 1), ARMSE obviously increased under 10 samples, while it did not clearly changed over 15 samples. To consider estimation accuracy and time cost for sampling, using about 10 to 15 samples was practical. Then, the number of samples decreasing, remained samples were based between low elevation in frontal plane and high elevation in sagittal plane. It was suggested that employing sampling position was based on this positions.

**CONCLUSIONS**

The error patterns were examined for humerus elevation and elevation plane. Employing linear regression, dynamic measurement of scapula kinematics from skin is possible. For practical way, the number of samples and sampling humerus positions were suggested.

## CENTRAL AND PERIPHERAL CONTROL OF MUSCLE STIFFNESS IN HOPPING

### INTRODUCTION

In stretch-shortening cycle (SSC), a transition period from the eccentric to the concentric phases is called coupling time (Ct). If duration of Ct increases, the release of the elastic energy in the concentric phase would decrease. Thus, minimizing Ct is important for the elastic energy utilization in SSC.

Although Ct depends on the total movement time [2], the mechanisms responsible for this phenomenon were not well-known. Linsel-Corbeil and Goubel (1990) reported that an increase in muscle stiffness during the eccentric phase would reduce Ct. Therefore, it is hypothesized that stiffness regulation during the eccentric phase could be key to solve above-mentioned problem.

The purpose of this study was to investigate the neural control mechanism of the triceps surae to reduce Ct during hopping.

### METHODS

Seven male subjects performed two-legged hopping at the preferred and the lowest frequency (PF, LF, respectively). The subjects determined these frequencies voluntarily. To differentiate Ct, two different ground contact time were manipulated during stance phase at each frequency: preferred and the shortest possible time (PCT and SCT, respectively).

An ankle angle was measured by a goniometer to calculate Ct, which was computed as the time period of 5 % threshold levels above the minimum ankle angle [1]. The surface electromyography (EMG) activities of the medial gastrocnemius (MG) and soleus (SOL) muscles were recorded with telemetric system. Obtained EMG signals were amplified, full wave rectified, and then integrated over the fixed interval of 20 ms. All data were compared PCT with SCT conditions.

### RESULTS AND DISCUSSION

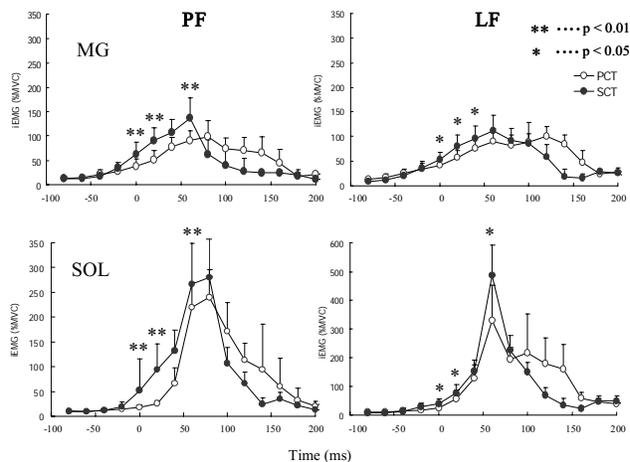

As shown in Table 1, we could differentiate Ct by manipulating ground contact time in same hopping frequency.

The most important finding of this study was that increased pre- and post-landing EMG activity was observed in SCT conditions at each frequency (Figure 1).

**Table 1:** Mechanical data for PCT and SCT.

	Preferred frequency		Lowest frequency	
	PCT	SCT	PCT	SCT
Hopping frequency (Hz)	2.12 ± 0.1	2.11 ± 0.08	1.87 ± 0.2	1.87 ± 0.2
Ground contact time (ms)	238 ± 32	203 ± 32**	210 ± 33	198 ± 28**
Coupling time (ms)	39 ± 15	32 ± 9 **	33 ± 11	29 ± 10**

\*\* p < 0.01

**Figure 1:** Representative EMG activities during hopping. The records were lined up with ground contact as reference (Zero time).

EMG activity observed at pre-landing was thought to be feed-forward motor program that made in central nervous system [3]. In addition, post-landing EMG is mentioned as short-latency stretch reflexes triggered by dorsiflexion [5]. Both EMG activities have an effect to regulate muscle stiffness during the eccentric phase [3, 5].

Considering that an increase in muscle stiffness during the eccentric phase would reduce Ct [4], increased EMG activity in SCT conditions can be interpreted as adaptations to regulate muscle stiffness for reduction of Ct by central and peripheral nervous system.

### CONCLUSIONS

Neuromuscular control of the triceps surae to reduce Ct was investigated. These results clearly show that stiffness regulation by central and peripheral nervous system contributes to reduce Ct.

## A VALIDATION STUDY: USING CT SCANS TO CALCULATE VOLUME, WEIGHT AND DENSITY

<sup>1</sup>Sylvana García, <sup>1</sup>Jill Schmidt, <sup>1</sup>Heidi Ploeg

<sup>1</sup>Department of Mechanical Engineering, University of Wisconsin-Madison  
email: garcial@wisc.edu, web: www.engr.wisc.edu/groups/BM/

### INTRODUCTION

Virtual modeling is a rapidly growing pre-clinical evaluation tool in the biomedical field. Not only is it a non-invasive method to predict biomechanical behavior, but it can also be performed to gain insights before clinical applications [1-4], thus increasing the efficiency of the design process. Computerized Tomography (CT) scans can provide data on the shape and density distribution [5] of a tissue required for a virtual a model.

The purpose of this study was to determine an empirical relationship between the CT gray values (Hounsfield Units, HU) and the density of polymeric materials, and to apply this relationship to volumes constructed from the segmented CT data. These results were compared to physically measured volumes and weights.

### METHODS

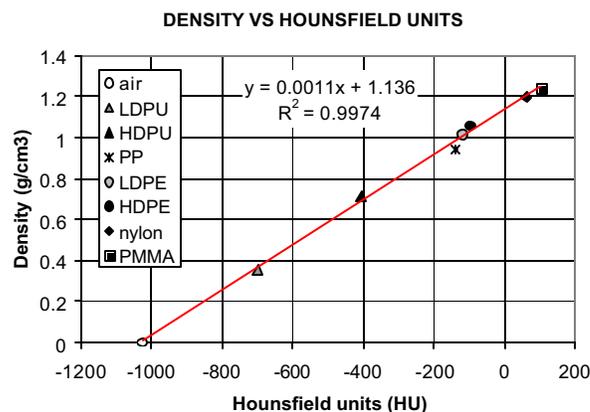

In this study, cylinders made from 8 materials were scanned with a clinical CT scanner: low density polyethylene, high density polyethylene, polymethylmethacrylate, polypropylene, Nylon 66, and low density polyurethane (LDPU) were 10 mm diameter by 7 mm height; and, high density PU (HDPU), and aluminum, were 10 mm diameter by 5 mm height. Each cylinder was measured and weighed prior to CT scanning (UW Hospital, 120 kV, 30 mA, 0.43 mm pixel size, GE LiteSpeed<sup>16</sup>, GE Medical Systems). The cylinders were CT scanned with their axes oriented in a vertical direction.

The CT data were imported into Mimics 8.11 (Materialise, Ann Arbor, MI) software. Using the thresholding procedure "masks" were created which consisted of a group of pixels within the relevant range of HU's. The masks were not manually edited in this protocol. A mean value of HU was recorded for each material. Based on the masks, a 3D model of each material was constructed and its volume was determined. The 3D models were surface-meshed with triangles using Mimics and imported into MSC/Patran 2003 (MSC.Software, Santa Ana, CA) to create a volume mesh with tetrahedral-shaped elements, which was imported back into Mimics, to assign density to each element, based on the HU's. The volume mesh with assigned density was then re-imported into MSC/Patran 2003 to find its volume and weight.

### RESULTS

An empirical relationship between HU and the polymeric densities (measured mass/volume) was derived (Figure 1). A mean of the absolute errors of 12% (-7%-19%) between the Mimics derived volumes and the measured volumes was found. The error between the Mimics and MSC/Patran volumes was insignificant. A comparison of the measured weights and densities to the MSC/Patran derived values found a mean of the absolute errors of 7% (-15% to -1%) and 12%

(-17% to 20%), respectively, excluding the results from PU foams, which produced the largest errors (76% and 183%) on the weights of the HDPU and LDPU, respectively.

**Figure 1:** Density versus Hounsfield units for 7 polymers and air ( $\rho = 0 \text{ g/cm}^3$ , at  $\text{HU} = -1024$ ).

### DISCUSSION AND CONCLUSIONS

The volume error of segmented models was due to CT scanning resolution which caused the cylinders to be slightly sectioned perpendicular to the scanning direction. Also, the thresholding procedure was imprecise at the base of the cylinders due to the material interfaces. The large errors in the weights and densities of LDPU and HDPU foams were caused by modeling them as a continuum. This result is particularly relevant to similarly derived models of trabecular bone and the study of its micro- and macro-mechanical properties.

CT scans of cylinders of various materials were used to construct 3D virtual models. A linear relationship ( $R^2 = 0.997$ ) between HU and density for 7 polymers and air was used to assign density to a volumetric mesh. The measured and constructed properties (volume, weight and density) for the cylinders were compared, finding errors in weight and density of 7% and 12%, respectively, excluding the results from the LDPU and HDPU. The sources of error were: CT scanning resolution, thresholding at material interfaces, and modeling of foam on a macro-scale. The relationship between micro- and macro-mechanical properties needs to be further investigated.

## INFLUENCE OF VOLUNTARY POSTURE SELECTION ON ENDPOINT STIFFNESS

Eric J. Perreault

Departments of Biomedical Engineering and Physical Medicine and Rehabilitation  
Northwestern University, Evanston, IL,

### INTRODUCTION

The endpoint stiffness of the human arm describes the relationship between postural perturbations applied at the hand and the steady-state forces generated in response to those displacements. As such, it characterizes the mechanical properties of the arm as seen at the point of contact with the environment and can be used to quantify limb stability. The stiffness properties of a limb are not fixed, but rather depend strongly on limb posture [1] and muscle activation [2]. It has been proposed that humans modulate limb stiffness to optimize the mechanical properties of a limb in a task-dependent manner [3]. However, most studies examining endpoint stiffness only have characterized 2D stiffness with the arm in the horizontal plane. Under these conditions, the direction of maximum stiffness is oriented approximately along the line connecting the shoulder and hand, and it appears that this orientation cannot easily be modified for a fixed arm posture. In contrast to these studies, functional tasks rarely are restricted to the horizontal plane. Hence, a more complete understanding of how endpoint stiffness is regulated during functional tasks requires an assessment 3D endpoint stiffness at self-selected arm postures. The purpose of this study is to quantify the 3D stiffness properties of the human arm and to examine if individuals voluntarily choose postures that optimize endpoint stiffness in a task-dependent manner.

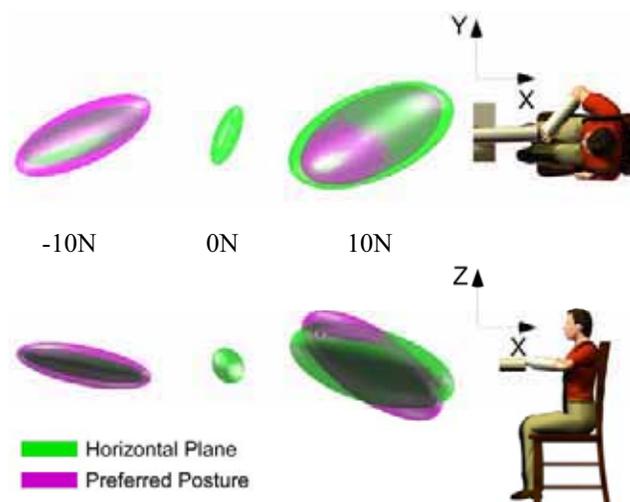

### METHODS

Endpoint stiffness was measured using a 3D robotic manipulator [HapticMaster; FCS Control Systems, The Netherlands], configured as a stiff position servo. The robot was used to apply random 3D displacements to the arm and to measure the 3D forces generated in response. Subjects were strapped into an adjustable height chair so that the trunk was fixed and positioned so that the hand was at shoulder height, approximately in front of the sternum. Although the shoulder and hand were fixed, the position of the elbow was free. In each trial subjects were instructed to exert a constant level of force against the robot and were assisted in this task by a 3D visual display of the force measured by the robot. Data were collected either with the arm positioned in the horizontal plane or positioned at a posture selected by the subject. The presented data focus on forces generated along the  $\pm X$ -axis (Fig. 1), which corresponds pushing or pulling along the intersection of the sagittal and horizontal planes.

Endpoint stiffness was estimated from the measured endpoint displacements and forces using system identification techniques presented previously [2, 4].

### RESULTS AND DISCUSSION

When the arm was kept in the horizontal plane, our 3D stiffness estimates were consistent with the 2D results that we and others have reported previously [1,2]. When allowed to

**Figure 1:** Endpoint stiffness measured at three different voluntary force levels along the X-axis.

self-select an arm posture, subjects always chose one in which the elbow was dropped below the horizontal plane connecting the shoulder and hand. Fig. 1 compares the stiffness estimated at two self-selected postures (purple) to those measured with the arm in the horizontal plane (green). Each ellipsoid represents the results of a separate endpoint force condition, indicated by the labels; the overlaid ellipsoids were collected at matched forces. The self-selected postures resulted in increased stiffness for forces along the  $-X$  axis, which tend to decrease limb stability [5], and increased stiffness for forces in the opposite direction, which tend to increase stability. Hence these postures may have been chosen to compensate for the effects of the constant forces applied at the hand.

### CONCLUSIONS

These initial results demonstrate our ability to measure endpoint stiffness in the three degrees of freedom relevant to most functional tasks. In addition, they demonstrate that subjects often work outside of the horizontal plane characterized in most previous studies and that these alternate postures influence endpoint stiffness. We currently are examining how self-selected postures influence limb stiffness and stability in a variety of tasks.

## A BIOMECHANICAL COMPARISON OF KENYAN AND JAPANESE ELITE LONG DISTANCE RUNNER'S TECHNIQUES

<sup>1</sup> Yasushi Enomoto and <sup>2</sup>Michiyoshi Ae

<sup>1</sup>Faculty of Education, Kyoto University of Education; enomoto@kyokyo-u.ac.jp

<sup>2</sup>Institute of Health and Sport Sciences, University of Tsukuba

### INTRODUCTION

It is recognized that Kenyan runners have an excellent record in running events of various distances: they have mastered running techniques for the acquisition and maintenance of high speed over long distances. Although there are many world class Japanese long distance runners, comparing their running techniques with those of Kenyan elite runners seems to reveal differences in efficiency. This study will attempt to show reasons for the high performance of Kenyans through biomechanical analysis of their running techniques. The purpose of this study is to compare the running techniques of Kenyan and Japanese elite male long distance runners in 5000 m races.

### METHODS

Official 5000 m races were videotaped with a digital video camera at 60 Hz in the 2003 IAAF Grand Prix in Osaka; the 2004 Super Athletic Meets in Yokohama; and the 2004 Inter-high School Athletic Competition. Videotapes of nine Kenyan and nine Japanese runners were digitized through out the running cycle at the 2000 m and 4000 m marks. Their height, body mass, and race record were 1.69 m, 55.1 kg, 13 min 24.08 sec for Kenyans and 1.73 m, 55.8 kg, 13 min 34.92 sec for Japanese, respectively. Kinematic and kinetic variables were calculated using two-dimensional motion analysis. Joint and segment angles, center of mass, joint torque, and power of the lower limb were calculated for the evaluation.

### RESULTS AND DISCUSSION

Running velocity at the 2000 m and 4000 m marks was 6.16 and 6.28 m/s for the Kenyan and 6.08 and 6.11 m/s for the Japanese. There was no significant difference in running velocity, step length and step frequency. However, relative step length to the body height was greater in the Kenyans than the Japanese. There were few significant differences in lower limb angles and angular velocities between the Kenyan and the Japanese runners. One of the greatest differences was shown in the mean torso angle of the cycle, which indicates that Kenyan runners ran with greater forward lean of the torso than the Japanese. Ankle joint

angle at toe-off and angular displacement in the second half of the support phase were greater in the Japanese than the Kenyans. Thigh and shank angular velocity in the recovery phase tended to be greater in the Kenyans than the Japanese but there was not a statistically significant difference. The peak values of the joint torque and power at knee joint in the late recovery phase were greater in the Kenyans than the Japanese. These results suggest that hip and knee joint movement relative to the ankle joint was greater in the Kenyans than the Japanese.

The figure below shows stick pictures at each point in the cycle and the locus of the center of mass of the lower limb (CMleg) for typical subjects at the 4000 m mark, subject A is a Kenyan and subject B is a Japanese runner. It is shown that the locus of CMleg for subject A shows a wider and higher ellipse than subject B. There were significant differences in the horizontal displacement (range of horizontal movement) of CMleg relative to the body height and the maximum horizontal (forward) velocity of CMleg relative to the center of mass of the body between the Kenyan and Japanese runners. It is important for a distance runner to swing both legs forward and backward coordinately in order to reduce energy waste [1]. These results suggest that the Kenyan runner swung the leg forward faster and more broadly so as to efficiently acquire the higher running velocity.

### CONCLUSIONS

One of the most significant characteristics of the Kenyan runner was the forward lean of the torso. Movement of the center of mass of the lower limb was greater and faster for the Kenyans than the Japanese, which indicates that the Kenyan runner could swing the leg forward faster and more broadly.

## THE KINEMATIC CHANGES OF PITCHING DURING A SIMULATED BASEBALL GAME

<sup>1</sup> Daisaku HIRAYAMA, <sup>2</sup> Norihisa FUJII

<sup>1</sup>Graduate School of Comprehensive Human Science, University of Tsukuba, Japan

<sup>2</sup>Institute of Health and Sport Sciences, University of Tsukuba, Japan

e-mail: daisaku-h@lasbim.taiiku.tsukuba.ac.jp

### INTRODUCTION

Maintaining consistent maximum ball velocity is an important factor for baseball pitchers. At the latter half of the game, ball velocity and control decrease due to fatigue by excess of pitching. Therefore, it is difficult for a baseball pitcher to pitch the whole game in many cases. The purpose of this study was to investigate the effect of fatigue on changes of pitching kinematics during a simulated baseball game.

### METHODS

Six male college baseball pitchers threw 15 pitches in an inning for 9 innings (135 pitched) in an indoor pitcher's mound. Rest time between innings was 6 minutes.

Three-dimensional positions of 47 reflective markers attached to subjects were tracked by an optical motion capture system (Vicon Motion System 612, Oxford Metrics) with eight cameras (250Hz). For each subject two fastball pitches (one in the 1<sup>st</sup> inning and one in the 7<sup>th</sup> inning) were chosen for analysis.

The pitching motion was divided into three phases by four instants of motion events: the first phase was defined as a phase from the instant for maximal knee height of the stride leg (MAXknee) to the instant for minimal ball height (MINball), the second phase from MINball to stride foot contact (SFC), and the third phase was from SFC to ball release (REL).

Differences among kinematic parameters were analyzed by paired t-test with significant level of 5%.

Kinematic parameters were analyzed as follows: ball velocity, knee angle of lead leg, shoulder rotation angle (Figure1), pelvis rotation angle, abduction angle and horizontal abduction angle of throwing arm, forward tilt angle (Figure2) and lateral tilt angle of trunk, backward tilt angle (Figure2) and lateral tilt angle of shank.

### RESULTS AND DISCUSSION

Four of ten kinematic parameters changed significantly between 1<sup>st</sup> inning and 7<sup>th</sup> inning (Table1).

1) The ball velocity of 7<sup>th</sup> inning was significantly smaller than that of 1<sup>st</sup> inning. It is generally accepted that the ball velocity often decreases when a pitcher throws about 100 pitches. Therefore, this research had the same tendency as the generally considered one.

2) The shoulder rotation of 7<sup>th</sup> inning at SFC was significantly larger than that of 1<sup>st</sup> inning. It shows that the shoulder is open up at SFC. Stodden et al.<sup>3)</sup> indicated that pitchers could generate larger momentum and transfer it from the trunk to the throwing arm when they were in a proper position to optimally rotate the pelvis and upper torso (shoulder). Therefore, it is important to twist the trunk appropriately.

3) The forward trunk tilt of 7<sup>th</sup> inning at REL was smaller than that of 1<sup>st</sup> inning. Matsuo et al<sup>1)</sup> found that ball velocity increased as forward trunk tilt increased. It is inferred that forward trunk tilting at REL might be appearance that the pitcher tried to enlarge the ball velocity.

4) The backward shank tilt of 7<sup>th</sup> inning at REL was larger than that of 1<sup>st</sup> inning. Murray et al.<sup>2)</sup> showed that the knee flexion angle at REL might indicate muscle fatigue. In turn, less energy was transferred from the support leg to the trunk, subsequently decreasing the amount of energy in the throwing arm at 7<sup>th</sup> inning.

### INTRODUCTION

Joint instability is one of the most common human afflictions. Capsulolabrum, articular surfaces, intracapsular pressure and muscle contractions are the factors in maintaining joint stability. The glenohumeral joint is a common dislocated large joint of the body [1]. Shoulder motion with improper muscular coordination or need of explosive muscle contraction is easy lead to joint dislocation such as baseball pitching. The purpose of this study was to examine how the muscle functions response for joint stability during baseball pitching. We hypothesize that muscle contraction force contributed the most to balance external loading to keep joint stability.

### METHODS

A graphic-based musculoskeletal model of the shoulder was utilized for the dynamic analysis [2] (Fig. 1). Ten muscles with fifteen action lines were included in the shoulder model. The pitching motion of a college baseball pitcher was captured using a Qualisys™ motion analysis system (Qualisys AB, Sweden) at a 500Hz sampling rate. Using the inverse dynamic problem solution and Newtonian analysis, the joint resultant forces and moments at shoulder were quantified. The indeterminate problem was solved using an optimization technique by minimizing the sum of the squares of muscle stresses. Additional inequality constraints on muscle stress were considered, thus making the present formulation a “mini-max” problem. Sequential quadratic programming and a steepest decent algorithm were used to search for the muscle contraction force. The magnitude and action line of resultant joint force, joint constraint force (joint contact force and passive element forces) and muscle contraction force was used to identify the contribution to joint stability. For the results presentation, the action line of the muscle, resultant joint force, and joint constraint force were projected to scapular coordinate and expressed as anterior/posterior (z-axis), superior/inferior (y-axis), centripetal/centrifugal (x-axis).

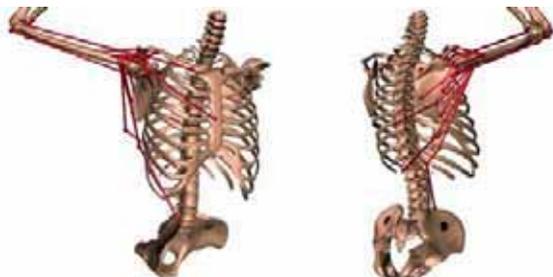

Fig. 1 The graphic-based musculoskeletal model of the shoulder.

### RESULTS AND DISCUSSION

Results showed that the resultant joint force has significant loading force until the end of late cocking phase. The maximum resultant joint force in centripetal direction (851N) was occurred in ball releasing, and inferior direction (479N) at the end of late cocking phase. The force in anterior/posterior direction was relative small and found the maximum loading force in follow through phase about 390N. From the muscle forces analysis, the joint constraint forces contributed very little to keep joint stability from the end of late cocking phase to the acceleration phase. During this period, eight of fifteen muscle action lines are mainly in the inferior direction (Table 1). Among these muscles, sternal and clavicle branch of the pectoralis major, infraspinatus, and supraspinatus had significant contraction forces. At this moment, glenohumeral joint could not rely on its geometry to keep joint stability. These muscles forces contribute to both joint motion and stabilization. On the contrary, at the ball release, only four muscle action lines are in the centripetal direction and only latissimus dorsi had significant contraction force. That means that joint contact force could provide enough joint stability.

Table 1. The magnitude and orientation of action line of joint resultant force and muscles at the end of late cocking phase.

	Orientation	Force (N)
Joint resultant force	(0.45, -0.89, 0.09)	479
Pectoralis major (sternal)	(-0.52, -0.84, -0.19)	95
Pectoralis major (clavicle)	(-0.18, -0.98, 0.11)	135
Infraspinatus	(0.46, -0.79, -0.41)	276
Supraspinatus	(0.35 -0.93, 0.06)	82

### CONCLUSIONS

This quantitative model improves our understanding of the role of shoulder muscles in glenohumeral joint during the baseball pitching. Muscles not only play the movers but also stabilizers especially when joint had anterior/posterior and superior/posterior external loading. Future study may optimize muscles strengthening to maximize compressive forces to keep joint stability

### INTRODUCTION

There is generally limited quantitative kinematic and electromyography (EMG) regarding the effect of Locomotor Training using body weight support Treadmill Training (BWST) for an extended period of time on a person with ASIA B classification. The objective of this case study is to determine the effects of Locomotor Training using BWST on kinematics, neural, and muscle activation changes for an individual with an incomplete SCI, one year post injury.

### METHODS

The participant (male, 26 years, ASIA B, no motor function below level of injury, injury level C6) trained for 35 sessions of Locomotor Training (T1), stopped training for 8.6 weeks, and recommenced training for another 62 sessions (21 weeks) (T2). Before T1 (PRE-T1), and before T2 (MID) kinematic and EMG data were collected [at 60% and 40% body weight support (BWS), treadmill speed at 1.6 mph]. After T2 (POST-T2) was completed, kinematic and EMG were collected bilaterally for 60%, 40% and 20% BWS.

A 6-camera Vicon system (sampled at 60Hz) was used to collect kinematic data. Spherical reflective markers were placed on right and left second and fifth metatarsal, calcaneus, tibial tuberosity, femoral epicondyle, greater trochanter, anterior inferior iliac spine, posterior inferior iliac spine. EMG was recorded using surface EMG for left and right medial gastrocnemius (L/R G), tibialis anterior (L/R TA), rectus femoris(L/R RF) and bicep femoris(L/R BF). EMG was collected at a bandwidth of 10-600 Hz, and sampled at 1500 or 1560 Hz. Raw EMG signals were filtered at a bandwidth of 30-150 Hz, full-wave rectified, then root mean squares (RMSs) were calculated over a 120ms window (2). EMG data was processed using MATLAB (MathWorks Inc., Version 6.1). Calculation of sagittal plane segment motion for the thigh, shank and foot was determined using MATLAB.

Limb kinematics were calculated in the local moving plane with calculation of orientation angles for each segment

relative to the right horizontal (3). 6-8 gait cycles were analyzed per condition.

### RESULTS AND DISCUSSION

After training, EMG firing patterns were consistent to kinematic profiles at the hip and knee. Before training the EMG firing profiles were not. Higher EMG amplitudes were observed after training [Pre vs. post (60%BWS): LBF: 19.64±23 vs. 43.76 ±5.10uV; LR: 19.64 ± 1.36 vs. 43.76 ± 1.13uV; LG:3.96 ± 1.29 vs. 23.73 ± 1.01uV].

For the LRF, LBF, and LTA the EMG activity were more rhythmical and less tonic after the first series of Locomotor Training sessions (Figure 1). Significantly, at PRE-T1, the LBF was firing for most of the gait cycle (GC) [i.e., mean burst duration (BD) was 88.1 ± 6.1% of the GC] whereas at MID, the mean BD decreased to 55 ±15% of the GC and at POST-T2 its BD decreased further to 41±15%. In general, the BD for the LTA and LG at MID and POST-T2 decreased with increasing load.

Further, there was a positive linear response in mean EMG amplitude to bodyweight (BW) load. At mid, mean EMG amplitudes for all muscles (LR, LBF, LTA, and LG) increased with loading from 40% to 60% BW and at POST-T2 the mean EMG amplitude for LG (at 40%, 60%, and 80% BW load) also increased. The results for LBF and LTA were more variable. Both of these muscles showed a decrement in mean EMG RMS amplitude (from 40% to 60% BW load) followed by an increase (from 60% and 80% BW load).

All of these results demonstrate the positive neural and muscle activation changes that occur after Locomotor Training for an individual with an incomplete SCI (ASIA B, 1-year post).

### INTRODUCTION

Several methods exist to parameterize 3D segment orientation of a multijoint system. Any method of attitude characterization requires coordinate data of a minimum of three non-collinear points located on each body segment during the movement (tracking markers). The method used to acquire the kinematic data and characterize the motion must be consistent with the research question and insensitive to the error introduced during the motion detection process. Choosing an appropriate method for a given research question depends on its performance in the following areas: immediate physical meaning, ease of calculations, singularities, smooth transition around 180°, and ability to describe sequential rotations [1].

In this study, we investigated the ability of the quaternion parameterization of rigid body orientation to characterize lower extremity joint kinematics during 3D human movements using experimental data.

A quaternion is an extension of complex numbers of the form:

$$\mathbf{q} = [\cos \theta, (\sin \theta \cdot \mathbf{n}_1, \sin \theta \cdot \mathbf{n}_2, \sin \theta \cdot \mathbf{n}_3)]^T$$

The four parameters represent the rotation of a rigid body about a unit vector  $\mathbf{n}$  by an angle  $2\theta$  [2]. Quaternions are advantageous because the addition of a fourth parameter avoids the singularities inherent in the Euler parameterization, the implementation is algebraic, and successive rotations are handled as an addition operation. Further, the axis/angle information embedded in the quaternion can be used to quantify out of plane motion and changes in the axis of rotation within a joint during movements.

### METHODS

Footwork skills were performed by a skilled athlete in accordance with the Institutional Review Board. Three non-collinear markers were mounted onto orthoplast and attached to the lateral aspect of the thigh and shank over a neoprene sleeve to minimize marker movement. Sagittal and frontal plane kinematics were recorded during the task using digital video (200 Hz, NAC C2S, Burbank, CA). Tracking markers and joint centers were manually digitized for the entire task (Peak Performance Inc, Englewood, CO). Bony landmarks were digitized for one frame to calibrate segment reference systems. 3D coordinate data for all points was acquired using direct linear transformation. Raw coordinate data was filtered using quintic splines and exported into Matlab.

Quaternions were calculated for both segments at each time step [3]. The shank and thigh quaternions were then used to calculate the knee angle. To validate the quaternion algorithm, these knee angles were compared to knee angles calculated using the digitized joint center coordinates (Figure 1).

### RESULTS AND DISCUSSION

Comparison of the joint angles calculated using digitized joint centers versus quaternions demonstrated the ability of the quaternion to accurately parameterize segment configuration. The RMS error for the knee angle calculated with the knee and hip quaternions was 2.53°. By increasing the number of tracking markers on each segment to four or five, this RMS error is likely to be reduced.

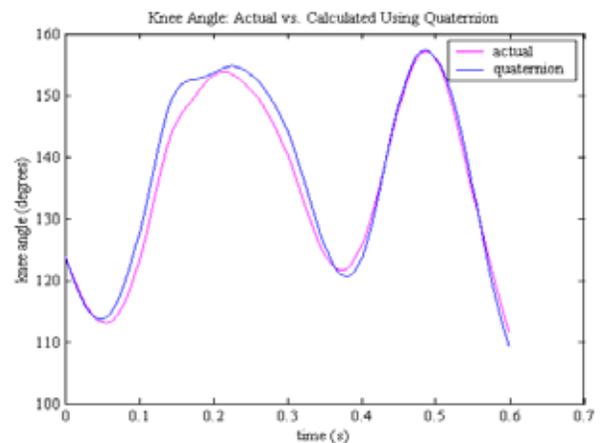

Figure 1. Comparison of knee angle computed using 3D coordinate data and knee angle determined using quaternion parameterization.

These results demonstrate that the quaternion parameterization of segment configuration can be used to characterize knee motion during foot work skills as performed in this study.

### CONCLUSIONS

The quaternion parameterization of rigid body orientation was found to be a reasonable method for characterizing lower extremity joint kinematics during 3D human movements. This parameterization provides advantages over alternative methods (Euler angles, screw method) because it provides biomechanically relevant information, is easy to implement, and avoids singularities. The axis/angle information embedded in the quaternions for each segment can be used to validate assumptions about joint characteristics and to quantify out of plane motion between adjacent segments.

## REPEATABILITY OF DRT4 LASER DOPPLER MICROVASCULAR MEASUREMENTS

<sup>1,2</sup> James A. Furmato, <sup>2</sup>Jinsup Song and <sup>2, 3</sup> Howard J. Hillstrom

<sup>1</sup>PhD Student, <sup>3</sup>School of Biomedical Engineering, Drexel University, Philadelphia, PA,

<sup>2</sup>Gait Study Center, Temple University School of Podiatric Medicine, Philadelphia, PA

### INTRODUCTION

The Moor DRT4 Laser Doppler Monitor (Moor Instruments, Devon, UK) uses fiber optic cables to deliver two channels of 780 nm, 1.0 mW laser light to the interrogated tissue. The system is designed to evaluate microcirculation in 1 mm<sup>3</sup> of tissue at a depth of 1.0 mm. Like other systems, the DRT4 is not able to provide flow output in physical units since the geometry of the capillary bed is unknown. This limitation is overlooked clinically since the monitor allows functional testing of microcirculation, provides sufficient screening of those vessels and is not used for absolute measurements[1].

Use of laser Doppler (LD) monitors to provide follow up studies at the same site depends on finding the same capillary structure. Measurements may also be affected by temperature of tissue, tissue thickness, location of the probe and its orientation. Where repeated measures are needed for a research study, the reliability of measurements comes into question. If repeated measures can be taken at the same location and with controlled amounts of displacement from the original site, similar signals should be captured.

### METHODS

Ten subjects from the general population were asked to refrain from eating, consuming alcohol or using nicotine products at least one hour before being studied. Each was studied in a reclined position that was relaxed and quiet. One LD probe was placed on the plantar hallux and the other under the first metatarsal head of the right foot as a control. Note that the control probe was never moved during the course of the experiment. The hallux location was marked with ink. The cable from the probe was directed proximally to register the orientation. Each probe collected data related to red blood cell motion (flux) and intensity of reflection (concentration).

**Table 1:** Interclass Correlations Coefficients (k=3, N=10). F=flux and C=concentration, both in arbitrary units; (1) sub-hallucial, (2) sub 1<sup>st</sup> metatarsal head [2].

Condition	F1	F2	C1	C2
Fixed position	0.94	0.97	0.94	0.97
Remove probe and replace	0.94	0.93	0.95	0.98
Remove probe and rotate 90	0.97	0.96	0.97	0.97
Remove probe and relocate 2 mm laterally	0.96	0.96	0.90	0.97
Remove probe and relocate 2 mm medially	0.92	0.92	0.90	0.98
Pooled Conditions	0.92	0.95	0.97	0.99

Data was collected in two-minute segments with approximately a one minute pause between measurements under five conditions for three trials each (see Table 1). Mean Flux and Concentration were evaluated using a Repeated Measures Analysis of Variance (ANOVA) in Staviw™ 5.0. Intra-class correlation coefficients (ICC(2,1)) of Fluxes and Concentrations were determined as described by Denegar and Ball[2].

### RESULTS AND DISCUSSION

ICCs were greater than 0.9 indicating that minor differences in DRT4 probe location were well tolerated in this test setting. The plantar big toe (hallux) has a high density of arterio-venous anastomoses presenting the best opportunity for interrogating microvascular flow with an LD on a repeatable basis[3]. Popel suggests the geometry of capillaries is not important since tissue is supplied from a network of vessels[4].

### CONCLUSIONS

The Moor DRT4 LD Monitor has excellent reliability and hence may be appropriate for evaluation of hallucial microcirculation. Future efforts should apply similar technique to assess repeatability at other locations.

## EFFECTS OF ARCH HEIGHT AND ACCOMODATION ON POSTURAL STABILITY

Esther H. Kim, Howard J. Hillstrom, Jinsup Song, and Benjamin P. Heilman  
 Gait Study Center, Temple University School of Podiatric Medicine  
 email: ekim@tuspm.temple.edu

### INTRODUCTION

The primary purpose of this study was to examine the effects of sandal arch height on postural stability. Secondly the effects of a two-month wear period on posture were determined as well. Five models of sandals were tested: Santa Cruz (SC), Iceland (IC), Arizona (AS, soft footbed), Arizona (AP, pronounced footbed), and Fulda (FU). Note that each of the aforementioned models shared similar footbed technology yet had progressively larger arch heights.

### METHODS

Data was collected on 20 healthy subjects with moderate pes planus feet. Each subject was tested in 5 different sandal conditions (Table 1). Center of pressure (COP) data was collected on each subject, in each shoe condition at 120 Hz using a Kistler™ (9261A) force plate. The subject was asked to stand upon the force plate in their comfortable angle and base of support. The subject's feet were then traced onto a white paper that was adhered to the force plate to ensure repeatability in each subject's foot position across all trials. Each subject stood for a total of 1 minute while only the last 40 seconds of data was analyzed to eliminate transient effects [1]. A total of 3 trials were collected for each shoe condition at the baseline visit. Data was also collected after 2 months in the Birkenstock® Arizona Sandal to examine the effects of accommodation. Best-fit elliptical and circular areas of COP excursion were calculated (Figure 1). Deviation from a postulated ideal COP position (i.e. the midpoint between the left and right feet at the posterior third of the foot length) was determined as well. A 2-way mixed effect ANOVA was performed for statistical analysis and all post-hoc analysis used the Bonferroni-Dunn test with significance at  $P < 0.005$ .

### RESULTS AND DISCUSSION

Mean elliptical sway area increased as a function of sandal arch height. Mean elliptical area for SC (lowest arch height) was 166.22 mm<sup>2</sup>, while mean elliptical sway area for FU (highest arch height) was 227.75 mm<sup>2</sup> (Table 1). Post-hoc's revealed that the SC and IC sandals were both statistically significantly smaller in sway area compared with FU. Following a 2-month accommodation period the mean elliptical sway area was reduced from 196.39 mm<sup>2</sup> to 172.28

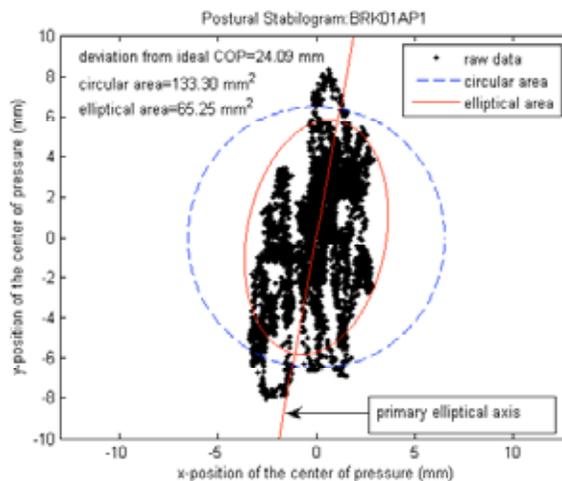

Figure 1: Sample postural stability analysis

mm<sup>2</sup> (Table 2) however this change was not significantly different.

### CONCLUSIONS

Comparison of postural sway areas across the 5 different sandal models suggests that the mean circular and elliptical sway areas are the smallest in the IC and SC sandals while largest for FU. This result suggests that there may be an optimal arch height in sandals for minimum postural sway. With a 2-month accommodation of the AP sandal, there was a trend toward decreasing sway at follow-up. If postural sway can be minimized by appropriate selection of arch support then these findings may have important implications for those at risk of falling.

## HOW DOES SHOE UPPER DESIGN INFLUENCE PLANTAR PRESSURE DISTRIBUTION?

Howard Hillstrom, Jinsup Song, Esther Kim, and Benjamin Heilman  
 Gait Study Center, Temple University School of Podiatric Medicine; email: hhillstrom@tuspm.temple.edu

### INTRODUCTION

The purpose of this study was to examine the immediate effects of footwear design on in-shoe plantar pressures during gait. This study is part of a larger investigation of the structural properties of Birkenstock® footwear technologies and their effect upon lower extremity function. Each of the shoe designs studied employed the identical Birkenstock footbed (ie. a deep heel cup with a ‘pronounced’ medial longitudinal arch support). The design differences were confined to the ‘uppers’ whereby the Boston (BO) was a clog, the London (LO) was a shoe, and the Arizona (AZ) was a sandal. The following research question was addressed: *Does the upper design affect shoe structure and foot function?*

### METHODS

Data was collected on 20 subjects (mean age=27) with moderate pes planus, each wearing the three shoe models described. The Novel Pedar-X system was used to measure in-shoe plantar pressures at a sampling frequency of 50 Hz. Following a 5-minute accommodation period, four trials of in-shoe plantar pressures were collected for each shoe condition while each subject walked at his or her self-selected comfortable speed. Each trial of plantar pressure data was analyzed using three separate masks (anatomical, medial-lateral, and anterior-posterior). The anatomical mask determined plantar loading as shown in Table 1. The medial-lateral mask determined plantar loading from the medial half versus lateral half of the shoe (*about its long axis*). The anterior-posterior mask determined plantar loading from the anterior half versus the posterior half of the shoe. Two parameters were calculated for each region in the aforementioned masks: peak pressure (N/cm<sup>2</sup>) and Pressure-time integral (Ns/cm<sup>2</sup>). Gait speed was captured with a light-based timing system. Two-way mixed effect Analysis of Co-Variance was performed, utilizing gait speed as a covariate. Post-hoc analysis consisted of the Bonferroni-Dunn test.

### RESULTS AND DISCUSSION

When examining pressures from the anatomical mask the LO had the lowest peak values and AP had the highest beneath the metatarsalphalangeal joints (MTPJ). In the medial/lateral mask the LO design had the lowest medial and lateral Pressure-time integral (PTI) and Peak pressure (PP) values. LO had the

Table 1: Peak Pressure for Each Anatomical Region

lowest anterior PTI, anterior PP, and Ant/Post ratios while AP had the highest. One plausible explanation for these differences in shoe gear with identical footbeds is that load sharing was afforded by the more extensive uppers in the LO design which could effectively reduce forefoot loading.

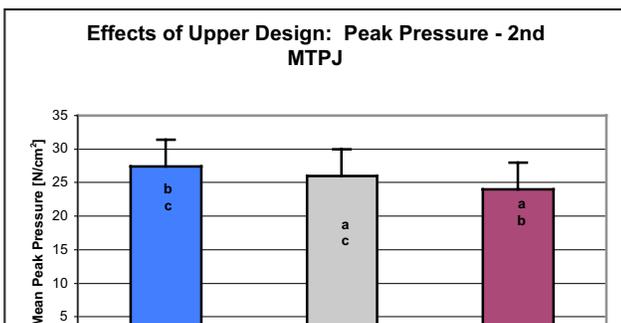

### CONCLUSIONS

The shoe upper design can influence biomechanical foot function.

## CAN A SANDAL ARCH SUPPORT REDUCE PLANTAR HALLUCIAL MICROCIRCULATION?

Jinsup Song, Howard Hillstrom, Nina Babu, and Yoko Miyazaki  
 Gait Study Center, Temple University School of Podiatric Medicine, email: jsong@temple.edu

### INTRODUCTION

It was postulated that the three-dimensional footbed of the Birkenstock sandal could improve weight distribution and promote improved microcirculation to the feet. To test this concept, plantar hallucial cutaneous microcirculation was captured at baseline and following a 2-month wear period of the Birkenstock Arizona sandal while non-weightbearing. In addition, weight-bearing plantar hallucial microcirculation was measured in the barefoot and sandal conditions.

### METHODS

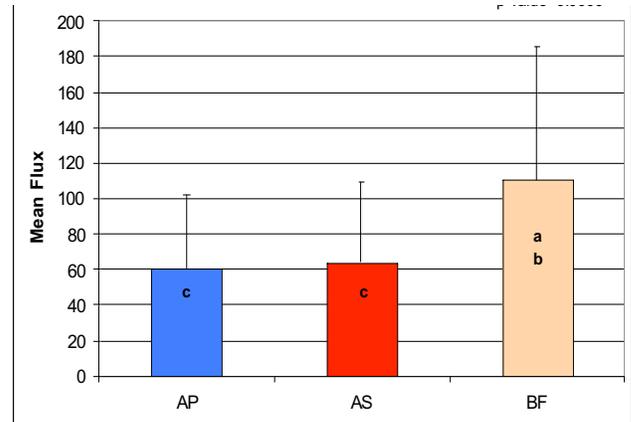

Twenty healthy subjects with mild to moderate pes planus feet were evaluated at baseline and following a 2-month use of Arizona sandals. Using a technique described previously [1], cutaneous microcirculation was assessed at the plantar halluc for a 2-minute resting condition, a 2-minute challenge of skin heating to 42°C, and following 5-minutes of occlusion. Mean flux (in arbitrary units) and skin temperature (°C) were measured using the DRT4 laser Doppler flowmeter (Moor Instruments, Willington, DE). Cutaneous microcirculation was also measured at the thumb (i.e. pollex) as a control. All subjects refrained from eating and drinking caffeinated beverages for greater than 1.5 hours prior to the assessment.

In addition, plantar hallucial microcirculation was measured while each subject stood in barefoot (BF), Arizonal sandal with a pronounced arch support (AP), and the Arizonal sandal with a soft foot bed (AS). For the barefoot condition, each subject stood on a 3/8" wooden platform, which had a 5mm diameter channel drilled for the DRT4 laser probe. Similarly, a 5mm diameter was also drilled through each sandal to allow for weight bearing plantar hallucial measurements. The DRT4 was placed leveled to the supporting surfaces. In each shoe condition, the laser Doppler flow meter was obtained during 2 minutes of sitting, 2 minutes of standing, and 2 additional minutes of sitting.

A repeated measures analysis of variance (ANOVA) model was utilized to ascertain group differences. Bonneferoni-Dunn post hoc analysis was conducted for significant ANOVA results for the weight-bearing assessment.

### RESULTS AND DISCUSSION

As shown in Table 1, the ratio of reactive hyperemia (RH) during the first minute post occlusion and the 2 minute resting

**Figure 1:** Mean flux (in a.u.f.) at the plantar halluc following 2-minutes of standing (reactive hyperemia) in 3 shoe conditions.

mean flux (RH1/Resting) was higher at 2 month follow up than at baseline (p value=0.0159). Mean flux during heating and peak flux during reactive hyperemia at the pollex also increased at 2-months. These changes were not accounted for by the room temperature.

During quiet comfortable stance, mean flux during reactive hyperemia reduced significantly in the Birkenstock sandal conditions as compared to barefoot (see Figure 1). This implies that there was less oxygen deprivation in the sandal conditions thereby requiring a reduced hyperemic response.

### CONCLUSIONS

These results suggest that the improved alignment as well as the increased contact area afforded by Birkenstock footbed technologies may help to minimize transient hypoxia in the plantar tissues while standing. It is also possible that wearing the Arizonal sandals for 2 months may influence endothelial-mediated vasodilation. Further studies are needed to confirm these findings.

## DEVELOPMENT OF A NOVEL BAREFOOT TORSIONAL FLEXIBILITY DEVICE: A PILOT STUDY

Laura E. Bray, M.S.; Esther H. Kim, B.S.; Howard J. Hillstrom, Ph.D.; Jinsup Song, Ph.D, DPM;  
and Benjamin P. Heilman, M.S.  
Gait Study Center, Temple University School of Podiatric Medicine

### INTRODUCTION

A novel instrument was developed to assess the torsional flexibility of the human barefoot to establish a common basis for comparison of the flexibility properties of foot wear and bare feet. Data was collected on the left foot of five subjects, with each subject being tested in weight bearing and non-weight bearing conditions. Torsional flexibility data was also collected for the Arizona Soft Birkenstock® sandal model. The comparison between the barefoot and sandal torsional flexibilities was made to ascertain differences between man-made shoe gear and man.

### METHODS

The Barefoot Torsional Flexibility Device mechanically grounded the heel while the forefoot was positioned on a plate that was rotated about the longitudinal axis of the foot (Figure 1). The goal was to measure the maximum moment and angular excursion of the foot when it was loaded in inversion and eversion. A torque was applied to each foot in inversion and eversion, cycling three times for each of the three trials collected. Only the inversion segment of each cycle was analyzed for this study, to simulate in vivo loading during propulsion. The sandal flexibilities were quantified with an Instron 4201 structural testing machine (*sampling rate = 20Hz*). Each sandal (size matched for a given subject) was loaded in inversion with the heel mechanically grounded.

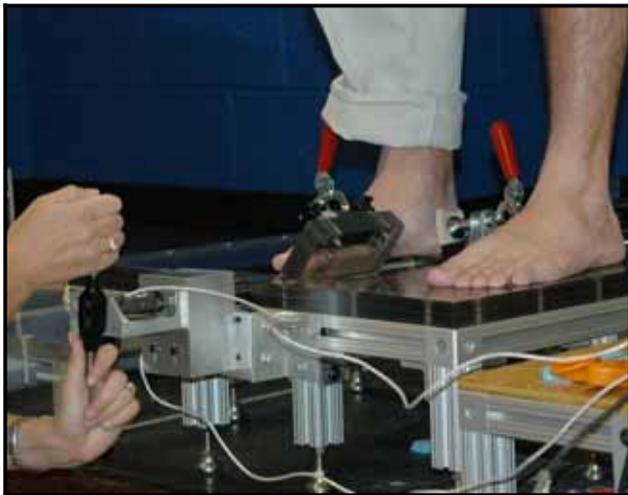

Figure 1: A subject's foot was loaded in inversion using the proposed Barefoot Torsional Flexibility Device.

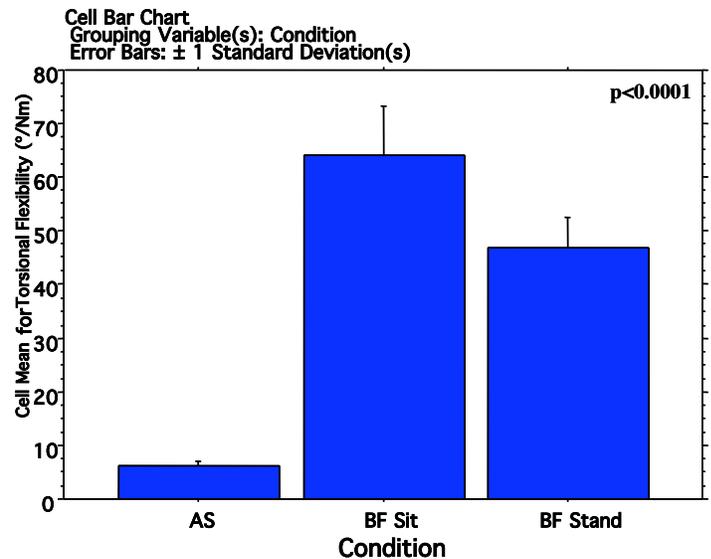

Figure 2: Mean Torsional Flexibilities for all subjects, across all conditions.

### RESULTS AND DISCUSSION

The Arizona Soft sandal had the lowest torsional flexibility (i.e. was the most stiff). Barefoot Torsional Flexibility was much higher, with non-weight bearing being the least stiff. A mixed effects analysis of variance (ANOVA) was used to test statistical significance in the three conditions. All of the torsional flexibility conditions were statistically different, the interaction between condition and subject was significant, and the relationship between subjects was not significant. A Bonferroni-Dunn post-hoc analysis was performed and all three conditions were significantly different ( $p < 0.0001$ ) from each other. Intra-class Correlation Coefficients (ICC(2,1)) demonstrated that the Seated Barefoot Torsional Flexibility (ICC=0.75) and Sandal Torsional Flexibility (ICC=0.99) tests were reliable. Standing Barefoot Torsional Flexibility had a lower reliability (ICC=0.45), which could be a result of non-stationary active contractile processes (i.e. muscles firing during standing).

### CONCLUSIONS

The lower flexibility of sandals compared to human bare feet indicate that sandals are likely to modify the function of feet. Because sandals are stiffer than feet, pedal movements may be restricted compared to that of barefoot. Further studies are needed to determine if, the structure of the sandal imposes a change in the function of feet during gait and posture.

## BIOMECHANICS REALATED TO RACKETS DESIGN AND CUSTOMIZATION

Federico Casolo, Michele Camposaragna, Barbara Cattaneo  
 Politecnico di Milano : [federico.casolo@polimi.it](mailto:federico.casolo@polimi.it) [camposaragna@mech.polimi.it](mailto:camposaragna@mech.polimi.it), [cattaneo@mech.polimi.it](mailto:cattaneo@mech.polimi.it)

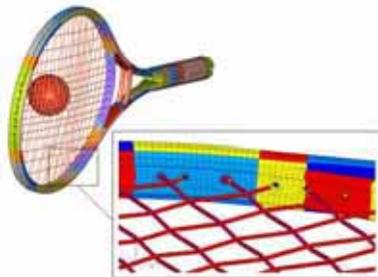

### INTRODUCTION

The new composite materials applied to tennis, supply the racket designers of many degrees of freedom. It is now possible, for instance, to build very light rackets, to differentiate the stiffness along the frame, to chose the mass distribution; to vary the position of the vibration nodes, the position of the center of percussion and the one of the point of maximum rebound. The impact sound can also be changed. To take advantage of the design freedom for this technological piece of equipment a computer simulation approach is essential. The same approach is profitable to identify the best suited racket for a specific player and to evaluate the consequences of the racket customization. Customization is usual for the elite athletes equipment – because they often are forced to use rackets chosen by their sponsors – but it is also very common among non professional players. A racket is often customized by adding extra masses, by stringing the oval by means original procedures or by adding some kinds of shock absorbers. Many customization procedures can produce some not desired, collateral effects which affect both the stoke and the action transmitted to the body of the athlete . This work mainly deals with the theoretical and experimental analysis of the customization concerning racket comfort.

### METHODS

A quantitative approach to the problem require to build complex models capable to simulate the impact dynamics.

**Figure 1:** F.E. model that take into account the orientation of the reinforce fibers of the layers of the frame and of the interaction among the strings

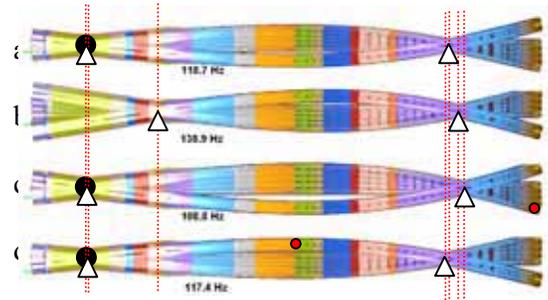

The main parameters to be monitored are: center of percussion location, the frequency and the nodes of the vibration modes, the strings tension and moment of inertia with respect to the handle.

Experimental tests are required to validate the models and also to identify level of the parameters related the subjective feeling of comfort with a racket.

### RESULTS AND DISCUSSION

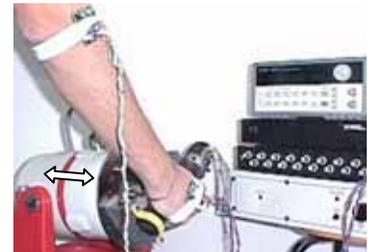

As an example the influence of an extra mass, added in two locations on a popular racket frame, is analyzed. (10 grams are added at the top or at the bottom of the stringed oval). Influences on maneuverability (J) can be easily evaluated, such as the influences on the position of the racket centre of percussion. About vibration (fundamental mode) fig.3 shows that when the racket is handled (the hand is represented by the black dot) one of the vibration nodes (white triangle) is forced

to move at the handle (a) and is not influenced (c)(d) by the extra mass. This mass affects, on the contrary, the position of the other node that is the point to which the impact don't excite that vibration mode. The little added mass, placed at the racket top, has a significant effect in lowering the fundamental mode of vibration frequency (fig.2)

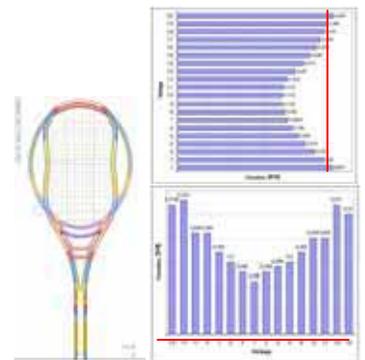

**Figure 2:** extra mass influence on the fundamental mode

**Figure 3:** shaker and arm instrumented by accelerometers

Experimental tests (fig.3) prove that lower frequencies propagate more on the arm and are less comfortable. Strings tension also affects rebound and comfort but the simulation of the stringing procedure show (fig.4) that at the end of the process string tension are different by the theoretical tension

**Figure 4:** a) Deformation of the frame (amplified) under the strings forces b)Graph of the string tension at the end of the stringing process. The red line is the theoretical string tension

set on the stringing machine because of the frame deformation

### CONCLUSIONS

Racket customization must be accurately planned and simulated to avoid collateral negative effects on the player. Special stringing techniques must also be tested to check the effective string tension on the frame at the end of the process.

## Effects of Knee Joint Angle on the Force-length and Velocity Characteristics of Gastrocnemius Muscle

<sup>1</sup>Taku Wakahara, <sup>2</sup>Hiroaki Kanehisa, <sup>3</sup>Yasuo Kawakami and <sup>3</sup>Tetsuo Fukunaga

<sup>3</sup>Faculty of Sport Sciences, Waseda University

### INTRODUCTION

Static plantar flexion torque developed in a knee extended position is greater than that in knee flexed position[1], in which the muscle fibers of gastrocnemius shorten. In concentric actions, however, the difference in torque between the knee extended and flexed positions decreases with increasing angular velocity of the ankle[2]. The reasons for this torque discrepancy between the static and concentric actions have not been clarified. This study aimed to examine the effect of knee joint angle on the plantar flexion torque from the viewpoint of the length-force and force-velocity relationships in the muscle fiber (fascicle) of the medial gastrocnemius (MG).

### METHODS

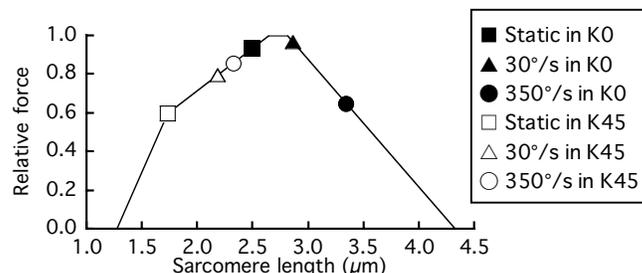

Six male subjects performed static and concentric plantar flexions at two different knee joint angles [fully extended (K0) and flexed at 45° (K45)] with the maximal effort. The ankle joint was fixed at 0° (neutral position) in the static action. The range of motion of the ankle joint in the concentric actions was -10° (dorsiflexed) to 30° (plantar flexed) and the angular velocities were set at 30 and 350°/s by a dynamometer.

The Achilles tendon force was calculated from the measured plantar flexion torque divided by the moment arm of the Achilles tendon. The fascicle length, pennation angle at the mid belly of MG, and the length change of the external tendon of MG were measured by two ultrasound apparatuses. Surface electromyograms (EMGs) were recorded from the MG, lateral gastrocnemius (LG), soleus and tibialis anterior muscles.

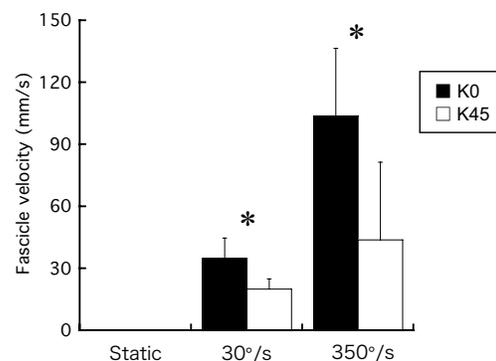

### RESULTS AND DISCUSSION

The difference in peak torque and tendon force between K0 and K45 decreased with increasing angular velocity of the ankle, i.e. no significant differences at higher angular velocity (Table 1). The average EMG activity of MG at 350°/s was significantly lower in K45 than in K0 (Table 1), while no significant differences were observed between K0 and K45 in the other angular velocities for MG and at all velocities for the EMGs of LG and soleus muscle.

We estimated the sarcomere lengths which were calculated from the fascicle lengths obtained from ultrasonography. It is considered that the MG muscle at the peak force had a greater force potential in K0 at static and 30°/s (Figure 1). However in

**Figure 1:** Estimated sarcomere lengths at peak tendon force and the length-force relationship of human sarcomeres[3].

**Figure 2:** Shortening velocity of fascicle at the peak tendon force. \* denotes a significant difference between K0 and K45.

the case of 350°/s, the MG fascicle may perform with higher force potential in K45 than in K0 (Figure 1).

The fascicle velocities were significantly lower in K45 than in K0 (Figure 2), even though nearly identical angular velocities. Thus, MG fascicles in K45 were more advantageous for producing force in the concentric actions, according to the force-velocity characteristics of a muscle.

### CONCLUSIONS

The present study showed the plantar flexion torque developed during concentric actions did not always decrease with knee flexion. This would be attributed to the length-force and force-velocity relationships and activation levels of the MG.

## MEASUREMENT SYSTEM WITH NANO-RESOLUTION FOR MICROSCOPIC BONE PROPERTY

J. H. Hong and Y. H. Park

Department of Control and Instrumentation Engineering, Korea University, Republic of Korea

### INTRODUCTION

To understand physiological and pathological behavior of human skeletal system, the accurate measurement of biomechanical properties for bone is the one of important works. Particularly, the microscopic measurement of human bone is important since the biomechanical behavior at the small scale of bone could be closely related to the remodeling of bone. The remodeling processes of bone have been investigated by using various mechanobiological models [1]. Thus, significant attempts have performed to directly measure the microscopic biomechanical properties of human bone using small scale specimens. They used the three-point or four-point bending, and tensile tests [2-4]. However, the use of coarse microtesting machines and irregular shape of micro-specimens could cause significant measurement errors. For example, the microscopic elastic modulus could vary from 4.59 GPa to 10.4 GPa for the human trabeculae at the same anatomical site depending on the selection of the test method [2-4]. In this study, a small scale compressive testing machine was developed to measure accurate microscopic elastic moduli of bone.

### METHODS

Fig. 1 (a) shows a schematic diagram of the small scale compressive testing machine. The testing machine had a PZT actuator (PI GmbH, Germany) for axial loading. The axial loading PZT actuator could load up to 3000 N with a full displacement range of 120  $\mu\text{m}$ . When a loading displacement was measured with 12-bit A/D converter, the resolution of the testing machine was 30 nm. To check the accuracy of the testing machine, A6061S-T6 aluminum alloy rectangular parallelepiped having the compressive strength of 265 MPa ( $2 \times 2 \times 4 \text{ mm}^3$ ) was manufactured and subjected to the compression test to examine the accuracy of measuring the compressive strength. When aluminum specimens were loaded up to a strain of 0.5 %, the measurement error was about 0.2 %. Thus the measurement system was accurate.

Five bovine cortical bone specimens were used in this study. A micro-milling machine (EGX-300, Roland, Japan) was used to obtain rectangular parallelepiped cortical specimens ( $300 \times 300 \times 600 \mu\text{m}^3$ ) from near the spinous process of lumbar vertebra. Fig. 1 (b) shows this specimen. Compressive strain of up to 1% was applied using the PZT actuator at a strain rate of 0.001/sec. The linear regression analysis was performed to represent the stress-strain relationship. The Young's modulus was determined as the slope of the tangential line to the regression curve.

### RESULTS

Figure 2 shows the mean stress-strain behavior. The mean Young's modulus of the bovine lumbar vertebral cortical bone measured in this study was 10.3 GPa ( $\text{SD} \pm 0.7$ ). Based on the previous studies, the elastic moduli of cortical bone obtained

from bovine femur were about 14 GPa in the macroscopic level [5], and 21 GPa at the osteon [6]. Since the microscopic elastic modulus in this study was obtained using bovine lumbar vertebrae, which are weaker than femur, the results would be reasonable.

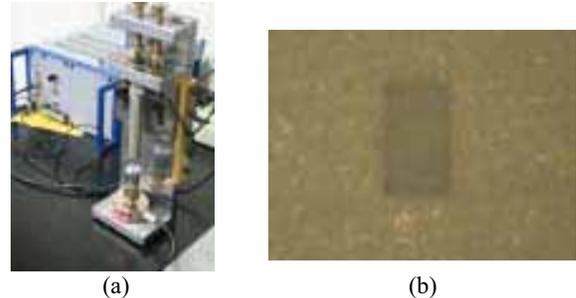

Figure 1: Developed measurement system and fabricated microscopic cortical specimen

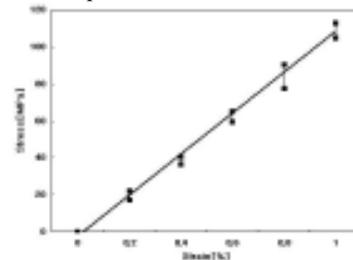

Figure 2: Obtained stress-strain curve with the standard deviation error bar

### CONCLUSIONS

In this study, a small scale compressive testing machine was developed to measure accurate microscopic elastic moduli of bone. Experiments were also conducted to validate the accuracy and suitability of the measurement system. The developed system will be useful to understand the biomechanics of the bones at a micro-scale.

## IMPACT FORCES, REARFOOT MOTION AND THE REST OF THE BODY IN HEEL-TOE RUNNING

<sup>1</sup>Uwe G. Kersting, <sup>2</sup>René E.D. Ferdinands

<sup>1</sup>Department of Sport and Exercise Science, The University of Auckland, New Zealand,

<sup>2</sup>Department of Physics and Electronic Engineering, The University of Waikato, New Zealand

### INTRODUCTION

The high incidence of overuse injuries in heel-toe running has inspired numerous researchers to identify their mechanical causes. High internal stresses experienced during the impact phase and excessive ranges of rearfoot motion have been the focus of interest in the past [1]. Recently a new paradigm has been proposed [2] which states that muscular activities being modulated by foot-shoe-ground interactions may play an important role in the development of overuse syndromes. If this is the case it can be expected that a variation in muscular activities would affect joint powers, energy transfer between body segments and therefore movement efficiency. Only a limited number of studies have taken into account full body mechanics in comparing effects shoe modifications.

The purpose of this study was to apply a three-dimensional model of the human body to heel-toe running. Systematic variations of rearfoot movement were compared with regard to their effect on torques and powers at various joints of the body.

### METHODS

Twelve trained distance runners served as subjects for this study. They were equipped with reflective markers to represent body segments and determine joint centers using static markers on anatomical landmarks. Runners had to run for 1.5 km in a standard running shoe (Nike Pegasus) prior to the collection of ground reaction forces (GRF) and kinematic data while running through the laboratory. Three versions of a heel insert were applied in randomized order (8 deg varus, neutral, 8 deg valgus). For each shoe insert runners had to hit the force platform five times with each foot.

Using an 8-camera 240 Hz motion analysis system (Motion Analysis Corp.) markers placed on the runner were recorded and tracked. A force plate (Bertec, 1200 Hz) was used to collect ground reaction forces. Ratings of perceived comfort and efficiency were recorded using visual analogue scales.

An inverse dynamics model of the runner was created using *Mathematica's Mechanical Systems Pack*. This is a set of packages designed for the analysis of spatial rigid body mechanisms by implementing a dynamics formulation with Lagrangian multipliers. The computer model gives a 3D representation of the human body as a system of fifteen rigid body segments with mass and inertia properties (Fig. 1). Joint kinematics, torques and joint powers were derived.

**Figure 1:** Graphical representation of the 15 segment model.

### RESULTS AND DISCUSSION

Results show that rearfoot movement varied systematically and consistently with the insert being used. However, GRF did not vary according to a frontal plane model proposed by Denoth [3]. In 58% of the subjects ankle flexion kinematics showed significant differences between shoe conditions. Thirty-three per cent of the runners demonstrated modified knee joint kinematics in this comparison. These differences were accompanied by significant variations in joint kinetics and power flows up the hip and trunk joints.

### CONCLUSIONS

The results of this study suggest that relatively subtle kinematic changes in foot placement and GRFs may be accompanied by considerable variations in segmental kinetics and energy transfer at the joints of the human body. It is likely that these variations will affect running efficiency and may therefore influence fatigue and overloading in distance running.

**INTRODUCTION**

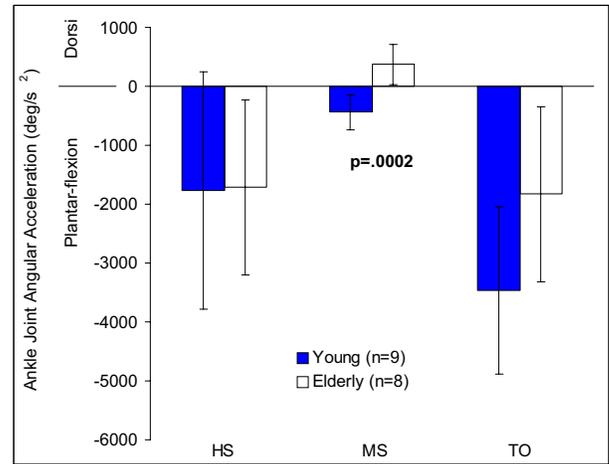

Bone fractures secondary to falls in the elderly continue to be a major healthcare and economic problem [1]. A greater understanding of the processes that contribute to the propensity of elderly females to fall may be obtained by kinematic and kinetic gait studies [2]. The purpose of this study was to examine the 3-D gait parameters in female subjects to determine the effects of aging and activity on selected biomechanical parameters and to determine if any measures might predict a predisposition to musculoskeletal dysfunctions and subsequent remedial intervention.

**METHODS**

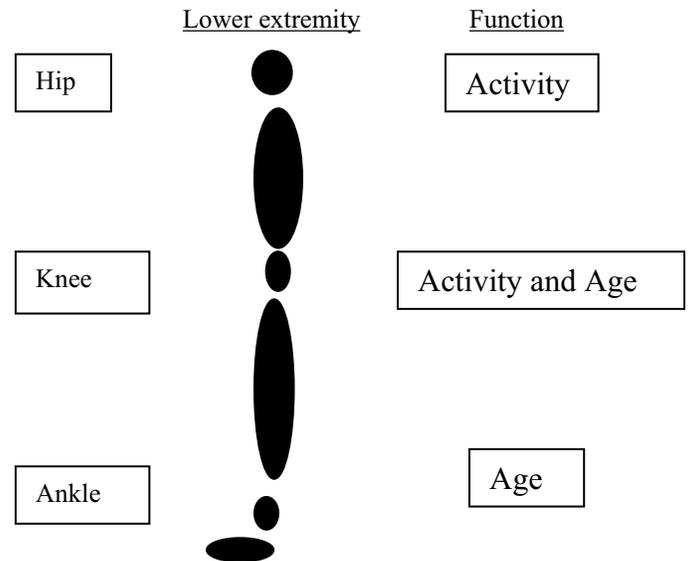

Younger (24 ± 1.6 yrs) and older (67 ± 7.1 yrs) healthy female volunteers (n=17 total) were divided into active and sedentary subgroups in this IRB approved study. Data from three-dimensional video images were collected by 5 high-speed (60 Hz) video cameras (FALCON HR 240, Motion Analysis Corporation, Santa Rose, CA). The basic simplified (“Helen Hays”) marker set of 15 retro-reflective external markers were attached to significant anatomical locations of the right lower extremity. Resulting video images were digitized by using the Motion Analysis HiRES analysis package. Ground reaction forces were measured by a Kistler force platform at 1000 Hz. Each subject was asked to walk at a self-selected pace across the force platform in a 20m walkway during which kinematic and kinetic data were collected for three seconds and analyzed during the stance phase of the gait cycle. The data were analyzed by repeated measures ANOVA and each model included the two factors of age and activity level. The Scheffe criteria was used for multiple group corrections. P-values less than 0.05 were considered indicative of significant difference.

**RESULTS AND DISCUSSION**

As expected, the elderly group had greater functional and mobility limitation in their lower extremity joints compared to the younger group [3], and of these, the largest differences were observed in the ankle (Fig. 1). Knee joint biodynamics were related to both activity and age. The hip was the most effected joint in sedentary population (Fig. 2). These findings led us to postulate that lower limb gait alterations may begin at the ankle, progress up the lower extremity, and eventually act in concert to predispose elderly and sedentary women to gait imbalances and subsequent slip-induced fall or low energy bone fracture. This is important because it means that there may exist specific physical activities involving targeted controlled 3-D muscle movements which help maintain lower limb joint kinematics, kinetics and their accompanying intrinsic postural control strategies that together help prevent gait imbalances and subsequent falls.

## AN APPROACH TO CALCULATING LINEAR HEAD ACCELERATIONS IS NOT AFFECTED BY ROTATIONAL HEAD ACCELERATIONS

<sup>1</sup> Joseph J. Crisco, <sup>2</sup>Jeffrey J. Chu and <sup>2</sup>Richard M. Greenwald  
<sup>1</sup>BrownMedical School/Rhode Island Hospital, <sup>2</sup>Simbex  
 email: [joseph\\_crisco@brown.edu](mailto:joseph_crisco@brown.edu), web: [brownbiomechanics.org](http://brownbiomechanics.org)

### INTRODUCTION

Mild traumatic brain injury (MTBI), or concussion, is a growing health concern especially for young athletes. A critical piece in the puzzle for understanding MTBI is the link between the mechanical input (trauma) that causes injury and the clinical outcome. We hypothesize that head acceleration due to impact is predictive of the type and severity of concussion, and correlates to specific clinical measures of concussion. One major limiting factor in testing this hypothesis and the development of strategies to reduce MTBI is the lack of sufficient *in vivo* biomechanical head impact data. Previously, we developed and validated the Head Impact Telemetry (HIT) System as an approach to measure linear head acceleration of a helmeted athlete [1]. The purpose of this work was to determine if the theoretical accuracy of calculating linear head acceleration using this approach was affected in the presence of rotational accelerations.

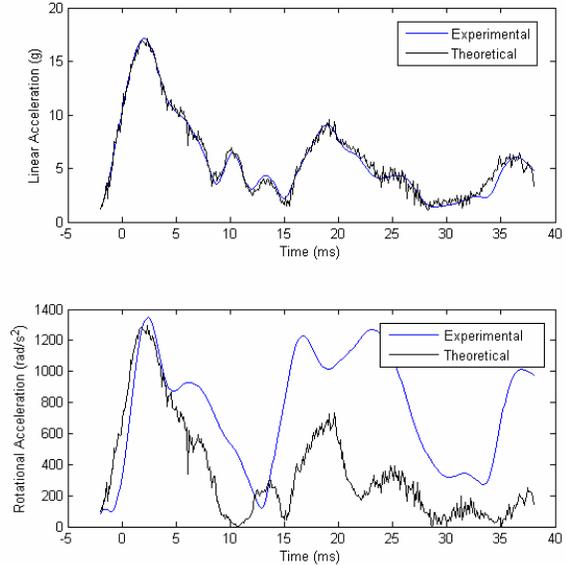

### METHODS

*Theory.* The HIT System consists of six linear accelerometers placed within the liner of a football helmet in close proximity and orthogonal to the skull. The system estimates the linear acceleration of the center of gravity of the head ( $\vec{H}$ ) due to an impact, with its direction specified in spherical coordinates (azimuth  $\theta$  and elevation  $\alpha$ ). The value of each accelerometer ( $\vec{a}_i$ ), located at  $(\theta_i, \alpha_i)$ , is used to minimize the least-square error,

$$\sum_{i=1}^6 (\|\vec{H}\| (\cos \alpha_i \cos \alpha_H \cos(\theta_i - \theta_H) + \sin \alpha_i \sin \alpha_H) - \|\vec{a}_i\|)^2,$$

and to obtain an estimate of the magnitude of the linear head acceleration  $\|\vec{H}\|$  and its impact location  $(\theta_H, \alpha_H)$ . Rotational accelerations were estimated assuming a fixed rotation point 10 cm inferior to the center of gravity of the head.

*Experiment.* Laboratory experiments were performed using a Hybrid III headform, neck and torso fit with a commercially available football helmet that was impacted (n=48) with a weighted pendulum (8.2 kg) at various locations about the helmet and at 3 impact speeds (3, 5, and 7 m/s). The linear and rotational accelerations of the Hybrid III headform were computed using a standard 3-2-2-2 accelerometer package and established algorithms (Biokinetics, Ottawa, CA). These experimentally measured accelerations were used to predict the accelerations of each HIT system accelerometer, which were then feed back into the theoretical algorithm. The differences between the experimentally measured headform accelerations (linear and rotational, GSI, and HIC15) and those predicted from the theoretical algorithm were compared using root mean square error (RMSE)

**Figure 1:** Typical acceleration-time curve.

### RESULTS AND DISCUSSION

A typical theoretical linear acceleration-time curve was in excellent agreement with the experimental curve, but there was only limited agreement with the rotational acceleration-time curve (Fig. 1.). The RSME errors for the peak linear acceleration, peak rotational acceleration, GSI, and HIC15 were 2.9g [experimental range of values: 15–82 g], 31 GSI [6.6–294 GSI], 16 HIC15 [4–232 HIC 15], 757 rad/s<sup>2</sup> [1201–4555 rad/s<sup>2</sup>], and the mean (1 s.d.) percent error was -4% (5), -17% (16), -10% (14), and -20% (32), respectively.

### CONCLUSIONS

Using helmeted impacts within a laboratory setting we were able to demonstrate that our previously reported algorithm is quite robust and can accurately (RSME 3 g's) predict linear head acceleration even when these impacts are associated with a wide range of rotational accelerations. An algorithm for more accurately measuring rotational acceleration with this approach remains to be further developed.

## BILATERAL COMPARISONS OF ISOKINETIC KNEE STRENGTH IN UNILATERAL TOTAL KNEE REPLACEMENT INDIVIDUALS

<sup>1</sup>John W. Chow, <sup>1</sup>Dana M. Otzel, <sup>1</sup>Mark D. Tillman, and <sup>2</sup>Richard Vlasak

<sup>1</sup>Department of Applied Physiology and Kinesiology, <sup>2</sup>Department of Orthopaedics and Rehabilitation

### INTRODUCTION

Knee function after total knee replacement (TKR) has been studied extensively. Several studies compared isokinetic knee flexion and extension strength of TKR knees with the uninvolved knees in unilateral TKR subjects and healthy knees in control subjects [1,2,3] and the results were equivocal. For example, Berman et al. [1] found significantly lower peak knee extension torques for 60 °/s in TKR knees at 2-yr post-op. However, Walsh et al. [3] did not find any significant bilateral differences in peak knee extension torques in unilateral TKR subjects. They only reported significantly lower peak knee flexion torques for speeds of 90 and 120°/s in TKR knees at 1-yr post-op in their male subjects (no differences in their female subjects). Interestingly, the knee angles at which peak torques occurred were not reported in previous studies. The purpose of this study was to examine the knee strength at different isokinetic speeds and the peak torque angles in unilateral TKR individuals.

### METHODS

Seven females and four males (age 67.6±10.9 years, height 168.7±8.0 cm, weight 876.3±218.5 N) with unilateral TKR knee (3.8±3.4 years post-op; 9 right involved knee, 2 left involved knee) participated in this study. Knee flexion and extension torques were assessed using a KinCom AP125 isokinetic dynamometer at speeds of 60, 180, and 240 °/s. Two maximum effort trials of three reciprocal repetitions were completed for each joint motion-speed-side condition. For each condition, the largest torque value among the six repetitions was identified as the *peak torque*. The *peak torque angle* was the knee flexion angle associated with a peak torque. T-tests with repeated measures were used to determine if bilateral differences exist (alpha = .05). No adjustment was made for multiple tests due to the exploratory nature of this study.

### RESULTS AND DISCUSSION

Significantly lower peak knee extension torques were found in

the involved knees for the speeds of 60 and 180 °/s, but not in the 240 °/s (Table 1). On average, peak torques of the involved knees were 73% and 80% of the uninvolved knees for the 60 and 180 °/s, respectively. These results support the quadriceps deficit reported by Berman et al. [1].

No bilateral difference in peak knee flexion torque was found for any of the isokinetic speeds (Table 1). This is in contrary to the findings of Walsh et al. [3]. It should be emphasized that the different durations of post-operation may explain some of the differences in findings reported in different studies.

Trends were detected in peak torque angles associated with the peak knee flexion torques for 180 and 240 °/s (Table 1). However, the average differences are relatively small and probably do not carry any functional significance.

The average flexion/extension ratios for the involved knee were 0.55, 0.88, and 1.06 for speeds of 60, 180, and 240 °/s, respectively. The corresponding values for the uninvolved knees were 0.44, 0.70, and 1.08, respectively. These values are comparable to those reported in the literature.

### CONCLUSIONS

Reduced knee extension strength seems to be common in TKR knees. Future studies should examine the possible causes of such a deficit.

### INTRODUCTION

The possibility of augmenting high-specification sportswear, for a broad range of users from enthusiasts to non-sporting people, through the integration of textile sensors and actuators that can monitor and respond to the emotional status of wearers, is being explored. The long-term aim is to develop clothing that could help wearers manage their emotional intelligence. Physiological sensors, such as heart rate monitor, sweat pads, etc., are widely used in sports and medical areas. However such sensors can also be used to gain an insight into the condition of affect in people. Body actions and gestures are well known to be reliable indicators of temporary emotional status in humans. It is, however important to classify and quantify in a systematic and to establish reliable set of controlled variables that allow to assess and control psychological status.

### METHODS

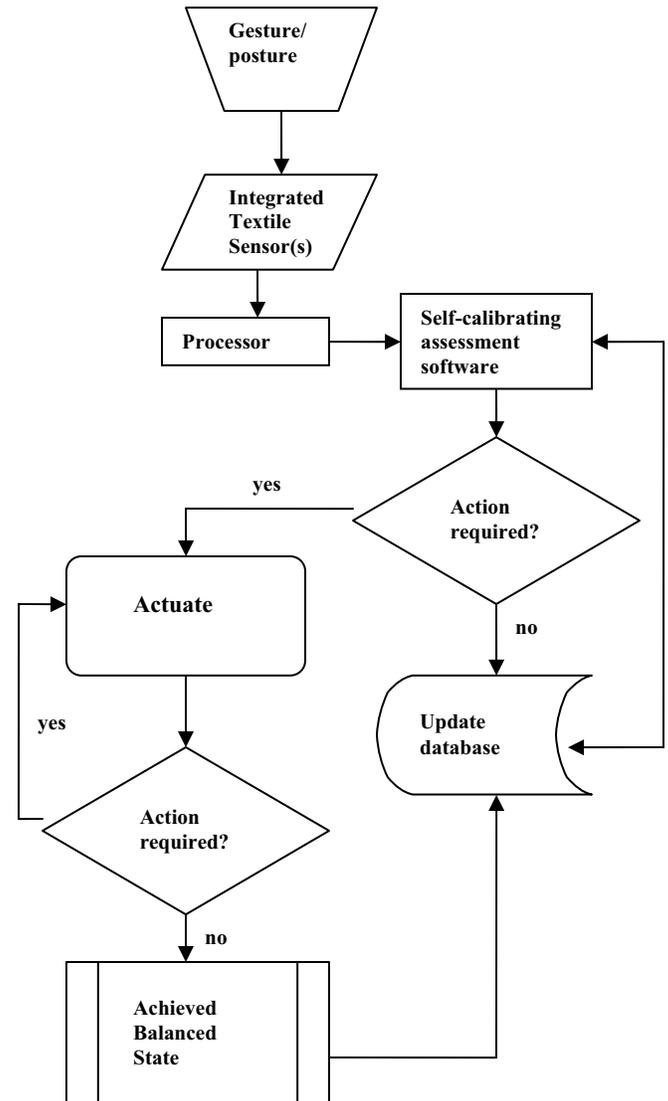

The current study focused on the on the initial design of close loop system for assessment and control of emotional responses by the sole use of kinematic and postural parameters, such as joint angles and joint angular velocity as an initial stage of the development.

Initial consideration was given to most common postures and gestures that allow reliable measurement through integrated textile sensors.

### RESULTS AND DISCUSSION

A key focus is to identify the possible emotional meanings of physiological and behavioural information within a range of sports/training contexts, and to determine whether these signals can be translated into a *language of emotions*, which wearers and trainers can use to manage emotions to positive effect in exercise and leisure activities. It is essential (Fig.1) to provide the clothing system with appropriate self-calibrating facilities to allow it to learn from its wearer, so that emotional identification and response become uniquely attached to that person. By being able to monitor an individual's emotional status, the amount of training or sports activity engaged in could be modulated and enhanced, thereby reducing the risk of over-training. Such a clothing system might also help with motivation, as hormones produced as a result of physical exercise are known to promote feelings of happiness, with the possible advantage of combating life/work stress. In general the idea is to shift the focus of the exercise from performance targets to level of satisfaction and sense of achievement that will allow to offset the boredom factor that stops many people from undertaking exercise. By monitoring and enhancing technique through force feedback actuators, a sense of achievement might be attained quickly, thereby enhancing wellbeing, and consequently motivation. Clothing that changes [e.g., colour, emits aroma] or produces sound/music according to mood, emotions, and environmental context

should help influence/modulate mood, promoting positive self-esteem. Integrated mobile communications, would enable the remote exchange of emotional impulses between wearers.

**Fig.1** Proposed design for emotionally responsive clothing. The project is in its infancy (although clothing with built-in electronic devices has been developed and used) and is to be expanded in the next few years as some large hardware and software manufacturers are to be involved in it.

## IS CHILD WEIGHT TO BAG WEIGHT THE BEST WAY TO ASSESS RISK OF LOW BACK PAIN IN CHILDREN DUE TO BACKPACK USE?

<sup>1</sup> Rebecca Whissell, <sup>2</sup>Eric Labrosse and <sup>1,3</sup>Sylvain Grenier

<sup>1</sup>Laurentian University,

<sup>3</sup>Sudbury and District Public health Unit, Health Promotion Division

<sup>3</sup>Occupational Health Clinics for Ontario Workers; email: [Ssgrenier@laurentian.ca](mailto:Ssgrenier@laurentian.ca), web: [www.humankinetics.laurentian.ca](http://www.humankinetics.laurentian.ca),  
<http://www.ohcow.on.ca/>

### INTRODUCTION

Studies of lower back-pain caused by the carrying of school bags have typically been investigated by using the weight of the bag, the weight of the person, or the height of the person as predictors of low pack pain. It is possible that an interaction of these variables such as a body mass index (BMI) to weight of the bag ratio could be more effective in understanding what causes back pain.

### METHODS

In this study, 119 children were measured for height, weight, mass of school bag, type of bag, method of carrying, method of getting home, distance from home and self-perceived lower back pain (due to running carrying and lifting), were recorded.

The validated questionnaire [1] was administered to volunteer students (as well as parents/guardians). The study addressed a representative sample of francophone students within grades 4-6 from the Conseil Scolaire du Grand Nord de l'Ontario. Students and their backpacks were weighed at the school on the testing day with a calibrated spring scale. At this time, students also completed the questionnaire. The questions asked were as follows:

How do you get to school?

How long does take to travel from home to school?

How long do you carry your bag for?

How do you carry your bag?

Are there days when you bring your bag home and don't use the contents?

Does carrying your bag make you tired?

Do you think your bag is too heavy?

If you have back pain is it made worse by carrying, lifting or running with your bag?

Each question had a limited selection of answers. Prior to the testing day the parents had consented to participation.

### RESULTS AND DISCUSSION

A linear regression showed that, in the children tested, lower back pain could be predicted ( $R^2=0.41$ ) from variables such as weight, height, bag weight, BMI, BMI/bag weight. Among the

physiological measures, the BMI to bag weight ratio had the greatest effect on the linear regression equation (Standardized beta weight=1.11).

Lower back pain due to carrying could also be predicted ( $R^2=0.48$ ). In this case, among the physiological measures, the BMI to bag weight ratio again had the greatest effect on the linear regression equation (Standardized beta weight=1.19).

Lower back pain due to lifting could also be predicted ( $R^2=0.36$ ), however in this case, of the physiological measures the weight of the person had the greatest effect on the linear regression equation (Standardized beta weight=1.815), but only slightly better than the BMI to bag weight ratio (Beta=1.41).

Lower back pain due to running was not found to be significantly predictable. When a discriminant analysis was performed to distinguish between those that had back pain and those that did not, the generated function correctly predicted 80.4% of the cases and the BMI to bag weight ratio was found to be the variable that contributed the most to the equation (s.c.c.c. 2.207).

### CONCLUSIONS

The results suggest that considering the ratio of backpack weight to body weight may not be sufficient. A more complex interaction of variables which account, at least partially, for activity level seems to provide a better indicator of LBP risk in children.

## THE EFFECT OF FOREARM SUPPORT ON EMG ACTIVITY OF THE UPPER EXTREMITIES DURING COMPUTER WORK: A CHAIR INTERVENTION STUDY

<sup>1</sup> Jaworski, K, <sup>1</sup>Moore, A, <sup>2</sup>Amick, B, <sup>3</sup>Robertson, M, <sup>4</sup>Bazzini, L, <sup>4</sup>Rooney, T, <sup>5</sup>DeRango, K, <sup>6</sup>Harrist, R and <sup>3</sup>Jackson, J

<sup>1</sup> School of Kinesiology and Health Science, York University, Canada email: [karl@yorku.ca](mailto:karl@yorku.ca),

<sup>2</sup>University of Texas School of Public Health, USA; <sup>3</sup>Liberty Mutual Research Institute for Safety, USA; <sup>4</sup>Health and Work Outcomes, USA; <sup>5</sup>Upjohn Research Institute, USA <sup>6</sup>Texas Program for Society and Health, Rice University, USA;

### INTRODUCTION

The use of computer keyboards has been linked to a number of musculoskeletal symptoms of the upper extremities. While proper workstation setup is a key element to reducing the risk of developing musculoskeletal disorders, the use of forearm support has been shown to increase comfort as well as to reduce the muscular load of the neck and shoulders [1]. Most of these results, however, are based on laboratory experiments or on studies where the arm support condition is compared with a “floating” or no-support condition. There is a need for further exploration of this topic, specifically whether workers use arm supports when provided and whether there is a greater benefit of a highly adjustable chair in comparison with an office chair with fixed arms height.

### METHODS

Thirty five participants were recruited from a medical insurance call centre and randomly assigned into either a control or intervention group (16 control, 19 intervention). The intervention consisted of supplying the workers with a chair with adjustable (both vertically and horizontally) forearm supports and office ergonomics training, while the control group remained with their existing office chair which had fixed forearm supports. Each participant took part in two, one-hour observation sessions before and after the intervention. During each of the four observations, the subjects were videotaped from the frontal and sagittal views while doing their usual office duties. The video was analyzed using commercial software (Observer Pro 5.0, Noldus Technology, Netherlands) to determine when participants were keyboarding, using a mouse or performing other office duties as well as whether the participants were using chair forearm supports. RMS EMG was collected at 10 Hz using a commercially available portable system (ME3000P8, MEGA Electronics, Finland) from the trapezius and extensor carpi radialis brevis (ECRB) muscles bilaterally. Changes in the static level of APDF[2] were analyzed. A 2 (pre, post) x 2 (control, intervention) repeated measures ANOVA was performed.

### RESULTS AND DISCUSSION

There was an increase in left armrest use for both groups post intervention (Figure 1), However there was a significant ( $p=.02134$ ) interaction term indicating that there was a much greater increase in armrest use with the highly adjustable arm rests. While the associated levels of the static EMG reflect these changes, the results were not significant.

The results for the right side reflect the more complex activity that occurs in the dominant arm. There was a small but not

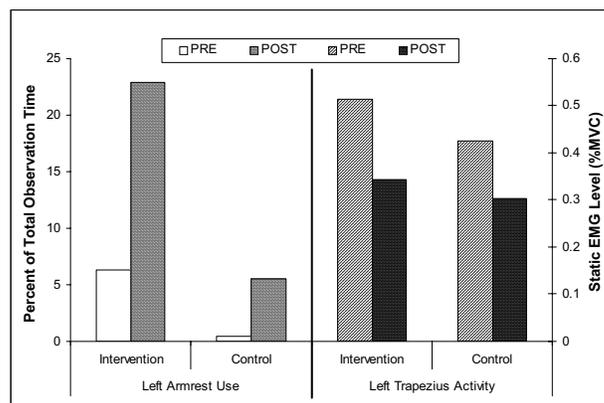

Figure 1. Left armrest use and associated static level EMG (left trapezius)

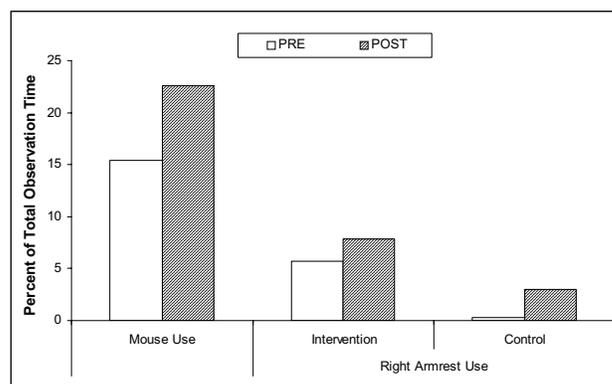

Figure 2 Mouse use (right hand) and Right Armrest use

significant increase in armrest use on the right side. However at the same time there was an increase in mouse use post intervention (Figure 2). These conflicting results may be responsible for the lack of significant changes in the static EMG in the right trapezius.

### CONCLUSIONS

Arm rest use on the left side in the workplace is significantly affected by chair design and training. However intervention use on the right is complicated by task changes. Further studies will isolate the EMG associated with arm rest use.

**IMPACT OF LIFT ASSISTIVE DEVICE ON LUMBAR COMPRESSIVE FORCE**  
 Mohammad Abdoli E\*, Michael Agnew, Joan Stevenson, Christy Lotz  
 Ergonomics Research Group, Rm 148, PEC, Queen's University,  
 Kingston, Ontario, Canada, \*oema@qmlink.queensu.ca

**INTRODUCTION**

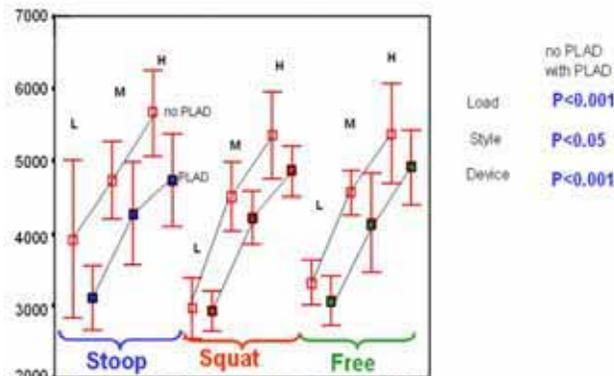

The goal of this research is to develop a strategy to reduce the lifting force requirements of back muscles and thus allow provide some support to returning injured workers to their jobs more quickly. To accomplish this goal, a personal lift assistive device (PLAD) was developed using elastic elements and attachment points at the shoulders, waist and knees. The PLAD acts parallel to the back muscles and can be thought of as an external force generator that provides additional elastic energy for lifting tasks, thus allowing the user to accomplish a lift using less of his/her own muscle force. During a lift, these internal forces are transferred by the PLAD to the shoulders, pelvis and lower legs during the down phase of lift and energy returned to the worker during the up phase of the lift. The purpose of this study is to demonstrate the effectiveness of the PLAD on the compressive force on the L4/L5 disc during a variety of lifting tasks.

**METHODS**

To validate these findings, nine male subjects with no history of back pain executed a variety of lifting tasks (symmetric/asymmetric, light/medium/heavy, free/stoop/squat) under the PLAD and No-PLAD conditions. Three Fastraks® were synchronized into one computer in order to provide 12 electromagnetic sensors with 6 dof. Simultaneous data were acquired at 30 Hz. On a slave computer, sampling at 1000 Hz, six custom strain gauges and eight EMG channels were recorded with all data synchronized using a hand switch. Fastrak® sensors were positioned at the centre of gravity of the hands, forearms, arms, thighs, as well as on the head, C7, T9 and L5. The fully dynamic 3D moments at L4/L5 were calculated using the Hof [1] validated model. A polynomial model [2] was used to predict the lumbar compressive force by the 3D estimated moments. Two approaches were used to determine the impact of the PLAD on back moments. When there is no PLAD, conventional LSM 3D dynamic calculations were used. When PLAD was worn two strategies were employed: first, the force contributions of the elastic elements were subtracted from the total L4/L5 moments so that the contribution due to the PLAD could be calculated. Second, the PLAD force contributions were ignored to see if postural effects alone influenced the results. Results of peak lumbar compressions were compared in symmetrical lifting for 3 different loads (5kg, 15kg, 25 kg) with 3 different styles (stooped, squat, free) under 2 conditions of PLAD/No-PLAD. Two 3-way repeated measure ANOVAs were used to examine the impact of peak compression under various conditions.

**RESULTS AND DISCUSSION**

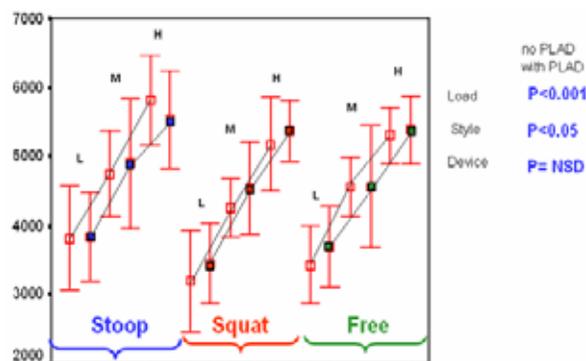

Figure 1 shows that regardless of load or style, the PLAD conditions were less than the no PLAD conditions by 5% to 20% ( $p < 0.001$ ). This difference was greatest for stoop conditions and least for freestyle lifts. Future designs could correct this problem. It also shows the ability of PLAD across different lifting styles ( $p < 0.05$ ) as well as for various loads

**Figure 1:** PLAD/no-PLAD comparison of 3 styles of lifting at 3 different types of loads.

( $p < 0.001$ ). Hence, regardless of the comparison, the PLAD proved to be effective at reducing the L4/L5 moments and compressive forces.

In Figure 2, when the impact of PLAD was removed mathematically, results revealed that there was no significant

**Figure 2:** Influence of posture on PLAD/no-PLAD comparison of 3 styles of lifting at 3 different types of loads.effect.

different in peak compressive force across all conditions.

**CONCLUSIONS**

These results prove that the PLAD does reduce the compressive force on the L4/L5 disc across a number of lifting conditions. Hence, it could be considered as a good device to increase the margin of safety for tissue tolerances in the spine during lifting tasks. Further research is needed to confirm its effectiveness in terms of electromyography and spinal stability as well as examining the impact of the PLAD over extended user trials.

## THE EFFECTS OF QUANTITATIVE FEEDBACK ON THE REDUCTION OF LANDING FORCE

<sup>1</sup>Sara C. Novotny and <sup>1</sup>Richard N. Hinrichs

<sup>1</sup>Department of Kinesiology, Arizona State University; email: [novotns@ccf.org](mailto:novotns@ccf.org)

### INTRODUCTION

Many sports involve regularly landing from a jump. Repetitive, high force landings have been associated with an increase in lower extremity injuries in active individuals [1]. Recently, the use of feedback has been implemented to aid athletes in reducing their landing forces. However, the feedback has generally been qualitative in nature [2]. This study aimed to evaluate the usefulness of providing quantitative feedback regarding landing force and landing sound.

### METHODS

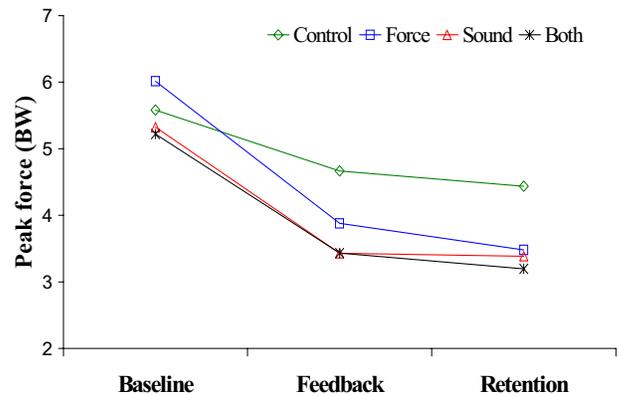

Forty recreationally active males and females were assigned to one of four feedback groups. Each group was comprised of five males and five females. The groups were given feedback about peak force only (Force), feedback about peak sound only (Sound), feedback about both peak force and peak sound (Both), or feedback about neither peak force nor peak sound (Control).

All subjects performed a series of drop landings from a set height onto a force platform, and vertical ground reaction force (GRF) and sound level were recorded for each landing. Subjects performed three trials without feedback, establishing baseline force and sound values. The appropriate feedback was given after each of the next five landings. The feedback was presented on a 1 to 10 scale, with 10 representing 100% of the baseline value. All subjects returned one week later to perform three landings without feedback. The effects of feedback on peak vertical GRF were computed using a 2 (peak sound level)  $\times$  2 (peak force) repeated measures ANOVA.

### RESULTS AND DISCUSSION

The main effect for time on peak force was significant,  $p < .01$ . Pairwise comparisons for peak force indicated that subjects significantly changed their landing forces from the baseline measures to the feedback measures,  $p < .01$ , and the baseline measures were significantly different from the retention measures,  $p < .01$  (Figure 1).

Overall, the feedback groups reduced their peak force by 0.80-1.39 times body weight (BW). However, the main effect for feedback group and the interaction effect between feedback group and time were not significant,  $p > .01$ . Since the main effect for group was non-significant, the differences between the feedback groups over time were examined by looking at the effect sizes between the four feedback groups. The effect size for the difference between the baseline and feedback measures was moderate to large when the each group was compared to the Control group, -1.16, -0.82, and -0.69 for Force, Sound, and Both groups respectively. (An effect size  $\leq 0.2$  was considered small. An effect size of approximately 0.5

**Figure 1:** Changes in peak force over time for different feedback groups.

was moderate and  $\geq 0.8$  was large. [3]). Similar effect sizes occurred for the difference between baseline and retention measures when the Control group was compared to the Force, Sound and Both groups, -1.17, -0.65, and -0.66 respectively. The effect sizes between the Force and Sound group were 0.21 from baseline to feedback and 0.52 from baseline to retention, while the effect sizes between the Force and Both groups were 0.29 and 0.41 for the same difference scores.

### CONCLUSIONS

All subjects decreased their landing force over the course of the study due to learning. The reduction in force was greater for the feedback groups, though not significantly greater. However, effect sizes indicated a trend towards any type of feedback being better than no feedback at all. An increased number of subjects per group might have solidified this trend. Feedback on peak force was the most effective feedback, as the feedback group had the largest effect sizes between both baseline and feedback and baseline and retention when compared to the other groups. Feedback on sound level was also effective, raising interesting questions about the potential for a more accessible method of providing feedback on landings. Sound has previously been shown to be a significant predictor of force, allowing for inferences of relative force to be made from relative sound [4].

### INTRODUCTION

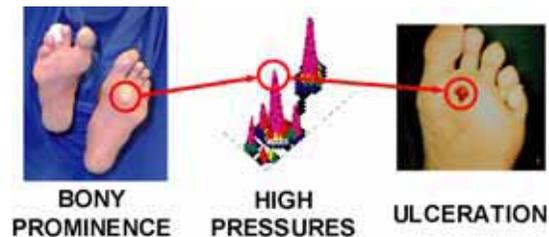

Foot ulceration is a common complication among diabetic patients with peripheral neuropathy [1]. Elevated foot pressures can cause skin breakdown that might lead to ulceration (Fig. 1). Therapeutic footwear is a typical intervention for relieving plantar pressures which can lead to ulceration [2], but scientific guidelines for selection of footwear are not well defined [3]. Although some experimental studies have attempted to establish such guidelines, e.g. [4], the systematic testing of multiple design variables is difficult. In practice, footwear selection still relies on the experience of the healthcare provider and on trial-and-error.

Finite element (FE) analysis allows the investigation of complex biological structures under load by discretization of the geometry into small uniformly shaped elements [5]. When boundary conditions, loading and friction at the foot-shoe interface are defined, the models can predict stresses under the foot. This approach permits the examination of a large number of footwear designs without the burden of high-volume experimentation. Once validated, the models can simulate variations in anatomy and footwear: for example, the insole geometry and material can be systematically varied to guide strategies for the prescription of therapeutic footwear. Our objective is to establish an integrated approach and use FE modeling for design of therapeutic footwear.

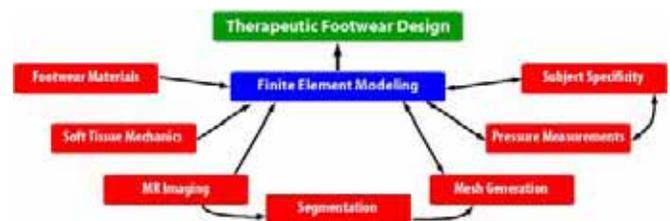

### METHODS

The modeling strategy employed includes representations of foot anatomy, footwear geometry, soft tissue properties, footwear materials, foot kinematics and loading and foot-footwear-ground interactions. Barefoot and in-shoe pressure measurements provide foot loading as well as validation data. Subject specificity is established by optimization protocols to map model predicted pressure measurements to those measured experimentally. Foundations of FE simulations rely on computational and experimental research in the areas listed above; the integrated approach provides the necessary input to develop two- and three-dimensional FE models (Fig. 2).

A variety of design criteria for therapeutic footwear are tested by systematically changing footwear properties (e.g. geometry, material) in FE models. It is possible to identify designs that result in effective pressure reduction overall. Footwear interventions to relieve local pressures under focal areas of the foot (e.g. heel pad, metatarsal head) are also investigated by FE simulations.

**Figure 1:** Potential pathway to foot ulceration in diabetic patients with peripheral neuropathy.

**Figure 2:** An integrated approach for therapeutic footwear design based on finite element modeling.

### EXAMPLES

Simulations using a plane strain model of the second metatarsal region have identified favorable plug designs to relieve local pressures underneath the metatarsal head. A plane strain model of the heel pad has provided guidelines on the selection of insole thickness, material and conformity to reduce heel pressures. A three-dimensional model of the first metatarsal and hallux has quantified the influence of material selection on plantar pressure reduction under the first ray.

Among the models under development are a planar heel-pad model to explore shear prediction under the foot; a three-dimensional forefoot model for evaluating load redistribution among the metatarsal heads; and a whole foot model to investigate transfer of forefoot loads to the arch using footwear.

## THE INFLUENCE OF GASTROCNEMIUS GEOMETRY ON ITS ACTION AT THE KNEE DURING STANCE

email: [goldbergs@cc.nih.gov](mailto:goldbergs@cc.nih.gov), web: <http://pdb.cc.nih.gov>

### INTRODUCTION

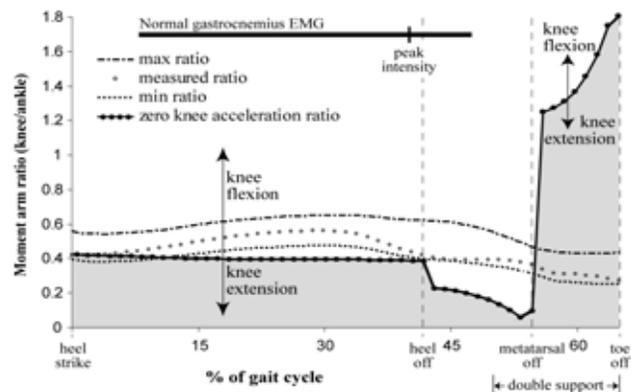

The gastrocnemius plays an important role in support of the body during stance [1] and in preparation of the limb for swing [2,3]. However, the action of this muscle at the knee is unclear; some dynamic analyses show that gastrocnemius acts mainly to flex the knee during double support [2], while others demonstrate that the muscle accelerates the knee into extension [3]. To clarify the action of gastrocnemius at the knee, we systematically altered the ratio of the moment arms of gastrocnemius to determine how changes in the geometry of this muscle affect its capacity to accelerate the knee during stance. Our objective was to determine the knee-to-ankle moment arm ratio that would result in zero knee acceleration, as this ratio represents the ratio at which muscle function changes from knee flexion to knee extension.

### METHODS

To calculate the acceleration of the knee joint generated by various gastrocnemius geometries, we fixed a 3-dimensional model of the lower extremity with a 2-degree-of-freedom ankle and 2-segment foot [4] in positions corresponding to every 2% of normal stance phase kinematics [4], assumed rigid contact of the foot with the ground [1], and applied moments about the knee, ankle, and subtalar joints corresponding to a range of knee-to-ankle moment arm ratios for gastrocnemius. Specifically, for each stance phase position, the ankle moment was set to 1 Nm, the subtalar moment was set to its normal size relative to this ankle moment, and the knee moment was varied until the knee was not accelerated. The relative values of the ankle and subtalar moments were chosen to correspond to those generated by gastrocnemius during normal gait [4]. Values for the knee-to-ankle moment arm ratio that gave rise to zero knee acceleration were insensitive to the absolute sizes of the knee and ankle moments; only their ratio mattered.

### RESULTS AND DISCUSSION

The knee-to-ankle moment arm ratio for gastrocnemius that resulted in zero knee acceleration was near or below a value of 0.4 until about 55% of the gait cycle (Figure 1). After the metatarsal joint left the ground, leaving only the toe in contact, the ratio rose dramatically to values ranging from 1.2 to 1.8 (Figure 1). Experimental data from cadavers places the knee-to-ankle moment arm ratio for gastrocnemius above 0.4 and below 0.7 for nearly all of stance [5,6,7] (Figure 1). This suggests that gastrocnemius, when generating force, would accelerate the knee into flexion for most of stance. After metatarsal-off, however, any normal moment arm ratio would result in gastrocnemius acting to extend the knee (Figure 1). Given that gastrocnemius flexes the knee during most of stance but extends it in late stance, it is difficult to determine

**Figure 1.** The gastrocnemius knee-to-ankle moment arm ratio that resulted in zero acceleration of the knee during stance compared to ratios estimated from experiments [5,6,7] and normal gastrocnemius EMG activity [8]. Ratios above (below) the zero-knee-acceleration ratio would accelerate the knee into flexion (extension). The measured ratio was based on data collected from a single specimen [5]. The max and min ratios were based on data from separate knee and ankle joint studies and represent the theoretical extremes of this ratio during stance [5,6,7].

the net action of this muscle. Since gastrocnemius typically generates the largest forces near heel-off [4,8], and since forces generated at the beginning of a movement are the most influential in determining the resulting net action over a period of time [2], it is likely that gastrocnemius acts in net to flex the knee. This is likely true even over double support, when gastrocnemius is generating force due to muscle deactivation. Indeed, perturbation analyses support this conclusion [2]. However, further investigation is needed before such conclusions can be drawn definitively. Specifically, future work will determine how other modeling variables, such as the way in which the foot and its contact with the ground are represented, affect the action of gastrocnemius at the knee.

## NEW OPEN-SOURCE TOOLS FOR 3D RECONSTRUCTION FROM MEDICAL IMAGES

<sup>1</sup>Todd Doehring, <sup>2</sup>Pavan Thangudu, <sup>2</sup>Josh Considine, <sup>1</sup>Peter R. Cavanagh

<sup>1</sup>Department of Biomedical Engineering, Cleveland Clinic Lerner College of Medicine of CWRU

<sup>2</sup>Department of Biomedical Engineering, CWRU

### INTRODUCTION

With the advent of new medical imaging technologies and options for non-invasive means of patient diagnosis, the need for better 3D segmentation and reconstruction tools for research and clinical practice is increasing. Unfortunately, segmenting and generating 3D anatomical models from 2D medical images is currently a time consuming process, usually requiring large amounts of manual labor and expensive, proprietary software. The available commercial software [1] is “closed-source”, restricting research and experimentation with the underlying algorithms. Also, commercial software is often not well suited to reconstruction of complex tissues from noisy magnetic resonance images (MRIs).

Because of these limitations of commercial software, the purpose of this research was to develop new software tools (“Super//Slicer”) for 3D segmentation and reconstruction from medical images, with an emphasis on reconstructing connective tissues. In this report we describe the basic components of the software. Super//Slicer is written in Matlab (Mathworks, Inc.) and is freely available [2].

### METHODS

A graphical user interface (GUI) was developed to maximize interactivity and user control. Image sequences can be loaded and saved, as well as entire segmentation sessions. The software has for main components: (1) a set of filters, including cropping, thresholding, noise reduction, and other filters, (2) a threshold-based contouring algorithm, (3) manual contour tracing and editing, and (4) a surface generation algorithm for generating spline-smoothed contour data and 3D “water-tight” triangular polygon surfaces. The contours and surfaces are output in “obj” format (Wavefront format, Alias, Inc.) compatible with most 3D solid modeling software. Once a contour is selected, the software uses an automatic selection algorithm to identify and select contours in adjacent images that are associated with the object that is being segmented. The user can specify multiple threshold values to vary the shape of the contour (“keyframing”). Manual tracing and editing functions were also included to enable the user to trace regions that could not be segmented with the contour function.

A typical process of segmentation and reconstruction is: (1) open the image files, (2) crop to the region of interest, (3) adjust the contour threshold and set keyframes to best fit the object to be segmented (i.e. ligament, muscle, bone, etc.), (4) automatically detect and select similar object contours (i.e. “super slice”), (5) add or delete contours as needed, using manual editing if necessary, and (6) automatically generate and output the contour data and resulting surface mesh.

Super//Slicer was designed to be easy to understand and program. The user can reprogram filters, add new filters, and otherwise modify the segmentation and surface generation

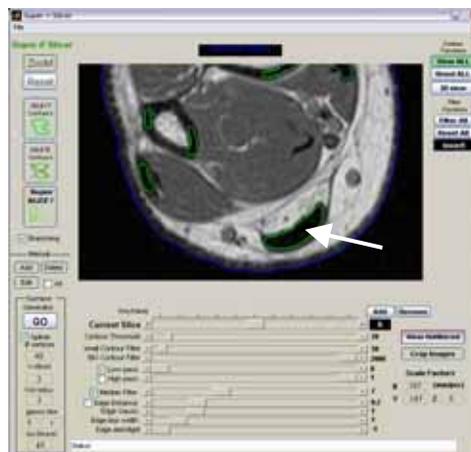

Figure 1: GUI and contoured image of the Achilles tendon.

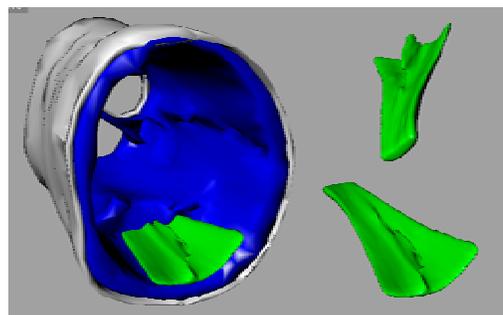

Figure 2: Reconstructions of lower leg skin, fatty tissues, and Achilles tendon (shown in two views for clarity).

codes. The current contouring and segmentation algorithms are simple, however, more advanced methods, such as active contours and neural network training are under development.

### RESULTS AND DISCUSSION

Development of Super//Slicer is ongoing, but already several complex 3D reconstructions of foot-related tissues have been performed (Fig. 2).

### CONCLUSIONS

The goal of this project was to construct a simple and efficient framework for development of new methods for 3D segmentation and model generation from medical images. Super//Slicer has exhibited potential in its ease of use, and ability to generate accurate models in a short amount of time. It is hoped that open-source availability will spark new research and development of improved methods for analysis of MRI and CT medical images.

## MECHANICAL EFFICACY OF TENDON TRANSFER OPERATIONS FOR FOOT DROP

<sup>1</sup>Tsuyoshi Jotoku; <sup>1</sup>Kristin Zhao; <sup>2</sup>Harold Kitaoka; <sup>1</sup>Lawrence Berglund; <sup>1</sup>Kota Watanabe; <sup>1</sup>Kenton Kaufman

### INTRODUCTION

There are multiple operations described for foot drop. Conventional posterior tibial tendon transfer through the interosseus membrane (IOM) is popular, but there are concerns that it may not be adequate to obviate continued bracing. The Bridle procedure (BRI) is promising [1] but involves 5-7 incisions and a higher potential for complications. The purpose of this study was to compare results of these two operations in cadaveric lower extremities using a dynamic ankle-foot simulator.

### METHODS

Seven fresh-frozen lower extremities without foot-ankle pathology were evaluated. The tibia and fibula were embedded in PMMA and specimen mounted in a previously-validated dynamic ankle-foot simulator [2], designed to recreate late swing phase and entire stance phase of gait in cadaveric specimens (Fig 1). Input data derived from anatomic, electromyographic, and gait analysis studies were used for ground reaction force profiles, tibial advancement, and application of forces to 6 distinct muscle groups. Axial and fore-aft shear forces were applied with servomotors, with profiles from gait analysis data [3]. Each specimen was pre-tested three times to reduce viscoelastic effect of soft tissue structures.

Three-dimensional kinematics were measured using a magnetic tracking device (3Space Fastrak system, Polhemus, Colchester, VT), focusing upon metatarsal motion relative to talus. Motor control and data acquisition were accomplished using Labview (National Instruments, Austin, TX). Specimens were tested in 4 conditions: 1) intact, 2) foot drop (tibialis anterior, extensor hallucis longus, extensor digitorum longus, and peroneals forces removed), 3) after IOM, and 4) after BRI. Statistical analysis included repeated measures ANOVA to evaluate the effect of each test condition on foot kinematics, with statistical significance set at  $p < 0.05$  level.

### RESULTS AND DISCUSSION

Typical metatarsal-tibial sagittal motions for normal, foot drop, BRI and IOM are shown in Figure 2. The position of the foot at initial contact in all three planes differed significantly between the intact and foot drop conditions, with the intact foot in a position of dorsiflexion ( $4.6 \pm 5.5$  deg), eversion ( $4.4 \pm 4.9$  deg), and external rotation ( $3.3 \pm 6.3$  deg) and the foot drop in a position of plantarflexion ( $-18.5 \pm 5.4$  deg), inversion ( $-13.1 \pm 3.8$  deg), and internal rotation ( $-9.8 \pm 6.1$  deg). Both operations improved foot position, as compared to foot drop, in all three planes. Neither the IOM nor the BRI conditions differed significantly from the intact condition, except for the sagittal position of the foot after the BRI procedure.

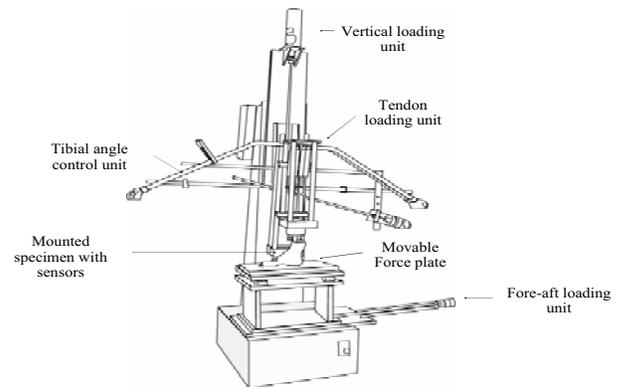

Figure 1: Dynamic ankle-foot simulator.

### CONCLUSIONS

These data suggest that the IOM and BRI procedures were successful in restoring the kinematics of the foot at heel strike in this cadaveric model of gait. The mechanical effects of these two procedures are similar, suggesting that either may be employed for the improvement of gait in patients with foot drop.

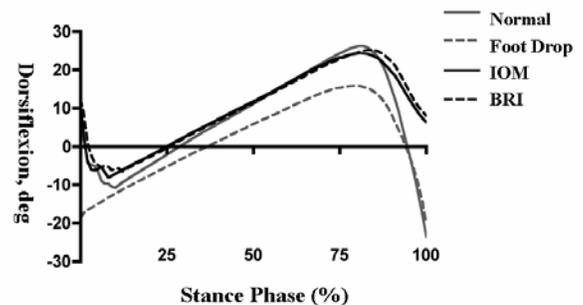

Figure 2: Metatarsal-tibial sagittal motion in intact, foot drop, IOM, and BRI conditions.

## SARCOMERE LENGTH MEASUREMENT PERMITS HIGH RESOLUTION NORMALIZATION OF MUSCLE FIBER LENGTH IN ARCHITECTURAL STUDIES

Amanda Felder, Samuel R. Ward and Richard L. Lieber

Departments of Orthopaedic Surgery and Bioengineering, University of California  
and Department of Veterans Affairs Medical Centers, San Diego, CA; email: [rlieber@ucsd.edu](mailto:rlieber@ucsd.edu)

### INTRODUCTION

The reliability of architectural information depends heavily on accurate fiber length ( $L_f$ ) values. One difficulty in obtaining accurate  $L_f$  values is compensating for the fiber length variation that occurs because muscles are fixed at various joint angles. The procedure typically used to compensate for such variation is to use sarcomere length measurements to normalize fiber length to a standard sarcomere length, using the equation:

$$L_f(cm) = \frac{L_f'(cm) \cdot L_s(\mu m)}{L_s'(\mu m)} \quad (\text{Equation 1})$$

where  $L_f$  is the normalized fiber length,  $L_f'$  is the experimentally measured (raw) fiber length,  $L_s$  is the standard sarcomere length and  $L_s'$  is the experimental sarcomere length measured at the experimentally measured fiber length. The purpose of this study was to test the accuracy and resolution of this method of fiber length normalization.

### METHODS

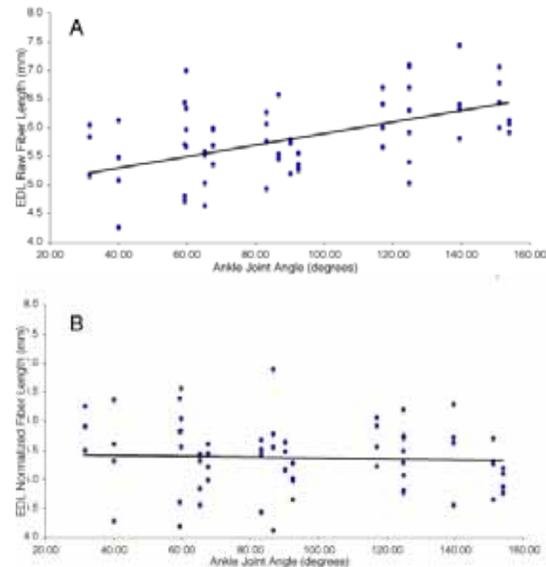

The mouse hindlimb was used as a model system. Limbs were disarticulated at the hip, the knee joints were set to  $90^\circ$ , ankle joints were set to angles ranging from  $30^\circ$  to  $150^\circ$  ( $n=2-4/\text{group}$ ), and the limbs were fixed in formalin. To determine the precise tibiotarsal and tibiofemoral angles of fixation, lateral radiographs were obtained of the limbs, and joint angles were digitized.

Tibialis anterior (TA), extensor digitorum longus (EDL), and soleus muscles were removed from limbs and digested in 15%  $H_2SO_4$  to facilitate fiber bundle dissection. Small fiber bundles were dissected from the whole muscles under 8X-20X magnification, with care to remove the entire bundle from tendon to tendon. Three to four bundles were removed from each muscle. Fiber bundle length was measured to the nearest 0.01 mm. After mounting the fibers, sarcomere length was measured at three different points along each bundle using laser diffraction as previously described [1].

Raw fiber lengths were normalized to a standard sarcomere length of  $2.5 \mu m$  using equation 1 shown above. Linear regression of raw and normalized fiber lengths over ankle angle was performed for each muscle. Additionally, raw and normalized fiber lengths were compared across angle groups by one-way analysis of variance (ANOVA). Finally, resolution of the normalization procedure was defined using the standard statistical power equations.

### RESULTS AND DISCUSSION

As anticipated, raw fiber bundle length was strongly dependent on tibiotarsal angle (Fig. 1A;  $p<0.002$  for all muscles,  $r^2$  range from 0.20-0.68), although the magnitude of the change was muscle-dependent, based on the different fiber

**FIGURE 1:** (A) EDL raw fiber length vs. ankle angle. (B) EDL normalized fiber length vs. ankle angle. Results from EDL are representative of TA and soleus as well.

length-moment arm relationships of each muscle [2]. Sarcomere length normalization eliminated the joint-angle dependent variation in fiber length in all muscles, as evidenced by both linear regression (Fig 1B;  $p>0.3$ ,  $r^2$  range from 0.009-0.022) and one-way ANOVA ( $p>0.1$ ). There was no significant variation of animal mass or tibial length across groups ( $p>0.9$ ,  $p>0.8$ , respectively). A large degree of natural fiber length variation occurs which is not eliminated after sarcomere length normalization. Statistical power analysis revealed a  $\sim 90\%$  chance of detecting a 15% fiber length difference and a  $\sim 60\%$  chance of detecting a 10% variation.

### CONCLUSIONS

We demonstrated that sarcomere length normalization eliminates the fiber length variability due to variation in joint angle. The use of sarcomere length normalization easily permits resolution of fiber length variations of 15%.

email: [Gail.P.Perusek@nasa.gov](mailto:Gail.P.Perusek@nasa.gov)

### INTRODUCTION

To mitigate the detrimental effects of microgravity on the human musculoskeletal system, astronauts on the International Space Station (ISS) currently exercise on three exercise countermeasures devices (TVIS, CEVIS, and iRED). However, it is known that astronauts on the first 6 Expeditions to the ISS lost lower-extremity bone mass despite exercising on these devices. Peak magnitude and rate-of-change of force elicited under the feet (F and dF/dt, respectively) are widely believed to be important criteria for efficacy of countermeasures against loss of bone mass, but there is no information in the literature to demonstrate F and dF/dt imposed on the lower extremities during exercise throughout the range of available gravity-replacement loads imposed on the subject during exercise on ISS. To address these issues, NASA Glenn Research Center and The Cleveland Clinic Foundation Center for Space Medicine have developed the Exercise Countermeasures Laboratory (ECL), a new ground-based test capability, for providing a more flight-like simulation of exercise and reduced-gravity locomotion. Finite element analysis (FEA) of crucial system components was used to verify structural modes of vibration do not couple with ground reaction force measurements in the simulator.

### METHODS

The ECL incorporates an enhanced Zero-g Locomotion Simulator (eZLS) which includes interface dynamics of those seen on the ISS, and the ability to provide variable structural dynamic interdependence to mimic variable interface configurations as seen on the ISS and other possible vehicle carriers. To allow interface forces to be accurately measured, non rigid-body structural modes of the ground-based testbed were analyzed using FEA, to ensure that the forcing function induced by the subject and subject load device are decoupled from non-rigid body modes of the simulator (Figure 1). Components of the simulator that were modeled included (i) the inertial ground frame reference, or ground reaction frame, (ii) the exercise device, and (iii) the 1 DOF off-loading and translation system for the exercise device. Target modes were set at 1.7 times the highest bandwidth of interest in the ground reaction force Z-axis component. The Z-axis is oriented normal to the running surface. Frequency content of human ground reaction force has been shown to be below 25Hz [1]. Acceptable non-rigid body structural modes were established to be 43 Hz or higher, to minimize structural interactions with the foot force measurements.

a.)

b.)

**Figure 1:** (a) Solid model of test subject in enhanced Zero-g Locomotion Simulator (eZLS). Subject suspension system not shown. (b) Finite element model of simulator components.

### RESULTS AND DISCUSSION

The inertial ground frame reference, or ground reaction frame, is a carbon steel box-tubing welded framework with grouted base pads which accept concrete anchors. Modes of vibration of this structure were found to meet the established criterion, with the first mode in the Z-axis direction at 70 Hz. The treadmill frame, which accommodates treadmill mechanical and electrical components, forceplate, and subject load device system, is an aluminum box-tubing welded framework. The treadmill base mounts to the 1 DOF linear translation system, or “Z-slide”, which offloads the weight of the treadmill system and allows frictionless movement in the Z-axis via air bearings. The treadmill frame and Z- slide assembly modes were also found to be acceptable, with the first Z-axis mode at 45 Hz.

### CONCLUSIONS

Interface forces to the subject, as well as to the exercise equipment and ground reaction frame, will be measured in the eZLS for various exercise modalities to develop a more detailed understanding of the human, subject load device, and exercise countermeasure equipment interactions, without interference from unwanted non-rigid body modes of the structural components in the system. FEA informed the design decisions for the system components and their interfaces, including the attachment method to ground for the ground reaction frame. The outcome will be that an integrated load (duration, intensity, frequency, time rate of change) may be identified for maximum benefit of counteracting the degenerative effects of space flight.

## SUB-CALCANEAL FAT-PAD INFILTRATION AND ITS EFFECT ON PLANTAR HEEL PRESSURES IN THE DIABETIC NEUROPATHIC FOOT

<sup>1,3</sup> Sicco Bus, <sup>2</sup> Mario Maas and <sup>2</sup> Erik Akkerman

Department of <sup>1</sup>Internal Medicine and <sup>2</sup>Radiology, Academic Medical Center, University of Amsterdam, The Netherlands

<sup>3</sup>Diabetic Foot Unit, Department of Surgery, Twenteborg Ziekenhuis, Almelo, The Netherlands

email: [s.a.bus@amc.uva.nl](mailto:s.a.bus@amc.uva.nl)

### INTRODUCTION

Diabetes mellitus and its complications are associated with several structural and physiological abnormalities in the foot, which can increase the risk for plantar ulceration [1]. These abnormalities also include changes in the sub-calcaneal and sub-metatarsal fat-pads used for cushioning. Micro-hemorrhage of sub-cutaneous tissue has been reported [1,2] and non-enzymatic glycosylation of proteins may lead to systemic fat pad tissue changes [3]. The purpose of this study was to use magnetic resonance imaging (MRI) to quantify pathologic changes in the sub-calcaneal fat pads and to determine the association with plantar pressures measured in the heel region in diabetic patients with peripheral neuropathy.

### METHODS

Fourteen diabetic patients with peripheral neuropathy (mean age 57.9 years (SD 6.9), body mass 81.7 kg (SD 11.4)) and five healthy age-matched control subjects (mean age 58.0 years (SD 1.7), body mass 73.4 kg (SD 6.1)) underwent MRI examination and plantar foot pressure measurement. Two-point Dixon chemical shift imaging was performed at 1.5-T using a Siemens Magnetom 63SP/4000 imager. Fat-only and water-only (fat-suppressed) images were created from which the fraction of fat signal in each pixel could be determined [4]. All images were high-resolution (512x512 pixels) T<sub>1</sub>-weighted sagittal plane spin-echo images of the foot and were obtained non-weight bearing. One centrally located slice was selected for quantitative analysis. Using Scilimage a region of interest (ROI) was defined in the heel and the fat signal fraction in this ROI was calculated (Figure 1).

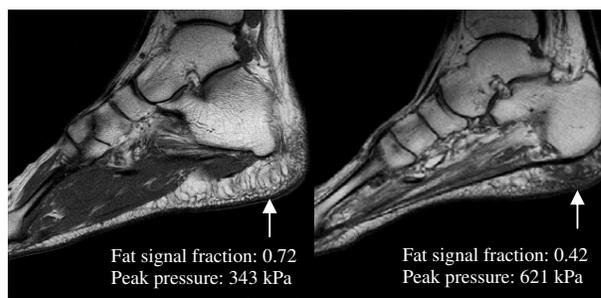

**Figure 1:** Water-only image in which ROI was defined between 1/12 and 3/12 of the foot length from the heel

Barefoot plantar pressures during gait were measured using an EMED pressure platform (Novel, Germany) while obtaining a second-step approach to the platform. Five repeated trials were collected from each subject. Peak pressures were calculated for the heel region. Mann-Whitney non-parametric tests were used to determine statistical significance between the groups ( $P < 0.05$ ).

### RESULTS

The mean fat signal fraction was 0.72 (SD 0.03, range 0.70-0.76) for the healthy control subjects and 0.55 (SD 0.11, range 0.34-0.67) for the diabetic patients; the mean difference was statistically significant ( $P < 0.005$ ). Peak pressure in the heel was 325 kPa (SD 53) and 391 kPa (SD 119) for the healthy controls and diabetic patients, respectively, which was not significantly different. Figure 2 shows examples of healthy and infiltrated sub-calcaneal fat-pad tissue. A significant inverse correlation of -0.59 was present between fat signal fraction and heel peak pressure ( $P < 0.01$ ).

**Figure 2:** Healthy subject with normal sub-calcaneal fat pads (left) and diabetic patient showing fat-pad infiltration (right)

### DISCUSSION

A substantial reduction in the ratio of fat to water signal in the sub-calcaneal fat pads was shown in a large percentage of neuropathic patients when compared with healthy control subjects. These results are consistent with data from Kao et al. [3] showing increased T<sub>1</sub>-relaxation times in cadaver diabetic heel fat pads. Increased amounts of collagen as a result of non-enzymatic glycosylation or micro-hemorrhage caused by repetitive minor trauma may explain these pathologic changes [1,2,3]. The data suggests reduced functionality of the sub-calcaneal fat pad as shown by the significant association between reduced fat signal fraction and increased pressure levels in the heel. Whether fat-pad infiltration or elevated mechanical pressure is the primary event in this association requires further prospective analysis. The findings from this study contribute to our understanding of the relationship between structural and functional parameters in the diabetic foot. Although heel ulcers are not common in the diabetic foot, fat-pad infiltration may play a role in their pathogenesis.

## DYNAMIC STABILITY STRATEGY FOR ELITE JUDOISTS IN BALANCE CONTROL FOR ANTERIOR AND POSTERIOR PERTURBATIONS

Chih-Hang Lien<sup>1</sup> and Wen-Tzu Tang<sup>1,2</sup>

<sup>1</sup>Graduate Institute of Coaching Science, National College of Physical Education and Sports, Taiwan.

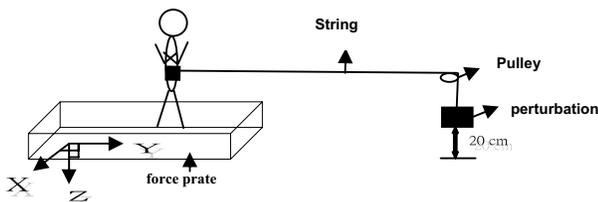

<sup>2</sup>Email: [wttang@mail.ncpes.edu.tw](mailto:wttang@mail.ncpes.edu.tw)

### INTRODUCTION

Balance control abilities are essential for top athletes to reach optimal performance in competitions, especially for judoists [1]. Judo can be divided into attack and defence abilities, both of which influence winning. For response to attack, control of proper distance and force application to destabilize the rival through movement derives from control in balance. Stability of the centre of body weight must be maintained through intersegmental controlling. In order to avoid being attacked and falling, training for balance control of the body is important to the judo player[2]. Several studies have shown that judoists represent high balance performance, as measured from the through size of the COP area or scores on a balance system [2] with unstable platform perturbation. However, quantitative principles of balance strategy for judoists are still unknown, especially with waist perturbation similar to that in judo throwing. Therefore, this study investigated responses in terms of balance performance (using COP) and balance responses as measured using reaction forces to direction-dependent perturbation without anticipation. Postural control in two directions (forward, backward) for different skill levels of judoists was measured using force plates. These results may provide valuable information for selecting and training judoists scientifically.

### METHODS

Experimental data were collected from fourteen elite-level judoists (Top twelve national level, Age: 21.2±1.9 years), fourteen subelite-level judoists (regional level from university teams, Age: 21.0±1. years), and fourteen non-judoist college students (Age: 21±2 years) performing perturbation balance control tests. All judoist subjects had a minimum number of five years of practice and no mechanical or functional instability from ligamentous, articular or muscle trauma or injury in the past three months. The perturbation test was performed by imposing a 10% body weight in 20 cm free-fall= without anticipation (Figure 1). An AMTI force plate (1000 Hz) was used to measure the reaction of participants with ground reaction force and COP trajectory. The balance response variables included maximum reaction force and balance performance variables including Maximum of Center of pressure (COP), total COP displacement, and averaged COP velocity. Three trials were collected for each test. Variables with length or weight units were normalized by height and weight of subjects, respectively. T-tests were performed between judoists and non-judoist groups.

**Figure 1.** Unanticipated direction-dependent perturbations

### RESULTS AND DISCUSSION

In forward perturbation tests, both levels of judoists

demonstrated significantly lower values than the non-judoist group for the COP averaged moving speed and total displacement (Table 1;  $p < .01$ ). In addition, only the elite group showed significantly lower values for COP reaction force than the non-judoist group. Postural adaptations of judoist group are more efficient, especially for elite groups, than the control group. Judoists can change their intersegmentary coordination in order to accommodate specific unpredictable perturbation of tasks, as in the judo throwing attack (Seoinage-drop-knee). The main reason that judoists perform better in balance control is not due to leg muscle strength, which should yield greater reaction force, but because of balance control as demonstrated by lower reaction force with less COP displacement and lower COP moving speed.

**Table 1** One-way ANOVA in National judoists (elite group), Regional judoists (subelite group) and Control group during unanticipated forward and backward perturbations

Forward N=14	Group National Judoists (N)	m (SD)		One-way Fishers N/R	ANOVA PLSD	
		Regional Judoists (R)	Controls (C)		R/C	N/C
Cop-X	0.07 ±0.07	0.09 ±0.06	0.56 ±1.68	NS	NS	NS
Cop-Y	0.08 ±0.02	0.1 ±0.03	0.61 ±1.73	NS	NS	NS
Fz	1.23 ±0.22	1.31 ±0.23	1.52 ±0.29	NS	NS	0.01
Avg velocity	66.5 ±22.4	77.6 ±11.8	99.9 ±22.5	NS	0.01	0.00
Length	261 ±88	305.5 ±46.6	415 ±73	NS	0.01	0.00
<b>Backward</b>						
Cop-X	0.17 ±0.03	0.15 ±0.01	0.15 ±0.01	NS	NS	0.02
Cop-Y	0.13 ±0.02	0.15 ±0.01	0.17 ±0.02	NS	NS	0.00
Fz	1.46 ±0.24	1.5 ±0.29	1.62 ±0.42	NS	NS	NS
Avg velocity	80 ±24.8	88.5 ±13.2	115 ±19.3	NS	0.00	0.00
Length	317 ±97	348 ±52	455 ±76	NS	0.00	0.00

In backward perturbation, both levels of judoists demonstrated significantly lower values than non-judoists for the COP-averaged moving speed and total displacement ( $p < .01$ ). In addition, only the elite group showed significantly lower values for COP y direction displacement and greater values for COP x direction displacement ( $p < .01$ ) than the control group. Elite judoists also tend to use more lateral movement skills to maintain balance and to control COP displacement. Postural adaptations of judo group are more efficient, especially for the elite group, relative control group.

### CONCLUSIONS

In this study, elite and subelite judoists showed a postural adaptation strategy of significantly lower values for COP-averaged moving speed and total displacement, and also lower reaction force following unpredictable perturbation relative to the control group. Elite and subelite judoists did not differ significantly in these variables. Postural adaptations of judoists are more efficient, especially in the elite group. Kinetic parameters can be utilized to evaluate the efficient strategy in judo balance control for different attack directions.

## ELELECTROMYOGRAPHIC LINEAR ENVELOPE ANALYSIS OF GOLF SWING FOR TRUNK MOTION IN ASIAN PLAYERS: A CASE STUDY

Chia-Nen Chan<sup>1</sup> and Wen-Tzu Tang<sup>2</sup>

<sup>1</sup>Chang-Gang University, Taoyuan, Taiwan, and<sup>2</sup>National College of Physical Education and Sports, Taoyuan, Taiwan  
email: [wttang@mail.ncpes.edu.tw](mailto:wttang@mail.ncpes.edu.tw)

### INTRODUCTION

Despite the significant prevalence of back pain among golfers at all levels of ability, the current literature does not fully address specific mechanisms responsible for this injury. The approach of studying trunk motion includes motion analysis and EMG measurements. Some studies show differences in trunk motion with kinematic variables for two groups with non-back pain and back pain, respectively [1]. Most EMG studies have measured EMG amplitude in each phase to understand general on/off activation of trunk muscles in different phases. However, little work evaluates back muscle activation patterns with the EMG envelope, which provides information on the the timing and duration of the burst, and also detail muscle activation characteristics integrated with kinematics variables. Moreover, most studies have recruited western players as participants who usually have higher anthropometric scores. Recently, Asian professional golf players have successful performances in American and Europe, albeit with lower anthropometric scores. . Investigation of trunk muscle activation pattern in an elite Asian player without pain history may provide useful information to explore the optimal swing for back loading. Therefore, this study identifies reproducible patterns of trunk muscle activity through use of the EMG envelope integrated the kinematic variables. We analyze the swing of a golfer who won a Gold Medal in 2002 Busan Asian Games. The participant had a low anthropometric anthropometry score relative to western players.

### METHODS

One male Gold Medal winner in 2002 Busan Asian game aged 25 years with height 160 cm and weight 65 kg, with 15 years of training, participated in this study. The subject is a typical right-handed player. Surface EMG data at sampling rate of 1200 Hz were collected by Biovision EMG System (Wehrheim, Germany). The muscles of abdominal oblique, erectus spinae, latissimus dorsi, and upper rectus abdominis in both right and left sides were studied. The distance of the interelectrode was 20 mm, and the placement of electrode was as described by Zipp (1982). A JVC 9800 digital camera at a sampling rate of 120 Hz captured the subject's swing with a #7 iron via markers on club, shoulder, elbow, wrist, ilium, and knee. EMG and video data were synchronized with a simple circuit that simultaneously lit an LED and sent a voltage signal to the Biovision input box. Kinematic data were analyzed by the Kwon3D Software. The swing was divided into five phases: Phase I, upswing; Phase II, forward swing; Phase III, acceleration; Phase IV, early follow through; Phase V, late follow through [2]. The subject was asked to perform 10 swings after a proper warm-up. The four best and most consistent strokes were chosen by the subject for later data analysis. The EMG signal was band-pass filtered at 4 to 500 Hz (Butterworth digital filter), full-wave rectified, and low-

**Figure 1:** EMG activity patterns of shoulder and trunk muscles on left and right sides during five swing phases pass filtered at 8 Hz by DasyLab 6.0 System to derive the EMG linear envelope.

### RESULTS AND DISCUSSION

To analyze the timing and duration of the firing pattern of back and shoulder muscles of the participant, the EMG linear envelope as shown in Figure 1 was studied for each muscle. In the early phase of the takeaway, all muscles presented extremely low activation. However, the latissimus dorsi on both sides started to activate during the tak-away. In particular, the latissimus dorsi on the right side continued activation until the top point of the takeaway phase. This muscle presented a similar pattern in the forward swing phase. Comparing the two sides, the left latissimus dorsi presented less activation, and the latissimus of both sides were silent until the end portion of the late follow through. The left and right erect spinae and right abdominal oblique presented significant activation until the top point of the take away, then decline. Overall, the forward and acceleration phases muscles on the upper torso did not showed burst activity except for the left erect spinae in acceleration phases. Other studies have demonstrated greater activation levels on the forward swing and acceleration relative to the upswing and follow through, as characterized by MVC percentage. The burst peak may be reduced in MVC percentage because of the long duration of the upswing and follow through phase. Furthermore, not many trunk muscle groups in our study exhibited a burst in the forward and acceleration phases, and it is possible that other deep trunk muscles not involved in this study may play an important role for these two phases, which should be further investigated for back pain research.

### CONCLUSIONS

From previous studies using EMG amplitude analysis for different swing phases, information is available on the general roles of each muscle in different phases. However, this work demonstrates dilution of the burst which may associate with back pain because of repetitive and cumulative acute motion. Also, reduced burst activation in the forward swing and acceleration which may imply the relevance of exploring deep muscles during the forward swing and acceleration.

## THE COMPARIION OF EFFECTIVENESS BETWEEN GRAB START AND TRACK START IN COMPETITIVE SWIMMING

Shu-ting Chen, Weng-tzu Tang

Institute of Coaching Science in National College of Physical Education and Sports, Taipei, Taiwan

Email: [wttang@ncpes.edu.tw](mailto:wttang@ncpes.edu.tw)

### INTRODUCTION

Performance in competitive swimming is influenced by swimmer's physique, strength and endurance of muscle factors, etc., but the most important and key factors are swimming techniques, including stroke, kick, turn, touch wall and start. The time a swimmer spends in the start ranges from 0.8% to 26.1% of the overall race time, depending on the event [1]. So the shorter the race distance, the more important the effect of the start. Many starting techniques are used in competitive swimming, such as the grab start, track start and swing start. The grab start and track start are the most popular techniques presently employed for individual events. Studies regarding the comparison of both starts have been investigated through kinematic and kinetics variables [1,2]. Kinematics variables are the outcome of kinetics variables, which provide information for coaches. However, the efficiency of integrated variables with kinematic and kinetics parameters, can provide further information for technique, but has not been studied. Therefore, the purpose of this study was to compare the grab start with the track start in kinematics (horizontal distance of entry) and kinetics variables (peak ground reaction force, peak vertical and horizontal force, speed strength index, i.e., SSI, impulse), and to integrate variables to estimate the starting efficiency (SSI-efficiency index, impulse-efficiency index) for both starts. The results of this study can provide coach and swimmer with different perspectives on comparative advantages of start techniques.

### METHODS

Eight competitive swimmers were used in this study: four males (19.75±0.96 years of age, 170.25±5.80 cm in height, 66.35±5.32kg in body mass) and four females (20.75±2.36 years, 161.75±5.87 cm, 56.83±7.98 kg). Participants had trained at least six years with no injury. Four participants had a grab start preference, and four participants used track starts; both groups had practiced both starts for at least three months after recruitment. All subjects were required to perform two start tests in random order (three trials by each subject for each of the grab start and and the track start).

A digital video camera (JVC/9800, 60 Hz) and a Kistler force plate (1000 Hz) were used to collect motion data and kinetic variables (peak resultant ground reaction force, vertical and horizontal force, SSI, and impulse). The SSI efficiency is derived as the horizontal distance of entry divided by SSI. Impulse efficiency is derived as the horizontal distance of entry divided by the impulse. All kinetics variables were normalized by body weight, and kinematics variables were normalized by body height. The force plate was fixed above the starting platform, and the camera was setting in the sagittal plane (Figure 1). An electronic trigger with light bulb

synchronized the force plate to the video camera.

Data were analyzed by t-tests with repeated measures. Measured kinetic parameters included peak ground reaction force (Fx,y), vertical and horizontal force (Fx,Fy), speed strength index (SSI), impulse, horizontal distance of entry, the SSI-effectiveness index, and the impulse-effectiveness index.

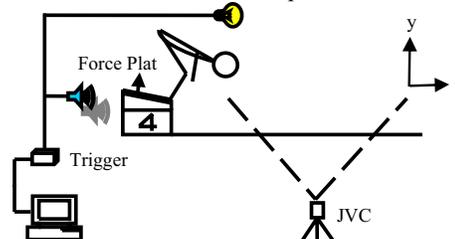

Figure 1: The diagram to show testing location.

### RESULTS AND DISCUSSION

Significant differences were found between the two start types in peak ground reaction force, SSI, impulse, horizontal distance of entry and impulse- efficiency index. However, there were no significant differences between the two starts either in peak vertical and horizontal force or SSI-efficiency index (Table 1). This may derive from difference in lower limb joint flexion and in the absence of coincidence of peak force (Fx,y<sub>max</sub>) of both limbs.

The impulse was a significant factor influencing flight velocity after takeoff. Impulse and horizontal distance of entry for the grab start were greater than for the track start in this study. However, the effectiveness of the track start was higher than that of the grab start (as measured by the impulse-efficiency index). The reason may due to the increased takeoff angle of track start, and then a higher flight trajectory. Such integration of kinetic and kinematics data together with derived efficiencies can provide coaches and competitive swimmers with specific technique information for swim starts.

### CONCLUSIONS

The general principles of a good start are high velocity, longer horizontal distance of entry, optimal entry angle, and similar parameters. However, quantitative assessment of starts may indicate not just one aspect of greater distance performance (e.g., grab start) or of reaction force, but also a greater efficiency (as in the track start) that will provide more insight into better starting skills.

**ROTATION CHARACTERISTICS OF THE SHOULDER, TORSO, AND PELVIS DURING PITCHING FOR TAIWAN ELITE AND SUBELITE COLLEGIATE BASEBALL PITCHERS**

Yi-Ling Chiang<sup>1</sup> and Wen-Tzu Tang<sup>1,2</sup>

<sup>1</sup>Graduate Institute of Coaching Science, National College of Physical Education and Sports, Taiwan

<sup>2</sup>email: [wttang@mail.ncpes.edu.tw](mailto:wttang@mail.ncpes.edu.tw)

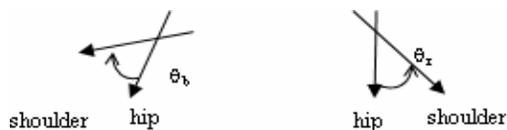

**INTRODUCTION**

Many kinematic variables from each phase of the baseball throw have been identified as being important to maximal throwing velocity[1] as well as to the potential for injury, especially in the elbow, shoulder, and hip joints. Although torso motion can produce high force relative to distal extremities, very few of the trunk kinematic variables were described, only trunk tilt and later trunk tilt angle, trunk flexion [2,3].

However, trunk rotation and twist rotation in terms of the stretch X-factor, which in golf is the difference between shoulder and pelvis rotation during the swing, have not been studied for the baseball throw. It is believed that extra stretch during the early down swing allows the upper-body muscles to contract more forcefully and hence to provide more power. Therefore, this study investigates kinematics of the upper torso and pelvis, including the horizontal rotation of upper torso and pelvis, twist of the trunk (i.e., the X-factor, the difference of the included angle between shoulder and pelvis), and flexion of the trunk during windup, stride, arm cocking, arm acceleration, arm deceleration and follow-through [4]. Integrated study of the torso, shoulder, and pelvis motions may not only contribute to pitching strategy, but also could be helpful to reduce the harm to the shoulder. Through studying Taiwan Elite pitchers and subelite pitchers who usually has less muscle mass and weight, and different pitching pattern compared to west pitchers.

**METHODS**

3D motion data of the entire body during fastballs thrown by ten collegiate pitchers were collected at 250 Hz by seven high speed cameras attached to a VICON 3D motion analysis system (Oxford Metrics, UK). Pitchers were chosen from the top four collegiate teams in Taiwan, and represented both elite and sub-elite groups. Reflective markers were attached at multiple points on the entire body of subjects. Using calculated 3D positional data of the entire body, kinematic characteristics of the pitch, including horizontal rotation of upper torso and pelvis, twist of trunk (X-factor), and trunk flexion of trunk were obtained. X-factor, the difference of the included angle between shoulder and pelvis from maximum backward twist to ball release, was illustrated in Figure 1.

(a) at max. backward twist (b) at release  
**Figure 1:** Definition of X-factor: (a) and (b) are top-view of the subject, X-factor is equal to  $\theta_r - \theta_b$ , where  $\theta_r$  is negative.

**RESULTS AND DISCUSSION**

Representative data from the two groups are presented in Table 1. Elite pitchers exhibited proper sequential movement of the entire body, with a greater angular velocity of twist and flexion motions, and larger X-factors. They also pitched faster, and the net torques at the shoulder before ball release, as calculated by inverse dynamics, were higher.

Such proper mechanics also delay the onset of fatigue, leading to more consistent performance [5]. In the long term, overuse injuries, which may result from cumulative microtrauma, may be reduced through utilizing aforementioned techniques.

**CONCLUSIONS**

The experimental data may give more detail look to the integrated shoulder, torso, and pelvis motion. Greater range and speed of trunk flexion and twist rotation demonstrate better ball speed performance. The results confirmed the point of view that the motion of trunk, in proper order, is also an important factor to the speed of pitched ball [6] and help to achieve the optimal pitching and contribute to injury prevention of shoulder in baseball players.

### INTRODUCTION

Fluid flow through the pericellular network plays a key role in molecular transport through the dense tissue of bone. Fluid flow also serves as the dominant mechanism by which exogenous mechanical stimuli are translated to cells and trigger cellular remodeling activity as well as tissue level adaptation. Osteocytes, the putative mechanosensors in bone, are organized in a functional syncytium that provides a biological network for transport and communication within and across bone tissue. Although osteocyte mechanobiology has thrived as a research arena in recent years, we still do not understand the prevailing mechanobiological environment of osteocytes *in situ* or how extrinsic stimuli are transduced at a cellular level. Here we implement a novel approach to bridge gaps in understanding between cell and tissue mechanobiology in bone using *in silico* virtual as well as scaled up physical models; these experimentally validated models give us a novel platform to extrapolate prevailing *in situ* flow regimes around single cells and networks of cells (which, together with their extracellular matrix comprise bone tissue) that are currently impossible to measure or observe directly.

### METHODS

#### *In Silico Models:*

To explore fluid flow at the level of the cell and within the pericellular space of the lacunocanalicular network, an idealized osteocyte was modeled with multiple connecting canaliculi using a computational fluid dynamics package (CFD-ACE). Fluid flow was induced by a pressure gradient of 300 Pa over the length of the osteocyte with a perfusate medium similar to water ( $\rho=997 \text{ kg/m}^3$ ,  $\mu=0.000855 \text{ kg/ms}$ ). Simulations of steady flow (governed by Navier-Stokes equations) provided velocity and pressure profiles within the fluid space, where shear stress at the surface of the cell and processes was calculated from wall strain rate and laminar viscosity [after 1]. In order to address lower length scales, we studied parametrically the effect of subcellular structures on prevailing flow regimes and network permeability. This was accomplished by calculating velocity and pressure profiles as a function of i) the presence and state of the macromolecular network in the pericellular space as well as ii) differences in relative gap size for flow between the osteocyte body–lacuna and the osteocyte process–canaliculus.

#### *Scaled-Up Physical Models:*

To study fluid flow at the tissue level (flow around networks of cells), experimental tissue permeability measurements were carried out on scaled-up (1000x), anatomically accurate (hollow) physical models of the lacunocanalicular network. Specimens were obtained from the cortical sheath of the femoral neck from human patients undergoing orthopaedic surgery (IRB approved). Hard-tissue histological sectioning and the creation of a three-dimensional image stack using confocal microscopy (SP2 AOBS, Leica) was used as the template for the rapid prototyping of a physical scaled-up

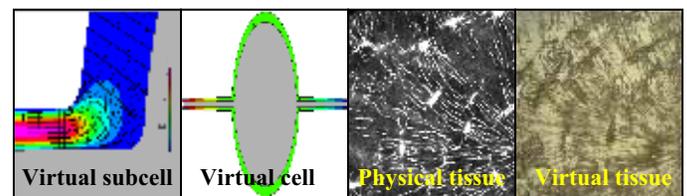

(1000x) model. Permeability was tested in the transverse plane of the specimen for both water and viscous silicone oil (1000x viscosity of water, to counter effect of scaling) as the perfusate medium. By incorporating this scaling coefficient, appropriate permeability estimates can be made of the osteocyte syncytium by scaling back down to cellular length scales. Darcy's Law was used to calculate permeability for a specific mass flow rate and pressure gradient [after 2].

### RESULTS AND DISCUSSION

Cell level *in silico* models show that fluid flow resulting from mechanical loads subjects the virtual osteocyte surface to hydrodynamic pressure of nearly constant magnitude within the lacuna, and high gradients of shear stress along the processes within the canaliculi. Incorporation of subcellular structures into this virtual model reveals a dominant effect of gap size ratio (between fluid gap size within the lacuna and within canaliculi) as compared to the presence of a fluid saturated macromolecular mesh within the pericellular space. Tissue level physical models allow for actual measurements of permeability based on scaled-up, anatomic cell network dimensions. In the scaled-up physical model, permeability is calculated to be  $2.78 \times 10^{-10} \text{ m}^2$  with 1.8% uncertainty in the transverse direction using silicone oil. Using the scale-factor relationship, specimen permeability at the cellular length scale is  $2.78 \times 10^{-16} \text{ m}^2$  for hollow geometry. Hence, actual permeability can be calculated from model-based experimentally determined permeability using,

$$k_{1x} = \frac{k_{1000x}}{\text{scalefactor } r^2}$$

The differently scaled models are then bridged by applying the relationship acquired in the sub-/cellular *in silico* models to the experimentally measured data of the hollow physical network model to calculate permeability for a partially (cell and process) filled virtual network model (Figure).

### CONCLUSIONS

These studies provide, for first time to our knowledge, a novel platform to elucidate fluid flow within the lacunocanalicular network of bone across length scales, from the subcellular to the tissue level. An accurate description of flow across length scales paves the way for understanding the prevailing mechanical environment of bone cells, which will yield unique insight regarding translation of extrinsic signals to the cellular, tissue and organ level and its role in bone (patho)physiology.

**INTERMUSCULAR COORDINATION ANALYSIS OF SKILLED DOUBLE-HANDED BACKHAND AND SINGLE-FOREHAND PLAYERS**

Yi-Ming Huang<sup>1</sup>, Wen-Tzu Tang<sup>1,2</sup>, and Shi-Ting Wang<sup>1</sup>

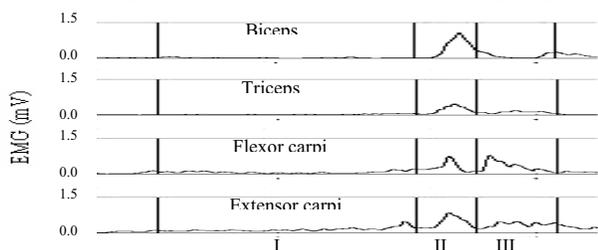

<sup>1</sup>Graduate Institute of Coaching Science, National College of Physical Education and Sports, Taiwan  
 email: [wttang@mail.ncpes.edu.tw](mailto:wttang@mail.ncpes.edu.tw)

**INTRODUCTION**

Experienced coaches and players may easily identify performance by visual observation, whereas testing tools have been used to evaluate players' motor performance to understand coordination mechanisms [1]. Electromyography (EMG) has been widely applied in studies of intermuscular coordination, and is helpful to categorize and understand the agonist and antagonist muscular activity at different skill levels in many sports, including tennis. In tennis, each player usually has a better skill level for one single stroke (e.g., forehand or backhand), and also has his or her own advantage in side movements. Although this phenomenon can be easily judged by professional coaches, the underlying EMG patterns are unknown. Agonist-antagonist co-contraction patterns for stability and the strong agonist pattern for acceleration has been studied in simple fast goal-directed movement [2,3], but not for tennis. Therefore, agonist-antagonist pattern in terms of onset-offset and normalized amplitude with MVC (Maximum Voluntary Contraction), and their ratio were analyzed to understand EMG patterns and to examine whether the agonist-antagonist ratio can be an effective parameter to assess intermuscular coordination in single-forehand and double-handed backhand strokes.

**METHODS**

Female tennis players participating in this study were characterized into two groups: skilled single-forehand and double-backhand. Subjects were typically right-handed players. A reliability assessment for identifying skilled single-forehand or double-backhand abilities was obtained from three expert tennis coaches prior to the study, and was highly consistent. Surface EMG data at a sampling rate of 1200 Hz, were collected with a Biovision EMG System synchronized with a JVC digital camera at sampling rate 120 Hz by a simple circuit with LED. Muscles measured were the biceps brachii, triceps brachii, flexor carpi and extensor carpi muscles on both right and left arms. The backhand and forehand stroke was divided into three phases: Phase I, the preparation, began with the backswing and ended with the first forward motion of the racket; Phase II, acceleration, ended at impact; Phase III, the follow-through, ended with completion of the swing (Figure 1).

**Figure 1** The EMG patterns of dominant (right) arm during double-handed backhand.

We analyzed individually the four best strokes (as evaluated by both subject and experts' observation) from a total of 15 backhand and 15 forehand strokes after a proper warm-up.

Maximum voluntary isometric contraction (MVC) for each muscle was used to normalize values. The EMG signal was band-pass filtered at 10 to 500 Hz, full-wave rectified, and the integrated.

**RESULTS AND DISCUSSION**

Elbow flexor/extensor EMG ratio in the acceleration phase differed significantly between the two groups, as demonstrated for both forehand and backhand strokes with the example data (Table 1). A higher elbow flexor/extensor EMG ratio characterized the left arm of skilled double-handed backhand players and the right arm of skilled single-handed forehand players, although both groups are right-arm dominant. For skilled left double-handed backhand players, a stronger agonist activation pattern was evident in double-handed movements but also demonstrated was stronger co-contraction pattern for forehand movements. However, the opposite trend was seen for skilled right forehand players, who demonstrated stronger agonist activation in forehand movements, but also stronger co-contraction patterns for double backhand movements. The characteristics of elbow acceleration were clear in terms of a stronger agonist in the preferred skilled movement (either double back hand or forehand), and showed a stabilization function in terms of higher co-contraction for the less skilled movement. The elbow uncocking movement skill was different from the traditional method in that only shoulder joint was unlocked. However, the wrist flexor/extensor normalized EMG ratio demonstrated a stabilization function even for the skill movement, which differed from what was seen in the elbow. This may derive from the necessity of stabilization in the distal segment for withstanding impact.

**Table 1:** Ratio of elbow flexor/extensor normalized EMG for skilled double- backhand and single- forehand players

Elbow(n=4) Movement Arm	Group I Skilled double-backhand		Group II Skilled single-forehand	
	forehand right hand	backhand lefthand	Forehand right hand	Backhand left hand
<b>Phase I</b>	1.55 ±0.30	3.26 ±0.81	3.76 ±0.59	0.78 ±0.17
<b>Phase II</b>	1.84 ±0.28	8.71 ±1.61	6.87 ±0.49	1.38 ±0.22
<b>Phase III</b>	0.99 ±0.17	1.60 ±0.30	1.80 ±0.60	0.69 ±0.10

**CONCLUSIONS**

Tennis players showed a higher elbow flexor/extensor ratio for their preference arm during the acceleration phase of their stroke when performing their skilled movement. This may increase the elbow joint acceleration more efficiently. In addition, the parameter of the ratio of agonist to antagonist EMG can usefully assess coordination performance in skilled tennis strokes.

## MUSCLE ACTIVATION BY OLYMPIC FEMALE ARCHERS AT DIFFERENT RELEASING RHYTHMS

<sup>1</sup>Cheng-Ming Hu and <sup>2</sup>Wen-Tzu Tang

<sup>1,2</sup>National College of Physical Education and Sports, Graduate Institute of Coaching Science,

<sup>2</sup>email: wttang@mail.ncpes.edu.tw

### INTRODUCTION

Archery is a comparatively static sport requiring strength and endurance of the upper body, in particular of the forearm and shoulder girdle [1]. Through analysis of muscle activation of the shoulder girdle and forearm, stability and accuracy for archers can be evaluated [2,3]. However, archery conducted outside with disturbance from the environment disturb archers during the process of arrow release, and archers must utilize different releasing rhythms within a time limitation. Little is known about optimal release rhythms and variation in muscle activation with faster rhythms. Thus, the purpose of this study was to analyze muscle activation patterns of archers' forearm and shoulder for both normal and fast releasing rhythms and to find an effective index to assess release performance.

### METHODS

Two female archers from the 2004 Olympic Chinese archery team were involved in this study. They were characterized as elite (awarded Fourth in Olympic Games 2004) and subelite archers (Fifty-fifth in Olympic Game 2004). Measurements were made under simulated Olympics game conditions on outdoor courts. Each participant completed two trials of 24 successful shots to get acquainted with measurement conditions. Timing of the anchor and release moments were determined with an electronic trigger controlled by the coach. Surface electrodes were placed on the central portion of principal muscles with Biovision EMG System (Wehrheim, Germany). Electromyographic activity of the shoulder and trunk muscles (i.e., M. extensor digitorum, trapezius muscle, and deltoid muscles) were recorded at a sampling frequency of 1000 Hz using synchronized electronic signals for a total of 24 shots by each participant. EMG activity amplitudes were determined during the anchoring phase to the time of release, and the reduction in level of muscle activity at release, were derived to evaluate release skill from the 0.1 s duration prior to (X) and after release (Y) from the following equation:

$$\text{Reduction in muscle activity} = 1 - Y/X \quad (1)$$

Mean scores and SD's (standard deviation) in amplitude and reduction level for back and shoulder muscles were calculated for each subject's shots under both fast and normal releasing rhythms. T-tests assuming independent samples were used for each participant to assess differences between the two release rhythms. A probability of  $\alpha=0.05$  was selected to indicate statistical significance.

### RESULTS AND DISCUSSION

For the elite archer, the electromyographic amplitude of right upper trapezius and left deltoid activity from anchoring to release was significantly different between fast and normal releasing rhythms (Table 1). The elite archer used more of the right upper trapezius in drawing the bow, and less of the left deltoid controlling the bow in fast releasing. For the subelite archer, the left lower trapezius, left deltoid, and right upper

**Table 1** The amplitude of muscle activity during anchoring for archers using two different releasing rhythms.

Fast VS Normal	Left lower Trapezius	Right Lower Trapezius	Left Deltoid	Right Deltoid	Right Upper Trapezius	Right Wrist Extensor
Elite Archer	none	none	*(N>F)	none	*(F>N)	none
Sub Elite Archer	*(F>N)	none	*(F>N)	none	*(F>N)	none

$\alpha < .05$  (F=Fast; N=normal)

**Table 2** Reduction level of muscle activation at release for archers using two different releasing rhythms

Reduction level (F Vs N)	Left lower Trapezius	Right Lower Trapezius	Left Deltoid	Right Deltoid	Right Upper Trapezius	Right Wrist Extensor
Elite Archer	none	none	none	*(F>N)	none	none
Sub Elite Archer	none	none	none	none	none	none

$\alpha < .05$  (F=Fast; N=Normal)

trapezius were significantly between the two releasing rhythms. The subelite archer used more muscle activity from the holding hand to supply sufficient power for fast release. Only the right deltoid of the elite archer was significantly between the two releasing rhythms. Overall, there was no strong difference in the reduction level of muscle activity between the two releasing rhythms (Table 2).

### CONCLUSIONS

Compared to the subelite archer, the elite archer presented a greater reduction in muscle activation at release and a more consistent pattern adaptation when using the fast releasing rhythm. The amplitude and reduction level can be useful indices to quantify release skill. These experiments have monitored differences of muscle activation for elite female archers for different releasing rhythm, and also supplied a guide for fast releasing training.

email: [stefano.corazza@stanford.edu](mailto:stefano.corazza@stanford.edu), web: [biomotion.stanford.edu](http://biomotion.stanford.edu)

### INTRODUCTION

In recent years, the development of new techniques for motion capture not involving the use of skin markers is receiving great interest. This is mainly due to several potential advantages that a non-invasive (markerless) technique has over stereophotogrammetry. These are mainly: i) no subject preparation, ii) intrinsically more robust with respect to soft tissue artifacts, and iii) potentially applicable in outdoor environments. A common way of capturing human motion is the construction of visual hulls. Human body segments are typically extracted by employing an articulated model. In this study a model-free approach for extracting human body kinematics from visual hull sequences through Laplacian Eigenmaps is presented.

### METHODS

A virtual gait sequence of 120 frames of a human form was created using Poser (Curious Labs, CA). Visual hulls of different quality using 8, 16 and 64 cameras were created using most favorable camera configurations [1]. Each visual hull was constructed as volume data set with a resolution of 2 cm. Human body segments were identified by mapping visual hulls to a multi-dimensional space through Laplacian Eigenmaps [2,3] (implementation code by Belkin, Surendran, and Bundschoten, University of Chicago). The resulting mapping (location) in the multi-dimensional space was invariant with respect to pose and position in the original Euclidean space, that is the same body segment mapped to the same location. Locations for the head, neck, torso, arms, forearms, hands, thighs, shanks and feet were determined allowing the identification of these segments in all frames in the Euclidean space (Figure 1a). The main geometric axes were calculated, approximating a segment's anatomical axes. Joint angles for the sagittal and frontal plane were calculated as angles between corresponding axes of neighboring segments. Accuracy of human body kinematics was calculated as the average deviation of joints angles derived from visual hulls compared to joints angles derived from the Poser sequence over the gait cycle.

### RESULTS

The accuracy of visual hulls is greatly affected by the number of cameras used [1], which potentially affects body segment identification. Body segments were identified accurately for visual hull sequences constructed using 16 or more cameras. The patterns of sagittal and frontal plane kinematics derived from all visual hulls were very similar to those derived from Poser (Figure 1). The accuracy of hip, knee and ankle flexion-extension and ab-adduction angles for visual hulls constructed using 16 cameras was 1°, 3° and 8°, and 3°, 3° and 5°, respectively.

### DISCUSSION

This study demonstrates the feasibility of accurately measuring 3D human body kinematics using a model-free markerless motion capture system on the basis of visual hulls and Laplacian Eigenmaps. The ankle joint angles are the most critical to measure due to the small size of the foot. The approach can be easily extended to upper limb measurements. The model free approach described here represents an important step towards making markerless motion capture practical, since the total time and manual intervention for a complete analysis are substantially reduced. The presented gait cycle of 120 frames takes approximately 3 hours to be processed in the Matlab code on a 3GHz pc. Limitations of this study are the use of a rigid human form for constructing visual hulls. However, inaccuracies in visual hull construction, might outweigh segment deformations in the living human. Thus, it is expected that similar results will be obtained in experimental set-ups with limitations due to camera calibration and fore-background separation.

## PROXIMO-DISTAL DISTRIBUTION OF MECHANICAL WORK AND CAPACITY FOR ELASTIC ENERGY STORAGE IN THE LIMB JOINTS OF RUNNING GOATS

David V. Lee, M. Polly McGuigan, and Andrew A. Biewener  
Concord Field Station, Harvard University  
email: [dylee@fas.harvard.edu](mailto:dylee@fas.harvard.edu), web: <http://www.oeb.harvard.edu/cfs/>

### INTRODUCTION

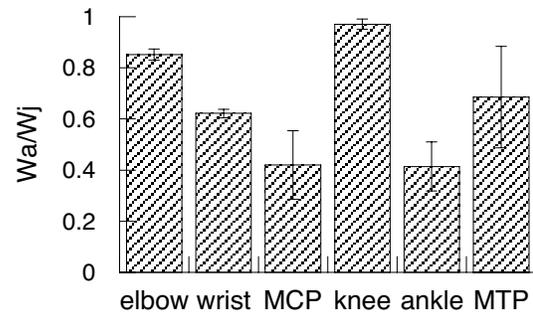

The legs of running animals generally shorten during the first half of stance and lengthen during the second half. In a multi-segment limb, this basic pattern requires flexion (or closing) followed by extension (or opening) of at least some of the joints, thus presenting opportunities for storage and return of elastic strain energy via springs.[1] The Equine metacarpo-phalangeal (MCP) joint provides an elegant example of such a springy joint, the flexion of which is linearly related to the ground reaction force at the foot.[2] In fact, the long digital flexor tendons acting about this joint have almost no capacity to actuate the joint, due to their extremely short muscle fibers. Nevertheless, joints proximal to the MCP (or MTP in the hindlimb) lack these anatomical constraints and are often actuated by muscles with longer fibers and shorter tendons. Here we investigate the joint mechanical work that is done by actuators and that which may be stored and returned. Forelimb (elbow, wrist, and MCP) and hindlimb (knee, ankle, and MTP) joints were measured in running goats and a simple model was used to identify spring and actuator components of joint work. Distal joints were predicted to have greater capacities for elastic energy storage and return than more proximal joints.

### METHODS

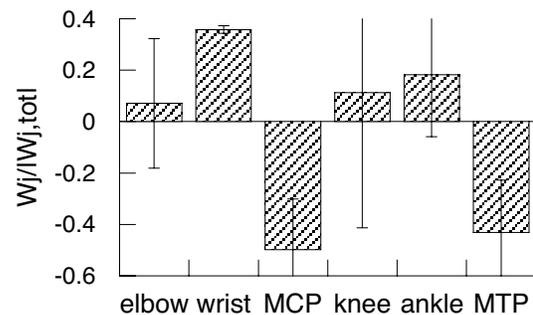

Three goats were run at various speeds across a pair of force platforms in series and ground reaction forces were recorded at 2,400 Hz. Concomitantly, an infrared motion capture system tracked joint and trunk positions at 240 Hz. Joint angles were determined from motion capture data and joint moments were given by the cross product of joint position and ground reaction force vectors. Joint work was determined by integrating the product of joint angular velocity and moment over the stance time of a given footfall. Using measured joint angles and moments, a simple model comprising an in-series rotational actuator and rotational spring was implemented to examine the potential for elastic energy storage and return. This was done by manipulating the spring constant and constraining the actuator to match the experimental joint angles while the experimental joint moments were applied. Searching the parameter space produced a spring constant that minimized positive + negative actuator work. Expressing this rectified actuator work as a fraction of rectified joint work provides a useful index of the actuator work contribution.

### RESULTS AND DISCUSSION

As expected, the proximal most joints investigated (i.e., the elbow and knee) showed the greatest actuator contributions (values > 0.80) (Figure 1). The MCP and ankle showed the smallest actuator contributions (approximately 0.40), indicating substantial elastic energy storage and return (Figure 1). Surprisingly, similarly low values were not observed in

**Figure 1:** Ratio of rectified actuator work to rectified joint work in three forelimb and three hindlimb joints. Smaller values indicate greater spring contributions. Error bars show 95% confidence intervals.

**Figure 2:** Ratio of joint work to the sum of joint work magnitudes across the three joints of the forelimb or hindlimb. Error bars show 95% confidence intervals.

the MTP, the distal most hindlimb joint. The wrist and MTP showed intermediate actuator contributions between 0.60 and 0.70 (Figure 1). This may be due in part to the function of the MTP as a damper, although the MCP also shows substantial negative net work (Figure 2). In contrast, the wrist shows substantial positive net work, while the elbow, knee, and ankle do little net work (Figure 2).

### CONCLUSIONS

Greater actuator contributions were found at the more proximal joints. Although the joints with the greatest capacity for elastic energy storage were a distal (MCP) and a mid (ankle) joint, the predicted proximo-distal pattern generally held.

## TRANSFER OF ANGULAR MOMENTUM IN THE BASEBALL BATTING

Tomohisa Miyanishi

Faculty of Physical Education, Sendai College, Miyagi, Japan  
 email: tm-miyanishi@scn.ac.jp, web: www.sendaidaigaku.jp

### INTRODUCTION

In a full swing batting motion, one of the most important factors should be to obtain a large amount of angular momentum from the ground, and then transfer as much of it as possible to the batting arms and also bat. Angular momentum for the combined batter-plus-bat system can be separated into two parts, associated respectively with the motions of the body-minus-batting arms (“body-minus-arms”) and of the batting arms-plus-bat (“arms-plus-bat”). The purpose of this study was to clarify the changes in the angular momentum for the system during the baseball batting, and the transmission of angular momentum to the arms-plus-bat system.

### METHODS

After the take-off of the lead leg (LOF), a right-handed batter elevates the lead leg and turns the trunk toward the right, steps forward, plants the lead leg (LON), and impacts the ball (IMP) in general. The batter is in single-support (SS) phase between LOF and LON, and in double-support (DS) phase between LON and IMP. Batting motions with maximum effort by eight right-handed male varsity batters were videotaped using three-dimensional (3D) DLT procedures. The 3D coordinate data of the 21 body landmarks, the 2 bat’s portions (tip and tail) and the ball center were obtained for the best battings (hit a ball squarely toward a center field) of each subject, and smoothed using quintic spline as selected by the optimal cutoff frequencies for each coordinate [3]. The coordinates were expressed in an orthogonal reference frame: The X axis pointed toward the right (normal to the direction of pitcher’s mound), the Y axis the pitcher’s mound, and the Z axis upward. The angular momentum values of 16 body segments and of the bat were calculated using a method based on previous study [1]. The location of the center of mass and the moment of inertia about the transversal axis of bat were measured using the balance and pendulum methods, respectively. The SS and DS phases were each divided into two equal time periods. The 3D angular momentum of the body-minus-arms, arms-plus-bat and combined system were calculated for five instants: (1) LOF, (2) the mid-point of SS, (3) LON, (4) the mid-point of DS, and (5) IMP.

### RESULTS AND DISCUSSION

Average angular momentum values for the eight swings are shown in Table 1. To facilitate the following discussion, the terms “clockwise” (CW) and “counterclockwise” (CCW) will replace the signs of the X, Y and Z angular momentum components; the directions will correspond to views from the right, from behind and from overhead for the H<sub>x</sub>, H<sub>y</sub> and H<sub>z</sub> angular momentum components, respectively.

**Table 1.** Angular momentum (kg·m<sup>2</sup>/s). (M±SD)

Times:	1	2	3	4	5
	LOF		LON		IMP
<b>H<sub>x</sub></b>					
body-minus-arms	1±2	1±2	1±3	3±4	3±4
arms-plus-bat	0±0	0±0	2±1	1±1	3±1
system	1±2	1±2	3±3	3±3	6±4
<b>H<sub>y</sub></b>					
body-minus-arms	-1±3	0±3	2±4	1±3	3±3
arms-plus-bat	-1±1	-1±1	0±1	4±1	-3±2
system	-2±3	-1±2	2±4	5±3	0±4
<b>H<sub>z</sub></b>					
body-minus-arms	-2±1	0±2	4±2	9±2	3±2
arms-plus-bat	0±1	-1±0	0±1	8±2	21±4
system	-2±2	0±2	4±2	17±2	23±4

Note: Some of the values in this table may not fit perfectly with each other, because of rounding off.

The changes of the system angular momentums depend on the angular impulses of the ground reaction forces (GRFs) received by the batter’s feet. The changes in the system H<sub>x</sub> and H<sub>y</sub> values were much smaller than those of the system H<sub>z</sub> value because little angular momentum was needed in these directions. Therefore, in this discussion, we will concentrate on the changes in the H<sub>z</sub> value.

At LOF the system had a CW H<sub>z</sub> of 2 kg·m<sup>2</sup>/s. This value changed to a CCW H<sub>z</sub> of 4 kg·m<sup>2</sup>/s at LON. Since the GRF in the XY plane pointed rightward (toward a catcher) of both feet before LOF and leftward (toward a pitcher) of pivot foot after LOF [2], the change of the H<sub>z</sub> was produced by the horizontal GRF. The change from a CCW H<sub>z</sub> of 4 kg·m<sup>2</sup>/s at LON to a CCW H<sub>z</sub> of 23 kg·m<sup>2</sup>/s at IMP was produced by the backward and rightward GRFs of lead foot and also the forward and leftward GRFs of pivot foot during the DS [2].

At LOF, all the H<sub>z</sub> of the system was in the body-minus-arms, and most of the changes produced in the CCW H<sub>z</sub> during the SS by the GRF also went into the body-minus-arms. During the 1st half of DS there was a gain of H<sub>z</sub>, half of which was transmitted from the ground through the legs and trunk to the batting arms and also was generated by the legs and trunk, the remains was generated by the batting arms. During the 2nd half of DS there was a gain of H<sub>z</sub>, most of which was generated by the arms and bat.

## Optimal or Antagonistic? Muscle force solutions in the lower limb.

<sup>1</sup> Stansfield BW, <sup>1</sup> Nicol AC, <sup>1</sup> Paul JP, <sup>2</sup> Graichen F and <sup>2</sup> Bergmann G

<sup>1</sup> Bioengineering Unit, University of Strathclyde; email: [benedict.stansfield@strath.ac.uk](mailto:benedict.stansfield@strath.ac.uk)

<sup>2</sup> Biomechanics Lab., Charité - University Medicine Berlin; web: [www.biomechanik.de](http://www.biomechanik.de)

### INTRODUCTION

The musculature of the lower limb is redundant in nature. When calculating the muscle forces using a mathematical musculo-skeletal model it is necessary to select a criterion for muscle force distribution. For example, optimization may be used to minimize the sum of muscle forces, or minimize the maximum muscle stress. One method of validating these internal force distribution calculations is to use internal force measurements made with instrumented implants [2,4].

The current paper provides evidence of the appropriateness of various muscle force distribution protocols in a musculoskeletal model of the lower limb [1]. Calculated hip joint contact forces (HJCF) are directly compared with simultaneously acquired *in vivo* loads.

### METHODS

HJCF were measured *in-vivo* using instrumented femoral prostheses [3,4]. These measures provided the 'gold standard' for comparison with calculated forces. HJCF were calculated using a lower limb musculoskeletal model [1]. This model described the 3D anatomy of the lower limb including hip, knee and ankle. Inverse dynamic methods were applied to motion and force plate data. Two subjects took part in various tasks and results are presented for one male (170.4cm, 92.3kg, 58 years, 36 months post-op., right side THR). The calculations of HJCF during one typical walking trial are examined here.

The muscle force distribution problem was solved using four different optimization criteria (C):

- C1. Minimization of the sum of muscle forces
- C2. Minimization of the sum of the square of muscle forces
- C3. Minimization of the sum of the cube of muscle forces
- C4. Minimization of the maximum muscle stress

### RESULTS AND DISCUSSION

Figure 1 provides a comparison of HJCF calculated using the musculoskeletal model with forces simultaneously measured, using the instrumented implants. The forces are illustrated in an axis set attached to the femur with neutral orientation based on radiographs incorporating femoral neck anteversion.

Direct comparison of the calculated and measured forces illustrates a number of points:

- It was possible to provide a muscle force solution that satisfied equilibrium, but that consistently underestimated HJCF (C1) suggesting that the physiological solution does not use minimization of joint force as a criterion.
- Although solutions exist that 'optimize' criteria associated with muscle force, none of those used provided consistent agreement with the measured forces, e.g. C4 overestimated at some points in the gait cycle and underestimated at others.

- All criteria underestimated the HJCF during late stance suggesting that the body uses antagonism to provide extra stabilization at the joints during this phase of walking, or that the hip joint was hyper extended producing force in the ilio-femoral ligament that was not accounted for in the model.

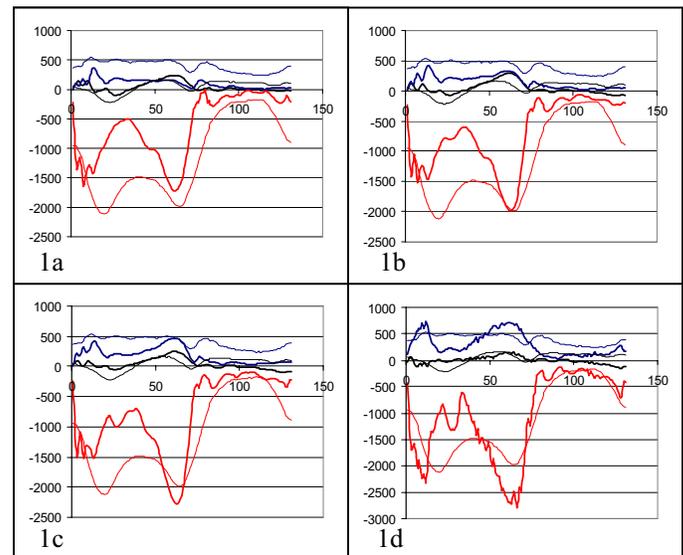

Figure 1 Calculated (thick lines) and measured (thin lines) HJCF (Newtons force vs. samples at 120Hz). Black – X (anterior-posterior); Red – Y (femoral long axis), Blue – Z (medio-lateral). 1a) C1; 1b) C2; 1c) C3; 1d) C4.

### CONCLUSIONS

Although the authors recognize the significant contribution of the musculoskeletal model in determining HJCF, the results suggest that the physiological solution to the redundancy problem is not to operate an optimal criterion aligned with any of those investigated.

The results also suggested that the body uses a degree of antagonism above that required to provide stability at certain instances during the walking cycle or, as at the knee, moments may be transmitted by forces in ligaments.

## JOINT VELOCITY SEQUENCE OF THE UPPER EXTREMITY DURING FLY-CASTING

<sup>1</sup> Katie B. O’Keefe, <sup>1</sup> Joshua R. Allen, <sup>2</sup> Timothy J. McCue and <sup>1</sup> Michael E. Hahn  
<sup>1</sup> Movement Science Laboratory, Montana State University, Bozeman, MT, USA  
<sup>2</sup> Fly Casting Institute, Missoula, MT, USA  
 email: [mhahn@montana.edu](mailto:mhahn@montana.edu)

### INTRODUCTION

Segmental chain analysis of the upper extremity can contribute to a deeper understanding of the coordination and control strategies used during overhand throwing tasks. The fly-casting stroke parallels throwing tasks in that the ultimate goal is accurate placement of a projectile at some distance from the body. Previous studies have shown differences in the sequence of peak joint velocities, based on the skill vs. power required for the task [1,2]. The focus of this study is to determine whether upper extremity sequencing during fly-casting is proximal-distal or distal-proximal. Establishing the order of sequence should add to the basic understanding of coordination involved in fly-casting.

### METHODS

The sample consisted of six subjects (five males, one female) ranging in age from 22 to 38. Each subject signed an informed consent and was medically evaluated for upper extremity health. Within the medical evaluation, subjects were asked to state the number of days spent fly-fishing per year. Responses varied from 3 days/year to over 100 days/year indicating a variety of experience. Segments of the upper body were defined by 25 spherical, reflective markers placed on bony landmarks (adapted from Rab et al. [3]). Marker position data were collected at 200 Hz using a 6-camera Vicon 460 system (Vicon Motion Systems, Lake Forest, CA).

Subjects were required to perform a series of casting trials, including 23 “false casts” followed by the “shooting” cast. The shooting cast from each of three trials was evaluated for each subject.

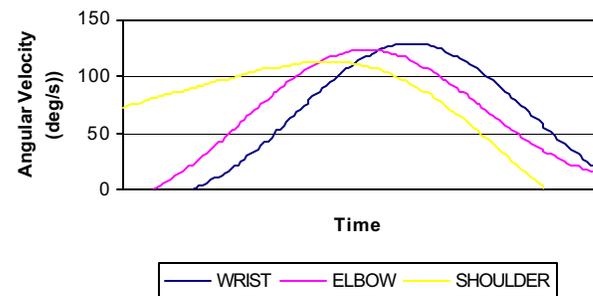

The upper extremity was modeled as a system of rigid bodies connected by pin joints. The wrist was modeled with a two-axis pin joint, the elbow as a one-axis pin joint, and the shoulder as a three-axis ball and socket joint. Time and magnitude of peak angular velocities were examined during the forward cast. Angular velocities were calculated using the central difference method and smoothed with a 4<sup>th</sup> order Butterworth low pass filter (cutoff = 2Hz). The peak velocities examined included shoulder internal rotation, elbow extension, and wrist ulnar deviation.

### RESULTS AND DISCUSSION

The motion of fly-casting includes a back cast in which the line is lifted and brought behind the caster followed by a pause. During the pause, the line is drawn behind the caster

due to the inertial force. This causes the line to load the rod at which point the caster will enter the forward cast. It is during this last phase that the line is directed to the target.

Segmental chain analysis revealed a pattern of proximal-to-distal motion of the upper extremity during the final forward casting phase. Figure 1 shows an example trial of the peak wrist, elbow and shoulder velocities as they occurred during the forward cast. Overall, the shoulder velocity peaked at an average of 80.5% ( $\pm$  8.5%) of the total casting time, elbow velocity at 86.3% ( $\pm$  8.3%), and wrist velocity at 89.1% ( $\pm$  8.8%). Each subject’s time to peak velocity is presented in Table 1.

**Figure 1:** Peak angular velocities during the forward cast.

Peak velocities generally corresponded to the expertise of the fly-caster. Those who fished 10 days/year or less were more likely to have a wrist velocity much higher than shoulder or elbow velocities and those who were more experienced (i.e. fishing guides) had a much higher shoulder velocity.

### CONCLUSIONS

Initial findings of this study indicate a proximal-to-distal sequence for angular velocities of the upper extremity joints during fly-casting. Though generally considered a skill-driven motion, a secondary goal is to produce high line velocities during the forward cast. This goal may require a more forceful coordination sequence similar to overhand throwing.

## Biomechanical and physiological determinants of skiing locomotion development

Formenti F., Ardigo' L.P., Minetti A.E.

Manchester Metropolitan University, Institute for Biophysical and Clinical Research into Human Movement  
e-mail: [f.formenti@mmu.ac.uk](mailto:f.formenti@mmu.ac.uk), web: [www.cheshire.mmu.ac.uk/exspsci/research/biomech/Biomech.html](http://www.cheshire.mmu.ac.uk/exspsci/research/biomech/Biomech.html)

### INTRODUCTION

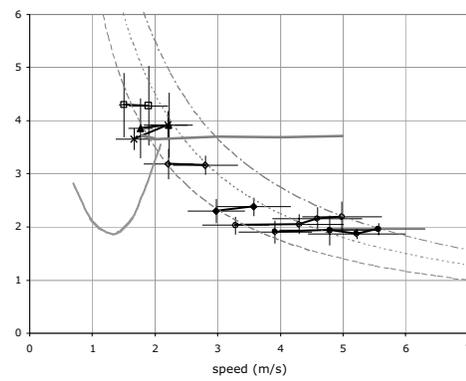

How far could man travel on snow five thousand years ago? What did man empirically understand to be the limiting factors for his skiing performance, from its very beginning to date? Very little research focused on the biomechanics and physiology of the development of cross-country skiing [1]. In the present study the evolution of skiing locomotion from 3000 BC to date is explored by investigating how humans adapted to move effectively in lands where a cover of snow, for several months every year, prevented from travelling as effectively as on dry ground. Following historical research, a few sets of skis were identified as the 'milestones' of skiing evolution in terms of ingenuity and technology. Their replicas were built and the metabolic energy associated to their use was measured in a climatic-controlled tunnel.

### METHODS

Seven sets of skis were tested, covering a span of about five thousand years. Original archaeological specimens could not be used for the present study, so accurate reproductions of the originals were made (Department of Design and Technology – MMU, Cheshire). Experiments took place at the Vuokatti ski tunnel, Finland, where temperature (mean±s.d., air  $-5.2\pm 1.1$  °C, snow  $-4.5\pm 0.5$  °C, n=115) and humidity ( $83.6\pm 1.4$  %, n=115) are monitored and controlled 24 hours a day by a computer controlled air conditioning system. Five healthy adult non-professional skiers took part in the experiments (age  $33.8\pm 11.8$  years, stature  $176\pm 2.8$  cm and body mass  $73.0\pm 4.8$  kg). Participants were requested to adopt two subjectively chosen speeds, the former defined as sustainable for 7 to 8 hours ('migration'), the latter for just 3 to 4 hours ('hunting'). When skiing with the 2004 AD models (classical and skating techniques) participants travelled at two additional faster speeds, the fastest being 70% of their maximum speed. Participants were equipped with a portable metabograph (Cosmed K4b2) that measured their heart rate (HR) ( $b\ min^{-1}$ ), carbon dioxide output (VCO<sub>2</sub>) ( $l\ min^{-1}$ ) and oxygen uptake (VO<sub>2</sub>) ( $l\ min^{-1}$ ) on a breath-by-breath basis. Oxygen uptake at rest was measured and was used to calculate the net oxygen consumption for skiing with each set of skis. VO<sub>2</sub> measurements (mlO<sub>2</sub>) were converted into equivalent units (J) according to the obtained respiratory quotient coefficient [2]. The metabolic cost of skiing (J/(kg m)) was calculated by integrating the net oxygen consumption over each trial duration and dividing it by the length of the track (2.5 km) and by the (body) mass. Kinematic variables relative to the skiers' movement were recorded by means of inertial sensors (MT9, Xsens) placed on the skiers' right thigh and shank. A stride has been defined as the distance/time between the ends of two successive kicks performed by the same leg. Euler angles from the data recorded on the legs were used to calculate the stride frequency (Hz) and estimate the internal work [3]. Ski friction was measured for all the pairs of skis by means of two inertial sensors during passive deceleration manoeuvres.

### RESULTS AND DISCUSSION

The decision to perform the experiments in the ski tunnel allowed recording data in standard conditions, hence reducing to a minimum the variability due to temperature changes. Results from the present study show that: a) for the same amount of metabolic power today it is possible to travel at twice the speed of ancient times (Figure 1) and b) the cost of transport is speed-independent for each ski model. By combining this finding with the physiological relationship between time of exhaustion and the fraction of sustainable metabolic power [4], a prediction of the maximum skiing speed according to the distance travelled is provided for all past epochs and can predict with a good precision modern competitions.

**Figure 1:** the metabolic cost (J/kg m) of skiing is here plotted against the speed for all the investigated skis. For sake of comparison, lines reporting walking and running costs are shown (walking in the tunnel is represented by the grey circle). Iso-power curves show the power chosen by participants.

Total stride length increased from 14.0% to 60.5% in the chronological ski sequence. We did not directly measure the 'body centre of mass' part of the external mechanical work, but it is expected to decrease along skiing history since the increase in the sliding length will allow distributing the raise of the body centre of mass across a longer distance. This was confirmed (-86.8%) when we calculated an 'estimated version' of it by subtracting from the measured cost the metabolic equivalent of both the work against friction and the internal work.

### CONCLUSIONS

Results from the present study will help historians to understand the times needed and distances covered during migrations in cold regions in the past. Our research shows that the performances of two legendary historical journeys (1206 and 1520 AD) on snow, the performances of races originating from them (Birkebeiner and Vasaloppet) and those of other modern competitions (skating vs. classical techniques) are well predicted by the evolution of skiing economy.

## SIMULATION OF LONGITUDINAL ARTERIAL STRETCH IN THE LOWER LIMBS DURING GAIT

Richard J. Beck, Antonie J. van den Bogert, Azita Tajaddini, and Brian L. Davis  
Biomedical Engineering Department, Cleveland Clinic Foundation, Cleveland, OH  
email: becker2@ccf.org

### INTRODUCTION

Peripheral arterial disease is common in patients with diabetes and is a major risk factor in the etiology of gangrenous lesions that can, in turn, lead to lower extremity amputations. Correction of stenosis using stents can maintain patency in affected vessels; however, these devices are susceptible to mechanical problems. A fractured strut within a stent can initialize new obstructions in the lumen. The incidence of fractures corresponds to the length of the stented segment and the number of implants [1].

The present study was based on the hypothesis that activities of daily living impose longitudinal stretch on arteries traversing the hip and knee regions, and that this elongation may play a role in stent failure. Thus the purpose of the current study was to estimate arterial stretch during gait and to relate this to joint excursions.

Figure 1: Views of the adapted SIMM graphical model.

### METHODS

Using SIMM (Software for Interactive Musculoskeletal Modeling, V.4.0.1, MusculoGraphics, Inc., Motion Analysis Corp., Santa Rosa, CA), a model of the lower extremity was modified to include representatives of the iliac, femoral, and popliteal arteries. This software sets realistic geometrical constraints on muscle objects by conforming the muscle length and orientation to the motion of the bones [2]. An object created as a muscle and placed in the location of an artery will follow the same geometric rules. Using a SIMM leg model of an adult subject with height of about 1.8 meters and weight of about 75 kg, attention was given to the general anatomical route of the vessels. The mechanical anchor that perivascular connective tissue provides was modeled as origin and insertion. The arteries are subjected to the influence of residual strain and constant tension, therefore the resting lengths of the model arteries are assumed to be identical to the resting lengths of the surrounding muscles.

To demonstrate iliofemoral stretch, a new digital muscle was created, with origin in the sacral region and insertion on the proximal tibia (Figure 1). The SIMM default placements of the medial and lateral heads of the gastrocnemius were used to model the popliteal artery (Figure 1). For both iliofemoral and

popliteal regions, the relationship of arterial length as a function of the gait cycle was predicted using SIMM.

### RESULTS AND DISCUSSION

Plots generated from SIMM indicate the estimated length change for the iliac and femoral arteries together to be about 2.5 cm (Figure 2A). Likewise, the popliteal artery stretches an estimated 4 cm (Figure 2B). These geometrical demands associated with normal gait illustrate the necessity for compliance in vascular tissue. Modern stents and vascular tissue have dissimilar properties, providing undesirable stresses at their interface. Arterial stretch may therefore play an important role in stent failure.

Limitations of the current approach include (i) selecting origin and insertion points that may not replicate normal anatomy, (ii) restricting the analysis to gait, (iii) modeling a single subject, (iv) estimating global rather than local stretch, and (v) including wrapping surfaces that may not replicate the exact course of an artery. Nevertheless, predictions from the model suggest that lower extremity arteries undergo substantial longitudinal stretch, and that stent and vascular graft designers should be cognizant of these biomechanical demands.

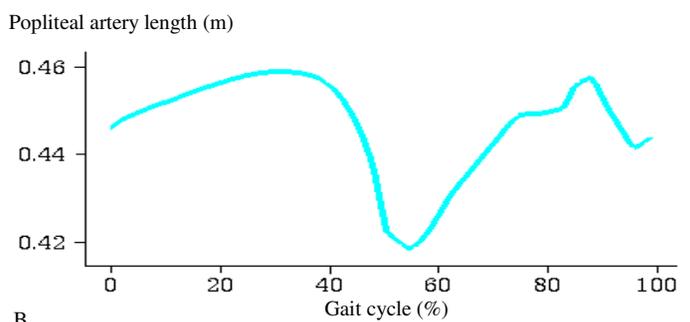

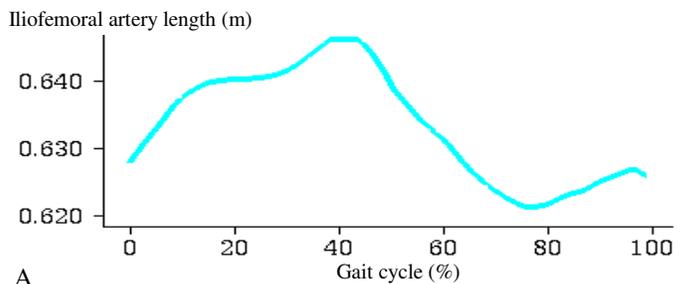

Figure 2: Iliofemoral length (A) and Popliteal length (B) plots from the SIMM model.

## CALIBRATION AND MONITORING OF PIEZORESISTIVE CONTACT STRESS SENSOR ARRAYS USING A TRAVELLING PRESSURE WAVE PROTOCOL

<sup>1</sup>Thomas E Baer, <sup>1</sup>Douglas R Pedersen, <sup>1</sup>M James Rudert, <sup>1</sup>Nicole A Kallemeyn, <sup>1</sup>Nicole M Grosland, <sup>1</sup>Thomas D Brown  
<sup>1</sup>University of Iowa, Iowa City, IA, email: [thomas-baer@uiowa.edu](mailto:thomas-baer@uiowa.edu) web: <http://mnypt.obrl.uiowa.edu>

### INTRODUCTION

To improve the accuracy and efficiency of measuring the distributions of intra-articular contact stresses during dynamic loading of cadaveric joint specimens, a novel hardware and software regime has been developed for calibrating Tekscan sensors.

In many experiments measuring contact stress, especially those involving cadaveric joints with malreduced fractures or total joint replacement prostheses, high localized stresses lead to significant local changes in sensor responses during a given testing session. The ability to easily and frequently recalibrate sensors is therefore desirable.

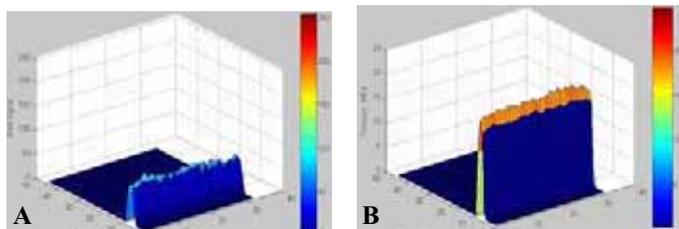

**Figure 1.** The calibration device with a sensor between the rollers.

### METHODS

To meet this challenge, a novel “wringer” device was built (Figure 1). Regulated air pressure applies a known force across a pair of elastomeric rollers. As the sensor is drawn between them, a traveling pressure wave is recorded (Figure 2A). Passage of the wave over each sensel is recorded as a time series signal. A finite element solution of the contact between parallel elastic cylinders provides a normalized distribution of pressure as a function of contact patch width.

The spatial position of every sensel within the contact patch is known, allowing local pressures at every point in time to be based on the FE solution. A provisional calibration is derived using iterative power law curve fitting to the sensel-specific signal-pressure data arrays.

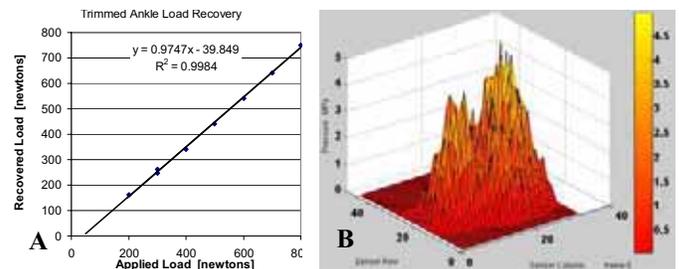

**Figure 2.** Traveling wave of raw (A) and pressure calibrated (B)

In these sensors, the area of the active pressure sensing elements constitute only about 10 percent of the total area over which the pressure is calculated. Calibration therefore depends

on the distribution of load between sensing and non-sensing areas of the sensel and is strongly affected by the compliance of the surfaces between which the sensors are used.

After the provisional calibration, a sensor was inserted into a joint specially prepared so that all the load across it is carried by the sensor, and the calibration was “fine-tuned” at a series of known loads to the specific surface compliance properties of the joint’s intra-articular environment. A *cartilage tuning factor* of 1.36 (the ratio of load applied to load recovered using the provisional calibration) was then used to adjust the provisional curves for each sensel. (Figure 3A). These final calibration curves were applied to eight other ankle loading experiments (Figure 3B).

**Figure 3.** (A) Recovered load versus applied load is linear. (B) Pressure distribution in a cadaveric ankle loaded to 800N.

### RESULTS AND DISCUSSION

The traveling wave technique serially calibrates the entire array of piezoresistive sensing elements over its full functional range while obviating the prohibitively high forces required for calibration using conventional whole-sensor-loading techniques.

At intervals during a typical experimental session, the sensor is removed from the joint and run through the device. Using the tuning factor already calculated, an updated calibration is calculated for each sensel. The sensor is then placed back in the joint and the experiment continues. If too much change (implicitly degradation) is seen to have occurred, the sensor is replaced. With minimal disruption of the protocol, the sensor’s performance can be evaluated as often as desired during the course of an experiment. Data that might otherwise be lost to sensor artifacts can be saved by these on-the-fly recalibrations.

### CONCLUSIONS

The manufacturer’s calibration procedure, which restricts sensel loadings to the low end of the functional range and cannot provide sensel-by-sensel calibrations, may be problematic in many research environments. The new device and method effectively overcome these limitations.

### INTRODUCTION

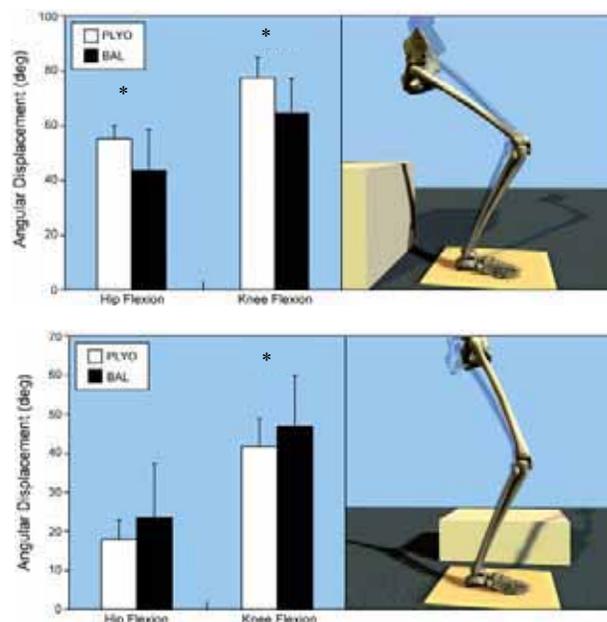

Females who participate in pivoting and jumping sports suffer anterior cruciate ligament (ACL) injuries at a 4 to 6-fold greater rate than males participating in the same sports. Neuromuscular training protocols that combine plyometric and dynamic stabilization and balance exercise components have been shown to significantly alter potentially hazardous lower limb biomechanics and reduce ACL injury risk in female athletes [1-4]. Currently, no studies have compared the effects of plyometric and dynamic stabilization training as a means to delineate the mechanism behind the successful modification of female biomechanics linked to ACL injury risk. The purpose of the current study was to compare the effects of maximum effort plyometric training (PLYO) versus dynamic stabilization and balance training (BAL) on female lower extremity kinematics during a drop vertical jump (DVJ) and a single leg medial drop landing (MDL). Specifically, we examined the effects of each training mode on resultant frontal and sagittal plane motions during each of these tasks, which incorporate potential high-risk neuromuscular control effects[1, 3].

### METHODS

Eighteen high school female athletes were randomized into one of two (BAL or PLYO) training (3 X/week) regimens for 7 weeks. The BAL (n=10) group performed dynamic stabilization and balance exercises and the PLYO (n=8) group performed maximum effort jumping and cutting tasks during training. Subjects had lower extremity (bi-lateral) three-dimensional (3D) kinematics data recorded during the execution of three DVJ and three MDL tasks, pre and post training. The 3D coordinates of external skin markers were recorded at 240 HZ during each trial using a high-speed motion analysis system (Motion Analysis, Santa Rosa CA). These data were submitted to Mocap Solver 6.17 to solve for each lower limb rotational degree of freedom. Ground reaction force data for each leg were collected at 1200Hz via AMTI force plates and used to normalize joint kinematic data to stance. Coronal and sagittal plane kinematics were calculated for the hip, knee and ankle. A mixed design ANOVA was utilized to test for the main effects of gender, task and side with alpha level of 0.05.

### RESULTS AND DISCUSSION

During the DVJ, both PLYO and BAL training reduced initial contact (IC) ( $p=0.002$ ), and maximum hip adduction angle ( $p=0.015$ ) and maximum ankle abduction angle ( $p=0.02$ ). When performing the MDL, both groups decreased IC ( $p=0.002$ ) and maximum knee abduction angle during stance ( $p=0.038$ ). While each training approach had a similar impact on coronal plane measures, distinct training effect differences were observed for the sagittal plane. Specifically for PLYO training significantly increased maximum hip ( $p=0.041$ ) and knee ( $p=0.031$ ) flexion during DVJ tasks but not during the MDL (Figure 1A). Conversely, BAL training increased knee

**Figure 1.** Effect of BAL (solid) and PLYO (transparent) training on hip and knee flexion during (A) DVJ and (B) MDL tasks.

( $p=0.005$ ) flexion during the MDL but not during the DVJ (Figure 1B). The results of the current study demonstrate that a reduction in lower limb dynamic valgus can be achieved via both PLYO and BAL training. The impact of each type of training exercise on potential sagittal plane risk factors however, appear to be most pronounced during movement tasks that incorporate similar underlying neuromuscular requirements (plyometric versus stabilization). If the ACL injury mechanisms is indeed governed by both coronal and sagittal neuromuscular factors therefore, then the inclusion of both BAL and PLYO training components appear warranted

### CONCLUSIONS

The results of the current study do not support excluding either plyometrics or dynamic stabilization exercises from an ACL injury prevention protocol. Future research should evaluate whether the combinatorial effects of these training methods in more detail to maximize both risk prevention and athlete compliance. Additionally, further investigation into the role of athlete awareness of potentially dangerous positions and feedback during dynamic tasks is warranted.

## MECHANOBIOLOGICAL INFLUENCES ON ENDOGENEOUS BONE TISSUE ENGINEERING STRATEGIES

<sup>1,3</sup>Kreuzer, S, <sup>1</sup>Ritzman, TF, <sup>1</sup>Knothe, UR, <sup>2</sup>Schneider E, <sup>1,3</sup>Knothe Tate, ML

<sup>1</sup>Orthopaedic Research Center, The Cleveland Clinic Foundation, Cleveland, OH; <sup>2</sup>AO ASIF Research Institute, Davos, CH; <sup>3</sup>Depts. of Mechanical & Aerospace and Biomedical Engineering, Case Western Reserve University, Cleveland, OH

### INTRODUCTION

In this study we implemented a previously developed surgical model [1, Figure] to quantify specific mechanobiological influences on endogeneous bone tissue engineering strategies.

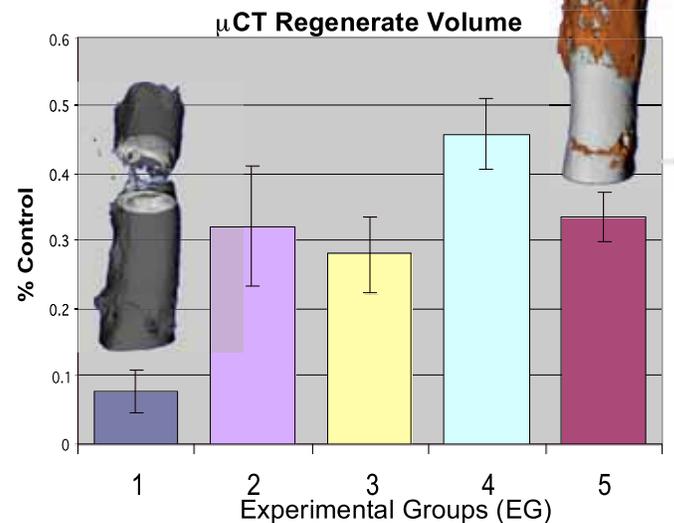

This surgical model allows for osteogenesis, osteoconduction and osteoinduction to take place *in situ*. The **periosteum** serves as a source of osteoprogenitor cells and osteoblastic precursors as well as a well-vascularized tissue bed. The periosteal sleeve also acts as a barrier to ingrowth of fibrous granulation tissue and allows for establishment of chemical gradients, *e.g.* of osteogenic substances, that otherwise could diffuse out to the surrounding soft tissue. In addition, use of vascularized and/or morcellized **bone grafts** may provide osteoblasts for *de novo* bone generation, a scaffold for osteoconduction and/or release of osteoinductive substances from the bony matrix of the host graft. Finally, an intramedullary nail provide mechanical stability for the entire construct. In implementing this model, we aimed to elucidate the influence of mechanics, availability of osteoprogenitor cells (from the periosteum), and autologous bone graft on density and spatial distribution of bone tissue regenerate.

### METHODS

An ovine femur model was implemented with a critical size (2.6 cm) diaphyseal defect in skeletally mature, females ( $n = 35$ )<sup>‡</sup>. The periosteum was elevated circumferentially off the proximal femoral diaphysis adjacent to the defect. The healthy “donor” bone was then osteotomized (Fig A) and transported distally over a retrograde IM nail to fill the defect (Fig B), thereby creating a new defect around which the healthy periosteum was sutured to form a sleeve (Fig C). The entire construct was stabilized with a custom made, interlocking, retrograde IM nail. Five groups of 7 sheep were investigated. In the control group, no periosteal sleeve enveloped the defect. The sleeve alone enveloped the defect in a 2<sup>nd</sup> group. Autogenous cancellous bone graft was placed within the sleeve of the 3<sup>rd</sup> group. Vascularized bone chips were left adhering to the periosteum in the 4<sup>th</sup> group. Bone graft and adherent bone chips were included in the 5<sup>th</sup> group.

<sup>‡</sup>All animal protocols were approved by the IACUC.

Mean density and spatial distribution of bone regenerate were calculated from high-resolution (20  $\mu\text{m}$ )  $\mu\text{-CT}$  data sets (Scanco Medical, Bassersdorf, Switzerland). Inter-group differences were assessed using ANOVA and Fisher’s protected least significant difference (PLSD) post-hoc tests (StatView, SAS Institute, Inc., Cary, NC). A  $p\text{-value} < 0.05$  was considered to be statistically significant.

### RESULTS AND DISCUSSION

All groups in which the periosteal sleeve was retained (EG 2-5, Fig.) exhibited significantly greater *volume of regenerate bone* within the defect zone than the group without periosteal sleeve (EG 1, Fig.,  $p < 0.0001$ ). The addition of bone graft (EG 3) in the defect zone did not increase regenerate volume compared to the periosteal sleeve alone (EG 2). The addition of graft (EG 5) in the defect zone resulted in a significantly decrease in regenerate volume compared to the periosteal sleeve with adherent, vascularized bone chips (EG 4). However, the observed increase in regenerate with addition of adherent, vascularized bone chips (EG 4) was not statistically significant, as compared to the periosteal sleeve alone (EG 2). Currently we are measuring the spatial distribution of the regenerate as a function of distance from the blood supply as well as the neutral axis. These data will allow us to colocalize distance to blood supply as well as predominate modes of mechanical loading (via matrix deformation and/or fluid flow) to spatially-resolved regenerate density data.

### CONCLUSIONS

For the first time to our knowledge, this experimental model provides a novel means to elucidate the relative influence of intrinsic and extrinsic factors on successful functional engineering of bone tissue replacements.

## FOOT PROGRESSION ANGLE AND THE KNEE ADDUCTION MOMENT IN INDIVIDUALS WITH MEDIAL KNEE OSTEOARTHRITIS

<sup>1</sup> Kurt Manal and <sup>1</sup>Mengtao Guo

<sup>1</sup>Center for Biomedical Engineering Research, University of Delaware

### INTRODUCTION

Progression of medial knee OA is associated with the external knee adduction moment [1]. Treatments to reduce the magnitude of the moment are therefore indicated for patients with knee OA. Regression analysis has revealed an inverse relationship between the adduction moment and an individual's self-selected foot progression angle (FPA) [2]. No study has examined if walking with a greater than self-selected FPA will further reduce the peak moment in this population. This simple strategy may be an effective method of reducing knee joint loading during activities of daily living for subjects with medial knee OA. The purpose of this study was to examine the effect of increasing FPA on the knee adduction moment during walking, stair ascent and descent in subjects with knee OA.

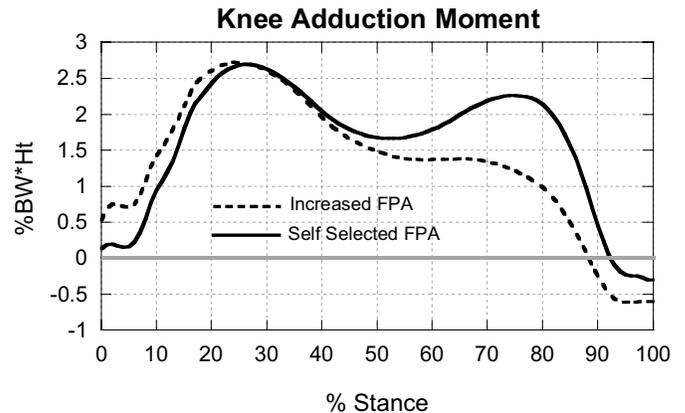

### METHODS

10 subjects with mild to moderate medial compartment knee OA participated in this study (mean age =  $63 \pm 5$  years, weight =  $81.8 \pm 12.7$  kg, height =  $1.68 \pm 0.08$  m). Subjects performed 5 walking, 5 stair ascent and 5 stair descent trials for each of two conditions: (1) self-selected FPA, and (2) increased FPA (self-selected FPA + 15 degrees). Video and force data were collected, and Visual3D (C-motion Inc.) was used to compute the normalized (% BW\*Ht) external knee adduction moment. The knee adduction moment has a characteristic 2 hump pattern (see Figure 1). Dependent t-tests were used to assess the effect of increasing FPA on the 1<sup>st</sup> and 2<sup>nd</sup> peak moments during walking, stair ascent and descent. The 1<sup>st</sup> and 2<sup>nd</sup> peak moments within each task were analyzed separately.

### RESULTS AND DISCUSSION

During walking, the 1<sup>st</sup> peak adduction moment did not change with increasing FPA, but the magnitude of the 2<sup>nd</sup> peak decreased significantly (Table 1). During stair ascent, a strong trend ( $p=0.051$ ) towards a reduced 2<sup>nd</sup> peak adduction moment was noted for the increased FPA condition. The potential benefit of a smaller 2<sup>nd</sup> peak moment however was likely overshadowed by a significantly greater 1<sup>st</sup> peak adduction moment with increased FPA. No differences in the peak moment were noted during stair descent. The results of this study suggest that walking with an increased FPA can reduce the magnitude of the 2<sup>nd</sup> peak knee adduction moment in subjects with knee OA. The adduction moment is an indirect

estimate of joint loading [3], and thus, this finding suggests that walking with an increased FPA can reduce joint contact forces.

**Figure 1.** External knee adduction moment during the stance phase of walking. The magnitude of the 2<sup>nd</sup> peak moment was significantly smaller when walking with an increased FPA.

### CONCLUSIONS

Increasing the degree of toe-out during walking decreased the peak adduction moment and presumably joint contact forces for subjects with medial compartment OA. This strategy may have beneficial effects, however it is premature to assert so at this time because the effect of increasing FPA at other joints, specifically the hip has not addressed. This will be the focus of future work.

## LIGAMENT ESTIMATION FROM *IN VIVO* KNEE MOTION: AN INVERSE-KINEMATICS MODEL

<sup>1</sup>Elvis C.S. Chen and <sup>1,2</sup>Randy E. Ellis

<sup>1</sup>School of Computing, Queen's University, Canada, <sup>2</sup>Harvard Medical School, U.S.A.

### INTRODUCTION

A forward-kinematics knee (FKK) model was previously introduced [1]: given a joint angle, the precise knowledge of the articular geometry plus mechanical properties of knee ligaments, the FKK model predicted where the femoro-tibial contacts were based on the principle of ligament energy-minimization. Knee motion was simulated by finding successive contacts from full extension to full flexion. We now introduce an inverse-kinematics knee (IKK) model that performs the opposite: given an observed knee motion, determine the joint angle and the *in vivo* femoro-tibial contact. The *in vivo* contacts were validated using Fuji-films. Together, the FKK/IKK pair form a *predictor-corrector* loop that can then be used in a parameter-estimation algorithm to find the ligament insertion locations and neutral length of the individual patient.

### METHODS

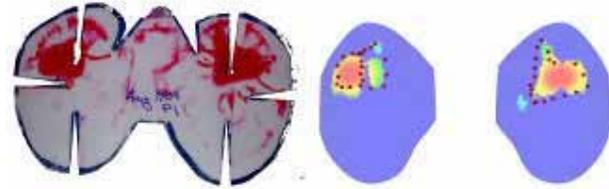

Articular surfaces of a Total Knee Replacement (TKR) prosthesis were laser-scanned at 0.25mm resolution and computer models of the surfaces, in the form of point clouds with surface normals, were reconstructed. TKR components were mounted to a knee-jig in which they were held in contact by tensile forces of 6 springs: 3 mimicking MCL, 3 mimicking LCL. The mechanical properties of each of the 6 springs, including length, spring constant, and insertion location relative to TKR components, were previously measured.

TKR components were attached with Dynamic Reference Bodies and their motion, while in contact with each other, were tracked by a 3D optical tracker. An image-free contact-determination algorithm was developed to find the *in vivo* femoro-tibial contacts. Based on proximity search and facilitated by a KD-tree, this algorithm was able to find the femoro-tibial contact under 1sec for each joint pose. For experiments involving Fuji-films, the entire knee jig was mounted to a FORCE5 manipulator that applied 100lb of downward force to produce imprints on Fuji-films

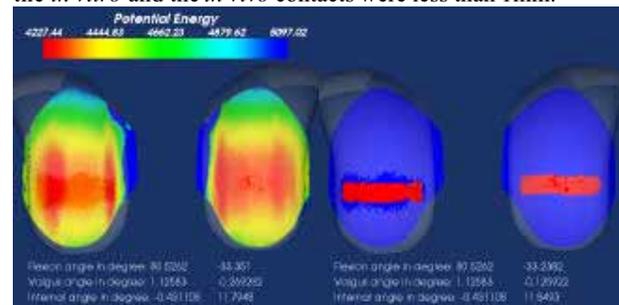

Two sets of contact locations were determined for each joint angle: one *predicted* from the FKK model and the other *observed* from the contact-determination algorithm. Together, they form a *predictor-corrector* pair that can then be fed into a parameter-estimation algorithm, in which the parameters to be estimated were the ligament mechanical properties (neutral length, insertion locations, and spring constant) that would produce the observed knee motion.

### RESULTS AND DISCUSSION

A size-3 Sigma Knee (Johnson & Johnson), represented by approximately 31,000 and 19,000 points for the femoral and tibial components respectively, was used for this study. The contact-determination algorithm was first validated using Fuji-films: the perimeter of the Fuji-film contacts were digitized and superimposed to those found by our algorithm. They showed high degree of conformity.

For each recorded joint pose, the joint angle (without translation), along with known ligament information, were fed to the FKK model. The FKK model produced an *energy map* and regions with the lowest energy were selected as the *in vivo* contact. The same pose was also fed into the contact-determination algorithm and the *in vivo* contact was produced. Numerically, the difference in the translations found between the *in vitro* and the *in vivo* contacts were less than 1mm.

These sets of predicted *in vitro* and observed *in vivo* contacts were then used in a parameter-estimation algorithm in which the ligament information was treated as the unknown. Our implementation was able to correctly estimate the ligament insertions that were intentionally and erroneously guessed at 10mm away from the correct location. The *predictor-corrector* paradigm can also be used to test different hypotheses of ligament model: simulations suggested that a single-fibre ligament model could produce kinematics that was similar to a multi-fibres (3) ligament model in Sigma Knee.

### CONCLUSIONS

We proposed an inverse-kinematics knee model. Combined with a forward-kinematics model, this *predictor-corrector* pair can be used to estimate ligament parameters such as ligament insertions. Furthermore, it can be used to test different hypotheses of the ligament model, based solely from a sequence of *in vivo* knee motion. We also introduced an image-free, nearly real-time contact-determination algorithm. Application includes, but not limited to, post-TKR assessment.

## LASER INDUCED AUTO-FLUORESCENCE (LIAF) AS A METHOD FOR ASSESSING SKIN STIFFNESS PRECEDING A DIABETIC ULCER FORMATION

<sup>1</sup> Azita Tajaddini, <sup>1</sup> Heather M. Scoffone, <sup>2</sup> Georgeanne Botek, and <sup>1</sup> Brian L. Davis  
 Departments of <sup>1</sup>Biomedical Engineering /ND20, and <sup>2</sup> Orthopaedic Surgery

 Cleveland, OH 44195; email: [tajadda@ccf.org](mailto:tajadda@ccf.org)

### INTRODUCTION

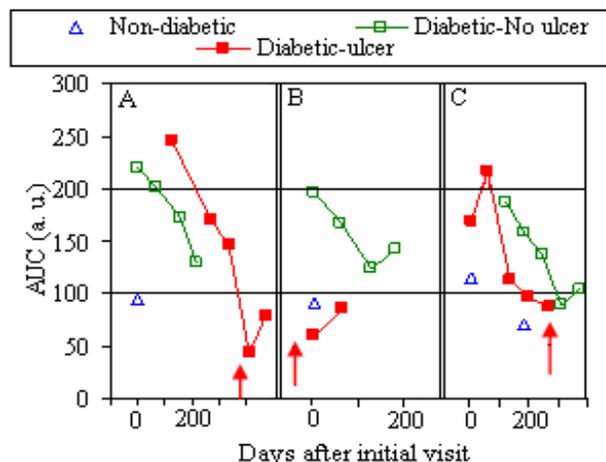

Diabetic foot ulceration is a leading cause of non-traumatic amputations. Discrepancy between the stiffness of the skin and the plantar soft tissues may influence the likelihood of ulceration. Changes in tissue properties with diabetes are mainly due to accumulation of glucose in tissues which promotes non-enzymatic glycation of structural proteins [1] such as collagen and keratin. Such intermolecular cross linking will alter the structure of the fibers and lead to their stiffening [2]. Our objective was to develop a non-invasive method for assessing skin properties in the context of ulcer formation on plantar surface of the foot in diabetic patients.

### METHODS

A nitrogen laser (Laser Science VSL-337 ND) with excitation wavelength at 337 nm was used to induce fluorescence of the plantar skin of hallux and fifth metatarsal head from 9 male subjects (age 70-82, Table 1). The auto-fluorescence spectra were collected from each site with a fiber optic probe using over 500 diodes in the detector, corresponding to wavelengths of 300 to 650 nm. The spectral area under the curve (AUC) was calculated in arbitrary units after background subtraction and normalization. The diabetic subjects were monitored more frequently than the control subjects. Data was not collected from callused or open wound areas. Two-way ANOVA and student's t-test were used for statistical testing as appropriate.

### RESULTS AND DISCUSSION

The two-way ANOVA of AUC indicated a significant difference among the three groups, but not due to skin sites. The AUC is significantly ( $p < 0.05$ ) higher for diabetic than in the non-diabetic individuals (Table 1). No significant difference was observed between the AUC of diabetic individuals based on ulcer formation. However most of those who developed an ulcer appear to have a sharp decrease in AUC about when the ulcer was detected (Figure 1). Only in one subject, the lowest point of AUC may have been missed since he started in the study while healing from an ulcer.

**Figure 1: Spectral characteristics of the plantar skin area of interest in age-matched subject groups based on time from their initial visit. AUC=area under the curve, au=Arbitrary Units. Arrows indicate ulcer.**

### CONCLUSIONS

The LIAF data indicates a higher signal for the diabetic individuals due to their altered state of intermolecular bonds. However, the AUC decreased prior to an ulcer formation suggesting its potential as a marker of tissue stiffness and thickness changes which precede ulceration in the diabetic foot. Additional data are needed to evaluate the differences within the diabetic population which predispose some to ulceration.

**DENSITY CHANGES IN BOVINE TENDON RESULTING FROM BUFFERED AND UNBUFFERED SOLUTIONS**

<sup>1</sup>Robin Adams, <sup>2</sup>Michele Oliver and <sup>2</sup>Taylor Murphy

<sup>1</sup>School of Biomedical Engineering, Dalhousie University, Halifax, Nova Scotia

<sup>2</sup>School of Engineering, University of Guelph, Guelph, Ontario; email: [Robin.Adams@dal.com](mailto:Robin.Adams@dal.com)

**INTRODUCTION**

Standard engineering materials can be characterized with a variety of parameters including elastic modulus, yield stress, and ultimate tensile strength. Many engineering materials behave in a well-characterized fashion, however, when applying the same methods to biological materials their performance is varied, and highly dependent upon the methods of *in-vitro* preparation. This has led to a variety of complications in biological materials research. The objective of this work was to address the issue of cross-sectional area prediction of biological tissues. One method, in particular, uses mass and length measurements and assumed values for tissue density to determine an average cross-sectional area as per the formula [1].

$$\frac{m}{dL} = \bar{A} \quad (1)$$

Where

*d* is the density of the specimen

*m* is the mass of the specimen

*L* is the length of the specimen and

$\bar{A}$  is the average cross-sectional area.

Using the definition of engineering stress, there is an inverse relationship between stress and average cross-sectional area.

$$\sigma = \frac{F}{A} = F \times \frac{dL}{m} \quad (2)$$

Where

*F* is the force applied and

$\sigma$  is stress.

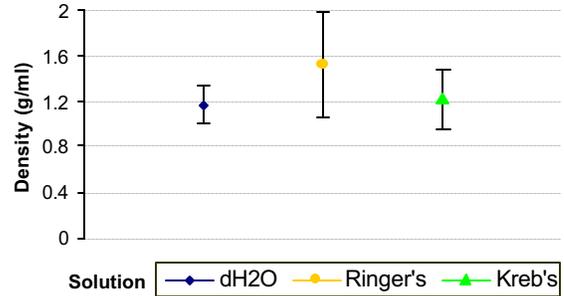

Tissue volume can be determined through fluid displacement. In itself this is not a problem; however, the submersion does bring into question how the tissue dimensions and density change in *in-vitro* solutions. Unbuffered hyper- or hypo-tonic solutions may cause bulk fluid transfer, changing the density of the sample as well as the overall sample dimensions [1]. Because submersion affects fluid retention, it is difficult to determine pre- and post-volume measurements. However, length and mass measurements may be performed independent of submersion with changes in this dimension being used to determine the sensitivity of a tissue to submersion. In this manner, the effect on the change in predicted stress ( $\Delta\sigma$ ) may be approximated.

$$\therefore \Delta\sigma \cong \left( \frac{FdL_0}{m_o} \right) - \left( \frac{Fd(L_0 + \delta_{Length})}{(m_o + \delta_{mass})} \right) \quad (3)$$

Where

$\delta_{Length}$  is the change in sample length

$\delta_{mass}$  is the change in sample mass

**Figure 1:** Predicted tissue densities for a 60 second submersion (mean±standard deviation).

**METHODS**

Three solutions were prepared (Ringer’s Solution, Kreb’s Solution and deionized water (dH<sub>2</sub>O)). Bovine hoof tendon samples (n=14) were obtained from the Ontario Veterinary College within one hour of slaughter and dissected longitudinally into 80mm lengths. Sample lengths and masses were evaluated pre- and post- submersion. All length measurements were made in triplicate using a MicroScribe™ 3D Digitizer (Immersion Corporation, San Jose, CA, USA). Tendon samples from each cow were submerged in one of the three solutions for approximately 60 seconds and their volumes were determined by their fluid displacement. A system of syringes was created for this purpose. Density was determined from the volume and the post-mass measurements.

**RESULTS AND DISCUSSION**

No significant post- minus pre-immersion changes in mass (p=0.73) or sample length (p=0.15) were observed as a result of solution type. However, a significant solution effect was found in the density values (p=0.01) where the Ringer’s solution tissue had higher values for density than the dH<sub>2</sub>O or the Kreb’s solutions. Interestingly there was no difference observed for stress variability ( $\Delta\sigma$ ) by solution (p=0.89) indicating that solution type did not alter the predicted stress.

**CONCLUSIONS**

Results suggest that while solution type affects density, any effects on predicted stress cancel out probably as a result of subtle mass and length changes in the tissue sample.

### INTRODUCTION

The mechanical behavior of cells plays a fundamental role in the tissue development and adaptation. Adherent cells are supported by their cytoskeleton (CSK), an internal pre-stressed framework composed of numerous interconnected filaments. For instance, contractile actin filaments (AF) generate tension forces toward the whole cell, especially in the basal side to strengthen the cell attachment to the extracellular matrix. This internal tension is balanced by microtubules (MT) associated to intermediate filaments (IF) that appear to resist to compression. By polymerization or depolymerization of AF and MT, the CSK continuously reorganizes itself according to the external mechanical microenvironment. Classical models based on tensegrity concept are consistent with biological observations of mechanical behavior of adherent cells such as strain-hardening, prestress-induced stiffening, viscoelastic properties [2,3] nonetheless the fixed connectivity between their constitutive elements (cables and struts) limits the description of the CSK reorganization. The aim of the present study is to develop a mechanical model based on divided medium theory to estimate the dynamical behavior of the CSK pre-stressed structure.

### METHODS

To describe the CSK of an adherent cell, our 2D model is composed of numerous rigid disks arranged in a compact configuration whose shape is a 80  $\mu\text{m}$ -diameter half disk and whose basal side is stuck on a flat substrate. Among these disks a larger one represents the nucleus (Figure 1). Within this assembly of elements in cohesive contact are distinguished several collections of elements on which particular interaction laws are applied. To represent the cell adhesion some disks of basal side interact with the substrate according to a highly cohesive contact law. To characterize the stress fibers that generate internal tension toward the whole cell a network of at-a-distance interactions of elastic tension are defined between some disks of the model boundary and especially between disks of the basal side that adhere to the substrate. The large disk that represents the nucleus interacts in the same way with those singular bodies. At-a-distance elastic tensions are also defined between disks of the apical side of the model to represent the cortical actin network located under the cell membrane. The model is then submitted to uniaxial compression at  $3.10^{-3}$  m/s for a final deformation of 30%. The mechanical equations are resolved using a numerical method of non-smooth contact dynamics [3].

**Figure 1:** Distribution of forces within the granular tensegrity model. (A) at reference state (before loading) and (B) at 30%-compressed state. The blue straight lines represent at-a-distance forces of tension and the purple diffused lattice shows the network of compression forces.

### RESULTS AND DISCUSSION

The first results obtained by the 2D granular tensegrity model show the internal force distribution (Figure 1). To balance the at-a-distance or cohesion tension forces, some elements in contact form chains of compression and thus a compression network inside the whole structure. Under compressive loading, elements rearrange themselves modifying their connectivity and the magnitude of interactions to balance the external applied force. Some at-a-distance elastic tensions vanish, new ones appear. Considering the prestretched actin network in analogy with the tension distribution and the MT associated to the IF network in analogy with the compression distribution, the 2D granular tensegrity model shows the organization of the CSK filaments and its variation under external applied stress and thus should provide a useful approach for investigating how each of the CSK substructures may be involved in the mechanical response of living cells.

## REPETITIVE HEAD LOADING: ACCELERATIONS DURING CYCLIC, EVERYDAY ACTIVITIES

### INTRODUCTION

Closed head injury research has primarily focused on acceleration and force thresholds for isolated impulses, such as those experienced in motor vehicle accidents or falls. The effects of activities that result in long duration cyclic exposure have been studied for the thoracic and lumbar spine and standards for vibration dosage have been generated. The international standard ISO 2631-1 [1] provides guidance on measuring and frequency weighting vibration input. This is done for a seated occupant from the seat bottom and seatback, and for person who is standing or recumbent. Health guidance limits are defined for the vibration exposure for a seated occupant, but are mainly related to the lumbar spine and connected nervous system. Little has been done with the head.

When involved in a cyclic activity, such as running or hopping, motion of the torso and neck result in head motion. The frequency content of the accelerations experienced by the head differs from the input. Goldsmith [2] stated that the head resonance is most pronounced at 8Hz for forced harmonic resonances at whole-body frequencies. This could result in signal amplification at response frequencies near 8Hz. The purpose of this study was to investigate the frequency content of linear head accelerations during various repetitive, common activities and determine if there is significant loading at 8Hz.

### METHODS

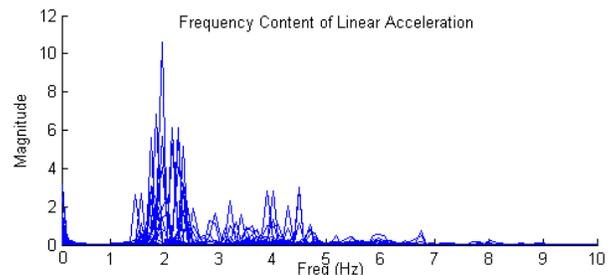

A head accelerometer apparatus was designed and constructed with linear accelerometers mounted to an adjustable lightweight headband. The sensor group had a range of  $\pm 10$ Gs (resolution: 0.0003Gs) along each axis. Each channel was low-pass filtered using a 100Hz anti-aliasing filter then digitally sampled at 500Hz. For testing, the headband was positioned so that the sensors were at the top of the head and its axes were coincident with the mid-sagittal plane and the coronal plane through both external auditory meati. The complete head apparatus weighed 85g.

Fifteen male and fifteen female participants voluntarily performed the activities chosen for the study: hopping (with two feet), running with an abrupt stop, jump rope, and running up and down stairs. Participants exhibited a wide range of age (from 18 to 44 years old), height (1.56 to 1.89m, mean 1.72m), and weight (51 to 106kg, mean 73kg). The subjects were asked to perform the tasks in a quick and precise manner.

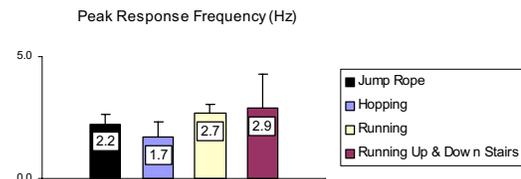

The data from the sensors were filtered digitally using a 50Hz low-pass filter. The linear acceleration data were used to determine the accelerations at the approximate center of gravity (CG) of the head. The distance from the sensor to the head CG was estimated using anthropometric measurements and regression formulae given by Zatsiorsky [3].

### RESULTS

All thirty participants were able to complete the tasks with no reports of injury or pain. A power spectrum density (PSD) analysis for each task across all subjects revealed that the magnitude decreased consistently by more than 30dB beyond 9Hz (see Figure 1). The largest loading was usually between 1 and 5Hz (see Figure 2). Not surprisingly, the torso and neck essentially acted as a low pass filter, not allowing the higher frequency loading to reach the head. The average number of impulses above 3Gs (a measure of dosage) was computed for each subject and each trial. On average, subjects experienced 58, 84, 24, and 4 impulses above 3Gs per minute for hopping, skipping rope, running, and stair running, respectively.

**Figure 1:** Compiled PSD of head acceleration while skipping rope, for all 30 subjects. The other tasks had similar plots.

**Figure 2:** Peak frequency response (mean  $\pm$  standard error).

### DISCUSSION AND CONCLUSIONS

Previous studies have documented forced resonance values of the head, but there is limited information available describing the frequency content of head accelerations during repetitive activities. In this study, we quantified the frequency content associated with a several non-injurious repetitive activities by measuring head accelerations. The response frequency of the head was generally between 0.1 and 9Hz, with the most significant frequency falling between 1 and 5Hz.

## A NEW APPROACH FOR MODELING AND ANALYZING THE VISCOELASTIC BEHAVIOR OF BLADDER WALL TISSUE

### INTRODUCTION

Previously our laboratory demonstrated using biaxial stress relaxation tests that the viscoelastic behavior of rat bladder wall is dependent on the health state (normal vs. neurogenic) as well as on the initial stress level [1]. Although these mechanical testing results were fitted relatively well to a reduced relaxation function (RRF: part of the Fung QLV theory [2]) we observed time-dependent residuals between the model prediction and the experimental data [1]. Since the bladder is composed largely of smooth muscle with varying amounts of collagen and elastin in the extracellular matrix, we hypothesized that modeling of the bladder wall would require multiple RRFs specific for each component.

The present study, thus, proposes a new modeling approach to predict the stress relaxation response of the bladder wall. Furthermore, an experimental method has been established to test the stress relaxation behavior of the decellularized bladder extracellular matrix in order to determine the contribution of the matrix on viscoelasticity of the bladder wall tissue.

### METHODS

#### *New Approach for Viscoelastic Modeling of Bladder Tissue*

In an attempt to dissociate the contributions of the extracellular matrix and the smooth muscle components of the bladder wall tissue, the following form of the reduced relaxation function, RRF, was suggested.

$$G_{total}(t) = (1 - e^{-\beta\sigma}) \cdot G_{ECM}(t) + e^{-\beta\sigma} \cdot G_{sm}(t) \quad (1)$$

In this formulation, the total RRF consists of two independent RRF's for the ECM and for smooth muscle, bound by an exponential recruitment function that is dependent on the initial stress level,  $\sigma$ , under the assumption that the higher the stress, the more ECM is loaded and contributes toward the overall stress relaxation response of the tissue.

According to the Fung QLV model, the RRF is formulated with a continuous relaxation spectrum. In the present study, based on the literature reports on the stress relaxation behavior of smooth muscle [3], we assumed that the smooth muscle component of the bladder tissue would follow this spectrum. For the extracellular matrix of the bladder, however, based on our previous results we assumed that the relaxation spectrum could not be described with a constant. Therefore, as a first attempt, we suggested that the following dual Gaussian form of the relaxation spectrum for the bladder ECM.

#### *Decellularization of Bladder Tissue Specimen and Biaxial Stress Relaxation Tests*

Whole bladders were harvested from female Sprague-Dawley rats and were placed immediately in tris-buffered saline (TBS)

at 4 °C for up to 48 hours. The bladders were then treated in a series of detergent solutions to decellularize using a method adapted from the literature [4].

Equi-biaxial stress relaxation tests were performed using a custom-made biaxial testing device [5] in modified Kreb's solution at 37 °C for up to 3 hours according to the established protocol [1]. Briefly, an equi-biaxial quasi-static testing run with 12 loading-unloading cycles was performed to precondition the tissue (at either 25 or 100 kPa) and to determine the strain levels necessary for the subsequent equi-biaxial stress relaxation run. Next, the specimen was loaded to the strain-levels representative of 25 or 100 kPa stress in both axes in 50-millisecond ramping time and was held at these strain levels to relax for the following 10,000 seconds (2 hours 47 minutes).

### RESULTS AND DISCUSSION

Decellularized bladder specimens were used in biaxial stress relaxation tests to determine the contribution of the extracellular matrix to the viscoelastic behavior of the bladder wall tissue. The results of stress relaxation tests provided evidence that compared to intact bladder tissue, the decellularized bladder tissue relax less over the testing period of 10,000 seconds. Based on these findings, the RRF for the extracellular matrix,  $G_{ECM}$ , was determined.

Finally, the stress relaxation data for normal rat bladder tissue were fitted successfully ( $r^2 > 0.99$ ) with our new viscoelastic model, which produced smaller residuals compared to the conventional QLV (data not shown).

### CONCLUSIONS

The present study demonstrated for the first time that stress relaxation response of the bladder tissue can be divided into the contributions of the extracellular matrix and smooth muscle components. Further experimental validation and detailed analyses of the structure of the ECM will allow development of this model into a structure-based viscoelastic model of the bladder.

## THREE VERSUS FOUR PEGGED GLENOID COMPONENTS: A BIOMECHANICAL EVALUATION OF FIXATION STABILITY WITH CYCLICAL LOADING

### INTRODUCTION

The most common complication in total shoulder arthroplasty is glenoid loosening [6, 2, 4]. Past studies analyzing loosening have concluded that some glenoid designs are superior to others. Rough-backed is better than smooth-backed [1, 2], curve-backed superior to flat-backed [1,2], all polyethylene better than metal-mesh backed [5, 1, 3], and pegs preferred over a keeled design [1]. To date, no studies have investigated the difference between a 4 peg and 3 peg glenoid design. The objective of this study was to characterize the loosening performance of a commonly used 3-peg design (Encore Foundation Total Shoulder Glenoid) versus a 4-peg design (Zimmer Anatomical Total Shoulder Glenoid).

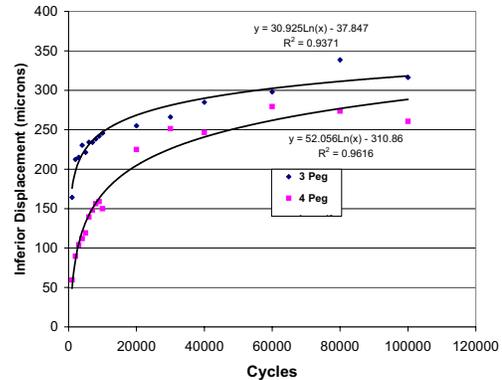

### METHODS

Fourteen glenoid components were cemented into bone stock (Model 1522-12, Pacific Research Labs) using standard surgical methods. Loosening of the components was evaluated by a previously established dynamic testing method (ASTM F2028-02) with slight modification. Four of the samples were used to determine the 90% sublaxation distance to be utilized in the dynamic testing method. This distance was found to be 4mm. The remaining ten samples were subjected to dynamic testing (n=5 per design).

A linear pneumatic cylinder aligned normal to the glenoid plane was used to compress the humeral head horizontally into the glenoid component at 112 lbs (+/- 11 lbs). The actuator of a servohydraulic materials testing system was used to displace the humeral head sinusoidally to 90% of the sublaxation distance in the superior and inferior directions. Samples were subjected to 100,000 cycles at 2 Hz.

Loosening was measured by two eddy current sensors (Model 4U, Kaman Inc.) aligned normal to the glenoid plane that detected the rocking motion of aluminum targets attached to the superior and inferior edges of the glenoid component. A 21 point calibration of the sensors was completed using a non-rotating micrometer with 0.001" resolution. Dynamic tests were paused at the following load cycles so that static edge displacements could be recorded after the humeral head was displaced to 90% of the sublaxation distance: 1K-10K (in 1K increments), 20K, 30K, 40K, 60K, 80K, 100K.

Superior and inferior edge displacements were compared between the glenoid designs at equivalent cycle numbers by a student's T-test. In addition, a two-way ANOVA was used to compare displacements as a function of glenoid design and cycle number. Edge displacements were also plotted as a function of cycle number. Logarithmic regressions of these plots were compared for each design using a dummy variables statistical approach.

**Figure 1:** Mean inferior edge displacement of glenoid as a function of cycle number for the 3 and 4 peg designs.

### RESULTS AND DISCUSSION

Both inferior and superior edge displacements were found to increase significantly with cycle number (Figure 1). While statistical analyses revealed the regressions of displacement versus cycle number differed with design, comparisons of displacements at specific cycle numbers revealed no difference with design except in the inferior displacement at 1000 cycles. Thus, while the 4 peg design displayed a slightly more stable fixation early, this did not prove to be significant over extended cycles. It is important to recognize that while the two designs did differ in peg number, they also differed in threading pattern of peg and in the width of the articular surface at the inferior pole. A limitation of this study is that inclination and cement mantle thickness were not controlled for.

### CONCLUSIONS

Both the 3 and 4 peg design displayed similar loosening over extended cycles. Clinically, the difference over time between the two is unlikely to be detected by the patient. However, further clinical studies involving patient surveys and radiographic analyses are needed to confirm these *in vitro* results.

## MMP-I UP-REGULATION AS A POTENTIAL MECHANISM FOR INCREASED COMPLIANCE IN MUSCLE-DERIVED STEM CELL-SEEDED SIS FOR UROLOGIC TISSUE ENGINEERING

Long, RA<sup>1</sup>, Nagatomi, J<sup>1,2</sup>, Chancellor, MB<sup>2,3</sup>, and Sacks, MS<sup>1,2</sup>

### INTRODUCTION

Porcine small intestinal submucosa (SIS, Cook Biotech) can be used as a sub-urethral sling device for treatment of Stress Urinary Incontinence (SUI). However, SIS, along with other biologically derived sling materials, has the tendency to degrade and lose mechanical integrity in vivo over time. In order to improve integrity and function, SIS may be seed with cells. Previously, we demonstrated that SIS seeded with MDSC formed a calcium-dependent contractile muscle-like tissue after 4 weeks of culture(1). We have also shown that MDSC seeded onto SIS increase the mechanical compliance of SIS (2). To date, however, the mechanisms by which the MDSC/SIS construct becomes more compliant are yet to be elucidated.

One possible mechanism responsible for an increase in compliance is the release of matrix metalloproteinase-I (MMP-I), which degrades collagen type-I, the main component of SIS. We hypothesize that the release of MMPs and break down in collagen fibers by MDSCs seeded onto SIS is a potential mechanism responsible for a change in the mechanical properties of MDSC/SIS compared to unseeded SIS. In the present study, we examined the impact of MMP-I on the mechanical properties and surface characteristics of SIS as well as the MMP-I activity of MDSC seeded onto SIS .

### METHODS

Samples of SIS (Cook Biotech) were cut into circles and attached with an o-ring to a modified costar transwell cell culture insert (Fisher Scientific) such that the growth area of the SIS was 4.7 cm<sup>2</sup>. SIS samples in the constructs were placed in 6 well tissue culture dishes. Mc13 cells (murine, transfected with a plasmid encoding for the b-galactosidase for the tracking purpose) passages 8-10, were seeded at 1x10<sup>6</sup> cells/ insert in 5.5 mL of in DMEM supplemented with 20% FBS, 1% penicillin streptomycin, and 500 µg/mL G418. Media were changed every 48 hours and supernatant and cell lysates were collected at time points of 1, 3, 5, 7, and 10 days for assays. In order to examine cell proliferation, a PicoGreen dsDNA quantitation kit (Molecular Probes, Eugene, OR) was used on cell lysates. MMP-I activity of MDSC on SIS in culture media at 1, 3, 5, 7, and 10 days was determined using a collagenase assay kit (Chondrex Inc.). The data were normalized by total protein concentration, which was determined using Coomassie Blue total protein kit (Fisher Scientific) as per the manufacturer's instructions.

Twenty samples of SIS were cut in 1 cm<sup>2</sup> squares, sterilized in 70% EtOH, and rehydrated in HBSS for 2 hours. Sixteen of the twenty samples were treated with culture media containing 0.16 U/mL collagenase type I (an equivalent amount of

collagenase activity as found at day 1 in the MDSC/SIS seeded samples) in DMEM for 3, 4.5, 5, and 24 hours. The enzyme reaction was stopped in 0.5 mM EDTA for 10 minutes. Four samples of SIS were treated in culture media not containing collagenase-I for 24 hours were used as a control. Biaxial testing was performed on all samples as described previously(2).

Six samples of MDSC/SIS and SIS digested in collagenase-I at varying time points were fixed in 2.5% glutaraldehyde, rinsed in PBS, soaked in 1% OsO<sub>4</sub>, and dehydrated in EtOH. Samples underwent critical point drying and sputter coating. Then, samples were viewed with a JSM6330F Scanning Electron Microscope in order examine initial cell attachment and surface degradation.

### RESULTS AND DISCUSSION

The results of biaxial mechanical testing provide evidence that digestion of SIS with collagenase-I for 5 hours increased up to 7%. This increase in compliance was statistically similar (p=0.356) to the compliance of MDSC seeded SIS at 10 days.

Furthermore, DNA quantification showed that the DNA content of MDSC/SIS increased over time indicating that SIS supports cell growth and proliferation. The MMP assay revealed that there was a significant amount (p<0.05) of MMP-I present in supernatant from soaked, unseeded SIS compared to media alone. Additionally, MMP-I activity of the MDSC seeded SIS was significantly higher (p<0.0025) after one day in culture compared to samples collected from subsequent time points and the unseeded control. These results suggest that the MDSC synthesize and release MMP-1 into the ECM to digest the SIS substrate, which may allow the cells to penetrate and to integrate into the substrate.

### CONCLUSIONS

The increase in mechanical compliance seen in MDSC seeded SIS may be mimicked with collagenase-I digestion. MDSC initially respond to SIS by releasing MMP-I, as exhibited through biological assays. The released MMP-I subsequently breaks down the collagen fibers in the SIS. The break down of collagen fibers, in turn may lead to the increase in compliance seen in the MDSC seeded SIS.

## AUTOMATIC MEASUREMENT OF LUMBAR SPINAL KINEMATICS FROM LATERAL RADIOGRAPHS

LW Sun, Steven Yang and Raymond YW Lee

Department of Rehabilitation Sciences,  
 The Hong Kong Polytechnic University, HKSAR, China  
 Email: lwsun.mike@polyu.edu.hk

### INTRODUCTION

A quantitative method for lumbar spinal kinematics has been developed by composing of the rapid and accurate measurement of vertebral shape and the reproducible and reliable determination of the intervertebral movements of the lumbosacral spine when performing Flexion-Extension motions. Current quantitative methods have suffered from the limitations of the variability of detecting vertebral body landmarks, labour and time-consuming of manual point placement and incompletely describe of the vertebral body shape. Techniques described herein intend to eliminate the limitations. This paper describes the accuracy and feasibility of an active shape model (ASM) and Genetic Algorithm (GA) to measure spine kinematics.

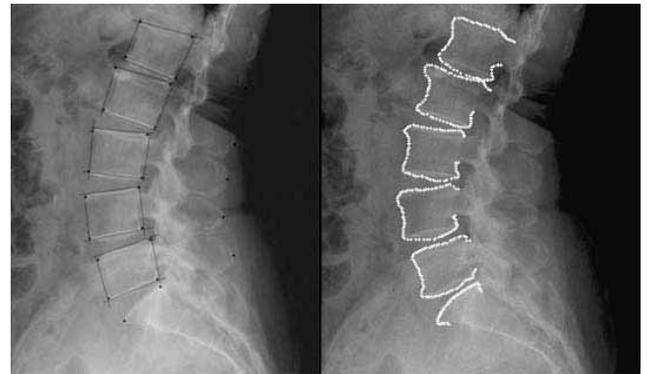

### METHODS

Twelve normal male subjects of mean age 21 years (Range, 20-22 years) were examined in this study. Lateral radiographs of the lumbar spine of each subject were taken in a neutral upright position, in full flexion and extension. The capital rotation and translations of the vertebrae on inter-segmental level from L1 to Sacrum were determined and compared between manual 4 corners quadrangles and ASM search finally. Intra class correlation was employed to determine the reliability of these data.

An active shape model (ASM) [1], a general contour method from the field of computer vision, to locate and measures the shapes of vertebrae in images. An ASM contains two separate components. Vertebral shape is described by means of a point distribution model (PDM) with 73 landmarks points along the vertebral contour, which is generated by performing statistical analysis of the object shapes observed over the set of training images. Then, principal component analysis is performed of the set of training profiles for that landmark point as a mean profile plus a set of modes of profile variation. Fourier descriptors were used to represent the vertebral shape. According to Fourier theory, a curve  $c(t)$  defines the positions of its points on the vertebral contour

$$c(t) = \begin{bmatrix} C_x(t) \\ C_y(t) \end{bmatrix} = a_0 + \sum_{k=1}^8 \begin{bmatrix} a_{xk} & b_{xk} \\ a_{yk} & b_{yk} \end{bmatrix} \begin{bmatrix} \cos(k\omega) \\ \sin(k\omega) \end{bmatrix} \quad (1)$$

Genetic algorithms, is a class of stochastic search methods, operate on a population of solutions. The relative motions between two vertebrae on images are determined by using searching of the 'best' value of coefficient of multiple correlations on GA. In this study, the angle of rotation  $\theta$  and translations of the vertebrae ( $x$   $y$ ) are the solutions. It encodes in a structure (genome or chromosome). The GA

**Figure 1:** Manual 4 corners quadrangles and ASM search on lumbosacral images.

creates a population of genomes then applies crossover and mutation to the individuals in the population to generate new generation. The objective function (fitness) determines how 'good' each individual is and the best individuals for mating to keep the population evolve.

### RESULTS AND DISCUSSION

Figures 1 show the Manual 4 corners quadrangles and ASM search on lumbosacral images. Table 1 summarized the mean of the kinematics on 4 corners quadrangles and ASM method for each vertebral level. High R value (0.998) of ICC(3,1) among subjects was reported.

Ang/°	L1/2	L2/3	L3/4	L4/5	L5/S
4 point	9.0	14.8	11.9	15.4	16.8
ASM	9.2*	14.2*	12.1*	15.3*	17.0*

Table 1: Mean value of angle of rotation (\*  $R > 0.995$ )

### CONCLUSIONS

This study demonstrated the accuracy and feasibility of using ASM and GA to determine the intervertebral movements. Less variance and high R value showed that the method was studied to be valid.

## THE EFFECT OF ACUTE FATIGUE ON NEUROMUSCULAR ACTIVATION PATTERN DURING SIDE-CUTTING IN FEMALE TEAM HANDBALL PLAYERS

<sup>1</sup> Mette K. Zebis, <sup>3</sup> Jesper Bencke, <sup>1</sup> Michael Kjær and <sup>1,2</sup> Per Aagaard

<sup>1</sup> Institute of Sports Medicine Copenhagen, Bispebjerg Hospital, Denmark

<sup>2</sup> University of Southern Denmark, <sup>3</sup> Gait Laboratory, Hvidovre University Hospital, Denmark  
email: [mkz01@bbh.hosp.dk](mailto:mkz01@bbh.hosp.dk)

### INTRODUCTION

Female handball players have a 2-8 fold higher incidence of non-contact injury to the anterior cruciate ligament (ACL) compared to their male counterparts (Myklebust G et al., 1998). Alternated motor control strategies have been identified as a potential risk factor (Malinzak RM et al., 2001). Furthermore it has been shown that fatigue may alter the movement strategy (Wojtys EM et al., 1996), and that the majority injuries occur in the late stage of a match (Gabbett TJ, 2000; Pinto M et al., 1999).

The purpose of this study therefore was to investigate if muscle fatigue induced by a simulated handball match would result in altered leg muscle motor patterns during side-cutting movements in female elite team handball players. It was hypothesized that motor patterns would change following the simulated match in a way that could contribute to the increased risk of ACL injury.

### METHODS

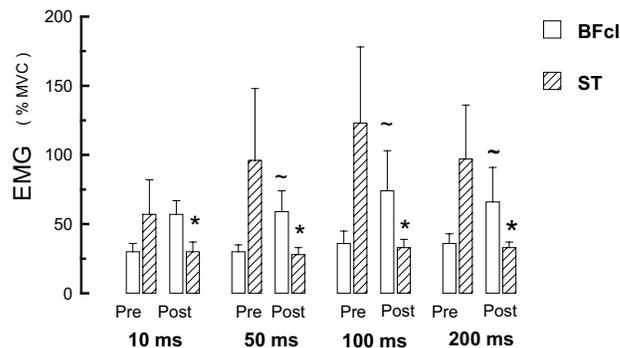

Neuromuscular activity (EMG; vastus lateralis and medialis, rectus femoris, biceps femoris, semitendinosus) was recorded (1 kHz) during a standardized side-cutting maneuver in fourteen female elite team handball players, pre and post a simulated handball match. Furthermore EMG was obtained during maximal isometric quadriceps and hamstring contraction (MVC) at a knee joint angle of 70° (0°=full extension). All EMG signals were highpass filtered (5 Hz cutoff) and smoothed by a moving RMS filter (30 ms time constant). EMG activity (mean average amplitude) during side-cutting was normalized to the peak EMG amplitude recorded during MVC. Median power frequency was determined by FFT analysis of the raw EMG signals subsequent to a Hanning window procedure.

The simulated handball match consisted of a series of intermittent exercises (side steps, cross over steps, jumps, high and low intensity running and sprinting) mimicking handball match activity (50 min).

### RESULTS AND DISCUSSION

The simulated handball match protocol caused a marked decrease in quadriceps (-21%) and hamstring (-16%) MVC ( $p < 0.05$ ). During the ground contact phase (in time intervals 10, 50, 100 and 200 ms after toe-down) the neuromuscular activity of semitendinosus decreased by 47-55% (Fig.1). A tendency towards an increase in activity of biceps femoris was observed (50, 100 and 200ms after toe down,  $p < 0.10$ ) (Fig.1). Median power frequency (MPF) in biceps femoris increased after the simulated handball match from  $109 \pm 19$  to  $122 \pm 32$  Hz ( $p < 0.05$ ). In contrast, MPF remained unchanged in semitendinosus,  $97 \pm 25$  vs  $90 \pm 14$  Hz. EMG activity (RMS

amplitude) and MPF remained unchanged in all other muscles examined.

**Figure 1:** EMG activity of biceps femoris (BFcl) and semitendinosus (ST) during braking phase in a side-cutting maneuver. \*denotes significant difference ( $p < 0.05$ ). ~denotes a tendency towards a difference ( $p < 0.1$ ).

### CONCLUSIONS

This study indicates that acute fatigue induced by handball match play, involving substantial eccentric and rotational forces, cause changes in the neuromuscular motor pattern during a standardized side-cutting maneuver.

The simulated handball match resulted in substantial decreases in maximal quadriceps and hamstring contraction strength. Likewise, alterations were observed in the neuromuscular activation pattern: Median power frequency increased in biceps femoris which could indicate recruitment of more type II motor units and/or a decrease in the amount of motor unit synchronization at the end of the simulated match. Furthermore, reduced EMG activity was found in the semitendinosus muscle in response to match-induced fatigue, which may potentially represent an elevated risk factor for ACL-injury. The typically female non-contact rupture of the anterior cruciate ligament (ACL) involves the knee in valgus, the foot fixed on the ground, and external rotation of the tibia. Since m. semitendinosus acts as an internal rotator of the tibia, the observed decrease in m. semitendinosus EMG activity may predispose for excessive external tibia rotation during side-cutting, thereby increasing the risk of ACL overloading.

## EFFECTS OF CORRECTIVE SHOEINGS ON THE EQUINE SUPERFICIAL DIGITAL FLEXOR TENDON LOAD, EVALUATED BY A NON-INVASIVE ULTRASONIC TECHNIQUE

Nathalie Crevier-Denoix, Bérangère Ravary, Jean-Marie Denoix and Philippe Pourcelot  
UMR INRA/ENVA Biomécanique et Pathologie Locomotrice du Cheval, Ecole Vétérinaire d'Alfort, France

### INTRODUCTION

Corrective shoeings are often recommended for tendinitis management, although their effects on tendon tension lack scientific evidence. Previous studies dealing with the quantification of the effects of corrective shoeings on equine tendon loads are indeed few [1,2], mainly because of the difficulty to obtain reliable *in vivo* data about tendon loads or strains, and because of the invasive nature of the techniques used so far (implanted transducers). A non invasive method to measure tendon loads has been developed [3]. This method is based on the measurement of the propagation velocity of ultrasound (US) in the tendon. It has been demonstrated that the speed of sound (SOS) changes in a logarithmic manner with the load applied to the tendon.

The objective of this paper is to report results of evaluation of the effects of 4 corrective shoes on the equine superficial digital flexor tendon (SDFT) load using this novel non-invasive technique.

### METHODS

Ultrasonic (US) measurements were performed on a group of 4 sound horses (8.5±4.0 years; 501±28 kg) using a dedicated device composed of an electronic battery-powered module (placed on the horse back by means of a saddle) and an ultrasonic probe. The probe is made of 6 transducer elements, one acting as an emitter and the others as receivers. The SOS was measured using the axial transmission method along the long axis of the tendon. Skin facing the right SDFT in the palmar metacarpal area was clipped. The probe was placed in contact with the skin by means of a gaiter.

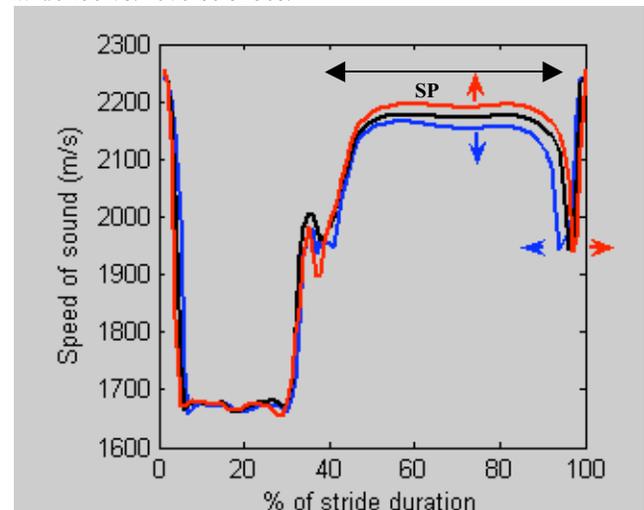

After preliminary trimming, both front hooves of each horse were equipped with a support shoe (nailed). The standard and corrective shoes to be tested (6° toe and 6° heel elevation on hard ground, reverse shoe and wide toe-narrow branches shoe on soft ground) were successively screwed on the support shoes of both limbs. For each shoe test, a 10 minute habituation was performed then horses were led at the walk along a 30 m long track. Ultrasonic and accelerometric recordings (100 Hz) were repeated 3 times.

For each recording, a mean pattern of SOS was calculated after time normalization by averaging the SOS data over 10 successive strides. Finally, data from the 3 recordings of a shoe test were averaged.

The SOS values at the beginning, the 2 peaks and the end of the stance phase, as well as the corresponding temporal parameters (in % of stride duration) were considered for statistical analysis. An ANOVA was performed to test the effects ( $P<0.05$ ) of the different shoes, each corrective shoe being compared both with the standard shoe and the opposite shoe, on a given ground (toe vs. heel elevation on hard ground, reverse shoe vs. wide toe-narrow branches shoe on soft ground).

### RESULTS AND DISCUSSION

Comparison of the SOS patterns demonstrated that heel elevation and reverse shoe induce a significant increase of both the intensity (about 0.2 to 0.3 N/kg of bodyweight, at the second peak), and the relative duration, of tendon loading during the stance phase (especially propulsion, i.e. second part of the stance), compared with standard shoe. The inverse effects were observed with toe elevation (about 0.2 N/kg of bodyweight load decrease) and, to a lesser extent, with wide toe shoe. In terms of loading intensity, the effects of toe vs. heel elevation on hard ground were more marked than those of wide toe vs. reverse shoes.

**Figure 1:** Effects of toe (blue) and heel (red) elevation, compared with a standard shoe (black), on the ultrasonic velocity pattern, at the walk on hard ground (SP = stance phase).

### CONCLUSIONS

This study confirms the results reported by the two previous studies [1,2] dealing with the effects of heel/toe elevation on the SDFT loading (increased / decreased tendon tension). It brings new information about reverse shoes and wide toe shoes, more recommended in practice, and tested on soft grounds as those used for training and competition. This study also revealed significant changes in tendon loading duration, induced by the corrective shoeings tested, on both ground surfaces.

**Quantitative Match Analysis of Soccer Games with Two Dimensional DLT Procedures**

Sumiyo Toki and Shinji Sakurai  
 School of Health and Sport Sciences, Chukyo University, Japan

**INTRODUCTION**

Match analysis has been widely executed for soccer games. For many years these analyses were mainly based on "observation sheets" methods, in which a tester took charge of a player to draw his trajectory on a sheet. Ohashi et al (2000) developed a quantitative method for the match analysis using trigonometric surveying with two potentiometers. However, it is not realistic to analyze the movement of all the players in a match, because these methods basically need at least one or two testers for one player. The purpose of this study was to develop a new simple quantitative method for match analysis of soccer games with a single video camera filming.

**METHODS**

Two-dimensional DLT procedures were used for the calculation of the players' positions, with an assumption that all the players' movement was on the same level (Z=0). A game of Japanese Professional Soccer League (J-League, Nagoya vs. Kashima) was filmed with a video camcorder set at the highest point of the audience stand of a stadium. The actual image of the video was shown in Figure 1. Two-dimensional coordinate system was set as shown in the Figure 1 with X and Y axes along the goal line and the touchline, respectively. Twenty-nine points with an already known coordinates on the field, such as the intersection point of a touchline and the center line, were used for the reference points for 2D-DLT calculation. Standard errors for the estimation were X=0.40m and Y=0.55m. All the players were digitized every 0.5 second (2Hz) throughout the game. Trajectory, distance covered, and running speed were obtained for each player.

Figure 1: Video image and the coordinate system for the analysis

**RESULTS AND DISCUSSION**

Figure 2 shows moving trajectories of three players (defense=BK, midfielder=MF, and forward=FW) of Nagoya team during 2<sup>nd</sup> half of the match. The trajectories show the distinctive features of the players and the positions.

Distance covered by each player was obtained every 5 minutes in the 2<sup>nd</sup> half of the match and the changes are shown in Figure 3 for all the field players of Nagoya team. The average distance covered was 5886m. There was about 4 minutes interruption (29-33 min) over a judgment of a foul. The graph

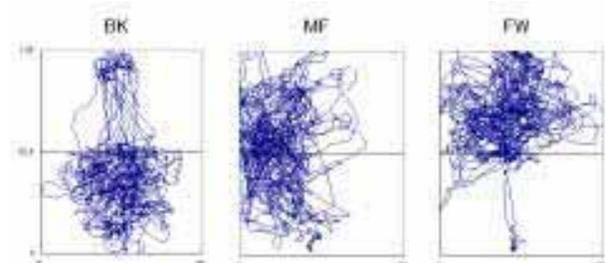

Figure 2: Trajectories of three players with different positions

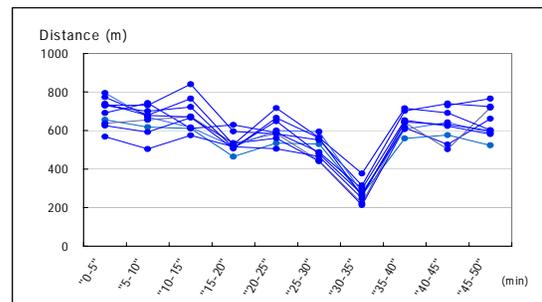

Figure 3: Changes of distance covered of all the players

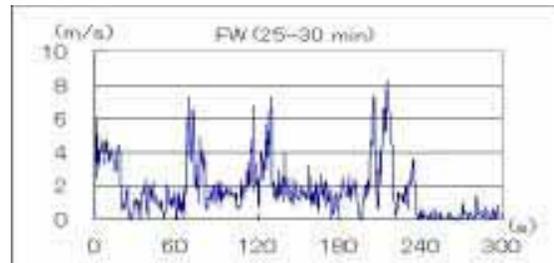

Figure 4: Speed changes of a forward player

well indicates an overall decreasing trend of the running distance with the progress of the match. It also clearly shows a short distance covered for all of the players during the interruption.

Speed changes were calculated from displacement changes for all of the players. Figure 4 shows an example of the speed changes of a forward player for 25-30 minute of the 2<sup>nd</sup> half. Forwards tended to move faster while their team played offense. Players far from the ball tended to move slower..

**CONCLUSIONS**

These results suggested useful information could be obtained from individual players' movement with this method. Moreover, team tactics or strategy can be examined because all the players' movement are clarified.

## METATARSAL AND TOE LOADING PATTERNS IN DIABETIC PATIENTS: POSSIBLE ROLE IN THE ETIOLOGY OF CHARCOT FOOT COMPLICATIONS.

Brian L. Davis, Ph.D., Kristian Walker, Heather Scoffone

Department of Biomedical Engineering (ND20), Cleveland Clinic Foundation, 9500 Euclid Ave, Cleveland, OH 44195  
 Email: davisb3@ccf.org

### INTRODUCTION

Charcot foot deformities are a complication for diabetic patients with neuropathy. The etiology is poorly understood, though many patients report minor trauma preceding the collapse of their foot. Under normal foot conditions there is a balance[1] in bending stresses applied to the first metatarsal (Figure 1). For this study, it was hypothesized that patients at risk for Charcot complications would exhibit higher imbalances in these loading profiles.

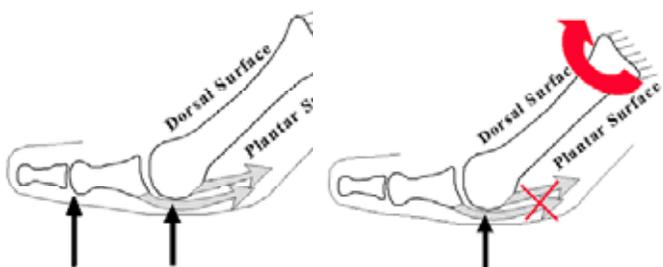

Figure 1. With normal foot conditions, the dorsiflexing forces under the metatarsal heads (vertical black arrow) are balanced by intrinsic muscle contractions (grey arrows). If intrinsic plantar flexor muscle forces are reduced (either through a surgical release or because of pathological changes) the metatarsals will experience greater bending moments.

### METHODS

Twelve subjects (five control patients, mean age  $58.8 \pm 7.89$ , and seven diabetic patients, mean age  $57.33 \pm 7.42$ ) were assessed. All diabetic subjects had plantar structural deformities related to Charcot foot disease. The subjects were not age matched, however age has not been found to be a significant factor in plantar pressure distribution. Written informed consent was obtained from all volunteers before data collection, in accordance with Institutional Review Board policies.

For all subjects, recordings of toe and metatarsal head forces were obtained during gait using an EMED pressure measurement system. Three trials were completed for each foot. Pressure masks were designed using Novel Multimask Evaluation software to divide the plantar footprint into anatomical regions, specifically, hallux, second toe, 1st metatarsal head (MTH) and 2nd MTH. Measurements of the arch index[2] for were obtained, with an increased arch index representing a flattened arch.

In terms of statistical analyses, a regression approach was used to relate the ratio of toe and MTH loading to arch index. Finally, ANOVA techniques were used to compare diabetic and control groups (level of significance was 0.05).

### RESULTS AND DISCUSSION

Control subjects exhibited a balance between toe and metatarsal loading, whereas diabetic patients had significantly reduced toe loads (Figure 2). The ratio of toe to metatarsal loading was significantly related to arch index (Figure 3).

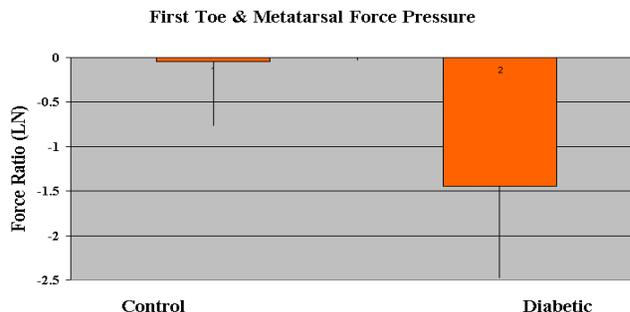

Figure 2: The relationship between forces of the first toe and metatarsal for each experimental group. In control subjects, there is a balance between toe and metatarsal loading, as evidenced by the logarithm being close to zero.

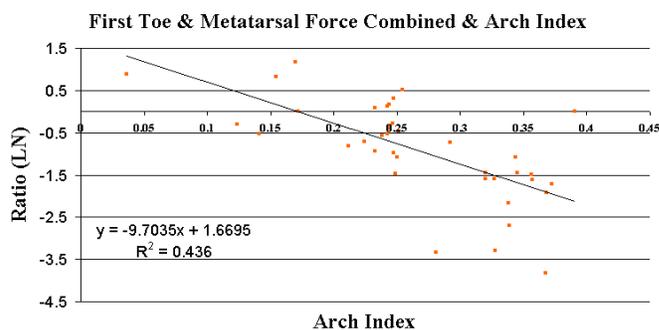

Figure 3. The ratio of toe loading to metatarsal loading was related to arch index ( $p < 0.05$ ), with the relationship given by:  $\text{Log}(\text{loading ratio}) = 1.67 - 9.7(\text{arch Index})$

### CONCLUSIONS

The fact that diabetic patients with signs of Charcot foot had (i) smaller forces in the first toe compared with non-diabetic patients, and (ii) increased values for their arch index, supports the hypothesis that diminished plantar muscle forces may increase the likelihood of Charcot foot problems.

## SHORT STATURE OR TALL STORY? HYPOTHESIS AND IMAGINATION IN BODY SIZE RECONSTRUCTION OF LB1 FROM FLORES, INDONESIA

<sup>1</sup>Robert B. Eckhardt, <sup>1</sup>Adam Kuperavage, <sup>2</sup>H. Joseph Sommer, III, and <sup>3</sup>Karol Galik

<sup>1</sup>Laboratory for the Comparative Study of Morphology, Mechanics and Molecules, Department of Kinesiology, The Pennsylvania State University; email: [eyl@psu.edu](mailto:eyl@psu.edu); <sup>2</sup>Department of Mechanical Engineering, The Pennsylvania State University; <sup>3</sup>Laboratory of Orthopedic Biomechanics, Allegheny General Hospital

### INTRODUCTION

The LB1 partial skeleton was recovered in September 2003 at a depth of 5.9 m during archeological excavations at the Liang Bua site on the island of Flores, Indonesia [1]. The individual has been diagnosed as female and dated to about 18 kyr, an estimate bracketed by thermoluminescence dates of  $35 \pm 4$  kyr and  $14 \pm 2$  kyr, although these figures are disputed [2]. This specimen has been described as the holotype (to which an associated left mandibular  $P_3$  was referred) of a new hominin species, *Homo floresiensis*. Among the features used to support the creation of this new taxon are some estimated dimensions that are extreme in relation to other human populations from this time period, including an endocranial volume of  $380 \text{ cm}^3$  and a stature of 106 cm. Here we focus on alternative stature reconstructions and their implications.

### METHODS

In the original report, the extremely short stature of 106 cm for LB1 had been reconstructed [1] using an average of results from three regression formulae derived from human pygmies [3]: least squares (LS), 109 cm; major axis (MA), 104 cm and reduced major axis (RMA), 106 cm. Because this result differed so widely from other human population means and no justification was given for the choice of formulae, we surveyed the substantial existing literature for alternative methods that had been used on populations broadly comparable to LB1.

All results reported in the following section are based on the data originally reported in [1]:

LB1 femur length (FL) = 28.0 cm, tibia length (TL) = 23.5 cm

### RESULTS AND DISCUSSION

Details of alternative samples and methods for stature estimation are provided in specific references cited below.

[4] African Pygmies, regression lines:

Stature =  $1.74 (\text{FL}) + 84.5 = 133.2 \text{ cm}$

Stature =  $1.85 (\text{TL}) + 88.8 = 132.3 \text{ cm}$

Stature =  $1.31 (\text{FL} + \text{TL}) + 55.3 = 122.7 \text{ cm}$

[4] African Pygmies, correlation axis:

Stature =  $3.42 (\text{FL}) + 17.1 = 112.9 \text{ cm}$

Stature =  $3.29 (\text{TL}) + 37.8 = 115.1 \text{ cm}$

Stature =  $1.61 (\text{FL} + \text{TL}) + 32.6 = 115.5 \text{ cm}$

[5] Mongoloid, regression:

Stature =  $2.15 (\text{FL}) + 72.57 = 132.8 \text{ cm}$

Stature =  $2.39 (\text{TL}) + 81.45 = 137.6 \text{ cm}$

Stature =  $1.22 (\text{FL} + \text{TL}) + 70.37 = 133.2 \text{ cm}$

[6] Javanese females, regression:

Stature =  $36.5 + 2.98 (\text{FL}) = 119.9 \text{ cm}$

Stature =  $52.0 + 3.08 (\text{TL}) = 124.4 \text{ cm}$

The unweighted average of the preceding 11 estimates is 125.4 cm, far closer to the estimate of 120 cm [2], which in turn approximates the regression based on femur length for Javanese females, than it is to the original estimate of 106 cm [1]. A stature of 120 to 125 cm is low for extant humans, but is only moderately below those recorded for insular Asian populations exhibiting normally short stature, such as a sample of 15 Andaman Island females averaging 137 cm [7].

### CONCLUSIONS

Representation of LB1 as the holotype of a new hominin species [1] was challenged initially, with the alternative hypothesis that the specimen instead was a microcephalic individual [8] accounting for the extremely low endocranial volume, which is about one third the average of extant *Homo sapiens* and comparable to chimpanzees and Plio-Pleistocene fossil hominids. The microcephalic hypothesis has been buttressed by subsequent studies of LB1 [2] and our own research on previously known Flores human specimens, which are short (152 cm) but not dwarfed. The idea of individual abnormality rather than phylogenetic novelty gains additional support from other features of the LB1 skeletal remains, comprising a skull vault that exhibits early fusion of cranial sutures, as well as the presence of several dental abnormalities, including tooth crowding, with both maxillary  $P^4$ s being rotated parallel to the tooth row, plus a congenitally absent left  $M^3$ . These and other postcranial details support the hypothesis that the endocranial volume and stature of the LB1 individual are consistent with known microcephalic members in extant *Homo sapiens* populations [9] of small stature.

## WAS THE EARLY HOMINID BRAIN MUSCLEBOUND?

Robert B. Eckhardt and Adam Kuperavage

Laboratory for the Comparative Study of Morphology, Mechanics and Molecules, Department of Kinesiology, The Pennsylvania State University, email: [eyl@psu.edu](mailto:eyl@psu.edu)

### INTRODUCTION

Stedman et al. [1] explored the possible influence that a gene encoding the myosin heavy chain (MYH) might have on the development of hominid masticatory muscles, mandibles and brains, with explicit attention to causal relationships between genetics and morphology in development and evolution. In this context, we read their concluding statement that “findings on the age of the inactivating mutation in the MYH16 gene raise the intriguing possibility that the decrement in masticatory muscle size removed an evolutionary constraint on encephalization...” as embodying a testable hypothesis.

### METHODS

It was noted [1] that “experimental animal models of the masticatory muscle resection or transposition have demonstrated the correlation between craniofacial morphology and the force of masticatory muscle contraction” [2]. However, in the rabbits subjected to manipulation of the temporal muscle attachment, no statistically significant changes in brain size were documented; while skull width decreased, length increased, suggesting conservation of endocranial volume. Classic experiments in this area include those in which Washburn [3] removed various muscles from one side of the skull in newborn rats, producing temporal lines either absent altogether or displaced far down in the temporal fossa; but brain endocasts were unchanged on the operated side.

Observationally, many domestic animals have jaws, teeth and brains that all are evolutionarily reduced relative to their wild ancestors. In comparison with skull morphology of *Canis lupus arctos*, cranial capacities of husky dogs are diminished along with measures of jaw size [4]. Among free-living hominoid primates, the largest nonhuman cranial capacity was recorded for a West African gorilla [5]. Its endocranial volume of 752 cc not only exceeds by 40% the average for 400 conspecifics, but also is higher than many of the fossil hominid crania for several hundred thousand years following the 2.4±0.3 my time estimated for the MYH16 mutation. The large gorilla skull also had a markedly high sagittal crest, indicative of massive jaw muscles.

Among extant humans, jaw musculature also can vary quite independently of endocranial volumes. For example, Smith Sound Eskimo were characterized by skulls high in internal volume that nonetheless externally showed markings for the large temporal muscles developed from a traditional diet that required heavy chewing. One male exhibited an intertemporal distance of only 7 mm, less than in some gorillas with endocranial volumes less than half as great [6]. His cephalic index ([head breadth/head length]x100) was 73.1, reflecting a low ratio of cranial width to anterior-posterior length. However, this pattern was not interpreted to mean that a more

elongated form of the hominoid skull is produced by greater lateral pressure of the temporal muscles, but rather that higher temporal lines are due to the more reduced insertion area for temporal muscles on skulls elongated for other reasons. Although the most dolichocephalic skull in the sample [7], its cranial capacity was 1545 cc, nearly at the 1563 cc mean for 9 skulls, some of which differed in proportions. An older study [8] of microcephalic human skulls discussed by the same author [6] showed that in these, the intertemporal distance varied tenfold (from 5 to 50 mm), while cephalic index ranged from 75 to 85 (dolichocephalic to brachycephalic), with the lowest intertemporal distance occurring in the most brachycephalic skull. Furthermore, the form of these small-brained skulls was not attributable to premature suture fusion, since the sutures remained open in most of the specimens. Last, the skull of LB1, a very small human discovered recently on the island of Flores, Indonesia, combines a low endocranial volume, in the range of 380 mm<sup>3</sup> [10] to 430 mm<sup>3</sup> [11], with a mandibular corpus that is proportional to its size.

### RESULTS AND DISCUSSION

The experiments and observations outlined above establish that in mammals, including hominoid primates, there is no effective constraint by masticatory muscles on encephalization.

### CONCLUSION

Our findings demonstrate that the size and attachment of jaw muscles make their marks principally on the external surfaces of the skulls rather than determining internal forms and volumes. Consequently, the idea that the early hominid brain was fettered by muscles whose confines were struck off by a single mutation stands as intriguing but as yet unproved. Nonetheless, it is important to note that although “Recently, evolutionary studies have been revitalized and revolutionized by an infusion of genetics into paleontology and systematics”[9], much of the promise remains to be realized.

**INTRODUCTION**

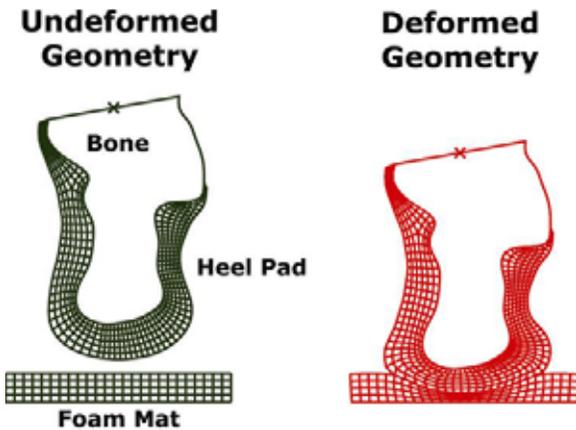

Elastomeric foams are represented in finite element (FE) models using constitutive equations containing one or more material specific parameters. Previous work has suggested that the test data used in material parameter determination may have a large effect on simulation results [1]. Specifically, parameters for simulations involving multi-mode deformations should be determined from test data describing all simulated deformation modes. The practical implications of multi-test parameter determination have not been shown in a FE simulation for footwear applications.

This investigation illustrates the effects of using data from multiple tests for foam parameter determination on predictions of clinical interest by simulating the indentation of a foam mat by the human heel pad.

**METHODS**

Two sets of Poron<sup>®</sup> foam parameters for a common compressible hyperelastic model [2] were determined using custom Matlab<sup>®</sup> optimization scripts. One parameter set was determined from uni-axial compression data alone and the other from a combination of uni-axial compression, simple shear, and volumetric compression data. The material parameters were incorporated into a pre-existing hyperfoam material model inherent in ABAQUS<sup>®</sup> FE software.

A plane-strain heel pad model described elsewhere in detail [3] was used to indent a 10mm thick foam mat (Figure 1). The simulation was run twice, once with each set of material parameters. Peak normal stress (plantar pressure) and shear stress were extracted.

**Figure 1. The undeformed and deformed heel pad indentation model. Final geometry was similar for both parameter sets.**

**RESULTS AND DISCUSSION**

Fitting parameters to compression data alone led to high errors in material model prediction of the shear and volumetric test data. Simultaneous fitting of all three deformation modes provided reasonable predictions (RMS error < 5% of maximum) of all test data (Table 2).

Test Data Used in	Order	Errors (RMS as a % of maximum)		
		Uni-axial Compression	Simple Shear	Volumetric Compression
Uni-axial Compression	1	0.67	1.34 x 10 <sup>6</sup>	58.5
Compression, Shear, Volumetric	3	4.24	1.30	2.04

**Table 1. Material model errors for the two sets of Poron<sup>®</sup> parameters.**

Although the heel pad simulation involves a strictly compressive load, non-linear geometry and friction lead to the generation of multi-axial deformation. When different test data sets were used in parameter determination, large differences between predicted peak stresses were present (Table 2).

Test Data Used in Parameter Determination	Order	Peak Pressure (kPa)	Peak Shear Stress (kPa)
Uni-axial Compression	1	288	62
Compression, Shear, Volumetric	3	258	36

**Table 2. Simulation predictions of peak stresses vary with the amount of data used in parameter determination.**

Parameters determined from compression alone can not accurately predict shear behavior, leading to an over estimation of about 72%. There is also a discrepancy in the peak pressure prediction that could be due to extrapolation error because the simulation strain has exceeded the maximum strain supplied in the test data.

## INFLUENCE OF FOOT ORIENTATION AND BONE STRUCTURE ON PLANTAR PRESSURE DISTRIBUTION

<sup>1,2</sup>Sachin P. Budhabhatti, <sup>2</sup>Ahmet Erdemir, and <sup>2,3</sup>Peter R. Cavanagh

<sup>1</sup>Dept. of Biomedical Engineering, Cleveland Clinic Foundation

e-mail: cavanap@ccf.org, web: www.lerner.ccf.org/bme/cavanagh

### INTRODUCTION

Foot orientation is an important component of variability in barefoot plantar pressures [1], a standard approach for assessing risk of ulceration in patients with diabetic neuropathy. Modeling of plantar pressure distribution can be used for the design of therapeutic footwear. In recent three-dimensional finite element (FE) models [2, 3], the orientation of the foot and the relative alignment of the bones was either based on unloaded positioning at the time of imaging or was roughly approximated by using kinematics information. The goal of the present study is to perform sensitivity analyses of i) foot orientation in the frontal plane and ii) relative metatarsal (MT) alignment on plantar pressure distribution.

### METHODS

Magnetic resonance images were obtained from the right foot of a male subject (24 yrs, 95 kg, 1.88 m). Bones (MT, phalanges, and sesmoids) and soft-tissue (ST) contours were digitized using custom Matlab (Mathworks Inc., Natick, MA) code and a FE mesh (57,544 eight-noded hexahedral elements) was generated using TrueGrid (XYZ Scientific Inc.) (Figure 1).

The bones were modeled as rigid and ST as incompressible hyperelastic material. Frictional contact between the plantar surface of the foot and the rigid floor was modeled.

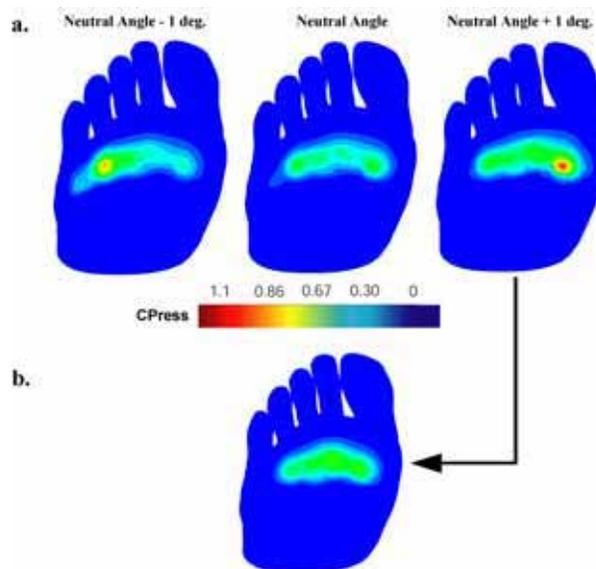

The foot was first positioned such that the inferior aspects metatarsal heads (MTH) were approximately parallel to the floor (neutral position). The floor was then displaced towards the foot to obtain contact and horizontal and vertical forces of 500 N and 90 N respectively were applied. The frontal plane orientation of the foot was changed by  $\pm 1^\circ$  from neutral position to test the sensitivity of plantar pressure distribution to this variable. In an additional simulation, of one of the rotated models (neutral +  $1^\circ$ ), the second MT was plantarflexed by 1.5 degrees and the first MT was dorsiflexed by 1.5 degrees. The bones were constrained to stay fixed with respect to each other once loading commenced.

**Figure 1:** Three-dimensional FE model of the forefoot. Arrows show the application of loads to the floor.

### RESULTS AND DISCUSSION

In the neutral model, there were no focal areas of high pressure (Figure 2a). Eversion by only one degree loaded MTH4 more prominently (MTH4: 40% increase); inversion by the same amount elevated MTH1 pressures by 35%. Dorsiflexion of MTH2 with respect to MTH1 allowed transfer of loads from MTH1 to MTH2 areas (MTH1: 30% decrease, MTH2: 15% increase with respect to the base model) (Figure 2b).

**Figure 2:** a. Plantar Pressure for orientation of the foot.  
b. Increase in MTH2 pressure.

These results show that the prediction of plantar pressures using the current FE model is acutely sensitive to foot orientation and bone alignment, probably much more sensitive than an actual foot in vivo. Before conducting simulations for footwear design, an optimization protocol could be used to provide the bone configuration and foot orientation that best represents experimental barefoot pressures. This study also demonstrates the possibility of changing the alignment of a generic model in order to represent different plantar pressures distributions (e.g. MTH1 predominant).

## LOWER LIMB STRUCTURE AND FUNCTION PREDICT BONE DENSITY OF THE PROXIMAL TIBIA

David Hudson, James Richards, and Todd Royer  
University of Delaware, Newark, DE; email: [dhudson@udel.edu](mailto:dhudson@udel.edu)

### INTRODUCTION

Hardening of subchondral bone is a hallmark of advanced osteoarthritis (OA) and is suspected to play a role in the pathogenesis of the disease[1]. Frontal plane knee alignment and moments have been linked to both subchondral bone mineral density (BMD) of the proximal tibia and knee OA[2, 3, 5]. The severity of knee OA has also been linked with medial tibial torsion and limited hip mobility; however, their association with tibial BMD has not been studied[6, 7]. This experiment determined if measures of lower limb structure and function could be used to predict BMD of the proximal tibia.

### METHODS

Fifty healthy limbs from 17 females and 8 males; average age: 34 (21-56); average BMI: 24.7 (21.2-28.0) were studied. Eight cameras operating at 120 Hz (Eagle; Motion Analysis Corporation, CA) and 2 force plates operating at 480 Hz (AMTI; MA) were used to collect gait data using a standard Helen Hayes marker set. Orthotrac software calculated the varus/valgus knee angles and moments.

Ultrasound (Sonosite 180plus; MA) was used to image the planes of the posterior tibial plateau and the distal anterior capsular margin. A digital inclinometer (AeroAngle PRO 160, Macklanburg-Duncan, OK) was mounted on the transducer to measure the angular difference between the proximal and distal landmarks. Subjects sat with the foot secured in a custom frame mounted on the wall with the knee flexed and the tibia parallel to the floor (Figure 1).

Hip internal and external rotations were measured using the inclinometer with subjects prone and the knees flexed. A hip rotation index was calculated as the difference between internal and external rotation.

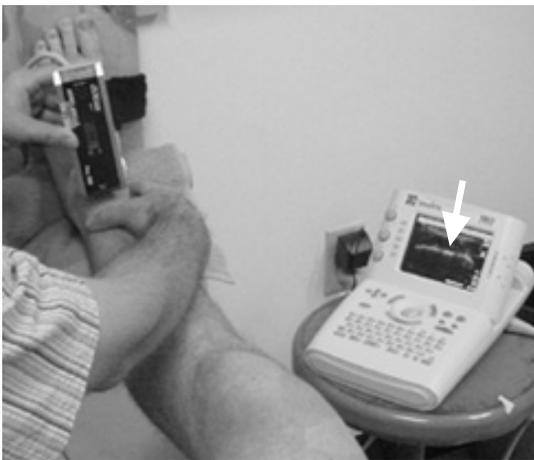

Figure 1. Distal tibial measurement. The arrow points to ultrasound image of the anterior capsular margin; the inclinometer measures the tilt of the transducer when the image is horizontal on the screen.

BMD within the medial and lateral compartments of the proximal tibia was measured using dual energy x-ray absorptiometry (Hologic Delphi W; MA). Compartment widths were  $\frac{1}{2}$  the proximal tibia width, and the height was from the cortical line to the superior margin of the fibular head.

Simple and forward stepwise regression was used to determine if maximal knee varus, maximal abduction moments, the hip rotation index and tibial torsion could predict the ratio of the medial to lateral compartment BMD in the proximal tibia.

### RESULTS AND DISCUSSION

The hip rotation index, tibial torsion, knee alignment and abduction moments were able to predict a significant portion of the variance associated with BMD distribution ( $r^2 = 0.68$ ;  $p = 0.004$ ). Individual relationships determined from simple regression are listed below (Table 1).

Table 1. Results of simple regression analyses.

Variable	r	sig.
hip rotation index	-0.58	0.001
tibial torsion	-0.40	0.004
abduction moment	0.40	0.005
knee alignment	-0.16	0.318

These results indicate that limb structure and function contribute significantly to BMD of the proximal tibia. Hip rotation and tibial torsion had not previously been investigated and appear to play an important role in this relationship. Knee alignment was less important in this experiment than previously reported[4]

### CONCLUSIONS

Limited internal rotation of the hip and medial tibial torsion were related to increased subchondral BMD in the medial compartment of the proximal tibia, and may play a role in the pathogenesis of knee OA.

**PROPRIOCEPTIVE DISTURBANCES IN RSI: A COMPARISON WITH CRPS**

<sup>1,2</sup> DirkJan Veeger, <sup>2</sup>Mark Arts and <sup>2</sup>Alfred Schouten  
<sup>1</sup>Vrije Universiteit Amsterdam,  
<sup>2</sup>Delft University of Technology; email: [h\\_e\\_j\\_veeger@fbw.vu.nl](mailto:h_e_j_veeger@fbw.vu.nl)

**INTRODUCTION**

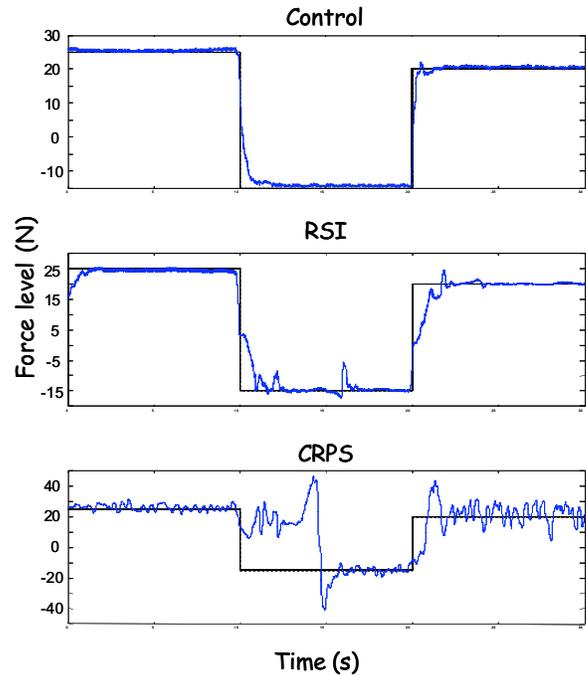

Repetitive Strain Injury (RSI) is a syndrome causing sickness absenteeism all over the world. An often reported symptom of RSI is dystonia, in which there are strong indications for the presence of proprioceptive disturbances. Since RSI is sharing a clinical spectrum along with Complex Regional Pain Syndrome (CRPS), it has been suggested that chronic RSI and CRPS might be related. Chronic RSI might be maintained as the consequence of sensory and proprioceptive disturbances, resulting in co-contraction, tremor, or disturbed proprioceptive response. RSI patients suffering from dystonia may show comparable deficits in performance as CRPS patients. To evaluate the existence of tremors, or deviating force control in patients with chronic RSI, RSI and CRPS patients and controls performed a bradykinesia experiment and a force-control task. We hypothesized that RSI patients would perform worse than controls, but still better than patients with CRPS.

**METHODS**

Nine RSI patients, 5 CRPS patients and 10 healthy subjects participated. Six RSI patients and all CRPS patients were diagnosed as having dystonia. All subjects filled in the Disabilities of Arm, Shoulder and Neck (DASH) questionnaire and the Shoulder Pain questionnaire.

In the bradykinesia test subjects were asked to open and close their thumb and index finger, as wide and as fast as possible for a period of 30 seconds. From recordings we derived the Total reached distance (TRD), root mean square (RMS) and median frequency (MF), for both the full 30 seconds and three consecutive 10-s intervals.

The force-control task was administered with a handle, positioned in front of the subject. Subjects were sitting with their arm in zero degrees elevation, the elbow in 90° flexion and pronation. Subjects were asked to follow a tracing signal on a computer screen that indicated the required force level. Applied force was plotted on-line (Figure 2). During the task EMG of two shoulder flexors and extensors was recorded. Mean Absolute Amplitude (MAA), transition time (TT) and muscle co-activity were analyzed.

**Figure 2**  
 Typical examples of results for the force-control task. Top: Differences between groups were determined using ANOVA and a Bonferroni post-hoc evaluation.

**RESULTS AND DISCUSSION**

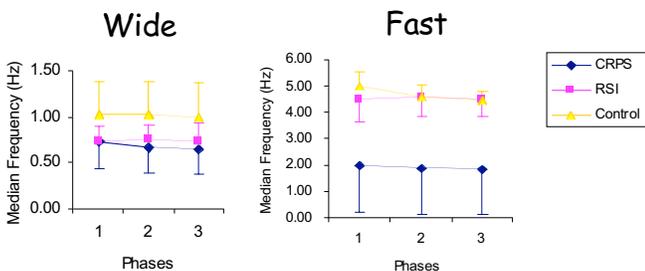

CRPS patients performed the bradykinesia experiment with a lower MF and a shorter TRD than RSI patients and controls (Figure 1). No significant differences were found between RSI and controls. The median frequency dropped marginally over the three 10-s periods, but not different for the three groups. Force-control parameters were not different between subjects with RSI and controls, but CRPS patients did show significantly shorter TT and a higher MAA (Figure 2). RSI patients and CRPS patients show not show a higher co-activation in the shoulder muscles than controls.

**CONCLUSIONS**

On the basis of the bradykinesia- and force-control test, it could not be concluded that RSI patients had proprioceptive disturbances. As such, these results could not support the theory by Johansson et al. (1) related to the development of RSI could not yet be supported. Evaluation of co-a

#### INTRODUCTION

Patient-specific computational modeling can be a useful component of pre-operative planning of cardiovascular surgeries such as those of valves and arteries. The deformation and stress analysis could also provide valuable insights into the tissue injury mechanisms.[1] The objective of this study was to simulate clamping of the aorta, a particularly challenging step, as it is computationally demanding and involves contact between rigid clamps and flexible aorta, contact within the artery walls, large deformations in tissues, and fluid-structure interactions (FSI).

#### METHODS

The models were created using Finite Element Analysis as well as Computer Aided Design packages. The aorta was modeled as a soft, non-linear material and the clamp was modeled as rigid. The soft tissue material was modeled using a custom in-house subroutine.[2,3] The fluid was modeled as Newtonian, incompressible and transient flow. For validation purpose, ascending porcine aortas were dissected from fresh unfixed hearts and clamped with actual surgical clamps. The external deformation profiles of the pinched aorta were imaged and compared with those of the simulations.

#### RESULTS AND DISCUSSION

Clamping of the aorta was simulated, producing occlusion of blood flow. The deformation profile of the simulated aorta matched well with that of the real tissue (see Figure 1), indicating that our material model and the simulation were reasonable. The computed deformation profile and stress distributions within the aorta, with and without the internal fluid, indicated significant difference between the two simulations, suggesting the importance of FSI in surgical modeling. The flow fields within the aorta were also computed (see Figure 2).

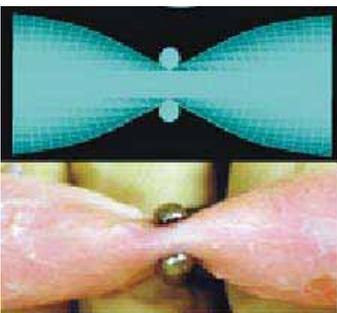

Figure 1. The simulated clamp test showing the deformed profile of the aorta that can be matched to real experiment data of the same deformation.

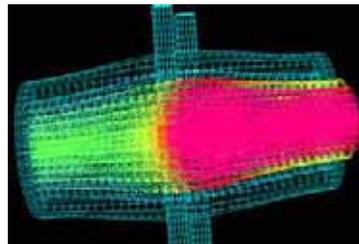

Figure 2. Top view of the fluid flow fields within the aorta during the clamping process; the colors correspond to magnitudes of flow velocities.

#### CONCLUSIONS

Clamping of a fluid-filled aorta, an important first step towards simulating of surgical procedures, was successfully modeled. The simulation was compared with actual aortic clamping, and deformation profiles of the simulations matched the experiment. The techniques developed in this project are applicable to valve FSI models and further surgery simulations. This model could also be linked with systemic Matlab simulations to have even more realistic modeling.

## THE EFFECT OF GLYCOSAMINOGLYCANS AND HYDRATION ON VISCOELASTIC PROPERTIES OF AORTIC VALVE

<sup>1</sup> Abhijit Bhatia, <sup>1</sup> Ivan Vesely  
<sup>1</sup>Childrens Hospital Los Angeles  
email: abhatia@chla.usc.edu

### INTRODUCTION

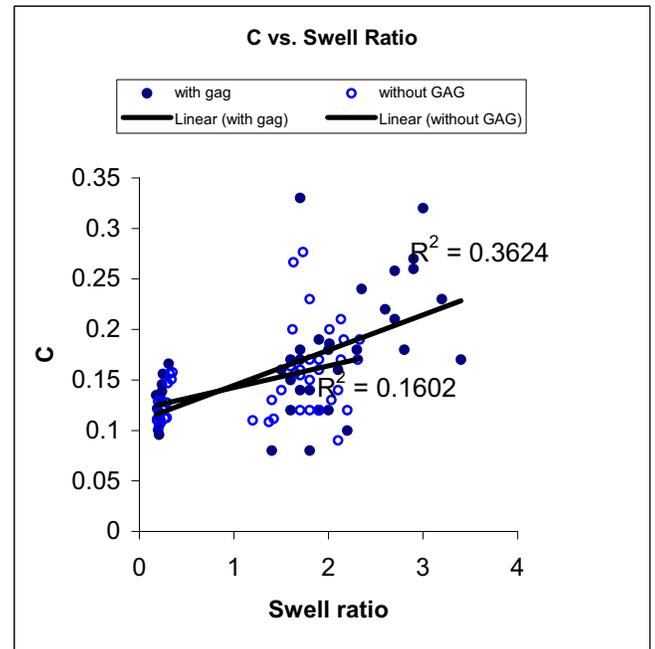

Glycosaminoglycans (GAG's), long chain sugar molecules that bind water due to their negative charge density, have been thought to be important in defining the viscoelastic properties of soft tissues such as skin [1]. Their importance in aortic valve mechanics however, has not been studied in detail. It has also been showed that cross-linked, commercially available bioprosthetic heart valves have less water content and less viscoelasticity. Therefore, the objective of this study was to determine the relative roles of hydration and GAG content on aortic valve cusp viscoelasticity.

### METHODS

To extract the GAGs from porcine aortic valve leaflets, specimens were immersed in three consecutive baths of 0.1M NaOH at room temperature, followed by three consecutive solutions of distilled water. GAG extraction was verified by the protianase-K method ( $\beta$  elimination) [2]. Stress relaxation and failure tests were performed on circumferential specimens before and after GAG extraction. To vary the degree of hydration of GAG-depleted specimens, samples were subjected to deswelling media such as mineral and baby oil, and swelling media such as water, sodium dodecyl sulfate and phosphate-buffered saline solution. After equilibrium was attained, the samples were subjected to a mechanical stretch and hold protocol and their Quasi-Linear Viscoelastic (QLV) parameters ( $\tau_1$ ,  $\tau_2$ , C) were obtained. Similar stress relaxation tests were performed on non-GAG depleted tissues, hydrated in swelling and deswelling media, and native tissue (control), tested immediately after harvesting.

### RESULTS AND DISCUSSION

The native tissues equilibrated in deswelling media showed a significant decrease in the QLV parameter C relative to unswelled native control tissue ( $0.12 \pm 0.01$  vs.  $0.15 \pm 0.02$ ). In contrast, samples equilibrated in swelling media showed an increase in C ( $0.21 \pm 0.03$  vs.  $0.15 \pm 0.02$ ). Swelling and water content therefore, affect the QLV parameter C. GAGs extracted tissues had a lower C value whether equilibrated in swelling ( $0.11 \pm 0.04$ ) or deswelling media ( $0.09 \pm 0.02$ ) as compared to the native control tissue ( $0.15 \pm 0.02$ ). GAG content therefore, also affects C in ways similar to water content. Regression analysis of the various samples in different media, with and without GAGs, showed an overall

**Figure 1:** Comparison of QLV parameter C for tissue samples (swelled and deswelled in various media) with and without GAGs.

increase in the QLV parameter C with the swell ratio (Figure 1) and hence with water content. However, there was no significant difference in the slopes of the regression lines for tissues swelled with and without GAGs.

### CONCLUSIONS

GAG depletion appears to affect the viscoelastic response of aortic valve tissue, although the major portion of this effect correlates with water content. Thus, it may be concluded that both GAGs and water content contribute to tissue viscoelasticity, with water being the major contributor.

### INTRODUCTION

Bone loss in the lower extremities is an established consequence of long-duration human space flight, whereas bone mass in the upper extremities appears to be maintained [1]. This difference may be the result of disuse of the lower extremities in space. Reduction in load bearing on the feet may play a key role in these changes, but no quantitative data showing loads in-orbit currently exist.

The purpose of the present experiment was to measure loads on the feet over an entire day in the same subject during daily life on the ground and on the International Space Station (ISS).

### METHODS

In-shoe forces were monitored with modified Pedar insoles (Novel GmbH, Munich, Germany) placed inside the shoes of a single astronaut on a 161-day ISS mission. DXA scans were also performed pre- and post-flight. All instrumentation was built into a Lower Extremity Monitoring Suit custom made for the subject, who gave informed consent to participate in the IRB-approved experiment. The force data were analyzed by a custom routine written in MATLAB (Mathworks Inc.).

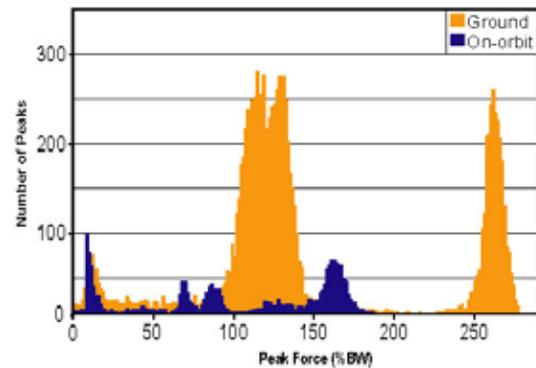

Daily load stimulus (DLS), a mathematical model used to relate changes in bone mineral density to daily loading histories, was calculated using in-shoe force profile data [2].

### RESULTS AND DISCUSSION

Average monthly BMD losses in the proximal femur, total hip, and lumbar spine regions were 0.64%, 0.72% and 2.31%, respectively. There was a net BMD gain of 0.32% per month in the arms.

Peak force histograms from sample days in 0g and 1g (Figure 1) show a marked shift in the two main modes of loading (walking and running from 260% and 120% BW in 1g to 160% and 90% BW in 0g). The total number of peaks above 5% BW is greatly reduced (10,112 peaks in 1g vs. 2,569 peaks in 0g) and force peaks greater than 200% BW are absent in 0g.

The ratio of mean DLS in 0g to that in 1g varied from 0.44 to 0.55 (using values of  $m$  between 3 and 8). Thus, exercise in space over an entire work day provided only approximately half the stimulus to bone experienced during a typical work day on Earth.

**Figure 1:** Peak force histograms in percent body weight (%BW) units for typical days on Earth (light – yellow) and on the ISS (dark – blue).

### CONCLUSIONS

A number of countermeasures have been attempted, so far unsuccessfully, to prevent loss of bone mass during long-duration space flight. The fact that cosmonauts and astronauts have lost bone mass despite exercising on-orbit has led some authorities to suggest that exercise is not a suitable countermeasure. When the reduced loading during locomotion on-orbit found in the present experiment is considered together with what appears to be a markedly lower total daily load to the feet, these results, if confirmed by ongoing measurements on other ISS astronauts, will present strong evidence that the “mechanical dose” derived from exercise needs to be increased. Such an increased dose could be obtained by increasing the load in the SLD, increasing the speeds available on the ISS treadmill, or by novel exercise. Since ground experiments in simulated zero gravity have shown that subjects can tolerate SLD loads of 1 BW [3], we believe that SLD loads should be increased for exercise on future ISS increments.

### INTRODUCTION

In a microgravity environment, the disuse of the lower extremities is known to cause physiological deconditioning of muscle. Previous studies have reported that considerable lower extremity muscle volume loss occurs during both short (Shuttle) and long-duration space flights (MIR), 3-10% and 5-17% loss respectively, even with exercise countermeasures [1]. It has been speculated that disuse of the lower extremity may be the principal mechanism of atrophy. The purpose of this study is to quantify the atrophy that occurs in the individual muscle groups of the lower and upper extremities of crewmembers on the International Space Station (ISS). This information will later be coupled with activity and strength data obtained from the same subjects.

### METHODS

Muscle volume changes were calculated using Magnetic Resonance (MR) images taken from two male ISS crewmembers before and after space flights of 161 and 194 days. Images of the thigh, calf, and arm were acquired pre- and post-flight (within 5 days of re-entry). Images of standard cylindrical calibration phantoms were also obtained to allow quantification of distortion in the images. The muscle groups of interest were the quadriceps, hamstrings, medial gastrocnemius, soleus, anterior calf, and anterior and posterior arm. The non-anatomical groupings (e.g. anterior calf) were used because of the difficulty in identifying individual muscles on MRI.

Each muscle group was traced manually from individual slices using custom MATLAB (MathWorks Inc.) software and then corrected for MRI distortion. The offset between pre- and post-flight images was accounted for by aligning each scan according to the endosteal area of the femur, tibia, or humerus. This alignment ensured that comparable regions were evaluated pre- and post-flight. The traced muscle contours were reconstructed using Rhinoceros 3D Modeling software (Robert McNeel & Associates) to visualize the muscle mass and volume measured.

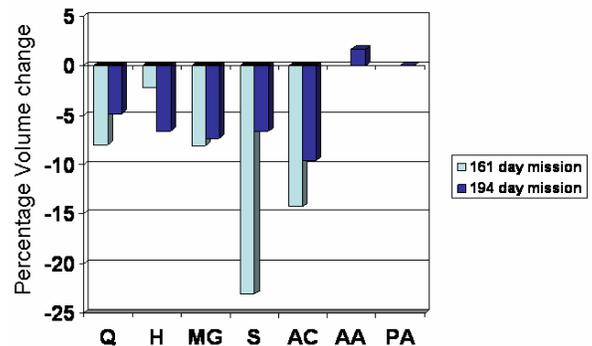

In order to estimate the user-reliability of the manual tracings, statistical analyses were performed in terms of intra-class correlation coefficient (ICC) based on two-way ANOVA. Three users traced three groups of muscles three times each in order to calculate the ICCs.

### RESULTS AND DISCUSSION

The mean intra-observer ICCs of all the muscle groups, calculated based on muscle cross-sectional area (CSA), for all observers were  $\geq 0.99$ , the mean inter-observer ICC for all

muscle groups based on muscle CSA were  $\geq 0.98$ . These high values indicate good agreement between and within observers.

The mean percentage volume changes, over the duration of the missions, of the quadriceps, hamstrings, medial gastrocnemius soleus, and the anterior calf, were found to be -6.4%, -4.4%, -7.7%, -16.4% and -11.9% respectively. In the anterior and posterior arm groups of muscles, the volume changes were 1.7% and no change respectively.

**Figure 1:** Percentage muscle volume changes for two subjects during 161- and 194-day missions on the ISS. Quadriceps (Q), hamstrings (H), medial gastrocnemius (MG), soleus (S), anterior calf (AC), anterior arm (AA), and posterior arm (PA)

### CONCLUSIONS

Although exercise countermeasures were performed on-orbit, significant muscle loss was observed in the lower extremities while no loss occurred in the arms (Figure 1). This atrophy is likely due to disuse of the lower extremity which was not adequately protected by the exercise regimens performed on-orbit [2]. The absence of substantial change in muscle volume in the arms is possibly due to the continued daily use of the upper extremities on-board the ISS. More research is needed to design and implement effective countermeasures to the changes observed and data from additional subjects will be available on future ISS missions. Current experiments using bedrest to evaluate proposed countermeasures and exercise prescriptions will provide valuable insights into muscle loss and its prevention during long-duration space flight.

<sup>5</sup>NASA Johnson Space Center, Houston, TX, USA  
email: [cavanap@ccf.org](mailto:cavanap@ccf.org)

### INTRODUCTION

Bone loss in the lower extremities during space flight has been a feature of post-flight reports since the Gemini missions. Although these early findings from short-duration flights were later found to be incorrect and linked to inappropriate biomedical instrumentation, the first definitive study on Skylab IV indicated the severity of the problem. Later studies of MIR Station flyers and now data from the first 6 crews on the International Space Station (ISS) have confirmed that bone continues to be lost in long-duration space flight today despite exercise countermeasures [1,2].

Providing Earth-like gravity replacement loads (GRL) during exercise on long-duration space missions may be critical to the maintenance of bone mass. Two devices are currently used on the International Space Station (ISS) to provide a restoring force to return the astronaut to the treadmill surface during treadmill exercise: a subject load device (SLD) and various bungee cord (BC) configurations.

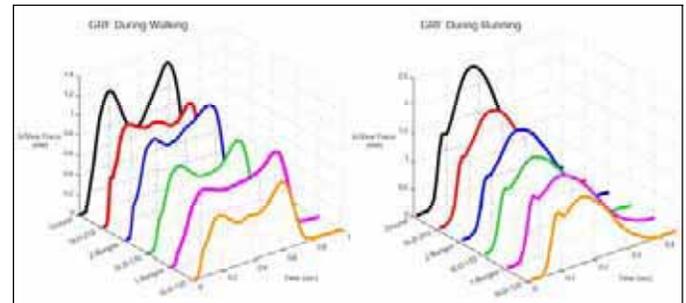

### METHODS

In this experiment, the loads on the feet during treadmill exercise on the ISS were measured while different combinations of GRLs were used. The results were compared to similar exercise protocols from the same subject on Earth. In-shoe forces were monitored using modified Pedar insoles (Novel GmbH, Munich, Germany) placed inside the shoes of a single astronaut, who gave his informed consent to participate in the IRB-approved experiment. Data were recorded at 128 Hz on a wearable computer and saved to a PCMCIA flash memory card. Thirty seconds of exercise data during 10 different loading conditions on orbit were collected and low-pass filtered using a 50 Hz cutoff frequency.

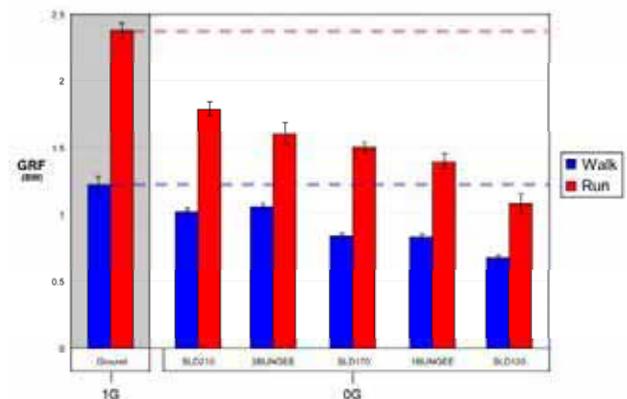

### RESULTS AND DISCUSSION

All on-orbit loading profiles showed a marked decrease in peak ground reaction force when compared to 1g loading. The mean active peak force was significantly larger in 1g compared to 0g for all ISS loading conditions (Figure 1).

Daily load stimulus (DLS), a mathematical model used to relate changes in bone mineral density to daily loading histories, was also calculated from the force data for each loading condition using an exponent,  $m$ , of 5. During treadmill running the ratio of DLS for a 30 second period of activity in 0g to that in 1g varied from 0.50 to 0.78 over the range of loading configurations. Thus, treadmill exercise in space provided a maximum of only approximately 75% of the stimulus to bone experienced during typical exercise on Earth.

**Figure 1:** Typical in-shoe force curves for running and walking over-ground (black – far left in each graph) and on-orbit using five different gravity replacement modalities.

**Figure 2:** Mean active peak force values for 30 seconds of 0g walking (blue) and running (red) using different loading modalities compared with the values for 1g (shaded area, also indicated by the dashed lines.)

### CONCLUSIONS

In order to evaluate treadmill exercise as an effective countermeasure, crewmembers must be able to comfortably apply a GRL of full body weight. However, these data suggest that the common loading conditions studied here that are currently used on the ISS do not produce loading of this magnitude. Further research is needed to improve SLD and harness design so that both load and comfort are improved in order to maximize the osteogenic effects of exercise in space.

## MICROMECHANICAL MODELING OF NONLINEAR VISCOELASTIC BEHAVIOR OF MITRAL VALVE CHORDAE

<sup>1</sup>Murat Surucu, <sup>2</sup>Daniel Einstein <sup>1</sup>Ivan Vesely

<sup>1</sup>Childrens Hospital Los Angeles, USC, Los Angeles, CA

### INTRODUCTION

Biological tissues, such as heart valves, consist of stiff fibers embedded in a soft matrix. Most computational analyses of the highly non-linear mechanical response that results are based on the concept of a continuum in which a constitutive model is postulated for an averaged volume. In order to more accurately model the specific interaction of tissue constituents, we have applied a micromechanical modeling approach, in which the macroscopic behavior emerges from the mechanical interaction of the internal microstructure. Our vision is to associate subgrid mechanics based on measured tissue microstructure with macroscopic computational models in order to resolve stress at the physiologically relevant scale.

### METHODS

#### Micromechanics Model and Geometry

We have implemented a high-fidelity modeling system that uses the generalized method of cells to represent the viscoelastic response of periodic materials with continuous reinforcement along the X1 direction. The model is characterized by a repeating unit cell with an arbitrary microstructure in X2-X3 plane [1]. The micromechanics analysis of the periodic multiphase material is based on approximating repeating unit cell by a rectangular grid (Fig.1).

#### Microscopic Constituents

The microstructure of mitral valve chordae was assumed to be composed of nonlinearly viscoelastic, crimped collagen fibrils, embedded in a nonlinearly elastic matrix. The nonlinear elastic response of both phases was modeled as a Mooney-Rivlin material, whose strain energy function ( $W$ ) is:

$$W = c_{10}(I_1 - 3) + c_{01}(I_2 - 3), \quad (1)$$

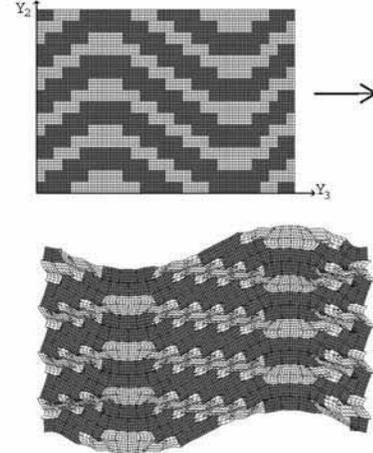

where  $c_{10}$  and  $c_{01}$  are material parameters. The viscoelastic response of the collagen fibers was assumed to be quasi-linear (QLV). Generally, the elastic response of each constituent is determined from the relationship between the second Piola-Kirchhoff stress  $S^e$  and the right Cauchy-Green deformation tensor [1]

$$S^e = 2 \frac{\partial W}{\partial C}. \quad (2)$$

Following the discrete spectrum approximation of Puso and Weiss [2], the time-dependent response is represented as:

$$S_{(t+\Delta t)} = G_e S_{(t+\Delta t)}^e + K \sum_{I=0}^N \left[ \exp\left(\frac{\Delta t}{v_I}\right) \mathbf{H}_{I(t)} + \left( S_{(t+\Delta t)}^e - S_{(t)}^e \right) \frac{1 - \exp\left(\frac{\Delta t}{v_I}\right)}{\Delta t v_I} \right]$$

$$K = \frac{G_0 - G_e}{Nd + 1}; \quad v_I = 10^{I+I_0}; \quad \mathbf{H}_I = \int_0^t \exp\left(-\frac{(t-s)}{v_I}\right) \frac{dS^e}{ds} ds$$

**Figure 1:** A wavy mesh representing crimped structure of collagen embedded in a nonlinearly elastic matrix: undeformed mesh (top), deformed mesh (bottom). Collagen fibers are in black.

$G_e$  is the equilibrium modulus,  $G_0$  is the initial modulus,  $Nd$  is the number of decades in the transition and  $10I_0$  is the lowest discernable relaxation time. As indicated by Puso and Weiss [2], these four parameters can be determined graphically from a logarithmic plot of  $G(t)$ . A non-zero deformation was applied in 33-direction ( $F_{33} \neq 0$ ). All tractions other than  $T_{33}$  were zero. Deformation was applied for 1.25 s at a strain rate of 40%/sec. From  $t = 1.25$  sec. to  $t = 3.25$  sec., extension was held constant to examine stress relaxation.

### RESULTS AND DISCUSSION

The deformation and stress distribution of the unit cell was as expected. Figure 1 shows both undeformed and deformed configurations. Extension of collagen crimp produced a toe region of the stress strain curve. As the collagen begins to bear the load, the stress-strain behavior becomes progressively linear. During the hold phase, stress in the fibers is relaxed.

### CONCLUSIONS

The nonlinear, viscoelastic response of chordae results from the interplay of its microstructure. This behavior was simulated in a subgrid micromechanics method. We continue to develop this micromechanical approach, toward the goal of resolving stress and damage on a scale that better inform device design and clinical understanding.

 email: francois.prince@umontreal.ca

### INTRODUCTION

The obesity is in constant increase since the last two decades and the problem is taking epidemic proportion in children [1]. Only few investigators looked at the possible effects of the obesity on the postural control in children. The two principal variables generally assessed in postural balance control are the center of pressure (COP) and the center of mass (COM). To control the equilibrium of the body during quiet standing, the COP must oscillate either side of the COM [2]. Furthermore, Winter et al. [2] demonstrate that postural equilibrium, for healthy adults, was regulated by two different mechanisms according to the observed direction of oscillation. In the anterior-posterior (A/P) direction, the COP<sub>net</sub> is mostly controlled by an ankle strategy called COP<sub>c</sub>. In the medio-lateral (M/L) direction, COP<sub>net</sub> is controlled by the hip abductor and adductor muscles and it is called hip strategy (COP<sub>v</sub>) and more specifically a load/unload strategy. The purpose of the present study is to compare the postural control between obese and non obese children during quiet standing and to assess degree of maturation compare to adult population.

### METHODS

Nine non obese children (mass: 32.5; SD: 8.9kg) and nine obese children (mass: 54.1; SD: 16.6kg) aged between 8 and 13 years participated in the study. The criterion for obesity was a BMI above 95e percentile for the age. Subjects were instructed to stay as still as possible in upright position with a comfortable width between the feet. Two trials of 120 seconds were collected at 60 Hz on two dynamometric force platforms (AMTI). The root-mean-square (RMS) of the centre of pressure velocity ( $V_{COP}$ ) and RMS amplitude of load/unload mechanism (COP<sub>v</sub>), the COP mechanism (COP<sub>c</sub>) and the COP<sub>net</sub> in the A/P and M/L directions were calculated. Finally, the contribution (in %) of the COP<sub>v</sub> and COP<sub>c</sub> to the COP<sub>net</sub> was also estimated. Data were also compared to adults[2]. Statistical analysis was realized with a one-way ANOVA. The statistical significant level was set at  $p < 0.05$ .

### RESULTS AND DISCUSSION

Figure 1 shows that the RMS amplitude of the COP<sub>v</sub> in the M/L direction was significantly superior in the obese group (X: 4.7; SD: 1.8mm) compared to control (X: 2.4; SD: 1.1mm). The RMS amplitude of the COP<sub>net</sub> in the M/L direction was also larger in obese children (X: 4.8; SD:

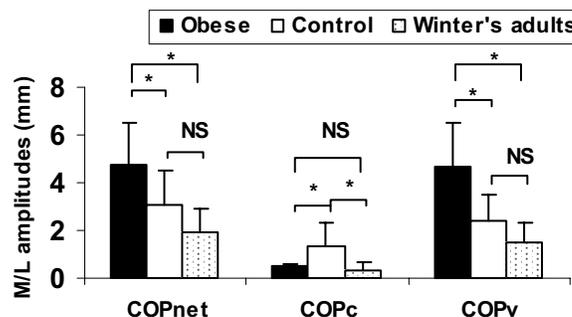

Figure 1: RMS amplitudes of COP<sub>net</sub>, COP<sub>c</sub> and COP<sub>v</sub> in M/L direction for the obese and control children. \*  $p < 0.05$ , NS = not significant.

1.7mm) than in control (X: 3.1; SD: 1.4mm) indicating that obese children could have problem with their postural balance. The contribution of the COP<sub>v</sub> to the COP<sub>net</sub> in the M/L direction was significantly different (X: 96.8; SD: 4.5%) for obese children compare to (X: 78.7; SD: 24.5%) the non obese children. Finally, the  $V_{COP}$  in the M/L direction was statistically smaller in the obese group (X: 5.8; SD: 0.9mm/s) when compared to the control group (X: 9.85; SD: 4.7mm/s). No difference was found in any of the parameters in the A/P direction. In regards to the COP<sub>v</sub> contribution to the COP<sub>net</sub> (96.8%) and to the  $V_{COP}$  in the M/L direction (5.8 mm/s), obese children demonstrated a more mature postural control, much like the adults population [2], than the non obese children. However, because of their larger COP<sub>net</sub> amplitude in M/L direction (Figure 1), obese children could be more at risk of falls than normal-weight children.

### CONCLUSIONS

Results showed a difference in the postural control of the obese children compare to non obese in the M/L direction. Indeed, the contribution of the COP<sub>v</sub> to the COP<sub>net</sub> was more pronounced in the obese group, indicating an increased involvement of the abductor/adductor muscles to achieve postural stability. Notwithstanding, because of their higher body inertia obese children have difficulty to control their equilibrium.

## LOCAL DYNAMIC STABILITY OF PASSIVE DYNAMIC WALKING ON AN IRREGULAR SURFACE

### INTRODUCTION

Previous experiments have shown that stride-to-stride fluctuations in human walking kinematics are statistically distinguishable from linearly filtered white noise [1]. However, the human musculoskeletal system is very nonlinear. Therefore, these nonlinear fluctuations may still be due to a white noise source (of either biological and/or environmental origin) that is being nonlinearly filtered by the mechanics of the system. If this were the case, the perturbations induced by this process should dissipate very quickly. The purpose of this study was to determine how quickly local perturbations from a purely white noise source dissipate in a mechanical model of walking.

### METHODS

We modified an existing “simplest” model of passive dynamic walking [2] to allow us to examine the local dynamic stability characteristics [1,3] of walking in the presence of amplitude increasing white noise. Random perturbations were applied to the step transition constraint, making the task equivalent to walking down a “bumpy” slope (i.e., transitions occurred slightly earlier or later) The modified transition equation was:

$$\phi(t) - 2\theta(t) = \varepsilon \cdot U[-0.5, +0.5] \quad (1)$$

where  $\phi$  = the angle between the stance leg and the swing leg,  $\theta$  = the angle of the stance leg with respect to the slope normal, and  $\varepsilon$  was the amplitude (in rad) of the uniform white noise,  $U$ , applied to the system. Five trials of 300 strides (600 steps) of perturbed walking were simulated for each of 6 perturbation amplitudes ( $0 = \varepsilon = 0.1$  rad). All trials simulated walking down a slope of angle  $\gamma = 0.009$  rad, corresponding to stable period-1 limit cycle motion. Per-turbations were applied randomly to each step in each trial.

We used a previously established method [1,3], to calculate exponential divergence for each trial for each perturbation amplitude. Mean log divergence was calculated out past 2.5 strides (5 steps) (Fig. 1A). Local dynamic stability, defined as the exponential *rate* of divergence, was quantified from the instantaneous slopes of these curves, using a standard 3-point difference formula.

### RESULTS AND DISCUSSION

The amplitudes of the mean log divergence curves increased with increasing noise amplitude (Fig 1A). The slopes of the divergence curves, however, remained nearly identical (Fig 1B). Thus, the *rates* of divergence were controlled primarily by the inherent stability of the limit cycle motion, rather than by the amount of noise present. In fact, the rates of divergence dropped to near zero after only 2 steps, and were virtually zero after 3 steps.

This shows that this simple mechanical model of walking can dampen out the effects of these local perturbations very

quickly. This capacity does not depend very strongly on the amplitude of the perturbations (i.e. noise amplitude).

In humans, local perturbations exhibit continued divergence for well beyond 10 strides [1]. The present results suggest that this extended divergence seen in humans may not be due exclusively to the nonlinear filtering properties of this highly nonlinear mechanical walking mechanism. Rather, these results provide additional evidence that suggests the source of the nonlinear fluctuations in experimental walking data is at least partly biological (e.g., possibly due to reflex mechanisms) in origin and is not purely mechanical.

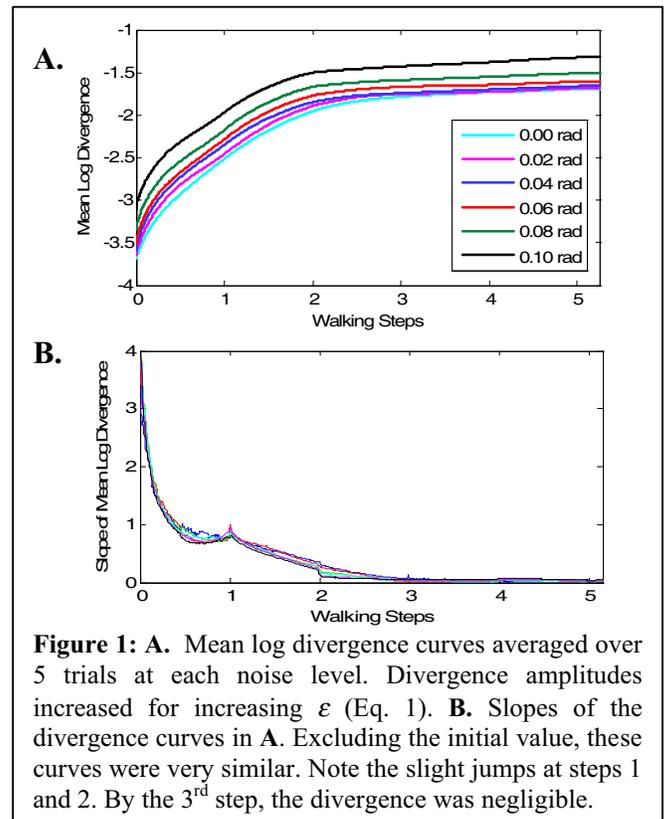

Future work will refine the walking model by making it more anthropometric, adding knees, and adding more biologically inspired control mechanisms. These efforts will allow us to determine the relative influences of different types of both biological and environmental noise on the local dynamic stability of walking.

## DIRECTION SENSITIVE SENSOR PROBE FOR THE EVALUATION OF VOLUNTARY AND REFLEX PELVIC FLOOR CONTRACTIONS

<sup>1</sup>Qiuy.Y. Peng and Chris. E. Constantinou  
 Urology, Stanford University Medical School, Stanford, CA. USA  
 Email: ceconst@stanford.edu

### INTRODUCTION

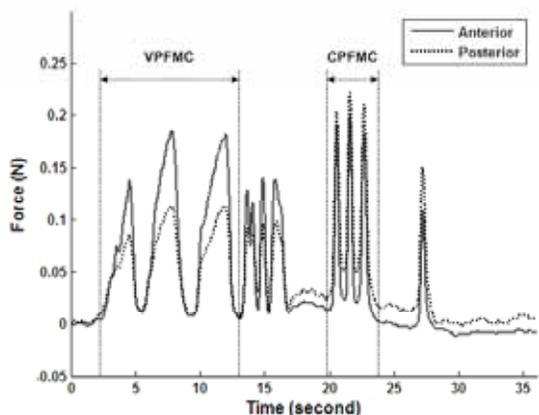

Reliable measurement of the ability of pelvic floor muscles (PFM) to contract voluntarily can be of clinical value in the assessment of women with urinary incontinence. Currently available devices, expected to measure PFM strength such as surface EMG or periniometry, are of limited anatomic specificity. Digital palpation, although more specific and reliable remains a subjective measurement. In this presentation we demonstrate the development of a novel sensor system to be used for the reliable measurement and recording of PFM strength emulating palpation.

### METHODS

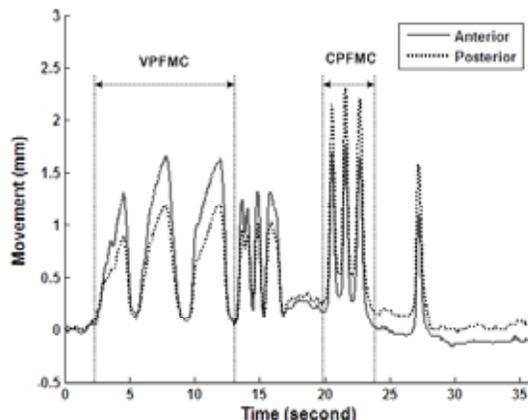

Prototype probe is equipped with 4 pairs of contact-force sensors and displacement transducers, each designed to move independently. For patient protection, probe is inserted in the vagina using a female condom placed over the sensor. By inserting the device into vagina, the movement and the force of PFM in the different four directions (anterior, posterior, right and left) were measured at a sample rate of 25Hz and presented on the computer screen as feedback to the patient. This system was used in the evaluation of 12 incontinent patients (mean age 63.2) recruited for this study. The PFM strength was first assessed in the lithotomy position using manual muscle testing and subsequently employing the probe of the sensor system. During the measurement, the patients were asked to perform 3 times voluntary pelvic floor muscle contractions (VPFMC) and 3 times coughing (CPFMC).

### RESULTS

Figure 1 shows the typical force (a) and movement (b) measured in the middle of the vaginal wall of a patient with urinary incontinence (UI). The measurements in the anterior direction and in the posterior direction are shown by the solid line and the dotted line respectively.

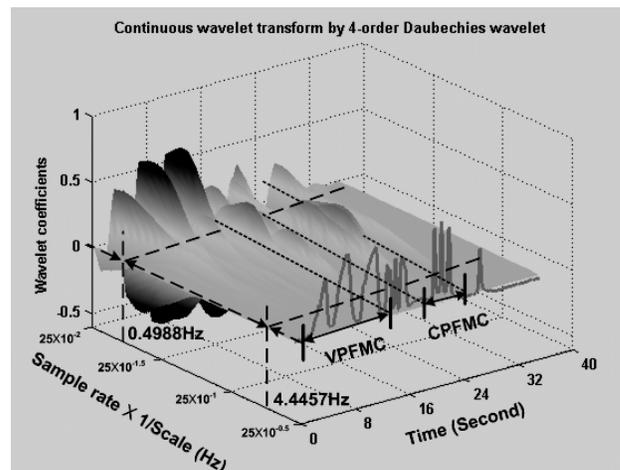

**Figure 1a:** Typical recording of force of contraction.

**Figure 1b:** Typical recording of displacement produced.

Force signals, Fig 2 during CPFMC have high-frequency components (0.5Hz to 4.4Hz). In contrast, VPFMC have much more the low-frequency components (0.25Hz to 0.5Hz).

**Figure 2:** Time-frequency distribution of the force signals in the anterior direction of the middle vaginal wall. Y-axis is the product of sample rate and the reciprocal of the scale of Continuous Wavelet Transform CWT.

### CONCLUSIONS

Sensor system provides direct measurements PFM strength and displacement. Analysis suggests that the modes of PFM contraction are different between voluntary PFM contraction and cough induced reflex PFM contraction.

**THE DIFFERENCE OF FITNESS LEVEL EVALUATED FROM THE MECHANICAL AND EXTERNAL WORK DURING BICYCLE EXERCISE**

<sup>1</sup> Takayuki Sato and <sup>1</sup> Tetsunari Nishiyama  
<sup>1</sup> Human Performance Laboratory, Nippon Sport Science University  
 email: takayuki@nittai.ac.jp, web: http://www.nittai.ac.jp/

**INTRODUCTION**

The conventional bicycle exercise test has traditionally been used to evaluate physical fitness. The load pedaled by the subjects in the traditional fitness test is actually the resultant force of the tangential and radial forces relative to the crank arm. Whereas the tangential work or power used in the fitness test has been based on the tangential load. Thus variation in the pedaling skill of the subjects will result in under- or over-estimation of the evaluated fitness level. The purpose of this study is to examine the difference in the evaluated levels determined for tangential and resultant pedal loads in bicycling exercise.

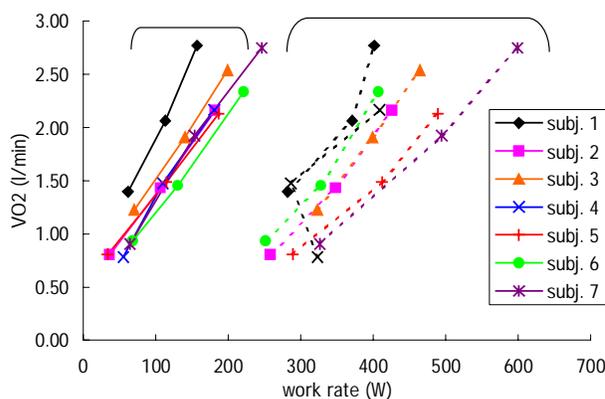

**METHODS**

Seven male subjects ( $28 \pm 4.1$  yr,  $174 \pm 6.2$  cm,  $67 \pm 4.7$  kg) participated in this study on two different days. To estimate the  $\dot{V}O_2$  max, on the first day of testing the subjects performed an incremental test on a bicycle ergometer. The resistance load was increased at each 0.5 kp every 2 min a target rate 70 rpm continuing until the subject was exhausted.  $\dot{V}O_2$  was measured breath by breath using a Metamax system (Cortex Inc.). On the second day of  $\dot{V}O_2$  max testing, the subjects pedaled while maintaining an intensity of 30, 50 and 70% of  $\dot{V}O_2$  max. Each resistance load test consisted of exercise periods of 5 min with a resting interval of 5 min between each resistance load.  $\dot{V}O_2$  were also measured. The original measurement system was constructed to obtain information on the load which was applied to the pedal. The pedal load was measured at the pedal

shaft using a strain gauge. The feet were fixed to the pedals with toe clips and straps. The height of the seat position was set to 107% of the symphysis pubis height from the floor. Tangential, radial pedal load and crank angular velocity data were collected and averaged over thirty pedaling cycles at the end of each resistance load. The work rate of the tangential (Tan-w) and resultant (Res-w) components were calculated. An index of effectiveness was calculated using the equation  $(\text{Tan-w}) / (\text{Res-w})$ .

**RESULTS & DISCUSSION**

Tan-w has been used for conventional physical fitness evaluation, such as the physical work capacity test (Fig.1, Tan-w). But this Tan-w is calculated from tangential pedal load, which is only a part of the subject-induced pedal load. Therefore, we also evaluated the resultant pedal load to eliminate the dependence on the subject's pedaling skill (Fig. 1, Res-w). Table 1 shows Tan-w and Res-w for each % $\dot{V}O_2$  max. The order of fitness level based on Tan-w was clearly different to that based on Res-w. If, based on Res-w, a subject has a higher fitness than another when their level is similar based on Tan-w, it is thought that the subject has an excellent fitness level but poor pedaling skill. The conventional bicycle exercise test is an excellent method to evaluate the bicycle exercise ability. In the case of evaluating physical fitness on a bicycle, both physical fitness and pedaling skill need to be considered.

### INTRODUCTION

The urinary bladder is a smooth muscle organ whose main functions are to store urine and to void when necessary. Since the most important aspect of the storage function of the bladder is to maintain low intravesical pressure in order to protect the upper urinary tract from backflow of urine, the compliance of the bladder wall is one of the key functional parameters to assess the health of this organ. Previously, using planar biaxial testing, we demonstrated that the mechanical compliance of bladder wall tissue in spinal cord injury (SCI) rats at 10 days post-injury was significantly greater compared to that of normal bladders under biaxial stretch [1]. These results contrasted typical, non-compliant bladder conditions found in chronic SCI patients [2]. In order to determine long-term alterations in the urinary bladder mechanical behavior due to SCI, the present study examined the biaxial mechanical properties of bladder wall tissues at various time points post-SCI. In addition, biochemical assays were used to quantify collagen and elastin contents of SCI bladders to correlate with tissue-level findings of biomechanical properties.

### METHODS

Female SD rats in the test group were subjected to complete transection of the spinal cord at the T9-T10 level, and the bladders were harvested at 3-week, 6-week and 10-week post-SCI. Normal rats were used as controls. Using our custom planar biaxial testing device, bladder specimens were subjected to equibiaxial stress (100kPa), and areal strain of the rat bladder wall, as an index of the mechanical compliance, was calculated for each group.

Following biaxial mechanical testing the bladder specimens were weighed, cut into smaller strips, and digested in 0.5N acetic acid supplemented with 1 mg/mL pepsin at 4 °C overnight. Acid-soluble collagen in the supernatant solution was quantified using a commercially available assay kit. The insoluble tissue materials (following acetic acid digestion) were further treated with 0.25M oxalic acid at 95 °C for 180 minutes. Elastin concentrations in these supernatants were also quantified using a commercially available assay kit. The data were normalized by wet tissue weight and expressed as average  $\pm$  SEM, analyzed using a t-test when compared to that of normal and 3-week SCI bladders from our previous study and the difference was considered significant if  $p < 0.05$  [3].

### RESULTS AND DISCUSSION

Bladder wall compliance was significantly greater at three and six weeks after spinal cord injury, when compared to normal. The increase in compliance, however, diminished by ten weeks post-injury, and was similar to that of normal bladder.

Furthermore, when maximum axial stretches in two anatomical directions were compared, it was significantly ( $p < 0.05$ ) greater in the circumferential direction than in the longitudinal direction in 3-, 6- and 10-week SCI bladders. The different mechanical responses in two directions found in 3-, 6- and 10-week SCI bladder tissues indicate material anisotropy in these samples. This finding contrasted the isotropic behavior found in 10-day SCI bladders, suggesting that material class of bladder tissue continues to change from 10-day to 10-week after SCI.

Collagen concentrations (*i.e.* collagen mass normalized by wet tissue weight of bladder sample) of the 3-week and 10-week SCI rat bladders were similar to each other but significantly lower compared to the normal bladders, due to increased mass of hypertrophied bladder. However, the collagen content (*i.e.* total collagen mass per bladder sample) of 10-week SCI bladders was significantly greater than both normal and 3-week SCI samples, indicating increased collagen production by smooth muscle cells between three and ten weeks after injury. Elastin concentrations (and contents) of the 3-week and 10-week SCI bladders were similar to each other and significantly higher than that of normal bladders. These results suggest that elastin content primarily increases over the first three weeks following injury and remains constant after that.

### CONCLUSIONS

The changes in the tissue mechanical compliance, composition and material class of bladder wall over a 10-week period of time post-SCI indicate that the bladder tissue continuously remodels after spinal cord injury. The results of the present study provide first evidence that early and late responses of bladder tissue following spinal cord injury were distinct from each other. Understanding that the bladder wall functional behavior continuously alters over the time, urologists may need to choose different clinical approaches regarding treatment of non-compliant bladder in SCI patients, based on injury's time-course.

## DYNAMOMETRY TO MEASURE PELVIC FLOOR FUNCTION

<sup>1</sup>Chantale Dumoulin, <sup>1</sup>Daniel Bourbonnais, <sup>1</sup>Denis Gravel, <sup>2</sup>Marie-Claude Lemieux, <sup>1</sup>Mélanie Morin,  
<sup>1</sup>School of rehabilitation, University of Montreal,  
<sup>2</sup>Faculty of Medicine, University of Montreal; [dumoulin@sympatico.ca](mailto:dumoulin@sympatico.ca)

### INTRODUCTION

Evaluation of the pelvic floor muscle (PFM) function is an important parameter in clinical and scientific issues regarding PFM training, the first-line treatment of Stress Urinary Incontinence (SUI) [1]. Until recently, clinicians have been relying on digital assessment, a subjective measure that lack sensitivity, or on indirect sources of measurements of the PFM function such as surface EMG and pressure measurements, which do not offer adequate specificity [2]. This research report addresses the development and psychometric evaluation of a new dynamometer for measuring PFM function in women.

### METHODS

The new dynamometer comprises a computerized central unit and a peripheral, a dynamometric speculum.

Through *in vitro* calibration studies, the dynamometer was assessed for linearity, repeatability and its capacity to measure a force independently of its point of application on the dynamometer branch. Subsequently, 29 female subjects aged between 27 and 42 and presenting different severity levels of SUI participated in an *in vivo* test-retest reliability study where the PFM evaluation was repeated in three successive sessions. During each session, maximum strength at 19mm and 24mm vaginal aperture, endurance, speed and rapidity of PFM contraction were recorded.

### RESULTS AND DISCUSSION

The calibration results suggest that the voltage outputs of the apparatus are linearly related to applied forces. Repeated calibration with dead weights has shown that the force measurements are also repeatable. Furthermore, calibration performed by applying forces at different locations on the moving branch of the dynamometer confirms that the

measurement is independent of the site of application of the resultant force.

The reliability coefficients found in the test-retest reliability study (coefficient of dependability and standard error of measurement) indicated good to very good reliability of all PFM measurements (Table 1). Furthermore, the subjects' unanimous appreciation implied that the instrument is acceptable and the measuring procedure comfortable.

### CONCLUSIONS

This study demonstrates that the new dynamometer accurately measures forces applied to its instrumented branch, takes reliable measurements of the PFM function and is deemed acceptable by women.

### Introduction

Tissue engineered cartilage covered scaffolds offer one solution to resurfacing damaged cartilage in young and active arthritis patients. Cyclically loading cells is expected to provide more rugged aligned tissues than those grown in static culture. No direct *in vivo* measurements of loads during gait, acting on cartilage tissues are available, making it difficult to select appropriate loads to apply during tissue growth. In addition no monitoring technique currently exists to monitor loading of implanted tissue engineered constructs. It was the goal of this study to develop a monitoring system and use it in an animal model to collect *in vivo* cartilage load measurements.

### Methods

Polybutylene terephthalate (PBT) scaffolds were manufactured using an extrusion freeform fabrication rapid prototyping process. A grid pattern, which developed bone ingrowth in a previous study, was modified so that strands were rotated 45° between layers.

**Figure 1:** Scaffold showing cross layered polymer pattern. Layer labeled top is solid and has a dome shaped section above it to support tissue engineered cartilage.

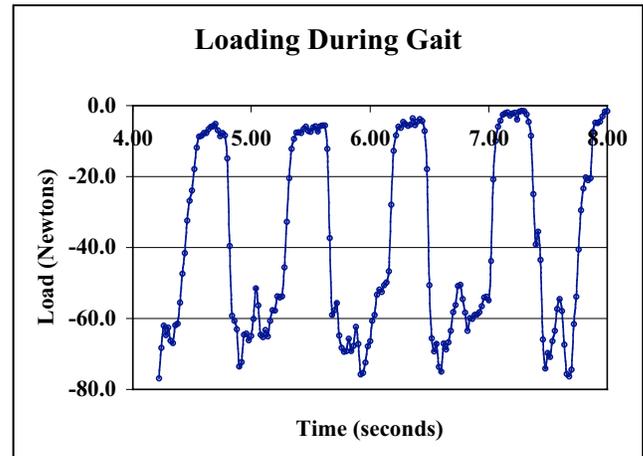

Three 1000 ohm single element strain gauges were aligned and attached along the long axis of the scaffold surface with a 120 degree separation. Gauges were wired to a cable and waterproofed using a published procedure. Scaffolds were loaded in confined compression on an MTS at a load rate simulating gait speeds and load vs. strain calibration curves were prepared. Wired scaffolds were cleaned, sterilized using ethylene oxide and aerated.

Six tall male hounds weighing between 29 and 35 Kg were selected for implantation surgery. The NIH Guide-lines for animal care and use were observed during animal experiments. Following preparation of one hind limb of each of six hounds, an incision was made exposing the medial femoral condyle and a scaffold was implanted by drilling two concentric holes (one for the cable and the second for the scaffold). The cable exited the lateral aspect of the femur and was coiled subcutaneously for later retrieval. Following a 3 month holding period retrieved wires were connected to a hard wired and/or a radio transmitter system. Strains were collected while dogs walked on a treadmill and calibration curves were used to assess loading. Following *in vivo* monitoring bones were explanted and loaded using a bench top loading system. Finally bones were dehydrated and embedded using a published undecalcified tissue embedding technique. They were sectioned and stained and histomorphometry was used to assess bone growth.

### Results

Strain vs. load curves for gauged scaffolds were noted to be linear up to the peak test load of 147 N (15 Kg). *In vivo* strain patterns were similar to patterns collected directly from the mid-diaphysis of the femora of dogs during earlier *in vivo* studies. Each gait cycle contained a low load swing phase which was assigned the zero strain value. Load vs. time graphs converted by using calibration curves indicated that peak loads ranged from approximately 80 to 120 N during gait (Figure 2) for this

test animal (weighing 34 Kg). Standing relaxed prior to and following gait, a load of  $65 \pm 6.5$  N was recorded from this animal.

**Figure 2:** Representative load patterns determined from strains collected during gait. Measurements were zero adjusted assuming the lowest combination of bodyweight and muscle loads during swing phase. At this gait speed swing phase lasts approximately 0.3 seconds.

Gross examination of knee surfaces in the explanted hind limbs, showed that scaffolds were adequately recessed but mild scoring of the tibial cartilage was noted in some animals. Scaffolds were securely fixed by extensive bone in-growth with no visible adverse reaction to the scaffold material. Cables were surrounded by a thin fibrous tissue layer which prevented them from migrating. Fluid infiltration into cables lead to some visible corrosion and precluded monitoring of some strain gauges.

### Discussion

Load measurements collected from strain gauged scaffolds were in general agreement with observations that dogs loaded at most 2 legs (one front and one back) simultaneously during gait at this speed. Results were also in agreement with evidence showing that, during stance, 40% of the dogs body weight is carried on the hind limbs (in this case 6.8 Kg/leg (67 N/per leg)). Telemetry was noted to function well when the exciting coil was accurately aligned with the subcutaneous transmitter but stopped transmitting when the power coil was slightly misaligned. Monitoring of telemetry output over a period of several days provided a consistent output suggesting that this system could be used over an extended period even though fluid infiltration was likely to incapacitate the system eventually.

Ongoing studies using cartilage covered "sensate" scaffolds are evaluating the effect of a tissue engineered cartilage layer. Development of better waterproofing coatings for connections between gauges and lead wires, and between lead wires and transmitters is expected to increase the length of time that these systems are able to provide measurements.

## CHANGES OF SPRING-LIKE LEG BEHAVIOR ACCORDING TO DIFFERENT TOUCH DOWN VELOCITIES IN DROP LONG JUMPS

<sup>1</sup> Koji Zushi, <sup>1</sup> Yasumitsu Ishii and <sup>2</sup> Bruce Elliott

<sup>1</sup> National Institute of Fitness and Sports in Kanoya, Japan ; email : zushi@nifs-k.ac.jp

<sup>2</sup> The School of Human Movement and Exercise Science, The University of Western Australia

### INTRODUCTION

Shortening and lengthening of the leg is a characteristic of hopping on the spot. On the other hand, jumping with the aim of moving forward consists of shortening-lengthening and rotation of the leg. The contribution of these two components may change according to the vertical and horizontal velocity of the center of mass (COM) and attack angle at the instance of touchdown. Moreover leg stiffness during the contact phase is affected by both the velocity and angle. A spring mass model was developed that represents the mechanical behavior of the integrated muscle-tendon system. The purpose of this study was to investigate the differences in spring-like leg behaviors of hopping on the spot and hopping following drop long jumps (Fig.1) with different touchdown velocities.

### METHODS

Nine college jumpers participated in this study. Subjects performed hopping on the spot (HJ) and hopping following a drop long jump (DLJ). Subjects were required to vary their running speed on the box (2m long, 0.3m high) to achieve landing distances of 1m, 2m and 3m onto a force platform (Fig.1). Vertical and horizontal GRF signals from the force platform were sampled at 1080Hz. 3D motions of the body were recorded at 120 Hz using a VICON motion analysis system (VICON612 Oxford United Kingdom). Selected 2D parameters were then placed into the model. Spring-like leg behaviors during the contact phase of HJ and DLJ were evaluated using the spring mass model (McMahon et al., 1990; Arampatzis et al., 1999 ; Farley et al., 1998) (Fig. 1). As the velocity of the COM is derived from leg rotation and shortening-lengthening, these were calculated by geometrics related to changes of rotating angle and the length L (Jacobs et al., 1992).

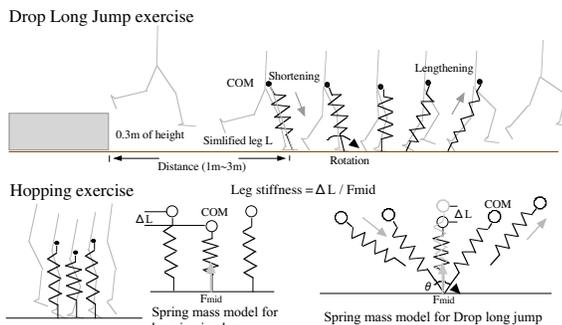

Fig. 1 Spring mass models for hopping in place and drop long jumping

### RESULTS AND DISCUSSION

Velocity of the COM and the attack angle at the instance of touch down and during early stance, as the jump distance increased, is related to greater compression of the leg L ( $\Delta L$ ) and larger vertical and horizontal GRF. However, leg stiffness decreased and contact time shortened over this period (Fig.2).

The model showed an approximate linear relationship between vertical GRF and  $\Delta L$  in the HJ but was non linear in each DLJ (Fig.3). Correlation coefficients between leg stiffness of HJ and each DLJ were not significant. These results suggest different spring-like leg behaviors in both HJ and DLJ. Horizontal and vertical velocity of the leg rotation markedly increased during contact phase as the jump distance increased. On the other hand, the influence of the leg shortening-lengthening on horizontal and vertical velocity increased with compression during the early stance but did not change during the recoiling motion latter in the stance phase (Fig.4). We concluded that the leg spring becomes compliant and does not recoil because of limitations of the muscle-tendon elasticity with a high impact GRF, while the rotary motion of the leg spring acts strongly as horizontal velocity increases in forward jumping following a faster approach.

### INTRODUCTION

Thermoplastic elastomers (TPE) constitute a relatively new group of polymeric materials classified as a separate category of rubbers. TPEs do not need to be vulcanized and therefore offer many advantages over chemically crosslinked elastomers, while being processible as classical thermoplastics. High performance TPEs with good solvent resistance, elasticity, tear strength and flex fatigue properties have found a wide range of applications in medicine such as medical tubing or equipment parts. Selected TPEs are also used for implant applications [1].

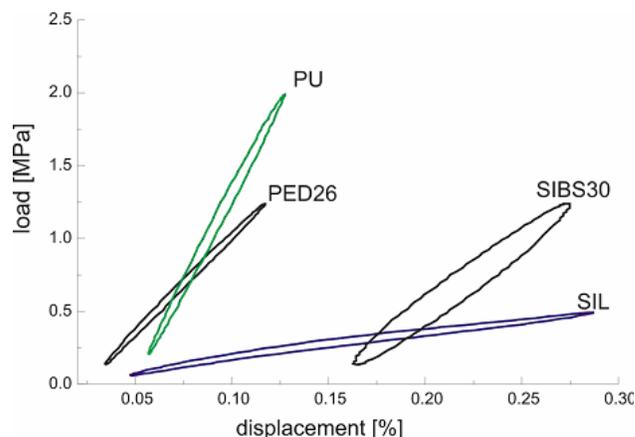

This paper will discuss the dynamic fatigue properties of medical grade silicone (SIL), a chemically crosslinked elastomer, and polyurethane (PU), a TPE, and two new TPE biomaterials: polystyrene-*b*- polyisobutylene-*b*-polystyrene (SIBS), recently FDA-approved as medicated coronary stent coating, and a segmented polyester TPE containing dimerized fatty acid (PED).

### METHODS

Fatigue testing was carried out using a servo-hydraulic test machine with a digital controller (Instron 8400/8800), equipped with a 200-N load cell, a 10 kN cylinder and an environmental chamber. For all tests, the load ratio  $R = \sigma_{\min}/\sigma_{\max}$  was held constant at 0.1. The strain was measured as the real-time clamp displacement. The possible phase shift between the stress and strain signals were minimized below 20  $\mu$ s by the experimental set-up. Testing in simulated body fluid (SBF) was carried out at 24 and 37°C. Testing was carried out using the SILT (Stepwise Increasing Load Test) and SLT (Single Load Test) methods. The DynMat Hysteresis Measurement Software V.1.1.0.1 was used for the evaluation of the hysteresis loops [2].

### RESULTS AND DISCUSSION

With SILT, SIL showed extremely low dynamic modulus, and large instantaneous elastic deformation. SIBS performed much better, with nearly ten times higher modulus than SIL, bridging the gap between SIL and PU. PED showed an intermediate behavior between SIBS and PU. SIBS and PED both displayed high damping. Figure 1 shows the hysteresis loop patterns. SIBS30 shows the largest area under the hysteresis loop, indicative of its high damping. The hysteresis

**Figure 1:** Hysteresis loop patterns.

loop of SIL exhibits large displacement at low forces. The much broader hysteresis loops of PU and SIBS compared to PED indicate structural changes, accompanied with high energy dissipation and larger creep.

SIBS demonstrated superior creep resistance compared to SIL *in vitro* (SBF, 37 °C), approaching the performance of PU and PED.

### CONCLUSIONS

The hysteresis method seems to be a useful new method to evaluate the dynamic behavior of biomaterials. The recently developed dendritic SIBS materials are expected to have improved dynamic fatigue and creep properties, on account of their branched structure [3]. This, coupled with the biocompatibility of SIBS, predicts a bright future for this novel biomaterial.

## IMPACT RESPONSE ANALYSIS OF THORAX BY THE THIN-LAYER METHOD

Abir Chakraborty

India Science Lab, General Motors Tech. Centre - India, ITPL, Bangalore-560066

### INTRODUCTION

Development of lung injury criteria is essential to understand the damage incurred by automobile accidents or high velocity projectile impacts. While the car accidents are characterized by low velocity, high mass transferring energy to the thoracic tissues over a relatively long time period (~60 ms), the bullet impacts generate two waves arriving at around 100  $\mu$ s and 1 ms. Thus, the thorax is subjected to a broad-band frequency loading throughout its life and it is essential to have a tool to characterize its behavior for both long and short duration loading.

A realistic Finite Element (FE) model of thorax with all its complexities is computationally very expensive especially for high frequency loading [1]. Following [1], it is assumed in this work that the thorax can be modeled as an assemblage of two-dimensional layered media. Among the existing methods, the Thin-Layer Method (TLM) is tailor-made for analyzing this kind of structure. The formulation is based on Fourier series representation of the unknown displacement components, which reduces the dimension of the problem and thus the cost of computation.

The method is employed to analyze thorax for several different stress pulses, which bring out the wave nature of the response (short duration load) and quasi-static behavior (large time load).

### METHODS

The layered model is assumed finite in the  $Z$  direction only. The TLM starts by Fourier series representation of the displacement field in the  $X$  direction, which upon substitution in the elastodynamic equation generates a set of partial differential equations, where  $z$  and  $t$  are the only independent variables. This equation is supplemented by the displacement and stress boundary conditions. Discretizing this reduced set of equations by following the regular FE procedure, a set of ordinary differential equation (ODE) is obtained. Both implicit Newmark method and explicit central difference methods are adopted to solve the ODE. Thus, along with regular constrained structures, unconstrained media can also be analyzed using this method, which is instrumental in modeling the thorax. Further, sliding contact condition without friction is also incorporated in the formulation, which is useful in modeling the interface between the bone and the lung.

### RESULTS AND DISCUSSION

The thorax is modeled by three layers of muscle, bone and lung, where the material properties and thickness of each layer are same as that given in Ref. [1]. Each layer is modeled with only 10 elements (system size  $61 \times 3$ ). Three different unit stress pulses are applied on top of the layer, whose time dependency is given by Blackman window function; with duration of 50, 100 and 200  $\mu$ s. The stresses are considered as

point loading in space for simplification although any kind of variation can be taken. Figure 1 shows the displacement of the thorax at the loading surface and interfaces for the three different stress pulses. For 50  $\mu$ s, considerable difference in displacement can be observed between the top layer and the interfaces, which suggests the predominant nature of the wave. However, for the longer duration loadings, all the three layers behave in the similar fashion, which signifies the quasi-static nature of the layers.

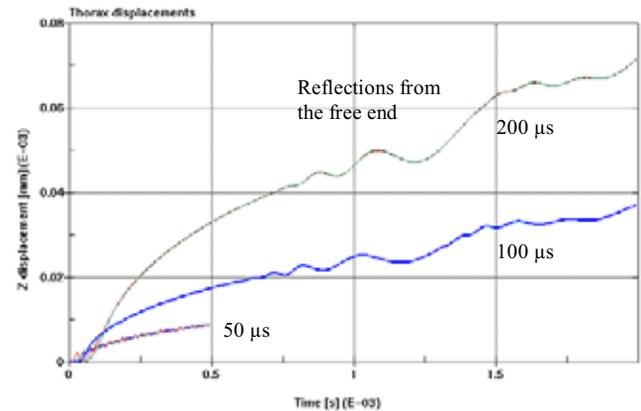

Figure 1: Displacement histories at the surface and interfaces

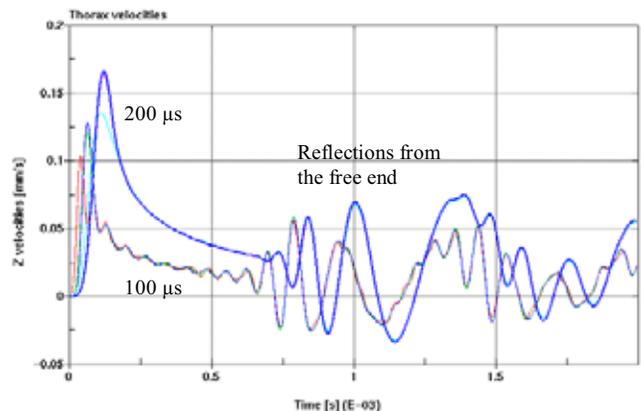

Figure 2: Velocity histories at the surface and interfaces

Figure 2 shows the velocity histories, where appreciable differences can be observed between surface and interface responses for 100  $\mu$ s, which is missing for 200  $\mu$ s loading. Further, the response is similar to that of a cantilever beam, whereas, for 50  $\mu$ s loading the response is that of a rod (not shown here). These observations can be used to make one-dimensional model of the thorax, which will be helpful in establishing the injury criteria. Overall, the example shows the efficiency of the TLM as a tool for analyzing thorax.

## Towards an advanced clinical expert system for patient-specific modeling and musculo-skeletal (MS) analysis?

<sup>1</sup>Serge VAN SINT JAN

<sup>1</sup>Department of Anatomy, Faculty of Medicine, Université Libre de Bruxelles (Belgium)  
email : [sintjans@ulb.ac.be](mailto:sintjans@ulb.ac.be), web: [www.ulb.ac.be/~anatem](http://www.ulb.ac.be/~anatem)

### INTRODUCTION

Current data collection procedures include numerous tools to collect data related to any part of the musculoskeletal system (MS) and its functions. Unfortunately, the MS complexity makes the simultaneous use of the above procedures difficult. The amount of procedures to possess is so large that no research center possesses them all. Therefore, inhomogeneous datasets must be first obtained from various sources (e.g., literature, colleagues), and registered if one wished to build complex MS models. Data format conventions and validation is therefore an important issue to insure the quality of the final models. Clinical data collection is even more problematic because of ethical constraints (no use of invasive tools), and time constraints (some category of patients are rapidly tired). Clinical MS analysis of patients is highly complex [1]. However, clinicians mostly rely on their experience and expertise to draw therapeutic conclusions because of the lack of other efficient tools. This lack is due to the current shortages (see above) of the state-of-the-art to generate a fully anatomically accurate and patient-customizable MS model.

Technologies found in modern simulations systems include advanced registration algorithms [2,3], state-of-the-art display [4], dynamic simulation [5], decision-making analysis [6,7] and knowledge-based management [8]. Most of them answer some local practical questions, either at fundamental research level or at clinical level. Unfortunately, most of these efforts appear to become not usable once it is exported to other locations where local needs or local resources are different.

This poor transportability of resources (data, hardware, protocols, software code, people, etc) can be explained at various levels: - complexity of the problems; - non-inhomogeneous data; - multidisciplinary; - lack of standardization; - lack of consensus about the goals to reach; - etc.

In summary, numerous efforts are currently spent in the world to answer local clinical needs. Unfortunately, none of them has been large enough to deliver a truly patient-specific clinical analysis tools.

### METHODS

A potential ideal system (Figure 1) would combine most above available technologies. It should be based on an anatomically accurate database including all components necessary to generate generic MS models using advanced registration tools (full arrow). Some parameters of the MS models will be registered to patient-specific data obtained through clinical analysis (dotted arrows). Knowledge-based algorithms that will offer a decision-making support to clinicians will then statistically analyze the "patient-customized" models.

### RESULTS

The final report produced by the system would help clinicians to orientate their diagnosis and final conclusions based on objective data analysis.

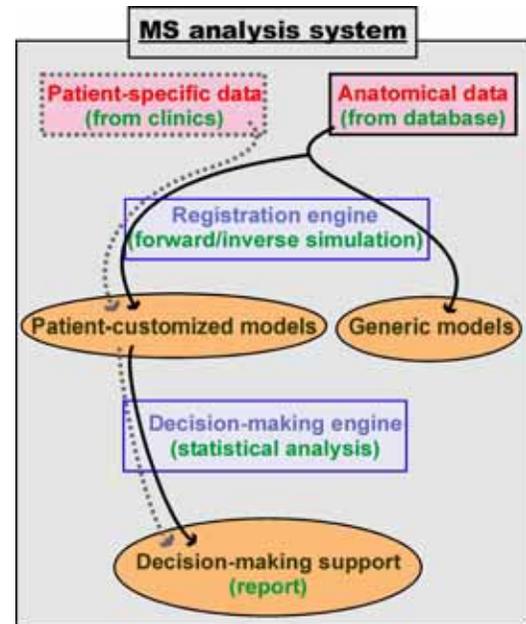

Figure 1. Sketch for MS analysis system.

### DISCUSSION

Such system is technologically possible, but will need an important, and well-organized multidisciplinary effort to gather all necessary expertises. This paper would like to emulate a discussion to determine is such effort is practically achievable. This will require a long-term effort coming from all fields available in Biomechanics.

## THE EFFECT OF AGING ON STROKE PARAMETERS IN SWIMMING

<sup>1,2</sup> Bryan Morrison, <sup>2</sup>Richard Hinrichs and <sup>2</sup>Bethany Larsen

<sup>1</sup>Valparaiso University, Department of Physical Education

<sup>2</sup>Arizona State University, Department of Kinesiology; email: Bryan.Morrison@valpo.edu

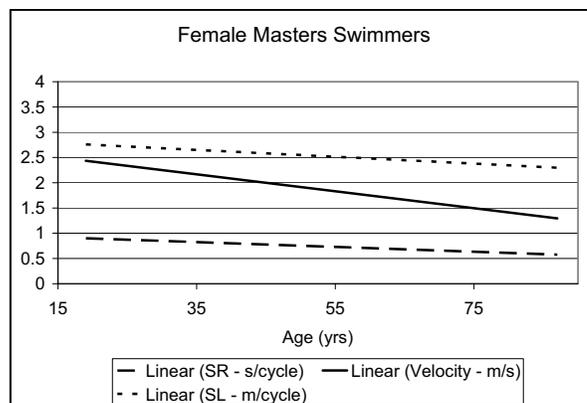

### INTRODUCTION

Recent studies have shown that swimming performance can be maintained through 35 years of age, but then linearly slows 9% for men and 5% for women per decade to age ~70 when women begin to slow at a greater rate than men [1]. They attribute this decline to a reduction in physiological functional capacity, which is the ability to perform the physical tasks of daily life and ease with which these tasks can be performed. Wilmore and Costill describe these changes more specifically as cardiorespiratory endurance, muscular strength, muscular endurance, flexibility, and body composition. These changes are likely to affect both the stroke rate (SR) and stroke length (SL). Hay [2] demonstrated that the changes in SR and SL with increased velocity for many activities including walking, running, and swimming are similar. Recently the relationship between running performance and age was investigated by Korhonen and colleagues [3] who reported similar declines of 5 % per decade in sprinters. They discovered that this was caused by a reduction in step length and no reduction in step rate. In longer races step rate was greater and step length was lower at the self-selected running velocity and was due to a significantly lower propulsive force. Swimmers appear to behave differently than runners. This can be seen at swim meets when the older swimmers tend to have a reduced SR during their races.

This leads to questions of why the SL-SR relationship with velocity is different for individuals and why it changes with age. If we are to train older swimmers to their potential, we have to determine what are the most important stroke techniques. Typically, journal and magazine articles are based on data from elite twenty-year-olds. This may or may not apply to older swimmers as they age and their bodies change. This research hopes to demonstrate the need for age-specific research in the SR-SL relationship and aging in swimming.

### METHODS

Two masters national swim meets were videotaped and analyzed. This gave 695 men and 276 women ranging in age from 19 to 88. The videotaping procedure involved setting up a 60 Hz camera in such a way as to be unobstructed throughout the races of interest. The second length of a short course 100-yard freestyle was used for analyses. This videotape was time coded to allow accurate frame specific times. Velocity was determined by measuring the time for the 15 yards between the flags from the time code on the videotape. The SR was determined from the elapsed time for

**Figure 1:** The best fit lines for velocity, SR, and DPS of female masters swimmers.

three stroke cycles (first water contact of the right hand to the next water contact of the right hand). SL was then be computed by dividing the velocity by the SR.

### RESULTS AND DISCUSSION

Velocity decreased as expected at a rate of 5.2 %/decade and 6.1 %/decade for men and women (Figure 1), respectively. This was due to a decrease in men of 9.6 %/decade and in women of 12.1 %/decade in SR. The SL declined slightly in both men and women to help increase the velocity reduction per decade. The SL for women declined 2.4 %/decade and the men declined 1.5 %/decade.

### CONCLUSIONS

The reduction in velocity seen by men and women masters swimmers can mainly be associated with a reduction in SR. The SL reduced slightly in both. However, the women were more affected by a reduction in SL. This demonstrates the need to promote tempo training with aging to help slow this velocity loss.

## CENTER OF PRESSURE TRAJECTORY DURING WHOLE BODY REACHING IN HEMIPLEGIC PATIENTS

<sup>1,2</sup>Jen-Suh Chern, <sup>2</sup>Saiwei Yang and <sup>2</sup>Wen-hun Yao

<sup>1</sup>Chang Gung University,

<sup>2</sup>Corresponding author, Yang Ming University; email: [swyang@bme.ym.edu.tw](mailto:swyang@bme.ym.edu.tw)

### INTRODUCTION

Center of pressure (COP) trajectory is one of the most common methods used to characterize the balance control of both normal subjects and patients with neurological disorders, such as stroke. Voluntary movements, such as targeted reaching, are practical essence for daily function and have been proved to be more effective in challenging and training the balance ability than simulated balance perturbations such as moving platforms [1,2]. Seated reaching for targets in different directions at the level of shoulder height has been shown to affect COP trajectory significantly. Whole body reaching (WBR) requires the subjects to pick up a target on the floor and the target distances were found to affect the movement of COP and activation patterns of postural muscles [3]. The purposes of this study were to compare the performance of WBR with different balance ability and the effects of target distances (10% body height vs 30% body height measured from the midpoint of both big toes) and directions (middle, M; left, L) on COP trajectory as measure by COP path excursion (WTP), COP maximum displacement in frontal (MML) and sagittal (MAP) direction.

### METHODS

Fifteen normal adults and 23 stroke subjects who fulfilled the inclusion criteria participated in this study. They were instructed to pick up a light weighted bean bag on the floor in two directions (in the middle and to the left or paretic side) at two distances (away from the big toe for 10% and 30% of body height) while standing erectly on RSSCAN pressure mat. A total of 12 trials (3 x 2x 2) were required. The functional reach distance (FR) was also measured as an indicator of balance ability.

The COP trajectory data were normalized (WTP to body height and foot length, MML to foot width, and MAP to body height and foot length) and averaged for statistical analysis. The FR was normalized by body height.

One way analysis of variance was used to compare the difference between normal and hemiplegic subjects. Repeated-measure analysis of variance was used to examine the target location effects. Pearson correlation coefficients were used to examine the performance of WBR for targets at various locations. The statistical significant level was set at  $\alpha = .05$  and all statistical analysis was performed using SPSS 8.0 software package for Windows.

### RESULTS AND DISCUSSION

As shown in table 1, FR was different between normal and hemiplegic subjects indicating that baseline balance ability of hemiplegic patients was inferior to the balance control of normal

subjects. The significant difference in COP trajectory between groups (Table 1) suggested that control of COP during whole body reaching could be an indicator of level of balance. Descriptive analysis showed that the amount of WTP, MML and MAP was larger in hemiplegic patients than in normal subjects, indicating that hemiplegic patients was not able to shift their COP according to the target location as much as normal subjects did. Targets locations were found to imposed graded dynamic balance challenge for both group [3].

Table 1. Comparison of group differences.

	S of MS	DF	F	P
10MWTP	0.001	1	30.602	<b>0.000</b>
MAP	0.003	1	42.147	<b>0.000</b>
MML	0.220	1	7.889	<b>0.008</b>
30MWTP	0.000	1	16.033	<b>0.000</b>
MAP	0.001	1	89.607	<b>0.000</b>
MML	0.258	1	6.101	<b>0.018</b>
10L WTP	0.002	1	8.075	<b>0.008</b>
MAP	0.004	1	41.976	<b>0.000</b>
MML	0.227	1	5.736	<b>0.023</b>
30LWTP	0.000	1	25.940	<b>0.000</b>
MAP	0.001	1	75.414	<b>0.000</b>
MML	0.278	1	5.468	<b>0.025</b>
FR	0.059	1	30.811	<b>0.000</b>

The correlation coefficients between FR and COP trajectory were negative, **significant and moderate**, indicating that the subjects with **shorter** FR shifted COP less in both frontal and sagittal directions than subjects with longer FR distance [4]. The correlations between FR and COP trajectory in frontal direction were the lowest indicating that FR might not be able to measure the balance control in frontal direction.

### CONCLUSIONS

The results of this study suggested that analysis of COP trajectory during WBR can distinguish subjects with different level of balance ability as measured by FR, indicating that WBR could be a dynamic balance training and evaluation tool for hemiplegic patients. Questioning of FR in measuring balance control in frontal direction [4] was supported by the correlation analysis in this study. Analysis of muscle activation patterns might be valuable for interpretation of balance mechanism.

**A NOVEL APPROACH FOR A SOLID OBJECT IMPACT ON HUMAN HEAD**

S. W. Gong, H. P. Lee, C. Lu

Institute of High Performance Computing, 1 Science Park Road, #01-01 The Capricorn  
 Singapore Science Park II, Singapore 117528 Email: [gongsw@ihpc.a-star.edu.sg](mailto:gongsw@ihpc.a-star.edu.sg)

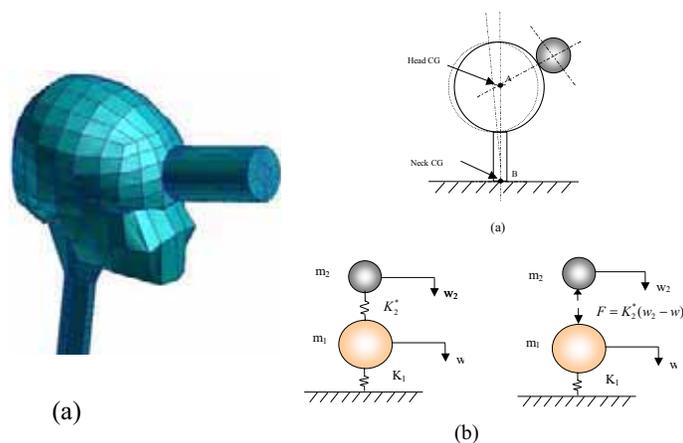

**INTRODUCTION**

This paper proposes a feasible methodology to estimate contact force between a solid striker and human head and to predict the human head response to the contact impact via an integration of a simple striker-head contact force model with finite element methods. The computational results from present methods were compared with Nahum’s experimental data [1]. The results closely matched the experimental data, showing that present approach facilitates the study on the problem of a solid object impacting on human head.

**METHODS**

Consider a solid object impacting on a static human head. The three-dimensional finite element model consists of both the head and striker as shown in Fig.1(a). The head model includes the skull, the brain, cerebrospinal fluid (CSF) and the neck. The striker is a solid cylinder attached with soft robber padding. It has a total weight of 5.6kg and impacted on the frontal bone of the head at 9.94m/s along the mid-sagittal plane, which is the similar with the condition used in Nahum’s test.

To estimate contact force between the solid object and human head during impact, a simple striker-head contact force model is proposed, as shown in Fig. 1(b). The striker-head contact force model contains five parameters; they are the head mass  $m_1$ , the striker mass  $m_2$ , the equivalent stiffness  $K_1$  of the human head and neck, the effective contact stiffness  $K_2^*$  and the initial striker velocity  $V$ .

**Figure 1:** (a) 3D FE head and striker model; (b) Striker-Head Contact force model.

Based on the striker-head contact force model, the contact force function is formulated in terms of the five parameters as follows:

$$F(t) = \begin{cases} K_2^* [a_1(c_1 - 1)\sin(\omega_1 t) + a_2(c_2 - 1)\sin(\omega_2 t)] & 0 < t < T \\ 0 & t > T \end{cases} \quad (1)$$

In the force function,  $T$  is the contact duration and

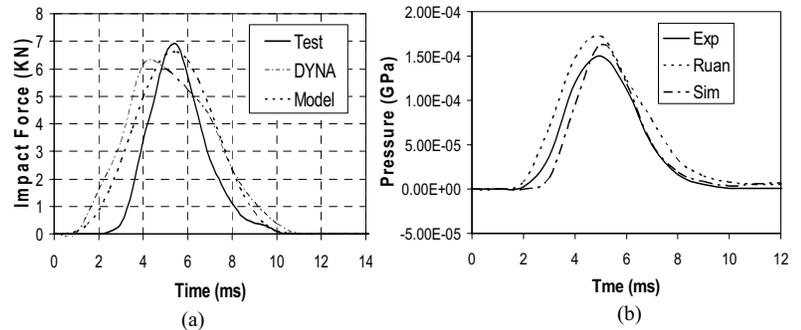

$$\omega_{1,2} = \frac{1}{2} \left( \frac{K_1 + K_2^*}{m_1} + \frac{K_2^*}{m_2} \right) \mp \sqrt{\frac{1}{4} \left( \frac{K_1 + K_2^*}{m_1} - \frac{K_2^*}{m_2} \right)^2 + \frac{K_2^{*2}}{m_1 m_2}}$$

$$c_1 = \frac{K_2^*}{K_2^* - \omega_1^2 m_2} \quad c_2 = \frac{K_2^*}{K_2^* - \omega_2^2 m_2} \quad a_1 = \frac{V}{\omega_1(c_2 - c_1)} \quad a_2 = \frac{V}{\omega_2(c_1 - c_2)}$$

The contact force predicted by Eq (1) can be directly applied to the FE head model to substitute the FE striker model.

**RESULTS AND DISCUSSION**

Figure 2(a) shows the contact force histories estimated by contact force function (1), computed by contact-impact algorithm implemented in the commercial code DYNA3D, and recorded from Nahum’s experiment, respectively. The comparison shows that the present contact force function (1) produces a reasonable result. Figure 2(b) shows a comparison between Nahum’s test results, Ruan’s numerical data [2] and present simulation outcomes. The present result has good agreement with the experimental results.

**Figure 2:** (a) Comparison of contact forces; (b) Comparison of Coup Pressures

**CONCLUSIONS**

The proposed approach facilitates the estimation of striker-head contact force and the prediction of human head response to solid contact impact. It can also be used to evaluate the influences of a solid striker’s material properties, mass and velocity on head injury.

#### INTRODUCTION

To maintain stability of the body when the perturbation was given while moving, the postural control is required otherwise it will cause falling. Although many studies reported on postural control to perturbation in standing[1,2], few study reported on postural control against to perturbation during walking[3]. The purpose of this study was to examine postural control against perturbation during treadmill walking. In addition, we hypothesized a strategy of postural control in such a situation and suggested the effect of aging on postural control.

#### METHODS

Ten young and twenty-nine elderly subjects participated in this study. We used a separated-belt treadmill (Figure 1), and perturbations were produced by rapidly decelerating one side of the walking-belt for 500 ms while walking. To young subjects, two types of the perturbation were given five times each in three minutes walking: 50% deceleration of the initial speed (moderate perturbation) and 100% deceleration of the initial speed (strong perturbation). To elderly subjects moderate perturbations were given five times in three minutes of walking. The electromyogram responses of leg, thigh, and trunk muscles on the both sides and the acceleration at the pelvis were measured. We classified subjects from reaction patterns of muscles, and compared them.

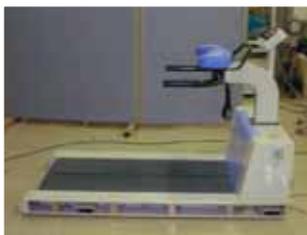

Figure 1: Separated-belt treadmill (PW21; Hitachi, Japan)

#### RESULTS AND DISCUSSION

Four reaction patterns of muscles were observed: “ankle strategy”, “mixed ankle and hip strategy”, and others (Figure 2). Comparing the ankle strategy seen in young and elderly subjects, the response of tibialis anterior on the perturbed side after the perturbation was significantly delayed in elderly subjects ( $p < .05$ )(Figure 3).

The “mixed ankle and hip strategy” observed in this study did not change with advancing trials, although the mixed strategy in standing is defined as the transitory pattern to pure ankle strategy or hip strategy when the stimulus exceeds the control limit. We therefore concluded that the mixed strategy

observed in this study was different from the mixed strategy seen in standing. The pattern of muscle recruitment was immediate antero-distal muscle activities followed by postero-proximal muscle activities after perturbation. This pattern resembled whiplash. We suggest this mixed strategy be established as a new strategy. It is thought that the posture of a subject moves like striking a whip since this new strategy showed the ankle strategy followed by the hip strategy, and we considered this new strategy to be a “whiplash strategy”. Also, this new strategy was seen when the body shake was large, so it is suggested that it is an important strategy for subjects who have low ability of postural control.

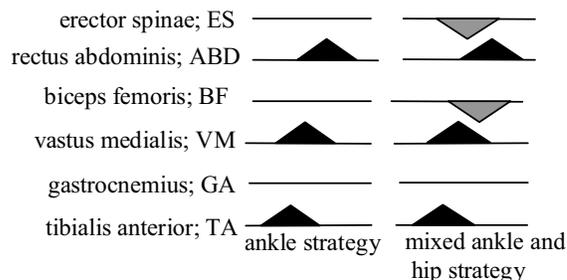

Figure 2: Reaction patterns of muscles

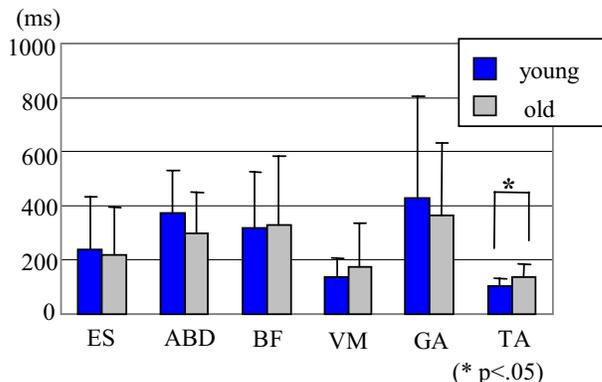

Figure 3: Comparing the ankle strategy (perturbed side) (\*  $p < .05$ )

#### CONCLUSIONS

From these results, we concluded that there is a specific postural control strategy in walking, and there are differences in postural control ability between elderly and young subjects.

## MODELING OF PELVIS AND THORAX ROTATIONS IN HEALTHY AND PATHOLOGICAL GAIT

### INTRODUCTION

During gait the pelvis and thorax rotate in the transverse plane in a near sinusoidal pattern [1]. With changes in gait velocity, the relation between these rotations changes, especially in terms of the relative timing. Whereas at low velocities the rotations are almost in phase, phase lead of the pelvis increases at increasing velocities up to around 2.5 radians (140 degrees; Figure 1). In several pathological conditions, among which low back pain [1] and pregnancy-related pelvic girdle pain (PPP) [2] this increase in phase difference has been shown to be less pronounced (Figure 1).

The out-of-phase relationship between pelvis and thorax rotation in healthy gait has been interpreted as a coordinative strategy to reduce body angular momentum around the vertical axis [3]. However, since stride frequency increases with gait velocity, it may be the case that this phase relationship emerges from second order dynamics of the system without any active coordination. The reduced phase difference in patients with disorders such as low back pain could then be accounted for by an increased stiffness, consequent to increased cocontraction [4]. Thus, we set out to model the relative rotations of pelvis and thorax in healthy and pathological gait as second order linear dynamics.

### METHODS

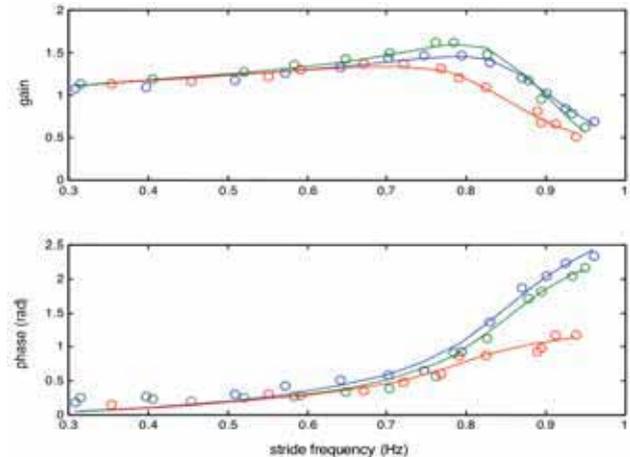

Data were derived from an earlier study on healthy nulliparous women, healthy pregnant women, and pregnant women with PPP [2]. Relations between pelvis and thorax rotations in the transverse plane were characterized as group averaged frequency responses (gain and phase as function of stride frequency).

Analytical solution of a linear second order system with harmonic position forcing was used to express gain and phase as function of frequency, inertia (of the thorax), stiffness and damping. Thorax inertia was estimated based on literature data [5]. First, this model was fitted to the experimental frequency response by optimizing a constant stiffness and gain. Then, a second model was developed in which stiffness and damping were modeled as sigmoidal functions of stride frequency.

### RESULTS AND DISCUSSION

The model with constant stiffness and damping did not permit an acceptable description of the experimental data.

The second model adequately described the data of all three groups (Figure 1). The model predicted stiffness and damping to decline above stride frequencies of 0.65 Hz. The declining stiffness and damping might be due to reduced activity of muscles, for example of left rotating muscles active when the trunk is right rotated (stiffness) or rotating to the right

**Figure 1:** Actual relations between transverse pelvis and thorax rotation (circles) during gait in healthy nulliparous (blue) pregnant (green) and pregnant women with PPP (red) modeled as the frequency responses of second order systems (lines) with stiffness and damping declining with frequency.

(damping). The stiffness, however, declines below values expected on the basis of passive trunk stiffness [6], which implies that at higher velocities active counter rotation is required to obtain the kinematics observed. This can be explained by increased activity of muscles producing for example left rotation when the trunk is already left rotated. For damping no reference data are available, but similarly the decreased damping could be a consequence of increased activity of left rotators when the trunk is rotating to the left and vice versa. The PPP patients differ from the healthy controls mostly in that the damping at higher stride frequencies is reduced less than in the controls.

### CONCLUSIONS

Relative transverse rotation between pelvis and thorax during gait can not be modeled as a passive second order system. With increasing stride frequency stiffness and damping are reduced, which suggests that counter rotation of the thorax is actively coordinated. This counter rotation is less pronounced in subjects with PPP than in healthy controls.

## CAN REPETITIVE SHEAR LOADING OF SPINAL MOTION SEGMENTS CAUSE DISC INJURY?

<sup>1,2</sup>Jaap H. van Dieën, <sup>1,3</sup>Albert van der Veen, <sup>1,3</sup>Barend J. van Royen and <sup>1,2</sup>Idsart Kingma

<sup>1</sup>Institute for Fundamental and Clinical Human Movement Sciences, <sup>2</sup>Faculty of Human Movement Sciences, Vrije Universiteit, Amsterdam, <sup>3</sup>VU Medical Center; email: [J.H.van.Dieen@fbw.vu.nl](mailto:J.H.van.Dieen@fbw.vu.nl)

### INTRODUCTION

The lumbar spine, especially at the L5/S1 level, is subjected to substantial anterior directed shear forces during many activities [1]. In vitro experiments have shown that shear loading of spinal segments can cause bony failure, most often of the pars interarticularis [2,3]. However, the intervertebral disc (IVD) has been reported to contribute significantly to shear stiffness [3] and may thus also be at risk of failure. Two in vitro experiments using porcine lumbar spine segments were performed to establish whether soft tissue damage could occur in repetitive shear loading.

### METHODS

In experiment 1, 14 lumbar spines of immature pigs (80 kg) obtained from the slaughterhouse were fresh frozen. Maximum shear strength of the T13/L1 segment was tested at a strain rate of 0.1 mm/s, while the segment was loaded with a compression force of 1600 N (800 N for 5 younger specimens tested in experiment 2). L2/L3 and L4/L5 segments were loaded with a sinusoidal varying shear force (0.5 Hz) between 20 and 80% of the strength of the corresponding T13/L1 segment, while again the segment was statically loaded in compression. Shear displacement and force were continuously recorded at 10 Hz. The posterior elements (PE) were removed in half of the segments, leaving the IVD as the only structure providing shear resistance. The groups with and without PE consisted of equal numbers of L2/L3 and L4/L5 segments.

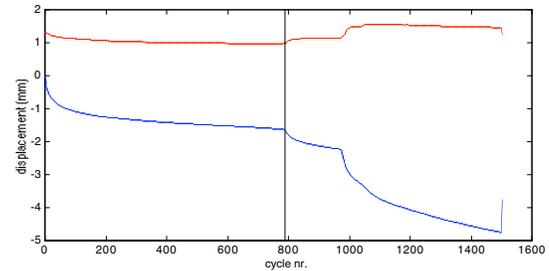

In experiment 2, 12 lumbar spines of immature pigs (40-80 kg) were used. The protocol was similar to experiment 1, except that all segments were left intact and that half of the segments were tested in the neutral position and half were tested in a 10 degrees flexed position.

The deformation within the initial cycles was determined as an indicator of shear stiffness. The time to failure (obvious discontinuity in overall deformation as well as range of deformation within the cycles; see Figure 1) was determined. Furthermore the deformation within the cycles just preceding failure and just after failure were compared to indicate changes in stiffness.

L4/L5 and L2/L3 segments from the same specimen were treated as dependent observations and all tests were done using a Wilcoxon matched pairs test.

### RESULTS AND DISCUSSION

Shear strength of the T13/L1 segments ranged from 1062 to 1985 N in experiment 1 and 428 to 2282 N in experiment 2, where spines of 40 kg animals were included.

**Figure 1:** Mean (blue) and amplitude (red) of deformation in each of 1500 subsequent loading cycles in anterior shear of an intact segment in a neutral position. The vertical line at cycle 789 indicates the instant of failure.

In experiment 1, shear loading caused a larger deformation (1.5 vs. 1.0 mm,  $p = 0.013$ ) during the initial cycles, when PE had been removed. In the group with PE, 6 segments did not fail within 1500 cycles. In the group without PE, 3 segments did not fail. Time to failure of the specimens that did fail was 3.3 times longer ( $p = 0.017$ ) in the group with PE. In this group, deformation within cycles after failure was larger than that preceding failure, indicating a loss of stiffness. Whereas in the group without PE, deformation within cycles decreased after failure, indicating increased stiffness. The results suggest bony failure in the segments with PE, which was confirmed by inspection of the specimen after testing. However, when PE were removed, soft tissue injury occurred already after relatively few cycles.

Since the IVD may be less protected by the PE when the specimen is flexed, experiment 2 compared specimens tested in flexed and neutral positions. However, for none of the variables studied were significant differences found between the flexed and neutrally positioned segments.

### CONCLUSIONS

Although repetitive anterior shear forces are capable of inducing IVD damage in porcine spine segments, this appears not to occur when PE are present, not even when the segment is flexed close to maximal flexion.

## NONLINEAR ANALYSIS OF THE BEHAVIOUR OF THE HUMAN CORNEA

Long-yuan Li and Brian Tighe

School of Engineering and Applied Science, Aston University, Birmingham B4 7ET, UK

Email: [l.y.li@aston.ac.uk](mailto:l.y.li@aston.ac.uk) and [b.j.tighe@aston.ac.uk](mailto:b.j.tighe@aston.ac.uk)

### INTRODUCTION

The biomechanical properties of the human cornea are fundamental to our understanding of corneal behaviour in response to keratorefractive surgery and aspects of corneal physiology where mechanics plays an important role. Recent research on the whole corneal structure has showed that the mechanical behaviour of the cornea is rather complicated [1-3]. The unexpected non-uniform distribution of strain in the meridian direction of the cornea measured in experiments indicates that the corneal has regionally different mechanical properties. The principal causes for the regional variability in mechanical properties of the human cornea may include the variability of the elastic modulus of fibrils, the reinforcing ratios of collagen fibrils, the orientation of fibrils, and/or the sequential recruitment of fibrils [3,4]. Previous studies showed that the diameter of fibrils is constant in the centre and para-centre, while there is increased variability in the diameter of fibrils in the corneal periphery. In the limbus, the diameter of fibrils increases. Unfortunately, no accurate quantitative determinations on the regional variation in the volume fraction of collagen fibrils are available, although variations possibly are small.

### METHODS

The cornea is approximated as a spherical cap with a variable thickness. The radius of curvature of the mid-surface of the shell is assumed to be  $R = 7.86$  mm. The horizontal diameter of the mid-surface of the shell at the edge is assumed to be  $D_b = 15$  mm (see Fig.1). The corneal thickness is assumed to increase linearly from  $h_{min} = 0.5$  mm at the centre to  $h_1 = 0.66$  mm at the limbus and to  $h_2 = 1.0$  mm at the edge. The cornea is subjected to the intra-ocular pressure of  $p = 2.135$  kPa. The boundary of the shell is assumed to be hinged at the edge. In the present nonlinear analysis the cornea is assumed to be perfectly axial-symmetric and the analysis is performed within the cross-section by using axial-symmetric plane elements.

The cornea material is modeled as an orthotropic, nonlinear elastic material with principal axes defined as in the directions of meridian and circumference. Since the reinforcing ratios of the collagen fibrils vary from the central region to the limbus the overall orthotropic moduli in meridian and circumference are not constants. The stress-strain equation in the uni-axial stress state, in the principal axes is assumed as [5]:

$$\sigma = \alpha \epsilon^2 + \beta \epsilon \quad (1)$$

where  $\sigma$  and  $\epsilon$  are the stress and strain,  $\alpha$  and  $\beta$  are constants. The nonlinear stress-strain equations for a three-dimensional orthotropic material can be derived based on the uni-axial stress-strain equation (1).

The problem is solved using the nonlinear finite element analysis program (Femlab). Because of axial-symmetry, only

half of the cornea within the axial-symmetric plane is analyzed.

### RESULTS AND DISCUSSION

Fig.1 shows the deformation of the cornea and corresponding von Mises stress distribution in the cross-section. The high stresses are found mainly in the areas close to the limbus and the edge where the boundary is fixed. More results and the comparisons between the model predictions and experimental results will be shown in the conference presentation. Results on the parametric studies will also be provided in the presentation.

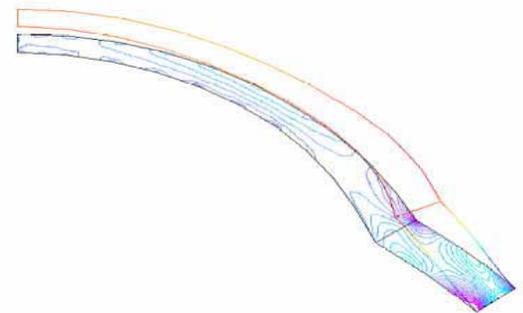

Fig.1 von-Mises stress distribution and deformed shape of the cornea subjected to intra-ocular pressure.

### CONCLUSIONS

This paper presents a numerical investigation on the mechanical behaviour of human corneas by using a nonlinear finite element analysis method. After verification, the FE model is used to examine both normal and keratoconic corneas. Future extensions of this research will include the interaction between the stress analysis model and the flow model of corneal hydration [6]. The research presents here is part of a long term project to develop accurate predictive tool that can assist the clinical management.

## SYMMETRY AND ASYMMETRY IN THE LOWER LIMBS OF ATHLETES DURING GAIT

<sup>1</sup>Shigehito Matsubara, <sup>1</sup>Tetsu Yamada, <sup>2</sup>Sekiya Koike and <sup>2</sup>Michiyoshi Ae

<sup>1</sup> Doctoral program in Health and Sport Sciences, University of Tsukuba; email: shige-m.taiiku.tsukuba.ac.jp

<sup>2</sup> Institute of Health and Sport Sciences, University of Tsukuba

### INTRODUCTION

Gait analysis is an effective tool for evaluating and quantifying effects of a surgical intervention or rehabilitation on a patient's gait (Schutte et al., 2000). Although gait symmetry has often been assumed to simplify data collection and analysis (Heydar et al., 2000), asymmetry of the lower limbs will be an indication for a risk of abnormality in the physical function. The similar idea may be applied to gait analysis for athletes who suffered from various injuries of the lower limbs. The symmetry-asymmetry analysis in athlete's gait will provide us with useful information to precaution and prevent from serious injuries which may be induced by the asymmetry in the lower limbs. Therefore, investigating symmetry and asymmetry in the lower limbs of athletes has a special significance. The purpose of this study was to investigate gait pattern of uninjured and injured athletes to determine symmetry and asymmetry in the lower limbs.

### METHODS

The gait of 8 injured athletes (age 20.3±2.3 yrs) and 10 uninjured athletes (age 19.2±0.8 yrs) from a university track club was analyzed. After the explanation of the procedure and safety of the experiment, informed consent was obtained from the subjects. Three-dimensional coordinates of 47 reflective markers attached to the subjects were obtained with an optical motion measurement system (VICON 612) with eight cameras operating at 120Hz, which was synchronized with two KISTLER force platforms. Subjects were asked to walk in barefoot at a self-selected speed on the laboratory floor under which the force platforms were mounted.

Kinematics and force platform data were used to estimate the joint torque and joint torque power at the hip, knee and ankle of the lower extremities during the stance phase by an inverse dynamic approach. Asymmetry index of the lower limbs was calculated for gait descriptors such as step length by the following equation.

$$AI = | \text{Right} - \text{Left} | * 100 / ( \text{Right} + \text{Left} ) / 2$$

ANOVA was used to test differences in gait descriptors and asymmetry index (AI) between two groups with significant level of 0.05.

### RESULTS AND DISCUSSION

Table 1 shows mean and standard deviation of AI. Although there was no significant differences in AIs of gait descriptors such as step length (SL), step frequency (SF)

Table 1: Asymmetry indexes for the athletes

\*: P<0.05

	step length(%)	step frequency(%)	walking ratio(%)	STT(%)	SWT(%)	SST(%)	DST(%)
uninjured	17.9±9.4	4.8±3.0	24.2±14.4	1.9±1.9	8.9±6.3	6.1±4.5	0.08±0.01*
injured	9.2±8.0	4.7±5.4	19.2±18.3	3.6±4.8	4.4±6.8	4.4±6.8	0.1±0.02*

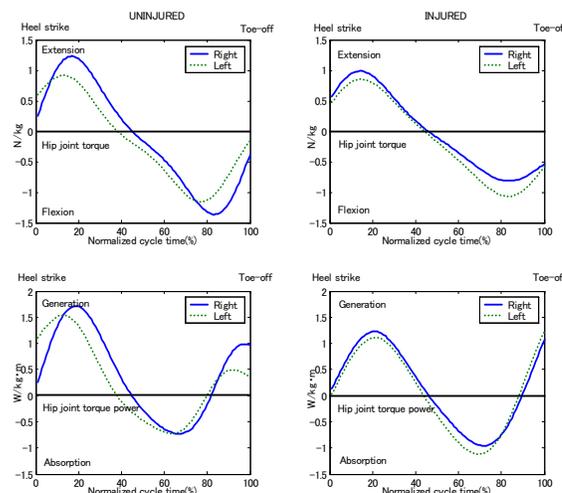

Figure 1: The hip joint torque and torque power for an uninjured and an injured athlete

and so forth, AI of SL and walking ratio(SL/SF) tended to be larger in the uninjured athletes than those of the injured athletes. The AI of double support time for the injured athletes was significantly larger than the uninjured athletes. Smaller AI of gait descriptors for the uninjured athletes was expected, but the results indicated that this hypothesis was not accepted, except for double support time which was a symptom of the asymmetry for the injured athletes.

Figure 1 shows hip joint torque and torque power patterns for the uninjured and injured athletes. The peak torque and torque power of the right hip for the uninjured athlete were greater than that of the injured athlete. However, no big difference was observed in the joint torque of the left leg between two athletes. This may be interpreted as an over-exertion of the torque and power at the right hip joint of the uninjured athlete because he could cancel out the asymmetry in joint kinetics through his adaptability. It is speculated from these results that injured athletes might change the gait pattern involuntarily not so as to be beyond the range of control, while uninjured athletes could control their gait pattern over their asymmetry in the lower limbs by the uninjured physical function. The other possible reason for the asymmetry of uninjured athletes may be laterality in their leg which is used as take-off leg and so forth.

## GENDER DIMORPHISM IN KNEE JOINT MECHANICS AFFECTS ACL LOADING

<sup>1</sup>Kiyonori Mizuno, <sup>2</sup>Jack Andrish and <sup>2</sup>Ton van den Bogert and <sup>1</sup>Scott McLean,

<sup>1</sup>Department of Biomedical Engineering, The Cleveland Clinic Foundation, Cleveland OH

<sup>2</sup>The Orthopaedic Research Center, The Cleveland Clinic Foundation, Cleveland OH; email: [mcleans@ccf.org](mailto:mcleans@ccf.org)

### INTRODUCTION

Anterior cruciate ligament (ACL) injury is a common and potentially traumatic knee joint injury. Women suffer ACL injuries more frequently than men (Arendt and Dick, 1995), with this disparity commonly attributed to a combination of neuromuscular, anatomical and hormonal factors. The potential for gender differences in ACL loading, and hence injury risk, stemming from a gender dimorphism in knee joint mechanics however, has not been addressed. The current study examined whether the ACL in the female knee experiences larger strain than its male counterpart, under application of the same three-dimensional (3D) knee joint loading state.

### METHODS

Methods for data collection have been described previously (Mizuno et al., 2004). Joint loads (forces and torques) were applied to 5 male (57 ± 13.4 yrs) and 5 female (58.3 ± 11.5 yrs) cadaveric specimens via a custom-designed loading device and were recorded with a 6 DOF load cell fixed to the tibia. Synchronous knee flexion data were recorded via an electro-goniometer secured across the joint. ACL strain was recorded via a microminiature differential variance reluctance transducer (DVRT, Microstrain, Burlington, VT) attached to the anterior-medial bundle (AMB). Data were collected at 10 Hz while flexion angle and loads were varied continuously for about 25 minutes. Regression analysis was applied to determine how ACL strain depended on seven independent variables: anterior-posterior, medial-lateral and compression force, flexion-extension, varus-valgus and internal-external rotation torques and knee flexion angle. Specifically, single specimen data were fit to the following model:

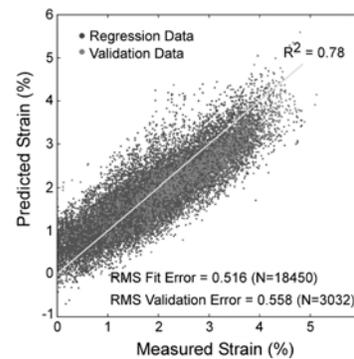

$$\varepsilon = a_0 + \sum_{i=1}^7 b_i x_i + \sum_{i=1}^7 \sum_{j=1}^i c_{ij} x_i x_j \quad (1)$$

where,  $\varepsilon$  corresponds to AMB strain and  $x_i$  is the  $i^{\text{th}}$  independent loading variable. Specimen-specific regression coefficients were obtained via least-squares fitting, following which model strain predictions were validated. A clinically relevant 3D knee joint loading state, comprising combined valgus (10 Nm) and internal rotation torque (10 Nm) was then input to each specimen-specific regression model, at flexion angles of 0, 15, 30, 60, and 90 degrees (Kanamori et al., 2000). Resulting ACL strains were submitted to a 2-way ANOVA to test for gender and flexion angle effects ( $P < 0.05$ ).

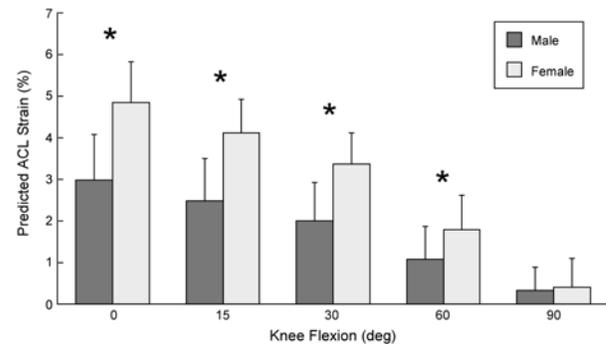

### RESULTS AND DISCUSSION

Male and female specimen specific regression models could predict ACL strain within  $0.51\% \pm 0.10\%$  and  $0.52\% \pm 0.07\%$  of the measured data respectively, and in each case explained more than 75% of the associated variance (Figure 1). Predicted strains in each model were also consistent with that obtained experimentally for the same loading and knee flexion conditions. Significant increases ( $p < 0.05$ ) in mean peak ACL

strains were observed in female compared to male models under the same load application (Figure 2). It is not clear which aspect of gender-dimorphic joint mechanics is responsible for this ACL strain increase. It is possible that the female ACL experiences the same force as the male ACL, but is more compliant and undergoes larger strains. It is equally plausible that female knee geometry is such that the ACL experiences a larger force than in the male knee when subjected to combined valgus and internal rotation loads. Further study is needed to quantify the contributions of these two potential mechanisms.

**Figure 1:** Model predicted versus measured ACL strain.

**Figure 2:** Gender comparisons of predicted strains.

### CONCLUSIONS

A gender dimorphism in knee joint mechanics exists, which may play an important role in ACL injury risk during dynamic sports postures. The ultimate success of current injury prevention strategies, typically teaching females to adopt “male” neuromuscular patterns, may thus be severely compromised. Elucidation of the underlying causes of this gender dimorphic behavior would facilitate more effective screening and prevention of ACL injury in the future.

## SAGITTAL PLANE BIOMECHANICS DURING SPORT MOVEMENTS DOES NOT EXPLAIN HIGHER INCIDENCE OF ACL INJURY IN FEMALES

<sup>1,2</sup> Scott McLean, <sup>1</sup>Xuemei Huang and <sup>1,2</sup>Ton van den Bogert

<sup>1</sup>Department of Biomedical Engineering, The Cleveland Clinic Foundation, Cleveland OH

<sup>2</sup>The Orthopaedic Research Center, The Cleveland Clinic Foundation, Cleveland OH; email: [mcleans@ccf.org](mailto:mcleans@ccf.org)

### INTRODUCTION

Anterior cruciate ligament (ACL) injury is a common and traumatic sports injury, particularly for females. Female neuromuscular control patterns can contribute to their increased risk of ACL injury. For example, women tend to land in a more extended (hip and knee) position than men (e.g. Malinzak et al., 2001). This places the patellar tendon in a more anterior orientation (Herzog and Read, 1993), which is theorized to increase the amount of quadriceps-induced ACL force, and thus contribute to ACL injury (DeMorat et al., 2004). During athletic movements, however, the quadriceps and ground reaction forces are not independent of flexion angle, or of each other, which is ignored in this theory. The current study quantified the contributions of gender specific sagittal plane knee biomechanics to the force in the ACL during an athletic movement linked to ACL injury.

### METHODS

Ten male and ten female NCAA basketball players had lower limb 3D kinematics and kinetics quantified during the stance phase of ten sidestep cutting maneuvers. A dynamic model of the pelvis and lower extremity was generated for each subject as described previously (McLean et al. 2003). Joint angles were obtained from Mocap Solver (Motion Analysis Corporation, Santa Rosa, CA) and intersegmental 3-D forces and moments at the knee were solved using standard inverse dynamics. Intersegmental loads were defined as components of external load on the joint, expressed in a joint coordinate system. Anterior tibial shear force ( $F_{ant}$ ), external flexion ( $M_{flex}$ ), valgus ( $M_{val}$ ), and internal rotation moments ( $M_{int}$ ) were used for further analysis. ACL force ( $F_{ACLsag}$ ) due to the sagittal plane joint loading mechanism was estimated as:

$$F_{ACLsag} = F_{ant} + \left( \frac{M_{flex}}{d(\theta)} \right) \times \sin \alpha(\theta),$$

where  $d$  is the moment arm of the patellar tendon as a function of knee flexion angle  $\theta$ , and  $\alpha$  represents the angle between the patellar tendon and the long axis of the tibia in degrees, also a function of knee flexion (Herzog and Read, 1993). This equation does not incorporate hamstring force contributions, and thus represents a worst-case scenario in terms of ACL injury risk during sidestepping. Peak joint loads,  $F_{ACLsag}$  and initial contact knee flexion data were obtained from each trial, averaged for each subject, and compared between genders using a Student t-test ( $p < 0.01$  after Bonferroni correction).

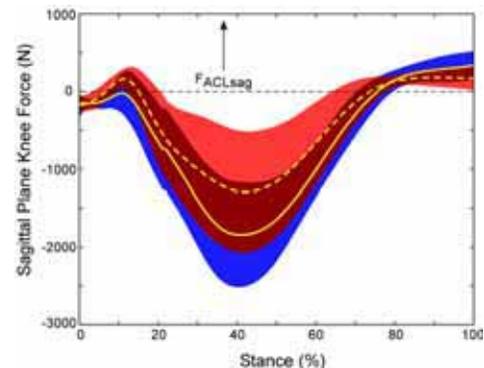

### RESULTS AND DISCUSSION

Women landed with less initial knee flexion (Table 1), similar to previous observations (Malinzak et al., 2001). Significant gender differences were found in peak valgus moment only (Figure 2), which is consistent with data obtained via gender specific forward dynamic simulations of sidestepping

movements (McLean et al., 2004). The sagittal plane loading mechanism failed to significantly load the ACL for either gender (Figure 1). In fact, the joint forces were mainly posterior, loading the PCL rather than the ACL. Females loaded the ACL during early stance, but the magnitude was much smaller than known failure loads. The closed-chain relationship between flexion angle, external ground reaction force, and quadriceps force appears to protect the ACL from excessive sagittal plane loading. Specifically, during early stance, the ground reaction force acts posteriorly on the tibia, protecting the ACL. Quadriceps force does not become large until later in stance, when the flexion angle is such that the patellar tendon orientation is no longer harmful.

**Table 1:** Peak load comparisons across gender (\* $p < 0.01$ ).

Variable	Male	Female
$\theta_{init}$ (deg)*	30.4 ± 3.6	24.0 ± 1.3
$F_{ant}$ (N)	294.2 ± 126.3	194 ± 85
$M_{flex}$ (Nm)	311.4 ± 84.4	282 ± 60
$M_{val}$ (Nm)*	36.6 ± 12.2	70.0 ± 19.8
$M_{int}$ (Nm)	31.7 ± 14.3	20.0 ± 16.2
$F_{ACLsag}$ (N)	378 ± 173	287 ± 110

**Figure 1:** Male and female sagittal plane ACL force.

### CONCLUSIONS

Gender differences in sagittal knee biomechanics do not alone explain the higher incidence of ACL injury in women. Gender differences observed in peak valgus moment add further support the evolving hypothesis that knee valgus is the primary extrinsic contributor to the female injury mechanism.

## CURRENT CHALLENGES IN CLINICAL GAIT ANALYSIS

Bruce A. MacWilliams and Jacques L. D'Astous  
Shriners Hospitals for Children, Intermountain Unit and the University of Utah, Dept. of Orthopaedics  
bmacwilliams@shrinenet.org

Video based systems for analyzing human movement began evolving in the early 1970s. By the mid 1980s, commercial systems had grown out of these early efforts. Basic, standard arrangements of reflective markers placed on the lower limbs and associated methods to compute joint angles from these markers were also developed. These marker sets were created to work with a small number of cameras (3 or 4) which by today's standards had exceedingly poor resolution. Capturing and reconstruction software was rudimentary, meaning that sometimes hours were needed to process a single trial. Thus, simplicity and a minimum number of markers were the imperative of the day. Today's gait laboratories typically have at least twice the number of cameras (8-12) that were the standard in the 1980s and 1990s. More importantly, each of these cameras has many times the resolution of their predecessors. The capturing and reconstruction software have advanced to the point where it is now possible to process data in real time. Modern systems are therefore easily capable of tracking many times the number of markers which limited the early model development. Yet with all these advances, most labs use the same commercial gait models that were developed for the earliest technology. Some of the specific clinical deficiencies of these gait models are:

*Joint axis identification.* There are various options for the user to attempt to align markers that reflect the axis about which knee and ankle motions occur. Attempting to specify these axes using surface markers is notoriously unreliable. This leads to a reduction in reported flexion and erroneous increases in other angles. Misalignment of the knee axis also directly affects hip rotation angles. Accurate representation of this parameter would be greatly beneficial in eliciting the effects of femoral anteversion. Errors of 10 to 15° are not uncommon, and these are of the same magnitude as pathologic values of anteversion, so this measure is not normally helpful.

*Hip joint center location.* In order to accurately compute hip kinematics and kinetics, the location of the femoral head must be known. Unlike the knee and ankle, the hip joint is not easily accessed. To locate hip joint centers, markers are placed on the pelvis, and the hip joint is determined using a calculation with parameters determined from normal individuals. Some or many of the patients seen for gait analysis may not fit this normal profile, particularly those with hip dysplasia. For these individuals, there are likely gross inaccuracies in hip joint kinematics and kinetics.

*Skin motion.* An inherent problem with any surface marker model is motion of the skin relative to the bone. The biomechanics of interest are those of the bony segments. As joints move and muscles change shape, the skin surface will translate relative to the underlying bone. Marker landmarks are chosen to avoid particularly muscular regions, but there

will always be some error. In current models there is no way to assess or compensate for these inaccuracies.

*Foot model.* One of the greatest frustrations with current models is the lack of useful information about the foot. Many multisegmental foot models have been developed and validated, yet commercial gait models treat the foot as a single rigid segment, essentially a "foot bone" and motions within the foot are attributed to the ankle joint. This approach to foot modeling is a direct result of limitations of older systems.

*Interlaboratory consistency.* A recent study<sup>1</sup> showed that while systems in different labs produced reliable and accurate data, there were large differences between labs due to marker placement (e.g. hip rotations varied by as much as 28°). This study highlights some of the sensitivities and difficulties of marker placement in current models.

*Additional segments.* During gait the trunk is often used to compensate for distal motor deficiencies. While trunk and upper extremity models are now commercially available, standardization on their implementation is lacking. Because these were only recently developed commercially, many users had already created their own models. Thus there is little agreement on marker placement and computational methods for the trunk, head and upper extremities.

*Additional quantitative parameters.* Current commercial software computes joint angles, temporal parameters and, if force plate data are present, joint moments and powers. There are other parameters however which may be useful in assessing a patient's current status or outcome. These include the "gait index" and functional muscle lengths. While these data may be processed with the information from current models, additional software and processing steps are required.

*Muscle Forces.* While EMG provides valuable information about muscle timing, there is no way to predict muscle forces with standard software. Information about individual muscle forces could be invaluable to treatment planning. This analysis requires muscle modeling and optimization techniques and may represent the next generation of gait software.

In summary, while current commercial gait models have been providing useful clinical data for many years, there are several recognized inherent deficiencies. New cameras allow for many more markers to be visualized and real time tracking technologies could be employed to develop more sophisticated data collection methods which may address these limitations. Recent commercial programs have made strides toward some of these issues, but most laboratories have yet to adopt these.

## THE EFFECT OF ANATOMICAL AND ROBUSTNESS CONSTRAINTS ON OPTIMUM JUMPING PERFORMANCE

Maurice R. Yeadon, Cassie Wilson and Mark A. King  
Loughborough University; email: M.R.Yeadon@lboro.ac.uk, web: www.lboro.ac.uk

### INTRODUCTION

Using a simple criterion, such as maximum jump height, in a simulation model optimisation study may lead to a theoretical performance which is not achievable due to the violation of anatomical constraints or due to the effects of timing perturbations on performance. The aim of this study was to determine the effects of imposing anatomical and robustness constraints on the optimisation of the height reached in a running jump.

### METHODS

A planar eight-segment torque-driven subject-specific computer simulation model of the contact phase in running jumps for height was developed. The model included eight torque generators, comprising contractile and elastic elements in series, situated on both sides of the ankle, knee, hip and shoulder joints to allow for co-contraction. Wobbling masses were included in the shank, thigh and trunk segments using non-linear spring-damper representations. The foot-ground interface was modelled using non-linear, spring-damper systems situated at the toe and the heel (Figure 1).

**Figure 1:** Eight-segment simulation model of the foot contact phase in running jumps from one leg.

The model was customised to an elite high jumper by determining subject-specific inertia and torque parameters. Anthropometric measurements of the jumper were taken and segmental inertia parameters were calculated using a mathematical model [1]. Torque measurements were taken during eccentric-concentric movements at the ankle, knee, hip and shoulder joints using an isovelocity dynamometer (Cybex NORM), with crank angular velocities ranging from 50°/s to 450°/s, in order to express maximum voluntary torque as a function of joint angle and angular velocity [2].

The simulation of a running jump for height was matched to an actual performance by varying the torque generator activation time histories and allowing small adjustments to the initial conditions in order to minimise the difference between the kinematics of simulation and performance. Using the

matching simulation as a starting point, an unconstrained optimisation of the contact phase was carried out to maximise the height reached by the centre of mass during the flight phase. This was achieved by varying the torque generator activation time histories, the initial configuration conditions and the approach velocity in order to obtain a simulation with maximum height. A second optimisation was carried out using constraints to ensure that the knee and ankle joint angles remained within anatomical limits during takeoff and flight. In a third optimisation perturbations of 5 ms in activation timings of the knee extensor torque were also introduced and the score to be maximised was taken to be the minimum height reached in a group of perturbed simulations.

### RESULTS AND DISCUSSION

**Table 1.** Optimised jump heights for the three conditions

	approach velocity [ms <sup>-1</sup> ]	jump height [m]
performance (track)	7.4	2.01
matching simulation	7.4	1.95
optimisation 1	7.4	2.74
optimisation 2	7.4	2.63
optimisation 3	7.4	2.32

Without any constraints the theoretical maximum jump height in optimisation 1 was an unrealistic 2.74 m while imposing anatomical constraints in optimisation 2 reduced this to 2.63 m. Perturbing the activation timings by 5 ms in optimisations 1 and 2 did not change jump heights but violated the anatomical constraints and the knee and ankle.

Requiring robustness to timing perturbations in optimisation 3 further reduced the jump height to 2.32 m. Perturbing the activation timings of optimisation 3 by 5 ms did not result in reduced jump height.

### CONCLUSIONS

When maximising performance using simulations it is important that considerations of anatomical constraints and robustness to timing perturbations are taken into consideration. Failure to do this can result in maximal solutions that are unrealistic and unachievable. Since the jumper in this study had a personal best high jumping performance of 2.31 m and since perturbations at hip and ankle must be accommodated it appears that activation timing must be better than 5 ms.

## CHALLENGES IN MUSCULOSKELETAL MODELING FOR CLINICAL USE

<sup>1</sup> John Rasmussen, <sup>2</sup>Michael Damsgaard, <sup>2</sup>Søren Tørholm Christensen and <sup>3</sup>Mark de Zee

<sup>1</sup>Institute of Mechanical Engineering, Aalborg University, Denmark, jr@ime.aau.dk

<sup>2</sup>AnyBody Technology, Aalborg, Denmark

<sup>3</sup>Department of Orthodontics, School of Dentistry, Faculty of Health Sciences, University of Aarhus, Denmark

### INTRODUCTION

Musculoskeletal modeling has evolved in the past five years from a field of scientific experiments to a tool applicable to solution of practical ergonomic problems. This paper very briefly points out a number of challenges the scientists and developers within this field must face in the forthcoming years in order to make the technology applicable also to clinical use.

Much of the scientific discussion concerning musculoskeletal modeling has been focused on the basic approaches and their divisions into forward and inverse dynamics with the former capturing the complexity of activation dynamics and the latter enabling models of realistic complexity. Recently, experiments with hybrid models have been reported (see, for instance, [1]), and with the development of computational technology, it must be foreseen that reliable analysis methods will be available in the future. This leaves the scientific community with the challenge of providing models with the necessary reliability, versatility and documentation for clinical applications.

### CLINICAL REQUIREMENTS OF MUSCULOSKELETAL MODELING

It is useful to attempt a categorization of the requirements for clinical use of musculoskeletal models.

**Morphological complexity:** Since clinical applications are diverse, models with an adequate complexity to cover a wide range of cases must be available. One of the challenges here is that it is necessary to divide many anatomical muscles into several separate mechanical units [2]. We estimate that a full body model will comprise some 1000 independent muscle units.

**Physical complexity:** Muscles have nonlinear elastic properties, they wrap over and slide on bones and other muscles, and their contraction is due to a complex electro-chemical process. Joints are rarely ideal hinges, and many of the reaction forces in the body are unilateral and hence form contact mechanics problems. These are some of the physical complexities that must be addressed.

**Individualization:** Many clinical applications require models to be individualized. This is in particular the case for modeling of physical disabilities or prospective surgical procedures. A musculoskeletal model comprises thousands of parameters, so a full individualization made operational in a clinical setting is a challenging requirement.

**Reliability and validation:** Clinical models are used to make decisions on diagnostics, treatment, and rehabilitation of patients, and hence they must be reliable and validated. Errors can come from many sources including input, the musculoskeletal model, and the software used to process it. Further-

**Figure 1:** Musculoskeletal model of a box lift comprising roughly 500 muscles [4].

more forward dynamics models assume that the body moves optimal according to some criteria. Are these criteria still valid for patients? Proper validation must treat all these elements and do so as separately as possible from each other.

### RESULTS AND STATE-OF-THE-ART

Due to space limitation, we shall focus on the issues of morphological and physical complexity. Anderson et al [3] demonstrated that a gait pattern can be reproduced in a model with reasonable morphological complexity in a forward dynamics model capturing the physical complexity of activation dynamics. Unfortunately, the computation times are prohibitive for clinical applications so far.

The AnyBody Research Group has announced an initiative [4] for assembling a public domain repository of musculoskeletal models written in the AnyScript body modeling language (Figure 1). The idea behind this initiative is that a public domain library will allow many scientists to contribute and scrutinize models, while the relation between the data and the computer model guarantees the completeness of the data. Recently, this library was reported to have been equipped with anthropometrical scaling [5] capable of partial individualization.

### CONCLUSIONS

Much work remains before musculoskeletal models are generally clinically applicable. The amount of work indicates that this must be a worldwide concerted effort, and models for managing this effort must be devised.

### INTRODUCTION

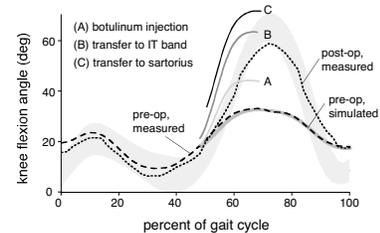

The management of gait abnormalities in persons with neuromuscular disorders is challenging. Theoretically, gait abnormalities can be alleviated by first identifying the biomechanical factors that contribute to abnormal movement and then (i) decreasing the muscle forces that disrupt normal movement (e.g., via tendon transfers or botulinum toxin injections) and/or (ii) increasing the muscle and ground reaction forces that have the potential to improve movement (e.g., via strengthening exercises, orthoses, or osteotomies). However, physical examination and gait analysis alone are often not sufficient to identify the cause of a patient's abnormal gait or to predict the consequences of treatments. The transformation from EMG patterns to multijoint movement is complex, and experimental approaches to infer a muscle's actions, based on the muscle's attachments, EMG activity, and measured motions of the body, cannot explain how forces produced by the muscle contribute to motions of the joints. At present, the treatment outcomes are inconsistent; some patients show dramatic improvements after treatment, while others show little improvement or get worse.

The following case study illustrates how dynamic simulation can be used, with gait analysis, to enhance our understanding of gait abnormalities and to provide a scientific basis for planning treatments. We generated a 3D muscle-actuated simulation of a subject with stiff-knee gait to determine the source of his diminished swing-phase knee flexion and to evaluate the potential efficacy of different treatments.

### CASE STUDY

The subject was a 12-year-old male with cerebral palsy. Preoperatively, his peak knee flexion during swing was 33°, and he exhibited abnormal activity of the rectus femoris throughout the gait cycle. We represented the subject's musculoskeletal system by a 21-degree-of-freedom linkage that was scaled to his size and actuated by 92 muscles. We used "computed muscle control" [1] to find a set of muscle excitations that, when used to drive a simulation of the preswing and swing phases, generated gait kinematics and kinetics that closely matched the experimental data (Fig. 1). The predicted muscle excitations were consistent with the subject's measured EMG activity.

Analysis of the simulation revealed that the subject's stiff-knee gait was caused by excessive rectus femoris forces during preswing. His average knee extension and hip flexion moments in early swing were within normal limits, as were his average hip and ankle flexion moments in preswing. However, his average knee extension moment in preswing was excessive, resulting in an abnormally low knee flexion velocity at toe-off.

**Figure 1.** Knee flexion trajectories following simulated treatments. The subject's measured knee angles before and after surgery are shown for comparison. Shaded area is the normal mean  $\pm$  1SD.

Decreasing the excessive excitation of rectus femoris, simulating the effects of botulinum toxin injection, increased knee flexion by about 10° (Fig. 1, A). Eliminating the excessive knee extension moment of rectus femoris while leaving the hip moment intact, simulating a surgical transfer of the rectus femoris insertion to a site lateral (Fig. 1, B) or posterior (Fig. 1, C) to the knee, increased the peak knee flexion by about 30°. A substantial improvement was achieved regardless of whether the muscle was converted to a knee flexor. The simulated improvements were similar to the subject's actual improvements after tendon transfer surgery.

### CHALLENGES

Simulation-based analyses of muscle function during walking provide insights not available from experimental methods alone [e.g., 2]. Before simulations can be widely used to guide treatment decisions for individual patients, however, advancements in the following areas are needed:

- Experimental data that more accurately describe patients' joint axes, trunk motions, and foot-floor interactions during consecutive strides.
- Models that more accurately and efficiently characterize patients' musculoskeletal geometry and joint kinematics.
- Muscle-tendon models that characterize the effects of pathology, surgery, and other treatments on the time course of muscle force generation.
- Methods for analyzing and validating simulations that better elucidate the actions of muscles and the consequences of neuromusculoskeletal impairments.
- Techniques for incorporating representations of sensory-motor control into simulations of normal and abnormal gait.
- Clinical studies that test whether subject-specific dynamic simulations can improve treatment outcomes.

## APPROXIMATION OF BALANCED LANDINGS IN GYMNASTIC DISMOUNTS

Alison L. Sheets and Mont Hubbard

University of California, Davis, USA  
 email: alsheets@ucdavis.edu , web: mae.ucdavis.edu/~biosport

### INTRODUCTION

Gymnastic dismount landing phases have two parts: a short duration impact phase when foot-mat contact forces are high, and a subsequent balancing phase during which the gymnast exerts active control over the resulting post-impact velocities to achieve a desired motionless terminal configuration. Simple impulse-momentum approximate models for the two phases can help in understanding what pre-impact motion states are controllable and thus are feasible targets for the end of flight.

### METHODS

Approximate quasi-rigid-body gymnast models are used for both impact and balance phases. Impact is characterized by larger forces over a shorter duration ( $\Delta t = 0.04$  sec) than the balancing phase [1]. Although large impulses at the feet create similar joint impulses and cause the body to deviate slightly from its presumed rigid pre-impact configuration, the short impact period motivates the approximation that the body remains rigid. Nevertheless, impact is long enough to make total rigid-body rotation ( $\sim 0.3$  rad) non-negligible. Whole-body rotation is included by assuming that angular velocity decreases linearly during impact and that the rigid body rotates about the ankle. Non-instantaneous linear and angular impulse and momentum relations approximate the impact phase. Horizontal and vertical impulses,  $\mathcal{G}_x$  and  $\mathcal{G}_y$ , applied to the gymnast's feet cause them to stop [1] and decrease body angular velocity according to

$$\mathcal{G}_y = m(v_{yf} - v_{yo}) + mg\Delta t_i \quad (1)$$

$$\mathcal{G}_x = m(v_{xf} - v_{xo}) \quad (2)$$

$$I_{cm}(\omega_f - \omega_o) = r(\mathcal{G}_x \cos \theta_{avg} + \mathcal{G}_y \sin \theta_{avg}) \quad (3)$$

where  $m$  is gymnast mass,  $r$  the distance from feet to center of mass (cm),  $g$  gravity,  $\theta_{avg} = (\omega_o + \omega_f)\Delta t / 4 + \theta_o$  the average angle between the line from ankle to cm and vertical during impact,  $I_{cm}$  the whole body inertia about the cm,  $\omega$  the angular velocity,  $v_x$  and  $v_y$  the horizontal and vertical velocities, and subscripts  $o$  and  $f$  denote prior to and after impact.

In a balanced landing, impulses reduce the angular velocity to an amount that can be controlled by multiple muscle torques during the balance phase. While the impulses may cause post-impact angular velocity to be exactly zero, balancing is possible over a range of landing configurations and velocities. Moreover, post-impact balance control is generally exerted at all joints and is a multi-input multi-output control problem. A conservative approximate model of balance allows the gymnast to attenuate the post impact angular velocity while remaining rigid and using only the ankle moment created by pressing the toe or heel into the ground. The ankle moment is limited since the ground reaction force ( $\sim mg$ ) must pass

through the foot. Minimum and maximum possible post-impact angular velocities  $\omega_{min}$  and  $\omega_{max}$  are calculated by solving differential equations for this motion,

$$I_{cm}\ddot{\theta}_{min} = mgr \sin \theta_{min} + mgd_t \quad (4)$$

$$I_{cm}\ddot{\theta}_{max} = mgr \sin \theta_{max} - mgd_h \quad (5)$$

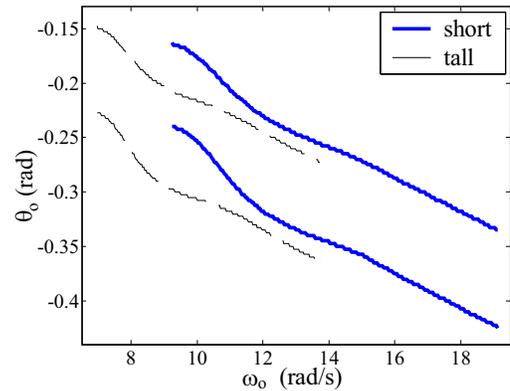

where  $d_t$  and  $d_h$  are horizontal distances from ankle to toe and heel, respectively.

### RESULTS AND DISCUSSION

Short and tall gymnasts with properties and bar release conditions shown in Table 1 can complete 3 and 2 dismount somersaults, respectively, and are configured differently at impact to reduce angular velocity enough to balance [2].

**Table 1:** Gymnast properties and bar release conditions

Ht (m)	Mass (kg)	$I_{cm}$ (kg·m <sup>2</sup> )	$\omega$ (rad/s)	$H_{cm}$ (kg·m <sup>2</sup> /s)
1.57	62.38	9.20	9.84	90.57
1.71	69.30	12.57	8.96	112.71

**Figure 1:** Ranges for pre-impact contact angles for balanced landings differ for short and tall gymnasts

The ranges of all possible landings for the short and tall gymnast's given their angular momentum  $H$  at bar release are shown in Figure 1. If the athlete has a larger impact angular velocity  $\omega_o$  and small inertia, she must contact the ground with a larger body angle relative to vertical  $\theta_o$  than an athlete with larger inertia and smaller angular momentum because she will rotate further during impact. The short gymnast is able to balance over a larger range of  $\omega_o$  than the tall one. With a given  $\omega_o$ , the tall gymnast is able to balance with a slightly larger range of  $\theta_o$  due to a relatively larger foot size which increases ankle moment (Figure 1). Although the range of possible  $\theta_o$  decreases for small values of  $\omega_o$ , the athlete is in controllable landing configurations longer since she rotates more slowly, making a balanced landing more likely.

## A NEUROMUSCULAR TRACKING METHOD FOR COMPUTING INDIVIDUAL MUSCLE FORCES DURING HUMAN MOVEMENT

Ajay Seth<sup>1</sup> and Marcus G. Pandy<sup>1,2</sup>

<sup>1</sup>Department of Biomedical Engineering, University of Texas at Austin, U.S.A.

<sup>2</sup>Department of Mechanical Engineering, University of Melbourne, Australia

### INTRODUCTION

Quantifying muscle forces in human performance is necessary to understand muscle coordination and to properly characterize skeletal loading. Inverse dynamics and static torque decomposition are often used to calculate individual muscle forces from joint kinematics and force measurements. In this case, the quality of the muscle forces depends significantly on the accuracy of the inverse dynamics solution. Legitimate questions about the accuracy of inverse dynamics arise when resultant torques/forces fail to drive a forward model through the observed motion. Furthermore, static decomposition can neglect the effects of muscle dynamics. While optimization of muscle controls that make forward dynamics match experimental observations is considered more accurate, the simplicity and low computational cost of inverse dynamics is often favored over the computationally intensive approach of dynamic optimization. There is a need to solve the motion-tracking problem with the accuracy of dynamic optimization, but with the solution speed of inverse dynamics.

### METHODS

The optimal control problem for maximum height jumping was solved via a large-scale parameter optimization approach [1]. This solution represented the “gold-standard” for muscle force estimates during jumping in a jumping model (Fig 1.). Noise was added to the optimal solution for joint kinematics and ground-reaction forces (GRFs) to simulate experimental observations. A two-stage tracking methodology was then used to compute individual muscle forces.

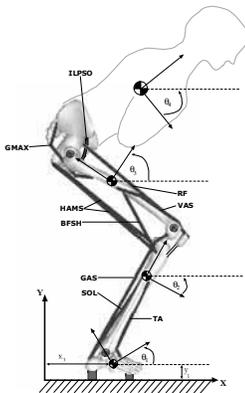

Figure 1: Planar jumping model with 4 segments, 6 dofs and 9 muscles

The method of computed torques [2] was extended to include GRFs as part of the tracking set. Because measurements of GRFs are more accurate than measured kinematics, the accuracy of the computed torques method can be improved. The complete representation of muscle dynamics, from nervous excitation to torque production at each joint, was encapsulated as a nonlinear neuromuscular system. This system was treated as its own plant, whose output torques were used to track the previously computed joint torques. Feedback linearization [3] was applied to cast the nonlinear

neuromuscular dynamics into a linear system. The new system was used to formulate a linear tracker and an optimal linear-quadratic tracker (LQT), with the cost function formulated by the sum of the squared tracking errors and muscle efforts.

### RESULTS AND DISCUSSION

The motion tracker produced stable joint torques that had less than 1° in segment angle and 1% of body weight tracking error. These torques were fed to the neuromuscular tracker to determine individual muscle forces (Fig. 2). The tracking solutions were computed in less than 100s on a desktop PC. In contrast, the parameter optimization required nearly 24hrs of computing. Nonetheless, the forces determined by the neuromuscular LQT were very similar to those predicted by the parameter optimization (Fig 2).

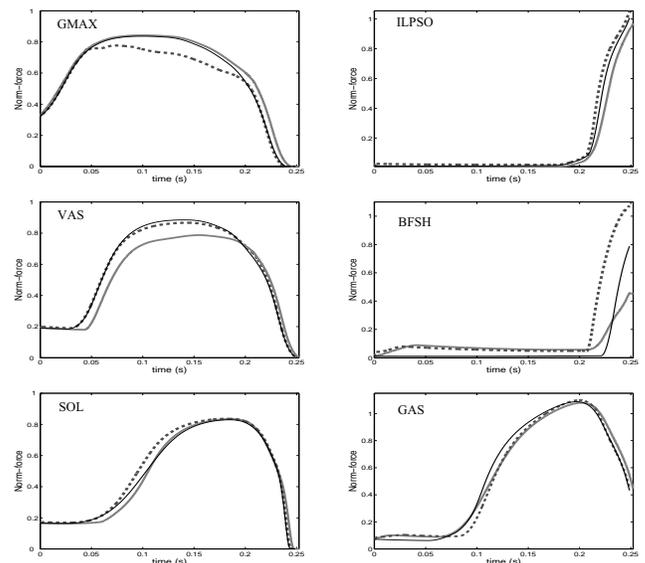

Figure 2: Normalized muscle forces obtained from a neuromuscular tracker (dashed lines) and an LQT (thick solid lines) compared to the parameter optimization solution (thin solid lines).

### CONCLUSIONS

A neuromuscular tracking method was developed that can provide accurate individual muscle forces with a time-savings of nearly 3 orders of magnitude over parameter optimization.

## CREATING A SKIN STRAIN FIELD MAP WITH APPLICATION TO ADVANCED LOCOMOTION SPACESUIT DESIGN

<sup>1</sup>Kristen Bethke, <sup>2</sup>Dava J. Newman, and <sup>3</sup>Raul Radovitzky

<sup>1</sup>Man-Vehicle Laboratory, Massachusetts Institute of Technology, email: kbethke@mit.edu

<sup>2</sup>Professor of Aeronautics and Astronautics and Engineering Systems, Director of Technology and Policy Program, Massachusetts Institute of Technology

<sup>3</sup>Professor of Aeronautics and Astronautics, Massachusetts Institute of Technology

### INTRODUCTION

An improved understanding of the deformation of the body's soft tissue during locomotion would enable quantitative design requirements for advanced spacesuits. A repeatable, quantitative technique for mapping the skin strain field on the human body in motion provides this understanding. The skin strain field map informs the design of a skintight spacesuit, called a mechanical counter pressure suit [1], whose fabric must stretch and rotate with the astronaut's skin to allow for maximum mobility.

### METHODS

To measure the strain of the human skin *in vivo* during locomotion, the non-invasive strain measurement technique of Digital Image Correlation is applied to data sets gathered by a 3D laser scanner rather than by optical cameras [2]. In this pilot study, knee flexion from 0 to 90 degrees, for one subject, is used as the representative movement for human locomotion. The leg surface is marked with 156 position trackers that can be identified in the laser scanner's 3D virtual reconstructions of the leg surface. Each tracked point is separated by approximately 3 cm from adjacent points, and each triad of points defines a local surface reference frame with a longitudinal and a circumferential direction. Normal strains emanating out from each tracked point are estimated by comparing the initial separation of each pair of adjacent points to the deformed separation of each pair. Strain gage rosette equations transform these strains from extension/contraction along arbitrary axes to the normal and shear components of the orthogonal strain tensor, with respect to the longitudinal and circumferential axes. Eigenvalue analysis of this strain tensor provides information about the directions and magnitudes of principal strain and of minimum normal strain.

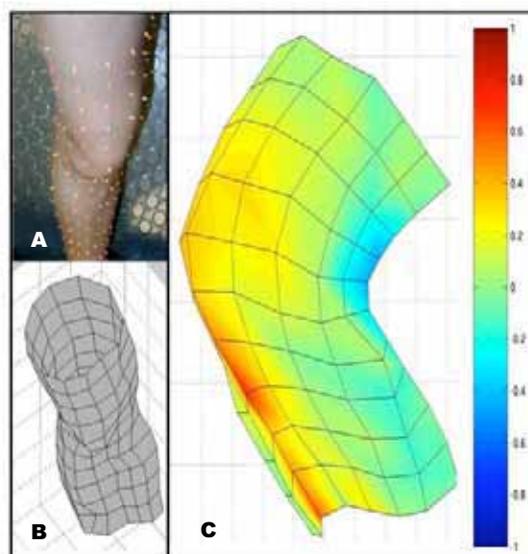

The goal of the analysis is to provide three types of strain information for all tracked body surface points: 1) the strain in the local longitudinal and circumferential directions, 2) the directions and magnitudes of purely normal strain, and 3) if they exist, the directions and magnitudes of purely shear strain. This information specifies in which directions and with what magnitudes an astronaut "second skin" pressure suit must stretch or contract at each location on the body surface.

### RESULTS AND DISCUSSION

For the one subject in this pilot study, the largest stretch of the leg skin in the longitudinal direction occurs 3 cm to 9 cm below the patella; longitudinal normal strain magnitudes in this region range from 0.3 to 0.7 (Figure 1). The largest stretching in the circumferential direction occurs on the anterior surface 3 cm below the patella and on the medial

surface of the mid-calf, with normal strain values of 0.6 and 0.5, respectively. Shear strain, or angular distortion of the skin, is near zero for most of the anterior and posterior surfaces of the leg.

Eigenvalue analysis transforms the orthogonal strain components into principal and minimum strain directions. The set of minimum normal strain directions suggests the "weave" direction of the tensile fibers of the spacesuit. Proper weave alignment will allow for maximum mobility and ease of locomotion, which are essential requirements for advanced spacesuit designs for future missions to the moon or Mars.

**Figure 1:** A. Raised position trackers covering the leg surface are identified in laser scans and serve as input for a virtual 3D model of the leg. B. Leg reconstruction in initial state, from upper thigh to mid calf, using only the positions of the tracked points. C. Leg reconstruction with 90-degree knee flexion angle, with the magnitude of skin's longitudinal strain overlaid in color.

## NO SINGLE LIFTING TECHNIQUE MINIMIZES LOW BACK LOAD

<sup>1</sup>Jaap H. van Dieën, <sup>1</sup>Anja Bakker, <sup>1</sup>Gert Faber and <sup>1</sup>Idsart Kingma

<sup>1</sup>Institute for Fundamental and Clinical Human Movement Sciences, Faculty of Human Movement Sciences, “Vrije Universiteit Amsterdam”, the Netherlands; email: J\_H\_van\_Dieën@FBW.VU.NL

### INTRODUCTION

From the epidemiological literature, lifting emerges as an important cause of low back injury and low back pain [1], likely due to the high mechanical loads on the low back that lifting causes. To prevent low back injuries, several lifting techniques have been advised in practice. However, some of the techniques advised do not appear to consistently reduce back load [2,3] and other techniques have not been studied. The aim of the present study was to compare low back load during lifting with four different techniques under varying task constraints.

### METHODS

In a repeated measures design, twelve healthy young males lifted 20 kg loads. Subjects used four techniques (stoop, squat, straddle, and archer's technique; Figure 1). Load widths of 0.30 and 0.60 m were used. In addition, loads were lifted from an initial hand position 0.05 and 0.29 m above floor level.

3D kinematics, ground reaction forces and EMG of selected trunk muscles were measured. These data in combination with anthropometrical measurements were used to estimate net moments around L5S1 and to estimate compression and shear forces acting at L5S1 using previously described methods [4].

### RESULTS AND DISCUSSION

Description of the results will in this abstract be limited to peak total (3D) net moments, since these not only reflect the overall outcomes in the present experiment fairly well, but in general appear to be predictive of peak spinal compression and anterior shear forces [5].

Peak net moments were significantly affected by main effects of technique, hand position, and load width and by both two-way interactions with technique. Post-hoc comparisons between techniques for each hand position / load width condition separately indicated the following. For low-lying narrow loads, no differences in back load occurred between techniques. For low-lying wide loads, squat and straddle techniques caused higher back loading than stoop and archer's

techniques. For high and narrow loads the stoop technique caused the highest back load, while the other techniques did not differ from each other. For high and wide loads all differences between techniques were significant. The squat technique caused the highest and the archer's technique the lowest back load. Differences in trunk inclination as well as the distance between load and the low back appear to explain the effects found.

Differences between lifting techniques within hand position and load width conditions ranged from 10 to 50 Nm or approximately 20%. Differences between low and high hand positions within techniques and load widths ranged from 6 to 35 Nm. Differences between load widths within techniques and hand positions ranged from 16 to 70 Nm.

The interactions found are in line with findings from an earlier study on self-selected, squat, and stoop techniques [3]. This result implies that, although differences between techniques were substantial in some cases, no single lifting technique can be advised and that other aspects than lifting technique merit attention in prevention. Furthermore, the results strongly support an approach towards lifting technique in which subjects are taught a problem solving approach, which allows them to deal with the highly varying task constraints encountered in practice, rather than a single strategy [6].

### CONCLUSIONS

Back load in lifting is affected by interactions of lifting technique and other task constraints, implying that no single technique can be advised.

## PRESCRIBING SKELETAL MOTION CAN SUBSTANTIALLY ENHANCE MECHANICAL POWER OUTPUT; A SIMULATION STUDY

A.J. "Knoek" van Soest and Richard Casius

Faculty of Human Movement Sciences and IFKB, Free University, Amsterdam, The Netherlands  
email: k.vansoest@fbw.vu.nl

### INTRODUCTION

Average mechanical power output (referred to as "power output" in what follows) is a key factor in determining performance in high-intensity periodic movements like cycling and rowing. We have recently investigated how power output is affected by adding/removing kinematic constraints on skeletal motion using a modelling/simulation approach. We have predicted that the power output of rowers may be limited by the fact that they must prevent "shooting the slide", and that strapping the rower to the sliding seat (i.e. adding a kinematic constraint) may thus improve power output [1]. In the context of FES cycling we have predicted that releasing the customarily fixed ankle joint and stimulating triceps surae and tibialis anterior, does not necessarily improve power output; removing the kinematic constraint at the ankle introduces a degree of freedom that has to be controlled through muscle actions, which counteracts the power gained by the extra muscle mass [2]. Regarding isokinetic sprint cycling we have predicted that prescribing the optimal leg kinematics for unconstrained conditions (i.e. adding a kinematic constraint), and thus removing the need to coordinate leg motion, does improve power output, albeit only marginally [3]. While the latter study confirmed that upon prescription of the optimal unconstrained kinematics power output can only improve, it did not answer the question to what extent power output of the leg muscles can theoretically be improved relative to the natural sprint cycling setup when the fully prescribed leg motion is optimized. The goal of this modelling/simulation study is to find the maximal power output that can be achieved when prescribing a periodic motion of hip, knee and ankle joint in a sagittal plane model.

### METHODS

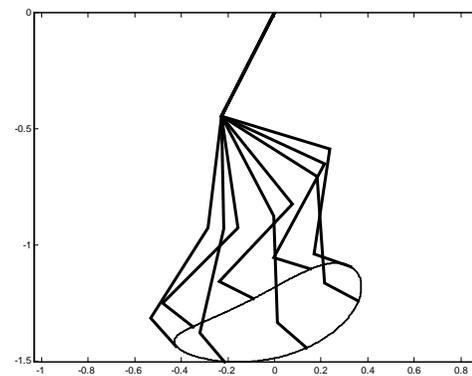

For comparability we adopt a model that was used previously in a study of isokinetic sprint cycling [4], where the highest power output occurred at a pedalling rate of 120 RPM. In this study we investigate 120 "RPM" prescribed sinusoidal movements of hip, knee and ankle, parameterized by average joint angle and joint angle amplitude for each of the three joints, and phase shifts between hip, knee and ankle joints. These parameters are optimized collectively with the stimulation pattern of 8 Hill-type muscles with realistic activation and contraction dynamics. The muscles are assumed to be maximally stimulated for one part of the period time and to receive no stimulation for the remaining part. The optimization is carried out using a genetic algorithm [5], with power output as the optimization criterion.

### RESULTS AND DISCUSSION

The optimal leg motion found is characterized by almost simultaneous extension (and flexion) of hip, knee and ankle joints. The hip joint range of motion is much larger than

during cycling, resulting in a leg motion (Fig. 1) that is quite different from that allowed by the circular path of the MTP joint as imposed during cycling. As expected for any setup where muscles are effectively decoupled, stimulation of each muscle is tightly tuned to maximization of its power output, i.e. full stimulation during shortening and none during lengthening. Most importantly, power output was found to be 1441 W., which is 135% of the optimal power output for the natural sprint cycling setup.

It must be expected that the theoretical maximal power output of the leg muscles is even higher than that calculated here, as neither the period time nor the form of the motion has been varied. It remains to be investigated if a mechanism that enforces the optimal lower extremity motion can be built, and if subjects are able to exploit the advantages of such a mechanism. It also remains to be established if such a mechanism has advantages during prolonged exercise, where central physiological processes may be performance-limiting. Irrespective of issues of practical implementability, this study illustrates the potential of a modelling/simulation approach for preliminary evaluation of hypotheses on the mechanics and energetics of human motion.

**Figure 1:** Optimal motion of foot, shank and thigh, plotted at regular time intervals, with fixed upper body. To facilitate comparison to the kinematics of cycling the complete path of the MTP joint is also plotted.

## EFFECTS OF TIMING OF MUSCLE ACTIVATION ON PERFORMANCE IN HUMAN VERTICAL JUMP

<sup>12</sup>Przemyslaw Prokopow, Stefan Szyniszewski<sup>3</sup> and <sup>12</sup>Ryutaro Himeno

<sup>1</sup>Computational Biomechanics Unit, RIKEN, Japan

<sup>3</sup>Graduate School of Natural Science and Technology, Kanazawa University, Japan

### INTRODUCTION

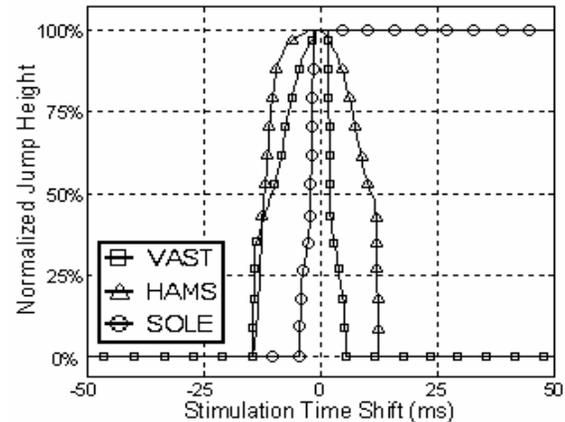

The sensitivity of human movement on precise neural control is noteworthy problem in terms of movement control and sports biomechanics. Previous studies demonstrated that human vertical squat jump is very sensitive to precise timing of muscle action [1,2]. Present study investigates quantitatively the effects of time shift of individual muscles and group of muscles on jump performance. Three research questions were addressed: (i) what is the effect of altered muscle activation timing on jump height and kinematics (ii) how disorder of muscle coordination cause decline in jump performance (iii) what is the minimal shift of muscle activation timing that significantly alter jump height.

### METHODS

Forward dynamics computer simulation of vertical squat jump was used in present study [3]. A human musculoskeletal model of lower extremities was three dimensional and consisted of nine rigid body segments (i.e. head-arms-trunk, right and left upper legs, right and left lower legs, right and left feet, and right and left toes). The body was modeled as 20 degree-of-freedom linkage which was free to make and break contact with ground. A total number of 26 Hill-type musculotendon actuators drove the model. An optimal control of muscles activation pattern was found through numerical optimization where Bremermann's method was applied. As an objective function we used a maximum height reached by the mass centroid of the body. In order to evaluate the effects of timing of muscles activation on the performance of vertical jump, the optimal activation time of each muscle was systematically altered by the interval of 0.1 ms in the range  $\pm 50$  ms. Altered were either muscle onset time, muscle offset time, or muscle switching time (total activation duration remained constant but onset and offset times were shifted equally). Time shift was applied separately to each of eight individual muscles (m. gluteus maximus, m. adductor magnus, hamstrings, m. rectus femoris, mm. vasti, m. gastrocnemius, m. soleus, and other plantarflexors) and to each muscle functional group.

### RESULTS AND DISCUSSION

The numerical optimization procedure generated a natural-looking and smooth squat jumping motion where jump height was 34.6 cm. Muscle control (i.e. muscle activation timing) in jump was very sensitive to a shift applied to onset activation time. It was found the changing activation timing of certain muscles (i.e. mm. vasti, m. soleus and hamstrings) by as little as 2-3 milliseconds resulted in a marked (over 10%) difference in jump height (Fig. 1). Muscle control was the most sensitive to precise tuning of muscles spanning the knee joint and ankle joint, where muscle control at the knee joint depended to a large extent on co-action of the monoarticular knee extensor

**Figure 1:** The effect of time shift applied to mm. vasti, hamstrings and m. soleus. Jump height is expressed as percentage of optimal jump height.

(mm. vasti) with biarticular muscles. Among individual muscles the control of mm. vasti, m. soleus, hamstrings and other plantarflexors were found to be especially important for coordination in jumping. Muscle control was found to be very sensitive to intermuscular coordination. The disintegration in coordination caused by earlier activation of mm. vasti was minimized when the hamstrings activation onset time was decreased by a similar amount. Earlier activation of other plantarflexors was found to reduce jump performance by a significantly smaller amount when hamstrings were activated jointly. Furthermore, the negative effects of other plantarflexors were mitigated by concurrent time shift in mm. vasti activation. Also the effect of later activation of mm. vasti was considerably smaller when m soleus activation was also delayed by the same amount. Mechanical effect of time shift applied to different muscles were found to be virtually the same for: earlier stimulation of mm. vasti and later stimulation of hamstrings; earlier stimulation of m. gluteus maximus and m. rectus femoris; later stimulation of m. adductor magnus and hamstrings; earlier stimulation of m. rectus femoris and m. gastrocnemius; earlier stimulation of m. gluteus maximus and m. adductor magnus; earlier stimulation of m. adductor magnus and m. rectus femoris, earlier stimulation of m. adductor magnus and m. gastrocnemius. A time shift applied to one of these two muscles had virtually the same effect on jump kinetics and kinematics as a time shift applied to the other muscle. Therefore it can be postulated that their action in vertical jump is to some extent mechanically linked.

## MODELING CEREBRAL ANEURYSM FORMATION AND ASSOCIATED STRUCTURAL CHANGES

Rachmadian Wulandana and Anne M. Robertson  
 Department of Mechanical Engineering, University of Pittsburgh  
 E-mail: rxwst2@pitt.edu

### INTRODUCTION

Intracranial aneurysms (ICA) are saccular dilations of cerebral arteries, most commonly found at the apices of arterial bifurcations on or near the Circle of Willis. Clinical and histological evidence support the hypothesis that an ICA develops from a local weakening of the wall, possibly due to mechanical or biochemical processes. It is hypothesized, that as a result, the bifurcation apex (A) bulges into an early stage aneurysm 'bleb' with no identifiable neck (B), and then into an aneurysm with a clear neck region (C). It is further hypothesized that the process from (B) to (C) is accompanied by collagen degradation and deposition. When the two processes are well balanced, the ICA is secured from rupture and develops into a complex aneurysm, exhibiting biological responses such as calcification and thrombosis (D) [4].

**Figure 1 Stages of Aneurysm Development**

We recently developed a dual-mechanism constitutive equation capable of modeling collagen recruitment and disruption of the IEL [2,3] based on the nonlinear inelastic behavior of cerebral arteries reported in [5]. This is the first ICA wall model that takes into account the IEL disruption, commonly observed in histological studies of ICA walls. This model was able to predict the "sac like" shape of the ICA and other important features of early aneurysm formation [1,2]. In this work, we extend the model to include the collagen degradation and synthesis.

### CONSTITUTIVE MODEL

Three mechanisms are employed in this model representing the passive mechanical elements of artery and aneurysm walls: elastin, recruited collagen and newly synthesized collagen. Each mechanism is activated at a different deformation level and thus has a unique reference configuration. A scalar function  $s$  that depends on the deformation gradient  $\mathbf{F}_1$  relative to the stress free initial reference configuration  $\kappa_1$  is introduced to quantify the level of deformation. The activation and deactivation of the mechanisms commence when  $s$  reaches critical values  $s_a$ ,  $s_b$ ,  $s_c$  and  $s_d$  corresponding to arterial collagen activation, elastin breakage, collagen degradation and the synthesis of new collagen, respectively. Following [2-3], we suppose that  $s_a < s_b$ .

At sufficiently low loads,  $s \leq s_a$ , only the elastin mechanism, which is presumed to depend on  $\mathbf{F}_1$ , is load bearing. When  $s = s_a$ , the collagen mechanism is activated in the mechanical response and the response is a function of the deformation

gradient  $\mathbf{F}_2$  relative to configuration  $\kappa_2$  occupied by the body at  $s=s_a$ . The elastin disruption is modeled by irreversible termination of the elastin response at  $s=s_b$ . Collagen degradation will be specified to commence when  $s=s_c$ . The gradual degradation is carried out by assigning a monotonically decreasing function  $b(s)$ , which is chosen such that  $b(s_c)=1$ , that represents the volume fraction of the remaining material (e.g. [6]). Furthermore, collagen synthesis is modeled as continuous integration of a new mechanism that begins when  $s=s_d$ . Assuming the existence of an incompressible isotropic exponential type strain energy function  $W_3$ , the extra stress tensor due to collagen synthesis is

$$\boldsymbol{\tau}_3 = 2 \int_{s_d}^s a(\hat{s}) \frac{dW_3}{d(I|\hat{s})} \mathbf{B}_1 \hat{s} d\hat{s} \quad (1)$$

(see, e.g.[6] for more details) where  $a(s)$  is related to the rate of synthesis. Following [1-3], the other two mechanisms are assumed to be described by strain energy density functions  $W_1$  and  $W_2$ , similar to  $W_3$ . For purely monotonically increasing  $s$ , the Cauchy extra stress tensor is given by,

$$\begin{aligned} \boldsymbol{\tau} &= \boldsymbol{\tau}_1 && \text{for } s \text{ in } [0, s_a) \\ \boldsymbol{\tau} &= \boldsymbol{\tau}_1 + \boldsymbol{\tau}_2 && \text{for } s \text{ in } [s_a, s_b) \\ \boldsymbol{\tau} &= \boldsymbol{\tau}_2 && \text{for } s \text{ in } [s_b, s_c) \\ \boldsymbol{\tau} &= b(s) \boldsymbol{\tau}_2 && \text{for } s \text{ in } [s_c, s_d) \\ \boldsymbol{\tau} &= b(s) \boldsymbol{\tau}_2 + \boldsymbol{\tau}_3 && \text{for } s > s_d \end{aligned} \quad (2)$$

where  $s = I_1 - 3$ ,  $\boldsymbol{\tau}_1 = 2 dW_1/dI_1 \mathbf{B}_1$ ,  $\boldsymbol{\tau}_2 = 2 dW_2/dI_2$  and  $\boldsymbol{\tau}_3$  is given by (1). As is shown in [1-3], the strain energy functions  $W_1$  and  $W_2$  are given by  $W_1 = C_1(e^{\gamma_1(I_1-3)} - 1)$  and  $W_2 = C_2(e^{\gamma_2(I_2-3)} - 1)$  where  $I_1, I_2$  are the first invariants of the left Cauchy Green tensors,  $\mathbf{B}_1 = \mathbf{F}_1 \mathbf{F}_1^T$  and  $\mathbf{B}_2 = \mathbf{F}_2 \mathbf{F}_2^T$ , respectively. The material constants  $C_1, C_2, \gamma_1$ , and  $\gamma_2$  were obtained using the experimental data of Scott *et al* [5].

## MODIFIED METHODOLOGY TO DETERMINE HEAD ACCELERATION IN HEAD-TO-BALL COLLISIONS IN SOCCER

Mariusz Ziejewski, Radu Danescu, Michael Stewart  
 Department of Mechanical Engineering, Impact Biomechanics Laboratory  
 North Dakota State University  
 E-mail: Radu.Danescu@ndsu.edu, Phone: (701) 231-8841

### INTRODUCTION

The cumulative effect of repetitive subconcussive head impacts with the soccer ball may lead to neurological dysfunction and permanent brain damage. Accurate information on head acceleration is therefore essential in reaching the ultimate goal of designing appropriate head protection devices. This paper proposes a set of features to be added to the test models in order to better predict the dynamics of the head/neck ensemble for the real conditions seen in a soccer game. The new features include the capability to adjust the elastic constant of the neck under bending loads in the sagittal plane and the inclusion of added linear resistance simulating the torso participation in the impact.

### METHODS

The experimental evaluation was performed on a Hybrid III male head/neck model instrumented with a linear, single-axis accelerometer placed in the center of gravity of the head. The direction of impact was restricted to the front of the model's head only. By tilting the model, the elevation angle varied between 0 and 30 degrees. In some tests, the head model was removed from the neck and mounted on a rotating plate fitted with a spring opposing its rotation. In others, it was mounted on a sliding carriage that simulated the added resistance of the torso in the process of heading the ball. To account for the skill level, muscle strength, and heading technique, the resistance opposed to head movement was simulated by a spring attached to the carriage.

Acceleration data was recorded using a data acquisition system. Baseline data was initially gathered using the head/neck model without headgear. Some of the impact tests were also replicated using a commercially available headgear.

Data analysis was performed on the experimentally generated acceleration curves. A computer code was developed to estimate the following parameters: (i) peak acceleration; (ii) characteristic time length of the impact; (iii) average slope for the rising portion of the curve, and (iv) the similarly defined average slope for the descending portion of the curve.

**TABLE 1** Head rotation, spring, 0 degrees

Speed (m/s)	Acceleration Peak (g)		
	No spring	Spring	% Decrease
3	8.0	7.6	5.0
9	15.6	14.1	9.6
15	24.8	23.4	5.6

### RESULTS

Table 1 shows the acceleration peaks recorded on the head model that first rotated freely in the sagittal plane, and then was fitted with a spring opposing its rotation. Addition of the spring reduced the acceleration peak between 5.0% and 9.6%. The acceleration rate did not change significantly.

A different set of results was generated for tests where the ball approached the head model at a 30-degree elevation angle (table not included in this abstract). The relative decrease in peak acceleration was between 8.6% and 19.5%, always lower when the spring was used. Acceleration rates were also decreased between 0 and 12.5%.

With the model mounted on the sliding carriage, acceleration was compared between spring and no-spring cases (Table 2). Adding the spring reduced peak acceleration between 2.0 and 14.2% and acceleration application rate between 13.8 and 24.0%. Relative differences were higher at higher ball speeds.

The tests were repeated with a protective soccer headgear mounted on the head model. Compared to no-gear cases, acceleration peak decreased between 8.4% and 32.1% while acceleration onset rate decreased between 6.0% and 34.7%.

### CONCLUSIONS

1. Addition of a spring limiting head rotation in the sagittal plane (strength, prepared player) reduces head acceleration.
2. Addition of a spring opposing translation (upper body added mass, prepared player) reduces head acceleration.
3. The maximum head acceleration occurred for the setup with no resistance to head rotational motion and no resistance to upper torso translation.
4. It is proposed to modify the existing models to account for different player's strength and skill level. New features include ability to control resistive torque at the head pivot as well as upper body dynamics.

**TABLE 2** Base of neck translation spring, 0 degrees

Speed (m/s)	Acceleration Peak (g)		
	No spring	Spring	% Decrease
3	10.2	10.0	2.0
9	26.6	23.0	13.5
15	43.6	37.4	14.2

**RELATIONSHIP BETWEEN PRESSURE AND SHEAR UNDER THE FOOT**

**INTRODUCTION**

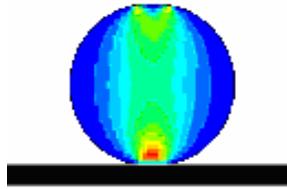

Skin ulceration of diabetic feet is a problem that has major repercussions to both the patient and the health care system. It is generally agreed that non-mechanical factors such as peripheral neuropathy, dry skin and/or vascular problems are often major contributing causes. However, current opinion is divided as to the principal *mechanical* factors leading to ulcer formation. Possible contributors to the formation of an ulcer are localized pressures and shear stresses. The purpose of this study was to examine the relationship between pressure and shear stresses under the forefoot of non-diabetic subjects.

**METHODS**

The method for examination of this relationship consisted of two parts. Part one required collection of pressure and shear data for 10 non-diabetic subjects. A shear and pressure measurement device (Figure 1) employing an array of 80 force transducers (cross-sectional area of 1.61 cm<sup>2</sup>) was used to collect data for 5 males and 5 females with a mean age of 24 years old.

**Figure 1:** Subject walking on a shear and pressure device.

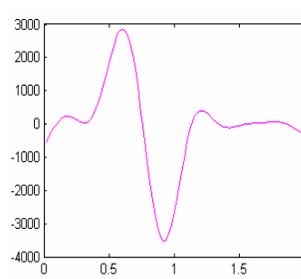

**Figure 2:** Finite element model of two surfaces in contact.

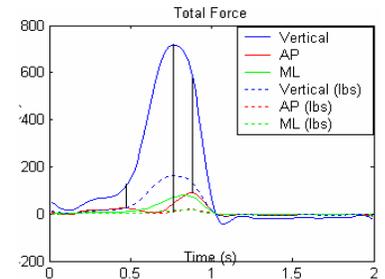

Data collection consisted of one trial for each subject, in which the subject walked in a straight line and had the right forefoot land on the shear and pressure device. Data were collected at 50Hz for 2 seconds. The data were processed using Matlab programs to convert the voltages into forces [1] followed by low pass filtering (Butterworth filter). Part two consisted of creating a plane-strain finite element model of a hyperelastic ball in contact with a rigid plate (Figure 2) to study the relationship between pressure and shear.

**RESULTS AND DISCUSSION**

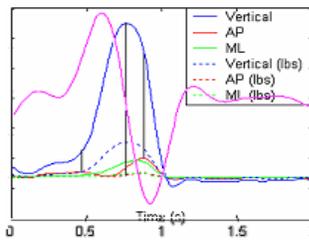

By obtaining the first time derivative of the pressure data, one can not only find the peak pressure in time, but can also gain some insight into the shear behavior (Figure 3). Based on this study's results, the instant of maximum pressure was very close to the instant of maximum shear (Figures 4, 5). Plotting the shear vs. derivative of pressure for all 10 subjects showed the best-fit lines to have similar slopes between -.014 and -.022 which indicates a good correlation between shear and derivative of pressure (Figure 6). The shear and pressure curves gathered from the finite element model had similar behavior when taking the pressure derivative with respect to position (Figure 7).

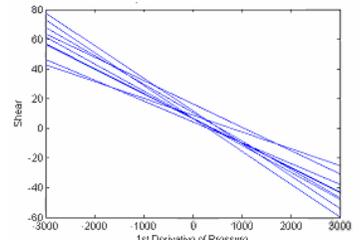

**Figure 3:** Pressure derivative.

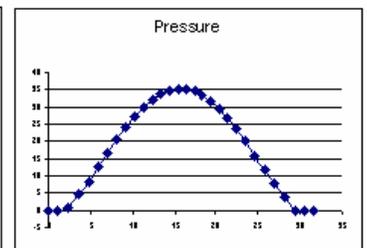

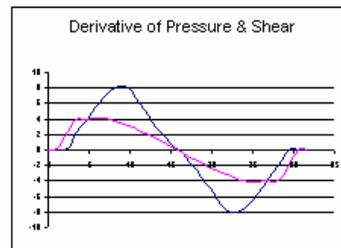

**Figure 4:** Pressure & shear.

**Figure 5:** Derivative of pressure overlapping figure 4

**Figure 6:** Best fit line of shear vs. derivative of pressure for 10 subjects.

**Figure 7:** Pressure, derivative of pressure and shear plots of the FEM data.

**CONCLUSION**

One can hypothesize that maximum shear forces occur at the time and location of peak pressures, however, difficulties in shear measurement impede validation. Based on the results of these trials for control subjects, peak shear position and timing corresponded well with the derivative of pressure. Therefore, through measurement of the pressures, approximate assumptions about the shear behavior can be made.

**THE VALIDITY OF ACTIVE SQUAT KEEN JOINT PROPRICEPTION TEST**

Ming-Feng Kao  
 National Taiwan College of Physical Education  
 email: eric3456733@yahoo.com.tw

**INTRODUCTION**

Proprioception is a sense of position and movement of one’s own limbs and body in the absence of vision, termed “limb-position sense” and “kinesthesia,” respectively. Proprioception has been shown to diminish with injury, age, and so on. Position sensibility can be measure by many methods. Several different testing techniques have been developed to measure the conscious submodalities of proprioception. There are 3 submodalities (joint position sense, JPS; Kinaesthesia and sense of tension). The JPS test measures the accuracy of position replication and can be conducted actively or passively in both open and closed kinetic chain position. Variety of equipment and instrument were developed to measure conscious appreciation of proprioception, such as commercial isokinetic dynamometers, electromagnetic tracking devices, custom-made jigs, and some new device. Recently a functional squat system (FSS) was introduced by MONITORED REHAB SYSTEMS that mimics the movement co-ordination pattern of squat jump, under the control of an external load. This device can be measure proprioception in actively closed kinetic chain. Compared to some open chain device, it shows more similar to daily activity. Therefore, some test need to investigate the reliability for FSS. The intraclass correlation coefficient (ICC) is used to measure inter-rater reliability. Although Pearson’s r may be used to assess test-retest reliability, ICC is preferred when sample size is small (<15) or when there are more than two tests (one test, one retest) to be correlated. Therefore, The purpose of the present study was to compare repeat-measures proprioceptive test in Functional Squat System.

**Figure 1:** Functional Squat System when performed repetitive squat exercises with one leg in standardized pace.

**METHODS**

Eighteen college students participated in this study (male=9, female=9; mean age, 22.1 ±3.5 years). Subject were used FSS in proprioception test program to measured low extremity in 25, 50 and 75 three different knee joint angel. For intrasession intratester reliability of the figure-of-two measurement, ICC (2,1) and the SEM were used. The ICC (2,1) was based on a subjects ×2-way analysis of variance (Shrout & Fleiss, 1979).

**RESULTS AND DISCUSSION**

The ICC (2,1) for repeat-measures knee proprioceptive test was 0.94 (P< .05). The means, SDs, and SEMs for these measurements and the repeat-measures proprioceptive test are summarized in table 1. the results of the correlations between two test are summarized in Table 2. In order to get an accurate measurements, the reliability coefficients should exceed 0.90 to ensure valid interpretations (Portney and Watkins, 1993). In this study, results demonstrated excellent intrasession intratester reliability and small measurement error for the repeat-measures proprioceptive test.

**Table 1:** Means, SDs, and SEMs, for 3 different knee angles repeat measurement test in FSS.

Measurement	Distance (cm)		
	Mean	SD	SEM
25°	70.70	18.58	1.89
50°	123.80	21.33	2.90
75°	171.51	23.76	1.43

\*Means based on 3 measurements obtained from 25 subjects.

**Table 2:** Pearson Product Moment correcltation coefficients (γ) of the relationship between repeat-measures proprioceptive test in FSS.

Measurement	r*
25°	0.89
50°	0.84
75°	0.96

\*p < .001

**CONCLUSIONS**

This study was conducted to determine the intrasession-intratester reliability and criterion-related validity of the repeat-measures knee proprioceptive test. The result shows that the FSS proprioception test was reliable and valid indirect method of measuring knee proprioception in individuals with this test.

### INTRODUCTION

Post-traumatic osteoarthritis (OA) is a frequent outcome following intra-articular fracture. Residual incongruities have long been associated with aberrant articular contact stress distributions [1]. While these atypical stresses likely play a role in predisposing an articular joint to post-traumatic OA, little is known concerning the relationships between altered surface anatomy and associated contact stress. With the advent of patient-specific finite element (FE) modeling techniques comes the ability to address this issue objectively. Here we present work characterizing aberrant contact stress exposure following intra-articular ankle fractures in a clinical series.

### METHODS

CT studies from a series of 6 patients with intra-articular ankle fractures were obtained following a standard orthopaedic protocol. Models were generated from both the fractured and intact contralateral ankles. Tibial and talar subchondral bone surfaces were segmented to yield geometric surface descriptions. An experienced ankle surgeon then used a medical data visualization program (Data Manager (beta2)) to bring these surfaces into apposition to match their weight-bearing radiographic appearance (Figure 1).

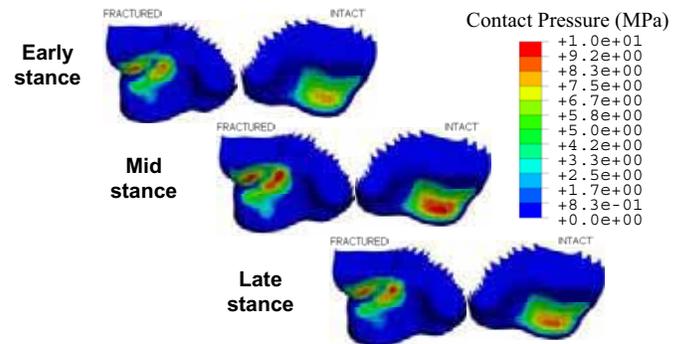

**Figure 1:** Post-operative CT image of fractured ankle (left) and resulting apposed surfaces (right).

Rigid bone surfaces were defined, and 1.5 mm layers of articular cartilage ( $E=12\text{MPa}$ ,  $\nu=0.42$ ) were meshed onto them using a ray projection-based in-house computer code. Apposing cartilage surfaces were defined as deformable contact pairs with a frictionless interface. FE simulations (ABAQUS (v6.4)) entailed solving a sequence of 13 loading cases to simulate the entire stance phase of gait [2]. The tibia is rotated about a flex/extension axis, while the talus is free to rotate as required by the tibio-talar articulation. Articular cartilage contact stress exposures were characterized by multiplying computed nodal contact stress values by their resident time in the gait cycle, then summing the result over the 13 loading increments and scaling to steps per year.

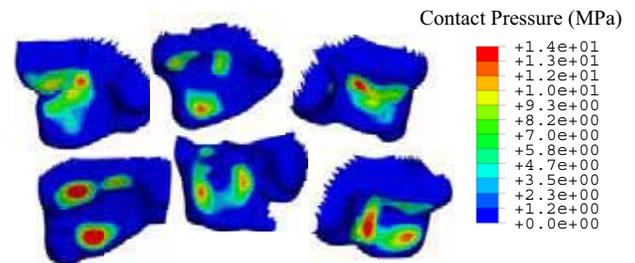

### RESULTS AND DISCUSSION

Computed contact stress distributions for the intact joint were continuous and relatively uniform, while distributions for fracture cases were discontinuous, and more heterogeneous (Figure 2). All 6 fracture cases showed similarly

**Figure 2:** Anterior views of contact stress for a fractured versus intact ankle.

discontinuous and heterogeneous pressure distributions (Figure 3). From these patient-specific contact stress predictions, site-specific chronic stress exposures are

**Figure 3:** Anterior views of contact stress distributions for individual fractured tibias.

computed for each patient with appropriate time scaling. Comparing the chronic exposure to known chronic stress tolerance levels affords prediction of the likelihood of onset of post-traumatic OA in a given injury.

### CONCLUSIONS

These patient-specific FE models of ankle loading during the stance phase of gait provide insight into the contact stress histories which articular cartilage experiences over many cycles each day. This opens new possibilities in studying the link between chronic stress exposure and the onset of post-traumatic OA in an actual clinical population.

### INTRODUCTION

Functional Electrical Stimulation (FES) is a technology that entails the stimulation of nerves and muscles with electrical current to restore movement in those with neurological movement disorders. The application of FES to upper extremities (UE) requires the control of gross motor tasks with a dynamic component. To date, the timing and amplitude of these artificial stimuli have been controlled by open loop pattern generators. It is thought that performance of FES systems can be improved by feedback control. This project involves the design of a controller for an UE model that implements the Proportional Derivative (PD) algorithm, and testing such a controller on a computational UE model that includes realistic dynamic properties of muscle.

### METHODS

Controller performance was evaluated using a biomechanical model for arm movement in the horizontal plane. The model had two segments and was driven by six muscles, two of which were biarticular. Each muscle was modeled using a Hill-based approach. The contractile elements (CE) had realistic force-length and force-velocity properties, as well as activation dynamics. Muscle force was transmitted to the skeleton via a nonlinear series elastic element (SEE). Equations of motion were generated using SD/FAST (PTC, Needham, MA).

The Proportional Derivative (PD) controller generates a stimulation value  $u$  for each muscle whose magnitude is proportional to the errors in shoulder and elbow angles and their time-derivatives:

$$u = K_{p,1}(\theta_1 - \theta_{1,target}) + K_{d,1}\dot{\theta}_1 + K_{p,2}(\theta_2 - \theta_{2,target}) + K_{d,2}\dot{\theta}_2,$$

where  $K_p$  and  $K_d$  are the proportional and derivative gains, respectively. Single joint muscles were only given feedback from one joint.

Forward dynamic simulations were performed for a single-target, planar reaching task. Initial joint angles were zero, and target joint angles were 45 and 90 degrees for shoulder and elbow, respectively. The feedback gains were set to identical values for all muscles and all joints, and varied to assess their effect on the performance of the reaching movement and on muscle forces.

### RESULTS AND DISCUSSION

As expected, PD controller performance depended on feedback gains (Figure 1). When gains were selected to produce movements of sufficient speed and accuracy, undamped oscillation resulted. Model performance improved under two conditions: (i) when inertia of the limb segments was significantly increased, and (ii) when muscle response time was reduced, either by stiffening of the SEE or reduction of time constants in the activation dynamics model.

### CONCLUSIONS

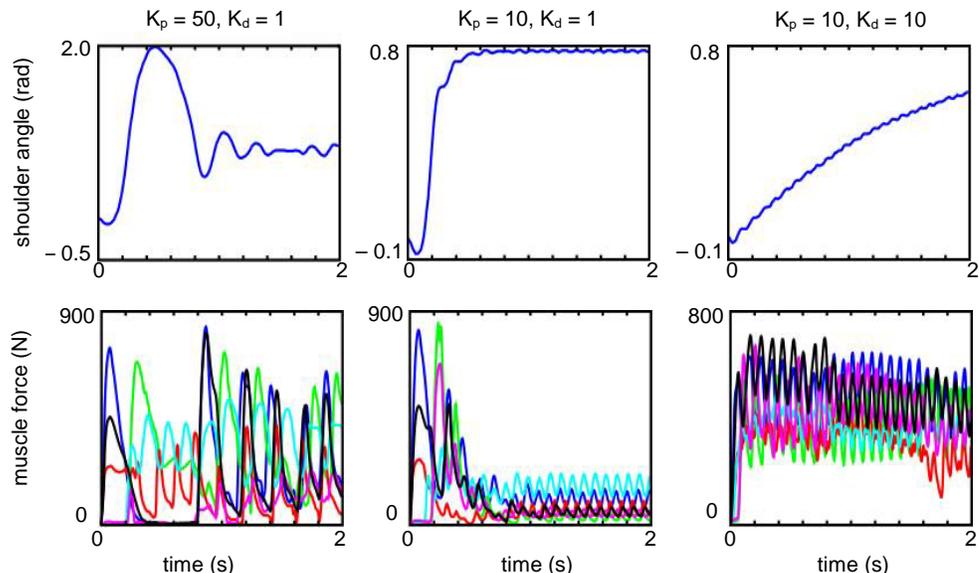

This computational model strongly suggests that oscillatory behavior may be an inevitable feature of proportional-derivative control for upper extremity FES. Further work will investigate the feasibility of an 'intelligent' controller based upon the Reinforcement Learning paradigm.

## ACHILLES AND PATELLAR TENDON LOADING DURING GAIT MEASURED USING A NON-INVASIVE ULTRASONIC TECHNIQUE

<sup>1</sup>Philippe Pourcelot, <sup>2</sup>Antonie J. van den Bogert, <sup>2</sup>Xuemei Huang and <sup>1</sup>Nathalie Crevier-Denoix

### INTRODUCTION

*In vivo* measurement of tendon and ligament loads remains a challenge. Forces acting on these structures during exercise have been either estimated indirectly using EMG and inverse dynamics or measured by means of invasive techniques [2]. Recently, a non-invasive technique has been proposed, based on the measurement of the velocity of ultrasound (US) propagation in the tendon [1]. It has been demonstrated that this velocity is dependent on the force applied to the tendon (Fig. 1A). In this paper we report preliminary results of measurements performed on the Achilles tendon and patellar tendon in humans during walking.

### METHODS

Ultrasonic (US) measurements were performed using a dedicated device composed of an electronic battery-powered module connected to an ultrasonic probe. The probe consists of 4 transducer elements, one acting as an emitter and the others as receivers. Knowing the distance separating these receivers, the speed of sound (SOS) is easily obtained by dividing this distance by the time required by the US waves to travel from one receiver to another.

Data were collected in four subjects (1 female, 52 kg, and 3 males, 68, 80 and 88 kg). Each subject performed 10 barefoot walking trials with the US probe on the right Achilles tendon and 10 other trials with the probe on the right patellar tendon.

An extra analog input on the US device was used to record the vertical ground reaction force (Fz) from an AMTI force plate. After time normalization to percentage of stride duration, SOS and Fz data were averaged over the 10 gait cycles.

### RESULTS AND DISCUSSION

Results obtained in the Achilles tendon (Fig. 1B) are consistent with those from implanted sensors. As described by Finni *et al.* [2], the tendon force decreases suddenly at heel contact on the ground followed by a steep rise in tendon load during the first part of the stance phase. The patellar tendon (Fig. 1C) shows a peak in the first half of stance, as seen in knee extensor moments during gait (Winter, 1983).

In all subjects, SOS was higher in the Achilles tendon, which may be due to higher tensile stress during gait. Between-subject differences in SOS were not related to body weight. These variations could be due to differences in muscle activation, or differences in elastic properties of the tendons. Further studies, using simultaneous EMG and inverse dynamic analyses, are needed to resolve this issue.

When compared to inverse dynamic analysis, the ultrasound method has several advantages. First, no assumptions on antagonistic co-contraction are needed. This enables direct inferences about individual muscle forces. Second, no low-pass filtering is needed and this results in better temporal resolution.

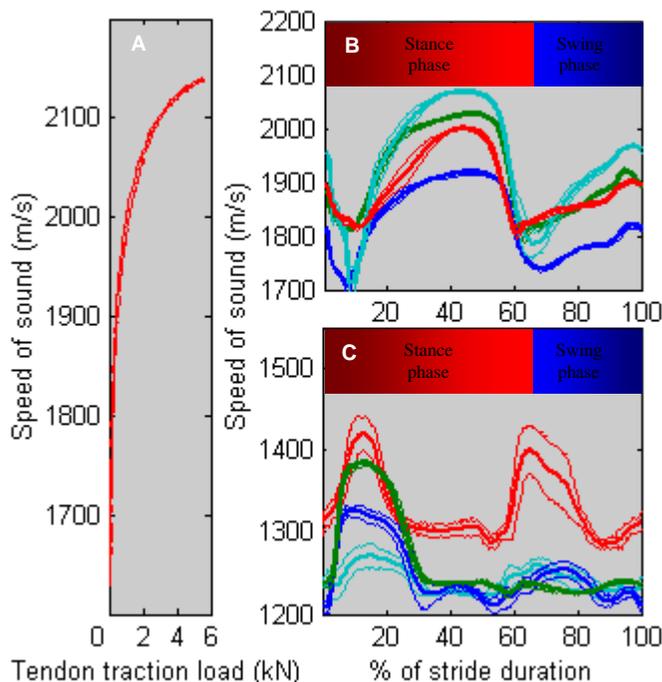

When compared to EMG, the ultrasound method has the advantage that calibration to force appears possible (Fig. 1A). Until we can non-invasively obtain a force-SOS relationship for a specific tendon in a specific subject, applications are limited to those that only require within-subject comparisons.

### CONCLUSIONS

This new non-invasive technique opens up a range of investigative opportunities in various fields of research. It should also be a useful clinical tool for diagnosis, evaluation and follow-up of muscle, tendon and ligament injuries or dysfunctions.

## SHIFTING TO POPULATION-BASED MODELS AND INFERRING MODEL STRUCTURE FROM DATA ARE TWO DIRECTIONS THAT WILL ENHANCE THE CLINICAL USEFULNESS OF MODELING

Cornell University, Ithaca, NY; email: [fv24@cornell.edu](mailto:fv24@cornell.edu), web: [www.mae.cornell.edu/valero](http://www.mae.cornell.edu/valero)

### INTRODUCTION

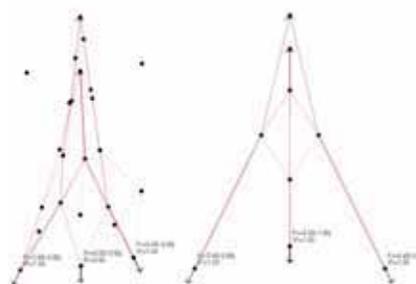

The clinical promise of biomechanical models lies in their ability to explain, illustrate and predict the functional consequences of injury, disease and treatment on the basis of first principles. Many advances in computational methods, computer hardware and computer graphics have greatly facilitated the creation and use of ever more complex models. We propose, however, that continuing on this path does not guarantee that modeling will revolutionize clinical care. We argue that the conceptual framework for modeling is, in general, limited because it is largely an exercise in parameter estimation that does not consider population variability. We underscore the need to adopt a population-based strategy where the structure of the model is inferred from data.

### POPULATION-BASED MODELS

A model is generally taken to be a single instantiation of a biological process that results in specific predictions. This frequentist approach applies well when simulating the behavior of either a single individual or the representative (i.e., mean) behavior of a group. It is less informative of the general trend of behavior in the general population, or of how the unavoidable variability in a population produces variable performance across the population. Bayesian inference techniques like Monte Carlo simulations [1-3] are well suited to approach these questions. In this Bayesian approach, model parameters are variables that, like people, are best described as randomly drawn values from statistical distributions (called “prior distributions”) instead of specific constant values. This approach produces “posterior distributions” describing the likely performance across the population. For example, the multimodal distributions of thumb kinematics arising from bone variability (Fig 1) enables the exploration of biomechanical explanations for the clinical reality that a same diagnosis leads to distinct groupings in the rate and amount of impairment and recovery after treatment. If there are truly several “types” of people, modeling can then explain why

**Figure 1:** Monte Carlo simulations suggest there are 4 “Types” of thumb kinematics, distinguished by the angle at joint #5 needed to reach a reference configuration [1].

**Figure 2:** The tendon network at left arose from the unsupervised inference of the hidden network at right via random loading of a uniform mesh at three nodes.

some are more/less susceptible to disease and more/less responsive to treatment.

### INFERRING MODEL STRUCTURE FROM DATA

For complex anatomical structures such as the hand, it is necessary to explicitly distinguish between model structure (i.e., the preconceived morphology) and parameter values (i.e., the particulars of that structure). The inevitable discrepancies between predicted and measured data can be attributed to unsatisfactory parameter values, inadequate model structure or both. In contrast, today’s biomechanical models consist of manually assembled structures where only the parameter values are systematically adjusted to explain and/or reproduce experimental data. Thus, improving current models necessitates that we explicitly investigate how the assumed model structure fundamentally determines and limits model behavior. Extending prior work [4], we now have unsupervised algorithms that simultaneously infer both the model structure and parameter values to best explain data (Fig 2). In this way, models can begin to clarify how disease and treatment affect the type, connectivity, properties, parameters and interactions of available “building blocks” such as bones, tissues, tendons, muscles, neural circuits, etc.

### CONCLUSIONS

Population-based models with data-driven structures will enable new and powerful clinical applications of modeling.

**MODELING AND CONTROL OF HUMAN POSTURAL SWAY**

<sup>1</sup>Radhika Kotina, <sup>1</sup>Zhiqiang Gao, <sup>2</sup>Antonie J. van den Bogert

<sup>1</sup>Department of Electrical Engineering, Cleveland State University

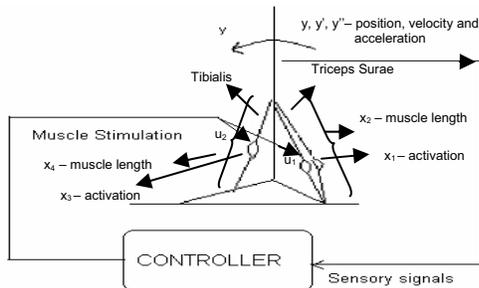

<sup>2</sup>Department of Biomedical Engineering, Cleveland Clinic Foundation; email: [r.kotina@csuohio.edu](mailto:r.kotina@csuohio.edu)

**INTRODUCTION**

For quiet standing, the ankle strategy is used for the control of human posture in which the body moves as a rigid mass around the ankle joints. In its simplest form, the body is regarded as a single-link inverted pendulum with movement at the ankle joint controlled by the human postural control system. In patients with neurological impairment, this function might be restored by functional electrical stimulation. A critical part of such a neural prosthesis is the control algorithm. The control techniques used for such dynamic and nonlinear models need to be robust, such that they can perform well in spite of variations in the dynamics and parameters when applied on a real human. Hence, it is the purpose of our study to develop such robust control algorithms for postural control and to evaluate their performance using a computational model of musculoskeletal dynamics.

**MODELING AND CONTROL DESIGN**

The musculoskeletal dynamics model (Figure 1) consisted of one rigid segment, and three muscles at the ankle joint. Muscles were modeled using nonlinear differential equations from McLean *et al.* [1]. The plant model is complex and nonlinear. Furthermore, there are significant uncertainties in the model, caused by biological variation in human muscle properties. All of these make model-based control designs such as pole-placement, feedback linearization, sliding model control and  $H_2/H_{inf}$  difficult to attain. This leaves proportional-integral-derivative controller (PID) as the only common alternative. However, the limitations of PID make its performance unsatisfactory for this application, as shown later.

**Figure 1: Closed-loop control strategy of the human ankle model**

As pointed out by Gao *et al.* [2], problems like this call for a control design framework that is not overly dependent on the mathematical model of the process. In particular, we suggest that the active disturbance rejection control (ADRC) concept fits the nature of this problem well. This is because that the motion problem can be treated as

$$\ddot{y} = f + b \cdot U \tag{1}$$

where  $y$  is the output position and  $f$  represents combined effects of internal nonlinear dynamics and external disturbances of the plant,  $b$  is a parameter and  $U$  is the control signal. In the ADRC framework, a unique state observer is

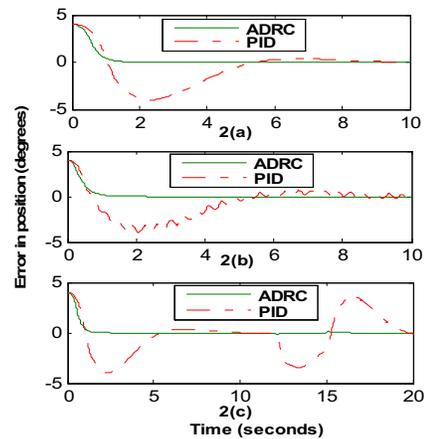

used to estimate the value of ' $f$ ' in real time without knowing its mathematical expression. Using this, the control law

$$U = (U_{or}f)/b \tag{2}$$

reduces the plant to a simple double integral plant, which can be easily controlled. A complete simulation model of the musculoskeletal system and both types of controller was built in Simulink. Desired posture in Figure 2 is  $4^\circ$  from vertical.

**RESULTS AND DISCUSSION**

The simulation results in Figure 2(a) were obtained at a nominal condition, for which PID and ADRC were tuned. In addition, inertia change and disturbance are added to test the robustness of the controllers as shown in Figures 2(b), 2(c).

**Figure 2: (a) nominal model, (b) with decreased inertia, (c) with a push of 60N-m at t = 12 secs for 3 secs**

Based on the simulation results, the response of ADRC appears to be very tolerant to the uncertain and disturbed models. For the nominal condition, results of ADRC show no overshoot, reaching to steady state in less than 2 secs, whereas the control of PID takes 8 secs with a large overshoot. PID results in oscillatory response with decrease inertia by 4 times the nominal value, proving that its performance is sensitive to parameter variations whereas ADRC performance remains consistent. The maximum push that ADRC could withstand is 120N-m but with PID no more than 60N-m could be achieved. Muscle strength was sufficient to recover from a forward lean of  $18^\circ$ . This was attained by ADRC whereas PID could not tolerate more than  $7^\circ$  lean. These initial results show promise that ADRC can be extended to multiple joints for a more complete study of human postural control.

## THE EFFECT OF SHOULDER GIRDLE COORDINATION ON UPPER EXTREMITY WORKSPACE IN STROKE

<sup>1</sup>Ana Maria Acosta and <sup>1,2</sup>Jules Dewald

<sup>1</sup>Northwestern University, Department of Physical Therapy and Human Movement Sciences, <sup>2</sup>Department of Physical Medicine and Rehabilitation, Department of Biomedical Engineering ; email: [a-acosta@northwestern.edu](mailto:a-acosta@northwestern.edu)

### INTRODUCTION

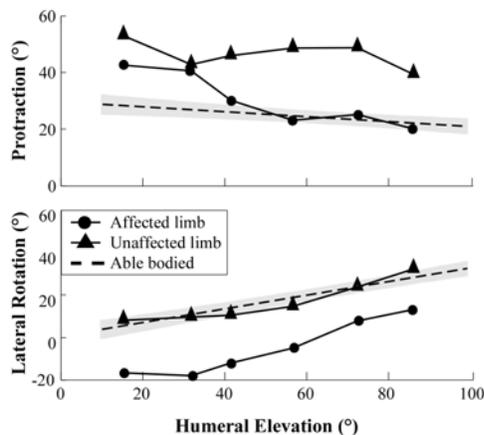

The extensive range of motion of the healthy shoulder is a result of the integrated movements of the sternoclavicular, acromioclavicular, glenohumeral, and scapulothoracic joints. These movements are achieved by the coordinated action of the shoulder muscles that also act to maintain joint stability. It is generally accepted that the interaction between rotator cuff muscles and the deltoid muscles is crucial for effective arm elevation while the coordinated action of trapezius, rhomboids and serratus anterior allows scapular rotation necessary for full arm elevation [1]. However, it is not known how these patterns of muscle activation change following stroke, and how this impacts the shoulder range of motion in this population. The goal of this work is to understand the effect of brain injury due to stroke on shoulder muscle coordination and its impact on arm workspace.

### METHODS

The shoulder kinematics were measured in one subject with unilateral brain injury resulting in left hemiparesis. The AROM in the affected limb was limited to 90° abduction. The kinematics, including scapular rotations, were measured statically using the standardized protocol developed by van der Helm [2]. The 3D position of the trunk, arm, forearm, and scapula was measured using a motion analysis system that tracked the location of infrared LEDs (IREDS) mounted on rigid bodies. Segment kinematics were calculated based on bony landmarks [3] that define their location and orientation. The locations of the scapular bony landmarks were recorded by placing a tripod instrumented with IREDS on the bone. In addition, surface EMG of a set of shoulder and elbow muscles was recorded simultaneously with the kinematics. The subject was asked to abduct (coronal plane) and flex (sagittal plane) the arm to specific angles in increments of 15° up to the maximum voluntary elevation in the affected side and maintain each posture for 5 s while the 3D location of the IREDS was recorded. The measurements were repeated twice with resting periods between trials to avoid muscle fatigue.

### RESULTS AND DISCUSSION

Figure 1 shows the scapular kinematics calculated for the

**Figure 1.** Scapular kinematics in a subject with stroke compared to able-bodied.

**Table 1.** Average EMG (%MVC) activity in upper and middle heads of the trapezius muscle in the stroke subject.

	Utrap	MTrap
Unaffected arm	84.4 ± 10.9	7.6 ± 1.6
Affected arm	42.2 ± 9.8	16.8 ± 3.7

affected (solid circles) and unaffected (solid triangles) limbs compared to able bodied (dashed line – gray area indicates 95% confidence interval). The able bodied kinematics are represented as the linear regression of the experimental data calculated from both limbs five subjects [3] with the associated 95% confidence interval. Note that the lateral rotation of the scapula, typically associated with the scapulo-humeral rhythm, in the unaffected side is similar to able bodied. However, in the affected side, the scapula is more medially rotated across arm elevations, indicating a more medial resting position. The scapulo-humeral rhythm or the relationship between the lateral rotation and the humeral elevation is similar between the affected and unaffected limbs. The mean or resting protraction angle of the scapula also differed across limbs, especially at higher elevation angles. In contrast, the tipping angle (not shown) was similar between limbs and to able bodied. Both of these angles represent the scapular winging. These results from a single subject are preliminary evidence to the alteration in muscle activation patterns. The scapular kinematics could be explained by increased activity in the Middle Trapezius (MTrap) and Rhomboid muscles and reduced activity of Upper Trapezius (UTrap) muscle as was actually observed in the EMG measurements. The average normalized MTrap EMG while supporting the arm at 90° abduction was twice as large for the affected arm than for the unaffected arm (see Table 1), while the activity of UTrap in the affected limb was approximately half of the activity measured in the unaffected limb. These results support the notion of altered coactivation patterns responsible for changes in the scapular kinematics. The increased activity in the affected side MTrap muscle pulls the scapula to a more medial rotation compared to the unaffected side. Note that although the activity in UTrap increased with arm elevation, it is still lower in the affected side, which may provide an explanation for the reduced range of motion in the affected arm. Under normal conditions, the scapula rotates laterally to allow the head of the humerus to clear the acromion. However, if the scapular rotation is not sufficient, the head of the humerus will encounter a physical stop that prevents the arm from being elevated above this point. Future work will provide further evidence for abnormal muscle coactivation patterns by measuring the activity of additional key muscles including rhomboids and rotator cuff muscles in a representative sample of stroke subjects.

## THE EFFECT OF TIBIOFEMORAL LOADING ON PROXIMAL TIBIOFIBULAR JOINT MOTION

Jacob Scott<sup>1</sup>, Antonie J. van den Bogert<sup>1,2</sup>, Ed Barber<sup>1</sup>, Wael Barsoum<sup>2</sup>

<sup>1</sup>Department of Biomedical Engineering, Cleveland Clinic Foundation, Cleveland, OH, USA

<sup>2</sup>Department of Orthopaedic Surgery, Cleveland Clinic Foundation, Cleveland, OH, USA

### INTRODUCTION

The posterolateral part of the knee joint has been largely ignored in past biomechanical studies. Specifically, little is known about the proximal tibiofibular joint (PTFJ) and its relationship to overall knee joint mechanics.

The proximal fibula serves as the insertion for several anatomic structures integral to knee stability – the lateral collateral ligament (LCL), arcuate ligament, posterolateral capsular complex, and biceps tendon all insert onto the proximal fibula. A recent study has shown that the force in the lateral-collateral ligament is greatest during external tibial rotation loading conditions [1].

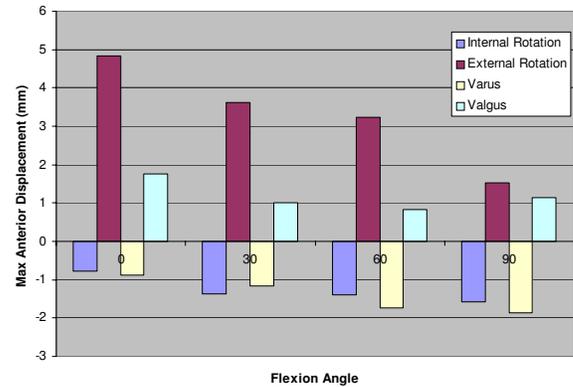

We hypothesize that these same loading conditions could cause motion in the PTFJ. Excessive motion in this joint may contribute to the development of posterior-lateral knee pain..

### METHODS

Fresh-frozen cadaveric knee specimens were tested with the knee joint fully intact. The tibia was mounted vertically on a six degree of freedom force/torque sensor (SI-2500-400, ATI Industrial Automation, Apex NC) mounted to the floor. The distal fibular connections to the tibia and talus were undisturbed during dissection and subsequent testing. Two reflective markers were mounted on pins driven into the tibial plateau and the head of the fibula at the proximal tibiofibular joint, respectively. Motion was recorded by a video camera (DALSA model #CL-C3 running Epix FrameGrabber software) at 10 frames per second. Load cell data was synchronized to the video data and recorded at 10 Hz.

The knee joint is then subjected to manual loading conditions in each of four flexion angles (0, 30, 60, 90 degrees as established by a manual goniometer). Varying loads were applied manually to a “handlebar” on the femur, in combination with a static compressive load of 40 lbs of compressive load to simulate weight bearing [2]. At each flexion angle, four discrete loading conditions were generated by the operator: varus, valgus, internal tibial rotation, and external tibial rotation. Peak moments were 20 Nm for internal-external rotation and 50 Nm for varus-valgus. To ensure standardized loading conditions, there is real time visual feedback of force/torque data.

Video images were digitized using custom Matlab software. The tibia marker was used as a reference and the displacement of the fibula marker, relative to its initial position, was computed to quantify PTFJ motion. Results from one typical specimen are presented.

**Figure 1:** Maximal anterior-posterior joint motion for the sixteen knee joint loading conditions. Positive values represent an anterior translation of the fibular head relative to the tibia.

### RESULTS AND DISCUSSION

Initial results indicate that there is significant tibiofibular joint motion. The greatest motion was seen in external rotation near full extension when we see the fibular head displacing more than 4 mm anteriorly relative to the tibia, at an external rotation moment of about 20 Nm. Results for all loading conditions are summarized in Figure 1.

The tibiofibular joint is a robustly encapsulated synovial joint that has very flat and smooth articular surfaces which do not mechanically resist translation. Considering the size of the joint itself (~7mm across), a translation of 4mm is substantial, and in the paradigm of any other joint would have to be considered traumatic.

While the applied rotation torques were much larger than typically seen during gait, the load-displacement relationship was nonlinear such that 2 mm displacement was already seen at 10 Nm external rotation torque which is more representative of in vivo loading. Frontal and transverse plane torques were only applied in isolation, and not combined. Because of the LCL, we would expect the PTFJ to be especially sensitive to external rotation in combination with varus loading. Further studies will investigate these interactions.

## A DUAL TRACK ACTUATED TREADMILL IN A VIRTUAL REALITY ENVIRONMENT AS A COUNTERMEASURE FOR NEUROVESTIBULAR ADAPTATIONS IN MICROGRAVITY

<sup>1</sup>Samantha M. Lane, <sup>2</sup>Michael W. Kahelin, <sup>3</sup>Philip O'Connor, <sup>3</sup>Jay G. Horowitz and <sup>2</sup>Susan E. D'Andrea  
<sup>1</sup>The University of Iowa, <sup>2</sup>The Cleveland Clinic Foundation, <sup>3</sup>NASA Glenn Research Center;  
Email: [susan.dandrea@gmail.com](mailto:susan.dandrea@gmail.com)

### INTRODUCTION

The neurovestibular system is primarily responsible for balance and stabilization and relies on vestibular, visual and proprioceptive cues. The microgravity environment alters these cues, resulting in sensory conflicts that cause crew members to experience gait and postural instabilities when returning to gravity environment. Longer durations in microgravity cause the adaptation process to be longer and more difficult [1]. During re-entry and post-flight, crew members suffer from disabling vertigo, oscillopsia, sudden loss of orientation, impaired coordination, sudden loss of postural ability, and overall decreased ability in standing and gait performance [2,3].

Travel to distant planets and extended durations of time aboard the International Space Station have made it necessary to develop effective countermeasure to aid in the adaptation process. The aim of this study was to determine if the dual-track actuated treadmill in a virtual reality environment significantly stimulates the neurovestibular system such that it would alleviate adverse adaptations.

### METHODS

Subjects walked on the treadmill at a speed of 3.5 mph in one of three conditions:

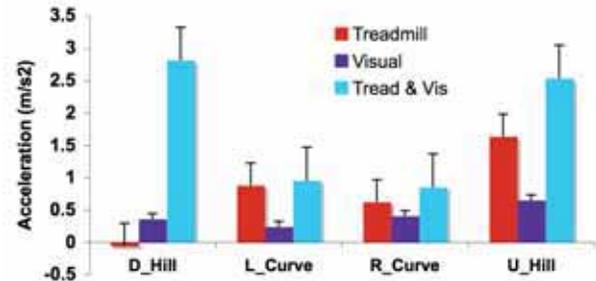

1. Visual Only: There was a visual display and the left and right treadmill tracks were the same as the Control condition.
2. Treadmill Only: There was no visual display and the treadmill tracks raised and lowered vertically, inclined and declined, and changed speeds.
3. Treadmill and Visual: There was a visual display that coincided with the treadmill tracks as they performed like the Treadmill Only condition.

Data were collected for ten seconds both in the first and last five minutes of the 30-minute trial during the simulated activities of walking straight, around curves, uphill and downhill. Measurements were also made in control conditions before and after testing in which there was no visual display and both treadmill tracks remained the same speed and height.

Electromyography of the neck as well as and head/trunk kinematics were measured. Head acceleration was measured by a head mounted tri-axial accelerometer. Footswitches fixed to the bottom of the shoe were used to determine gait events.

### RESULTS AND DISCUSSION

Results for head acceleration were analyzed to determine if the virtual reality treadmill alters the response to shock transients through the body. The resultant acceleration of the head was calculated and peak values were determined for each stride at

**Figure 1:** Normalized Head Acceleration During Five Activities By Experimental Condition

heel strike. Accelerations were normalized by subtracting the peak values found in the initial control condition (Figure 1).

Acceleration for each activity was highly correlated to the control condition. Normalized accelerations of the head increased while walking on the dual-track treadmill compared to normal treadmill walking. Similarly, no significance was found when using paired t tests to compare the data across conditions. This can be attributed to the large variability between subjects. Treadmill and Visual trials showed significantly larger acceleration than the Visual Only trials indicating the importance of actuated belts with regard to neurovestibular stimulation. Of particular interest is the fact that the accelerations remained elevated in the final Control Condition as seen in Figure 1.

### CONCLUSIONS

By increasing the input stimulus to the body, specifically the shock to the head, the treadmill forces the user to consistently activate their balance reflexes to maintain a consistent gait. This illustrates the potential for the dual track, actuated treadmill device with virtual reality to be an effective countermeasure to alleviate the postural and balance disturbances after exposure to microgravity. Analysis of the muscle activation patterns and the head/neck coordination will further clarify the extent to which the treadmill stimulates the neurovestibular system.

### INTRODUCTION

This paper described improvement of previous work [1] that allowed registration of both joint kinematics and medical imaging during in-vitro experiments. In that study, joint kinematics data were collected from three-dimensional (3D) electrogoniometry [2,3] and 3D bone morphological data from CT using inserted fiducial bony landmarks for registration. In parallel, Snel et al. [4] described an in-vivo method to study discrete wrist kinematics using dynamic 3D tomography.

The aim of this study was to develop a protocol of registration of in-vivo wrist kinematics using selected anatomical landmarks virtually and manually identified on both CT reconstruction and in situ.

### METHODS

**Subject.** One subject (male, 50 years old) volunteered for the entire protocol.

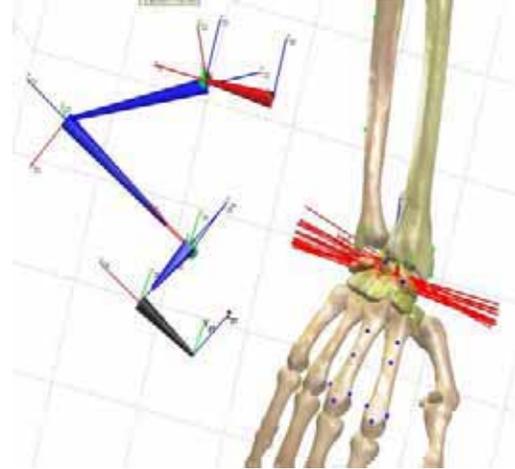

**Principle.** The aim of the overall protocol was to register two datasets: bone morphology from medical imaging (Siemens SOMATON Volume Zoom, Siemens Corp, Iselin, N.J.) and joint kinematics data from custom made electrogoniometry. Anatomical landmark (AL) location allowed this registration. Prior to 3D electrogoniometry (3DE), the 15 ALs selected in the method were virtually identified (palpated) on the 3D reconstructed bone surface of the subject. From this virtual palpation, a booklet was produced with various views of the virtual ALs to facilitate AL representation during manual palpation. The spatial location of the same bony ALs was determined using a 3D digitizer (Faro<sup>®</sup> arm, Bronze series, USA) just before collecting joint kinematics data by 3DE on the subject.

The origins of 3D digitizer and 3DE coordinate systems were made coincident. Joint kinematics collected using the 3DE could then be registered to the 3D bone models using the AL coordinated obtained during both virtual and manual palpation. The protocol has been fully implemented in Matlab and allows quasi real-time visualization of joint motion of the subject while the latter is performing the motion. Anatomical angle and helical axis parameters were computed to describe the joint kinematics.

**Precision.** The precision of the manual palpation was evaluated by four experimenters repeating five times the procedure and estimated by the error norm. The palpation effect was also estimated on the anatomical angular and translational values calculated during dorsopalmar flexion, radioulnar deviation and circumduction. The intraobserver precision was 2.6 (0.3) mm and 4.8 (1.2) mm for interobserver precision. The ICC for intra- and interobservation was greater than 0.95.

### RESULTS AND DISCUSSION

A view of animation is presented on Figure 1 with a set of Mean Helical Axis computed during the movement.

**Figure 1:** View of the animation. In red, the set of Mean Helical Axis during dorsopalmar flexion. The virtual representation of 3DE is also shown.

The propagation of the palpation error on anatomical angles and translation was less than 2° and 5 mm for the primary component of movement. For associated components, error curves showed some patterns underlying a “cross-talk” effect induced by the different definitions of the fixed anatomical coordinate system

### DISCUSSION

A new protocol of in-vivo registration was developed. This animation of wrist kinematics helps us to better understand several kinematical parameters as orientation and position of helical axis. Precisions of our measurements are better than those shown by Della Croce [5]. This was probably due to the availability of the booklet describing manual palpation precisely, and allowing the observer to reach a higher precision.

Before proposing this technique in clinics, a study of the influence of imaging parameters on the 3D bone reconstruction quality must be done to reduce the effective dose absorbed by the subject.

## LOWER EXTREMITY KINEMATICS DURING JOGGING: INFLUENCE OF TREADMILL SETTINGS

<sup>1</sup>Lan-Yuen Guo, <sup>2</sup>Chich-Haung Yang, <sup>1</sup>Wen-Lan Wu and <sup>3</sup>Fong-Chin Su

### INTRODUCTION

In recent years, more and more people have chosen to exercise using a treadmill in a gym or home setting. The main options available for jogging on a treadmill are (i) speed and (ii) inclination of the belt. Increased speeds and inclination not only increase the cardiopulmonary loading but also alter the lower extremity (LE) joint movement patterns[1, 2].

The current study to investigated LE joint movements during jogging at different speed and inclination settings.

### METHODS

Eighteen young males without neuromuscular or orthopedic problems were recruited in the experiment. The video-based motion capture system, HIREX Expert Vision System (Motion Analysis Corporation, CA, USA), with six CCD cameras, was used to collect kinematic data at a sampling frequency of 120Hz. Nineteen passive reflective markers were attached to bilateral lower extremities of the subject (Figure 1).

All subjects had a 5-minute warm-up period. One series of tests utilized four speeds (3.5 m/s, 3 m/s, 2.5 m/s, 2 m/s) with zero inclination. A second series of tests involved three slopes (15%, 10%, 5%) with the speed set at 3 m/s.

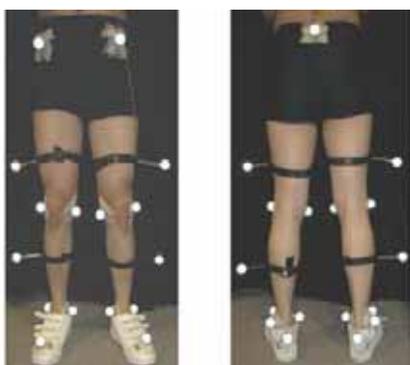

Figure 1: Marker setting

### RESULTS AND DISCUSSION

Increased the slope resulted in the lower extremity taking off the ground earlier during the jogging cycle. The main three joints of the LE had increased maximum flexion angles during the swing phase, but the maximum extension angles at stance phase were unchanged. For increased speeds, the hip and ankle joints had increased maximum joint extension angles during the stance phase, whereas the hip and knee joint had increased maximum flexion angles during the swing phase (Figure 2-4).

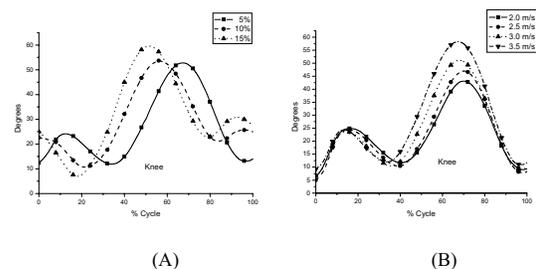

Figure 2: Knee joint motion during a jogging cycle with different incline (A) and speed (B) conditions.

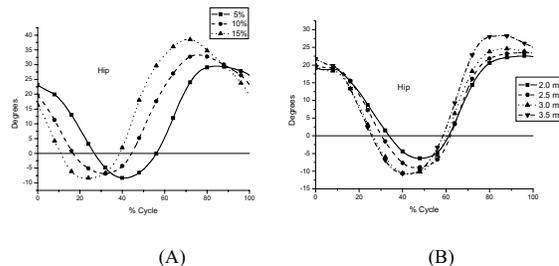

Figure 3: Hip joint motion during a jogging cycle with different incline (A) and speed (B) conditions.

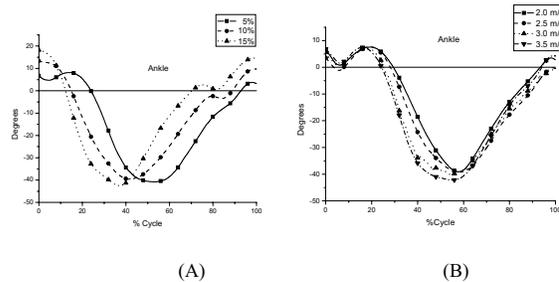

Figure 4: Ankle joint motion during a jogging cycle with different incline (A) and speed (B) conditions.

### CONCLUSIONS

Systematic kinematic investigations of the speed and incline settings on recreational treadmills show that LE joint motions are affected differently for each setting. This information can provide rehabilitation clinicians or athletic coaches with guidelines for selecting appropriate modes for jogging.

## THE EFFECTS OF HIKING DOWNHILL USING TWO TREKKING POLES WHILE CARRYING DIFFERENT EXTERNAL LOADS IN A BACKPACK

<sup>1</sup>Michael Bohne, <sup>2</sup>Julianne Abendroth-Smith and <sup>1</sup>Gary Heise

<sup>1</sup>University of Northern Colorado, Greeley, CO; email: [M-Bohne@wiu.edu](mailto:M-Bohne@wiu.edu); [gary.heise@unco.edu](mailto:gary.heise@unco.edu)

<sup>2</sup>Willamette University, Salem, OR; email: [jabendro@willamette.edu](mailto:jabendro@willamette.edu)

### INTRODUCTION

Hiking is commonly known as a recreational activity shown to offer significant positive effects on the human body. However, often times this requires transportation of an external load for supplies, with the most common and advantageous method by use of a backpack. Also, many people are required to walk downhill with an external load as part of their occupation. Walking downhill and the addition of an external load has been shown to increase the risk of musculoskeletal pain and injury. (1).

To alleviate some of the loading placed on the lower extremities, walking poles have become popular. The effectiveness of poles in downhill walking without packs has been demonstrated in that the poles successfully reduced forces placed on the lower extremities (2,3). Furthermore, poles used in uphill backpacking were successful in reducing muscle activity (4). It was hypothesized that the use of hiking poles would help reduce the net joint moments and net joint power for the ankle, knee and hip during the stance phase across all load conditions.

### METHODS

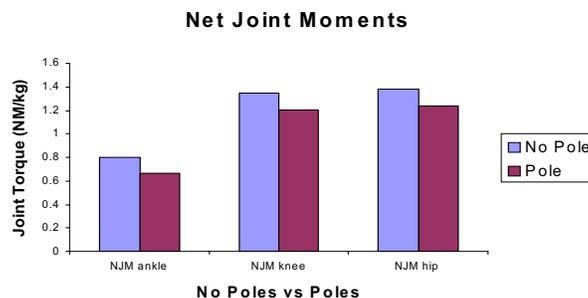

Fifteen male subjects (ages 20-49; height 1.36 m-1.68 m and weight: 600 N-1063N) were selected from hiking clubs in the Salem, Oregon area. All subjects were experienced hikers self-proclaimed to be comfortable with the use of hiking poles.

All participants were required to complete all conditions. Conditions included with and without the use of hiking poles for each of the three backpack conditions (no pack, day pack and large expedition pack). The day pack was loaded with 15% of body weight while the expedition pack was loaded with 30% of body weight. Ten trials were completed for each condition, for a total of 60 trials for each participant. All conditions were in random order for each participant.

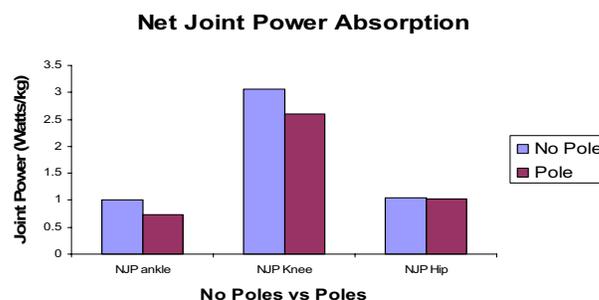

An average of each of the six conditions was used for analysis. The net joint moments and power at the ankle, knee and hip, as well as the net joint forces at the knee were examined statistically using a 2 X 3 (poles X packs) repeated measures ANOVA, with a family-wise alpha level of 0.05, using a Bonferonni adjustment, to protect against the running of multiple tests.

### RESULTS AND DISCUSSION

A significant reduction was observed for the dominant moment at each of the joints in the lower extremity (plantar flexion at the ankle, extension at the knee and hip) (See Figures 1). These results may be due to a reduction in the muscle activity which may help the muscle maintain the ability to help stabilize the joint, and, thus, reduce risk of injury.

**Figure 1:** Changes in net joint moment for the ankle knee and hip with pole use

**Figure 2:** Changes in net joint power for the ankle knee and hip with pole use

Reductions were also observed in the peak power absorption (See Figure 2) for the ankle and knee. These reductions are believed to result in a lessening of eccentric muscle actions, which may reduce the post exercise pain felt by participants. These results held true across pack conditions, as packs seemed to only result in a larger power generation at the hip.

### CONCLUSIONS

A reduction in the moments and power around the joint, with the use of poles, will help reduce the dangerous loading on the joints of the lower extremity. These reductions may lead to a larger portion of the population being able to enjoy a more active lifestyle.

## FORCE STEADINESS, NEUROMUSCULAR ACTIVATION AND MAXIMAL MUSCLE STRENGTH IN SUBJECTS SUFFERING FROM SUBACROMIAL IMPINGEMENT SYNDROME

### INTRODUCTION

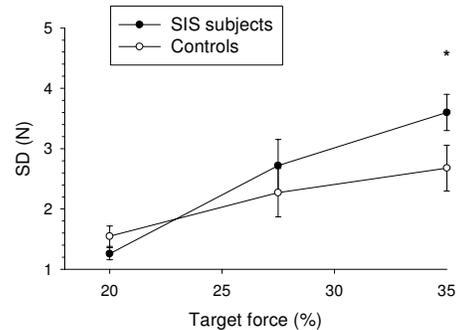

The therapeutic rehabilitation regime of subjects suffering from subacromial impingement syndrome (SIS) typically includes sensory-motor training of the shoulder. The rationale for this treatment is the assumption that the SIS causes an impairment of shoulder sensory-motor control. This view is in part supported by the findings of reduced maximal shoulder muscle strength [1], deltoid muscle fiber atrophy [2], and impaired kinesthetic sense of the shoulder [3] in patients with SIS. In the present study, therefore, it was hypothesized that shoulder sensory-motor control expressed as force steadiness would be impaired in subjects suffering from SIS.

### METHODS

Nine male subjects with unilateral SIS, who remained physically active in spite of shoulder pain ((mean)  $28.2 \pm 1.8$  yrs (SEM)) and 9 healthy matched controls ( $27.7 \pm 1.4$  yrs) were included. No significant between-group differences were noted at baseline for any of the variables used to match the two groups (height, weight, involvement in upper body sports or not, and participation in strength training or not). Shoulder sensory-motor control and maximal shoulder muscle strength (MVC) were assessed using an isokinetic dynamometer (KinCom). Isometric and dynamic submaximal shoulder abduction force steadiness was determined at target forces corresponding to 20, 27.5 and 35% of the maximal shoulder abductor torque and expressed as the standard deviation (SD) and coefficient of variation (CV) for the exerted abductor force. Isometric steadiness contractions (10 seconds duration) were performed at 90 degrees of shoulder abduction in the scapular plane and dynamic contractions (15 deg/sec) were performed from 30-120 degrees of abduction in the scapular plane. Shoulder MVC's were performed at 45 and 90 degrees of shoulder abduction. Neuromuscular activity (EMG) was assessed by surface and intra-muscular recordings in eight shoulder muscles: supraspinatus, infraspinatus, upper trapezius, lower trapezius, latissimus dorsi, serratus anterior, anterior and middle deltoid muscles.

### RESULTS AND DISCUSSION

While no differences were observed for isometric force steadiness, concentric submaximal force steadiness at the 35% target force level was reduced in SIS subjects (Figure 1). Thus, shoulder sensory-motor control expressed, as isometric submaximal force steadiness was not impaired in SIS subjects. Expressed as dynamic submaximal force steadiness, shoulder sensory-motor control was only impaired during concentric contractions at the highest target force level. It is possible that the pain-induced changes in shoulder afferent feed-back with SIS can be compensated for during isometric contractions.

**Figure 1:** Dynamic (concentric) shoulder force steadiness. \* denotes a statistical between-group difference.

This might not be the case during more complex movements. It seems that the control of contraction types requiring gradation of muscle force during articular movement with changes in muscle length/tension relationships, such as concentric contractions, are more prone to impairment in SIS subjects. All SIS and control subjects demonstrated activity in all of the investigated muscles for every target force level during both isometric and dynamic contractions. Muscle activity was similar between SIS and control subjects in almost all steadiness conditions examined. Only latissimus dorsi muscle activity during concentric submaximal force steadiness at the 20% target force level was elevated in the SIS subjects (SIS subjects:  $16.2 \pm 3.8\%$  EMGmax vs. controls:  $9.0 \pm 1.9\%$  EMGmax,  $p=0.046$ ). No differences in maximal shoulder muscle strength were found between groups (ABD45-SIS subjects:  $32.3 \pm 2.4$  Nm vs. controls:  $32.5 \pm 2.4$  Nm,  $p=1.00$ , and ABD90-SIS subjects:  $57.9 \pm 5.1$  Nm vs. controls:  $54.8 \pm 2.6$  Nm,  $p=0.537$ ). Thus, maximal shoulder abduction muscle strength was not found to be reduced in SIS subjects.

### CONCLUSIONS

In conclusion, the present results suggest that shoulder sensory-motor control expressed as force steadiness is only mildly impaired, with neuromuscular activation remaining largely unaffected, and maximal shoulder abductor muscle strength unaffected in SIS subjects who are able to continue with upper body physical activity in spite of shoulder pain.

### INTRODUCTION

Subacromial pathologies ranging from impingement to major cuff tearing are characterized clinically by shoulder pain and reduced arm mobility. The pathology is associated with a reduction of the subacromial space due to glenohumeral (GH) instability [1,2]. Arm mobility and GH-stability are both determined by shoulder muscle forces. Arm mobility requires a GH torque; stability requires GH force equilibrium [3,4].

We determined arm mobility, pain, external force and isometric muscle coordination before and after subacromial injection of lidocain in 6 patients with major rotator cuff tears. We will discuss our results in the scope of a torque versus force muscle function hypothesis.

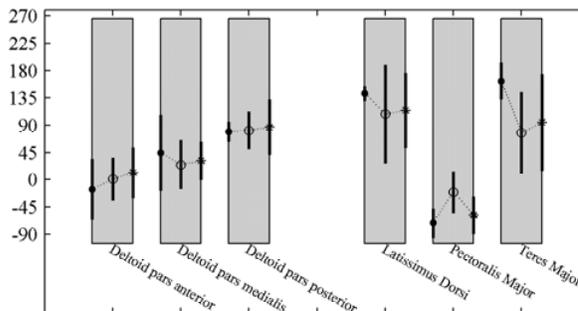

### METHODS

Six patients (4♂, 2♀, 61y SD=8) with irreparable rotator cuff tears, pain and reduced arm mobility were included prior to Teres Major tendon transfer surgery<sup>1</sup>. Before and 10 min. after sub-acromial lidocain injection (5ml, 1%) we quantified the Principal Action (PA) of 6 muscle(part)s, i.e. the direction of maximum muscle activation provoked by a force of constant magnitude rotated in a plane perpendicular to the humerus [5,6]. For this purpose, the injured arm was fixed into a splint and connected at the elbow onto a force transducer constraining only two translation degrees of freedom (dof's) perpendicular to the humerus. The arm was to be held still for the four remaining (dofs) in about 60° elevation in the 45° plane of abduction; the elbow was 90° flexed, the forearm positioned at 45° above the horizontal plane. The magnitude of the external force equaled the minimum of 12 maximum voluntary forces (MVF) generated in equidistant directions of 30° onto the force transducer. Shoulder pain was quantified using a Visual Analog Scale (VAS) and range of arm abduction (RoM) was determined by means of electromagnetic motion tracking [7].

### RESULTS AND DISCUSSION

The VAS decreased significantly after lidocain injection both in rest and during the experiment resulting in an increase of the minimum MVF with a factor 2.0 (SD 0.6). This was consistent with earlier reports [8]. The observed increase of ROM was not expected from model simulation, were transposition of the Teres Major muscle was found to be required for restoration of the insufficient GH abduction moment [4].

This study shows that the potential external muscle torque was not the limiting factor for ROM reduction. The possible explanation was found in the altered coordination of the shoulder muscles, illustrated here by the Principal Action (Figure 1). The ●-marks indicate the average normal function of the Deltoid muscle parts (Dlt), generating an abduction moment and activated around PA=0°, and the Latisimus Dorsi

**Figure 1:** Principal action (degrees) of six shoulder muscles recorded by means of surface EMG for normal subjects (●) ± 95% C.I. [6] and patients with cuff tear prior to (○) and after subacromial lidocain injection (\*). PA=0°: vertical abduction; PA=90°: horizontal adduction; PA=180°: vertical adduction; PA=270°: horizontal abduction.

(LD), Pectoralis Major (PM) and Teres Major muscles (TM), generating abduction and endoflexion moments and activated around PA=150° – 270° (i.e. equal to -90°)

Patients exhibit a relatively normal Deltoid PA. On average and prior to lidocain injection, the LD, PM and TM were co-activated during external abduction forces (change towards PA=0°). Lidocain injection reduced this effect and the external abduction moment and ROM were partly restored.

The underlying hypothesis is that the patients exhibit a GH instability. Superior translation of the humerus during abduction results in a reduction of the sub-acromial space and a pain sensation. Downward and inward directed muscle forces on the humerus stabilize the humeral position into the glenoid cavity. The LD, PM and TM muscles generate these downward and inward forces, which consequently results in the reduction of the abduction moment generated by the deltoid muscle and a reduction of RoM. Lidocain reduces the GH 'pain-feedback' activation of the adducting LD and TM, thus increasing the external moment and ROM.

## THE EFFECT OF GENERATING ANTI-GRAVITY SHOULDER TORQUES ON UPPER LIMB DISCOORDINATION FOLLOWING HEMIPARETIC STROKE

<sup>1,2,3</sup>Jules Dewald and <sup>1</sup> Jun Yao

<sup>1</sup>Northwestern University, Department of Physical Therapy and Human Movement Sciences, <sup>2</sup>Department of Physical Medicine and Rehabilitation, <sup>3</sup>Department of Biomedical Engineering ; email: [j-dewald@northwestern.edu](mailto:j-dewald@northwestern.edu)

### INTRODUCTION

Despite the variability of lesion location and spontaneous recovery experienced by individuals following hemiparetic stroke, the commonality among subjects is the presence of abnormal muscle synergy patterns and resulting stereotypical movement behaviors. These synergies and associated pathological coupling of joint torques were first observed in the clinic [1,2] and later verified quantitatively by Dewald et al [3,4] under static conditions. The synergies are expressed in strong coupling of shoulder abduction with elbow flexion (the flexion synergy) and shoulder adduction with elbow extension (the extension synergy). In this study we will compare the expression of the flexion synergy induced by generating isometric shoulder abduction (SABD) as opposed to elbow flexion (EF) torques at a maximal and a sub-maximal effort level. The goal of this study is to understand whether generation of anti-gravity torques at the shoulder has a more profound effect on the expression of the flexion synergy as opposed to torques generated at the elbow.

### METHODS

Hemiparetic stroke (n=7) and control (n=6) subjects were casted at the wrist and secured to a six degree of freedom (DOF) load cell with shoulder at 70° abduction and 40° flexion and the elbow at a 90° angle. In order to minimize the effect of trunk muscle activation, subjects were seated in a Biodex chair with the trunk secured and the shoulders strapped to the back of the chair. A computer monitor was placed in front of the subject to provide visual feedback in the form of a horizontal and vertical movement of a circular cursor on the screen representing elbow flexion-extension and shoulder abduction-adduction, respectively. Subjects were generating maximum voluntary torques (MVTs) and 25% of MVTs in the shoulder abduction and elbow flexion directions. Forces and

moments measured with the load cell were converted online to torques at the elbow (flexion/extension) and shoulder (flexion/extension, abduction/adduction, and external/internal rotation) using a Jacobian transformation. Subjects generated 3-5 trials in either direction. An analysis of variance (ANOVA) was performed at the 0.05 level of significance to test for the presence differences in secondary torques between stroke and control subjects.

### RESULTS AND DISCUSSION

Figure 1 shows a significant increase in elbow flexion torques in stroke compared to control subjects during the generation of maximum SABD torques. Conversely, during the generation of maximum EF no significant increases in SABD were observed. The dominance of shoulder anti-gravity torques on the expression of the flexion synergy persists even at the 25% of MVT level as shown in figure 2 although the significance level was reduced from p<0.01 to p<0.05.

These results indicate that the generation of shoulder abduction torques following stroke results in a strong expression of the flexion synergy whereas generating EF does not have the same effect. Apparently, the activation of postural anti-gravity muscles at the shoulder uniquely impacts arm discoordination following stroke both in static as well as during dynamic arm reaching tasks as demonstrated in our laboratory in an earlier study [5].

## SUPRASCAPULAR NERVE BLOCK DISRUPTS THE NORMAL PATTERN OF SCAPULAR KINEMATICS

Sean P McCully<sup>1</sup>, David N Suprak<sup>1</sup>, Peter Kosek<sup>2</sup>, Andrew R Karduna<sup>1</sup>

<sup>1</sup>Department of Human Physiology, University of Oregon, Eugene, Oregon, USA,

<sup>2</sup>Pain Consultants of Oregon, Eugene, Oregon, USA

email: karduna@uoregon.edu

### INTRODUCTION

Elevation of the arm is not accomplished by the motion of a single articulation, but rather is a combination of both glenohumeral and scapulothoracic motion. Previous research has demonstrated an increase in scapular upward rotation with alterations in rotator cuff activity, either due to tears [1] or fatigue. [2] We propose the use a suprascapular nerve block as an appropriate model of dysfunction of the supraspinatus and infraspinatus. It is our hypothesis that this block will result in a compensatory increase in scapular rotations, similar to what is observed due to fatigue and rotator cuff tears.

### METHODS

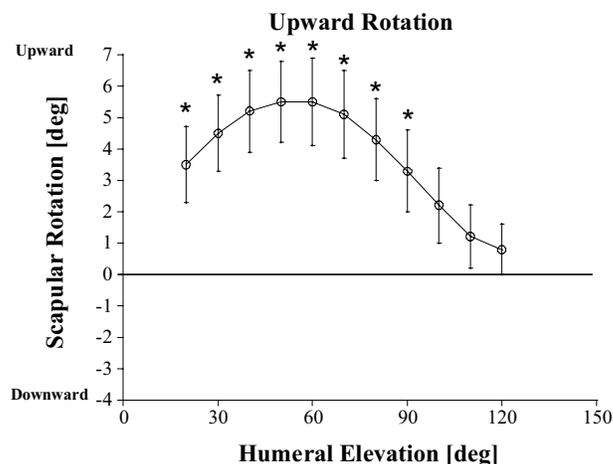

Ten subjects with no reported shoulder pathology successfully completed a nerve block protocol (age range 23-33). Kinematic and force data were collected prior to and immediately after a suprascapular nerve block. The 3Space Fastrak (Polhemus, Colchester, VT) was used to collect kinematic data. A thoracic receiver was placed over T3 with double sided tape, a humeral receiver was mounted on a molded cuff strapped to the distal humerus, and a scapular receiver was fixed to a scapular tracking device attached to the scapular spine and acromion. [3] Data were collected for scapular plane elevation and three scapular rotations were analyzed: posterior tilting, upward rotation, and external rotation. [3] Force production during shoulder external rotation with the arm at the side was measured with a 50 kg capacity load cell (Lebow, Troy, MI). The nerve block was performed by an Anesthesiologist (PK). After sterile prep of the skin, local anesthetic was infiltrated at a point 2 cm above the scapular spine and at the junction of the outer and middle one third of the spine. A 22 gage 5 cm insulated nerve stimulator needle was advanced to the scapular notch with 0.6 mA of current at 2 Hz. When motor stimulation was seen at current of less than 0.3 mA, 1.5 ml of 1.5% lidocaine was injected. Once repeat stimulation at 0.8 mV did not result in any muscle activity, the remaining 5.7 ml of 1.5 % lidocaine (total 100 mg) were injected and the needle was removed.

**Figure 1** Photograph demonstrating the location of the scapular sensor and injection of lidocaine.

### RESULTS AND DISCUSSION

There was no significant effect of the nerve block on posterior tilting and external rotation. However, for upward rotation, there was a significant effect of the block ( $p = 0.009$ ). The amount of scapular upward rotation was found to be significantly increased due to the block at humeral elevations from 20 to 90 degrees ( $p < 0.01$ ) (figure 2). The results of the present study are similar to changes due to cuff tears and fatigue, which also result in increases in upward rotation that peak in the mid ranges of motion. [1,2] Despite the fact that the muscles innervated by a suprascapular nerve (supraspinatus and infraspinatus) do not directly control the movement of the scapula, they appear to indirectly affect the scapulothoracic rhythm. The changes in scapulothoracic and humeral kinematics noted in the present study may lead to detrimental conditions such as a reduction in the subacromial space, mal-alignment of the humeral head and glenoid fossa, and a reduction in muscle mechanics (ideal muscle length and moment arms). Alternatively, the scapulothoracic kinematic changes might be considered beneficial as they may be compensatory motions helping to maintain joint stability.

**Figure 2** Changes in scapular rotations after the nerve block (Means  $\pm$  SEM).

### CONCLUSIONS

The results of this study indicate that abnormal kinematics patterns found in patients with rotator cuff tears may be compensatory in nature, rather than one of the underlying causes of the pathology.

## ALTERATIONS IN SCAPULAR KINEMATICS IN PATIENTS WITH SHOULDER IMPINGEMENT

Paula M. Ludewig

Program in Physical Therapy, School of Medicine  
University of Minnesota, Minneapolis, MN  
email: ludew001@umn.edu

### INTRODUCTION

Subacromial shoulder impingement is defined as compression and mechanical irritation of the rotator cuff and long head of the biceps tendons beneath the coracoacromial arch during elevation of the arm. In healthy subjects, the scapula must achieve a balance of adequate mobility to allow full arm motion, while maintaining stability on the thorax. Abnormal scapular motion on the thorax has been implicated as potentially contributing to shoulder impingement.<sup>1-6</sup> The purpose of this paper is to present an overview of findings regarding normal and abnormal scapular motion in subjects with shoulder impingement during elevation of the arm.

### METHODS

Several investigators have compared scapular kinematics in subjects with shoulder impingement to healthy controls.<sup>1-4, 6</sup> Subjects are identified based on a history of localized shoulder pain and clinical examination demonstrating positive impingement tests.<sup>3,4</sup> Methods of data collection have included two-dimensional topographic and radiographic analysis, and three-dimensional static digitizing of surface landmarks, and dynamic motion analysis with surface or bone fixed sensors on the thorax, scapular acromion process, and humerus.<sup>1-6</sup>

Three-dimensional (3-D) scapular data relative to the thorax are described using anatomically embedded reference frames. Ordered Cardan angles for scapular internal / external rotation (protraction / retraction); upward / downward rotation (lateral / medial rotation); and anterior / posterior tilting are described relative to thorax cardinal plane axes. Scapular angles are typically described across humeral elevation angles where shoulder impingement is believed to occur in the "painful arc" of motion (60° to 120° of humeral elevation relative to the thorax).<sup>3</sup> Data have been described in healthy and symptomatic populations during shoulder flexion, abduction, and scapular plane abduction.<sup>1-6</sup>

### RESULTS AND DISCUSSION

During elevation of the arm in the scapular plane in healthy subjects, the scapula typically undergoes upward rotation, external rotation, and posterior tilting,<sup>5</sup> while maintaining contact of the medial border and inferior angle of the scapula against the thorax. Subjects with impingement have demonstrated reductions in each of these component motions across different investigations. The most consistent abnormality across studies is a lack of normal posterior tilting.<sup>1-4</sup> Lack of normal posterior tilting and external rotation result in a loss of contact of the inferior angle (Figure 1) or medial border of the scapula with the thorax.<sup>6</sup> Some subjects demonstrate a pattern of progressive scapular anterior tilting throughout humeral elevation (Figure 2). Reductions in upward rotation early in the range of motion and reductions in

Figure 1: Subject demonstrating anterior tilting of the scapula during shoulder flexion.

external rotation under hand held loads have also been reported in impingement subjects.<sup>3</sup> The average magnitude of deviations is in the range of 4° to 6°. These deviations may be causative in the development of impingement syndrome or compensatory in response to pain and muscle inhibition. Although these deviations are believed to bring the acromion process in closer proximity to the humerus, the literature is inconsistent with regard to how these deviations may impact the subacromial space.

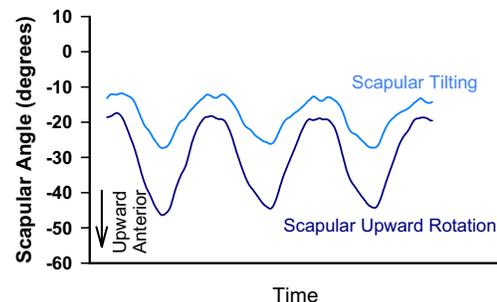

Figure 2. Graphical representation of anterior tilting pattern during three repetitions of humeral elevation.

### CONCLUSIONS

Significant alterations in (3-D) scapular motions on the thorax are seen in subjects with clinical signs of shoulder impingement as compared to healthy controls. Greater understanding is needed with regard to how these deviations impact the subacromial space and pathology of the rotator cuff and long head of the biceps tendons.

## POSITION OF THE HUMERAL HEAD SHIFTS IN THE GLENOID DUE TO THE PRESENCE OF OSTEOARTICULAR LESIONS

### INTRODUCTION

Osteoarticular lesions of the humeral head are often observed after shoulder dislocations [1]. The presence of such lesions could contribute to changes in position of the humeral head with respect to the glenoid. These alterations in the position of the humerus may lead to joint subluxation and the development of osteoarthritis [2]. The objective of this study was to determine the effects of osteoarticular lesions on the position of the humeral head during the application of a compressive force to the humerus.

### METHODS

Nine fresh-frozen cadaveric shoulders (age  $44.9 \pm 8.2$  years, humeral head diameter  $45.9 \pm 3.8$  mm) were dissected free of all skin and musculature except for the coracoacromial ligament and labrum. (Intact joint) The humerus and scapula were then potted in epoxy putty and fixed within a robotic/universal force-moment sensor (UFS) testing system [3]. The joint was initially oriented in the testing system at  $60^\circ$  of glenohumeral abduction and  $0^\circ$  of external rotation. A 22 N joint compressive force was applied by the testing system to the humerus while minimizing the forces in the orthogonal directions to center the humeral head within the glenoid cavity. The joint orientation was held constant during application of the compressive force. This protocol was then repeated after the joint was moved to  $60^\circ$  of glenohumeral abduction and  $60^\circ$  of external rotation. Three osteoarticular lesions on the posterolateral side of the humeral head were subsequently created to simulate an injury that would occur during joint dislocation at  $60^\circ$  of glenohumeral abduction and  $60^\circ$  of external rotation. The size of each lesion was approximately 12.5% (Lesion 1), 25% (Lesion 2), and 27.5% (Lesion 3) of the humeral head diameter and was created using an oscillating bone saw. (Figure 1) The compressive force was applied again to the shoulders at  $60^\circ$  glenohumeral abduction and both external rotation angles in each lesion state. The position of the humerus was recorded for each joint orientation following application of the compressive force. The change in the position of the humerus for each lesion state was then calculated and paired *t*-tests were used to determine significant differences between the position of the humerus for the intact joint and each lesion state ( $p < 0.05$ ).

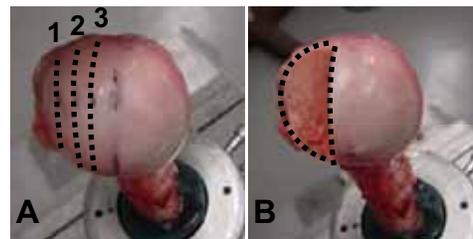

### RESULTS

No significant changes in joint position were found for all lesion states at  $0^\circ$  external rotation. (less than 1mm for each direction;  $p > 0.05$ ) The largest changes in position compared to the intact joint were found for Lesion 2 and 3 at  $60^\circ$  external rotation (Figure 2). The position of the humerus for Lesion 2 shifted  $1.3 \pm 1.4$  mm and  $2.5 \pm 1.6$  mm in the medial and posterior directions, respectively. The position of the humerus for

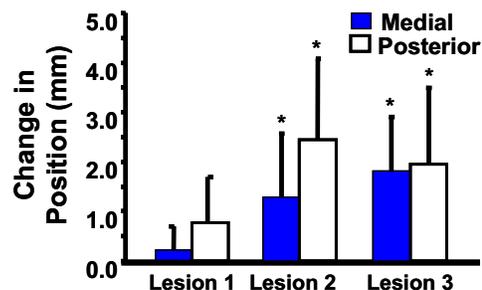

Lesion 3 shifted  $1.8 \pm 1.1$  mm and  $1.9 \pm 1.5$  mm in the medial and posterior directions, respectively. These changes in position were statistically significant ( $p < 0.05$ ). No significant changes in joint position were found for Lesion 1 with the humerus shifting by less than 1mm in all directions.

### DISCUSSION

This study evaluated the effect of osteoarticular lesions on the position of the humeral head with respect to the glenoid. A significant effect was found when the size of the lesion was 25% or more of the humeral head diameter (Lesions 2 & 3). However, smaller lesions did not affect bony contact between the humeral head and glenoid, and consequently the position of the humerus. In addition, the change in position was dependent on the location of the lesion and orientation of the joint. These altered joint positions could contribute to abnormal joint contact and the development of osteoarthritis [2]. In the future, the effect of the lesions on the contact forces and forces in the glenohumeral capsule will be examined.

**Figure 1:** A) Lines on humeral head indicating borders used for creation of Lesions 1, 2, and 3; B) humerus with Lesion 3.

**Figure 2:** Change in position of humerus with respect to intact joint at  $60^\circ$  of abduction and  $60^\circ$  of external rotation (mean  $\pm$  SD; \*  $p < 0.05$ ).

## Gait Data Collection Technology: Where are we, where are we going?

Lasse Roren

Vicon Peak, Oxford, United Kingdom

Email: [lasse.roren@vicon.com](mailto:lasse.roren@vicon.com)

### INTRODUCTION

Clinical gait analysis depends upon technology enabling the measurement of human movement. The availability of custom-designed hardware/software solutions has been key to the spread and popularity of clinical gait analysis.

### MATERIALS

The current state-of-the-art in gait analysis collection technology allows labs to collect data using high resolution cameras (up to 4 mega-pixels, see figure 1 below), high collection speeds (up to 2,000 Hz), small markers (down to 4mm diameter) and user friendly software that allows collection, processing and generation of clinical reports to be done in seconds ([1], [2]). A modern lab is able to capture full-body and foot data simultaneously using a large number of small markers, process both the full-body and foot models concurrently and generate a full clinical report long before the patient leaves the lab.

Labs have thus switched their focus from obtaining and processing data to the interpretation. The fact that reports can be generated quickly means that the lab has full confidence in the data quality before the patient leaves. Having to recall the patient because the data turned out to be poor is a thing of the past. In short, the recent increases in camera and software technology has resulted in significant accuracy and time saving gains.

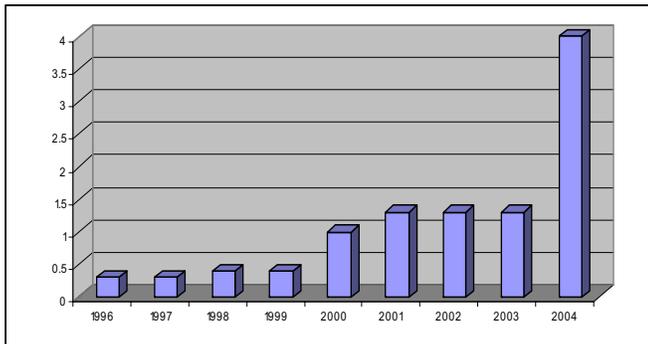

Figure 1: Maximum camera resolutions, in mega-pixels

### DISCUSSION

As the attention has switched from the data collection process to the analysis, it is becoming increasingly clear that the improved collection technology exposes shortcomings in the biomechanical modeling phase. Various papers have criticized the current standard, the Conventional Gait Model ([3]). Whereas data collection systems can determine marker centroids to typical accuracies in tenths of millimeters ([4]), the process of transforming these measurements to joint centers, kinematics and kinetics is subject to various sources of errors: soft tissue artifacts, anthropometric measurements

that are not subject specific, and inaccurate marker placement with respect to anatomical landmarks.

Solving these problems is currently a hot topic of research ([5]). It can be argued that the manufacturers themselves have done relatively little, although some research and development has taken place ([6]). The future will very likely see more emphasis being placed on the “next generation gait model”, both from researchers and manufacturers, and we will see competitive pressures forcing the manufacturers to act.

The main attention must focus on obtaining clinically validated and repeatable results. Manufacturers have to ensure that, whichever biomechanical model and protocol is adopted, the data can be processed through the model with a high degree of automation, confidence and accuracy. To this end, a cooperation between researchers in the gait community and the commercial development departments of manufacturers must be formalized. Also, the manufacturers must recognize that it is in everybody’s interest that the implementation of the model is open, published and streamlined – this will give researchers the double benefit of being able to conduct validation easily *and* having full confidence in the results.

Another topic which must be addressed is the financial viability of clinical labs. The manufacturers can address this in two ways: by developing systems that increase the intrinsic value of clinical gait through increased accuracy and standardization, and by developing systems that reduce the time and cost of conducting an analysis session.

As for the technology, initial development will focus on gradually increasing the system’s specifications in terms of accuracy and usability. However, the major technology breakthrough in the next 2-3 years is likely to be the development of markerless capture. Although it is too early to predict whether the clinical accuracy requirements will be satisfied, it is obvious that removing the need for markers would bring huge benefits to both patients and operators.

## CALCULATING ANATOMICAL LEG STRUCTURES FROM SURFACE CONTOURS

<sup>1</sup>Walter Rapp, <sup>2</sup>Marcin Witkowski, <sup>1</sup>Thomas Horstmann, <sup>3</sup>Burkhard Lembeck, <sup>4</sup>Jos Vander Sloten, and <sup>5</sup>Kjell Heitmann

E-mail: [walter.rapp@med.uni-tuebingen.de](mailto:walter.rapp@med.uni-tuebingen.de)

### INTRODUCTION

The analysis of objective movement parameters plays an important role in clinical diagnoses. State of the art motion analyzing tracks reflecting markers fixed on the skin over anatomical landmarks. When using such systems however, no information about the surrounding surface structures is available. Therefore, the purpose of this project is the development of a system able to reconstruct anatomical structures from the scanned surface volume of the lower leg under dynamic conditions. It was shown that a surface analysis of the back shape could be performed using white light raster line projection (Frobin&Hierholzer 1981, Drerup&Hierholzer 1987).

To achieve a system with the capacity to analyze the full volume of the lower extremities two main changes have to be developed. First, is the synchronization of four camera projection units and second, is to change from white light to laser light line projection.

The goal of the following pre-study is to evaluate the shape of the lower extremities using white light rasterstereographic technique to find surface areas which represent bony structures for the reconstruction of a musculo-skeletal model.

### METHODS

The surface contour of the lower leg was analyzed using the formetric® system (DIERS International, Germany). This system consists of a commercial slide projector and a fire wire camera which were mounted in a constant geometrical order. The maximum analyzing frequency is 15 Hz.

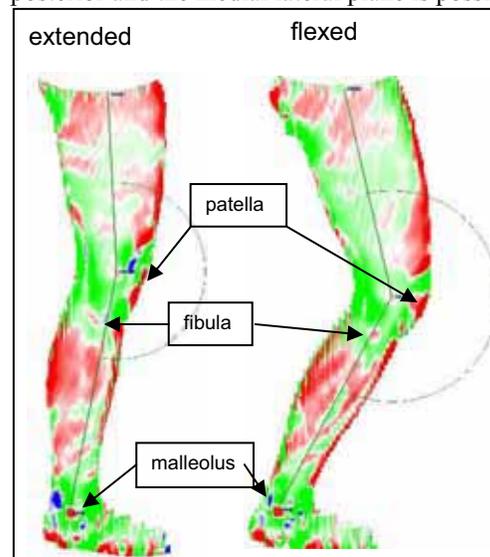

The method of rasterstereography is based on the curvature analysis of horizontal light lines which are projected onto the legs and stored as a video image. Transforming the light lines into a 3D-point cloud, the shape of the leg can be comprised of concave, convex and saddle shaped areas (Fig.1).

Five subjects participated in this pre-study. They were positioned in front of the recording system and performed slow knee bending during normal stance. The surface structures were scanned from an anterior, posterior and sagittal view separately. Black markers were fixed on significant anatomical landmarks, like the patella, tibial tubercle, the malleolus and the head of the fibula, for comparison with the previously palpated positions. Due to limitations of the measuring volume, the pelvis could not be analyzed. As an orientation, markers were placed 15cm beneath the spinea iliaca anterior and the trochanter major.

### RESULTS AND DISCUSSION

From the sagittal view the lateral malleolus are a rather prominent landmark detectable in every subject. Looking at the knee, the patella can be detected as a prominent convex area from the frontal view and is also detectable from the

lateral view (Fig. 1). At the shank, the maximum curvature of each horizontal line can be marked and linked vertically. This however, does not represent the line of the tibia due to the fact that the m. tibialis ant. obscures the tibia. As a further landmark, visible from the frontal view, the tibial tubercle is represented by a change from a convex to a saddle shaped area. As already mentioned, no significant landmarks can be detected from the thigh, neither from the frontal nor from the sagittal view. In this case alternative points must be marked manually to get the line passing the iliac spine or the trochanter. Thus a calculation of the angle in the anterior posterior and the medial lateral plane is possible.

**Figure 1: Image example from a sagittal view. The arrowed parts represent the detected landmarks.**

### CONCLUSIONS

It could be shown, that lower leg anatomical landmarks are detectable using this technique. The detection of these landmarks allows the computation of segments representing the anatomy of the lower extremities in 3D. Limitations must be seen that a movement sequence could only be analyzed from one view. The development of a four camera laser light based system, however, should solve this problem.

## HAMSTRING CO-CONTRACTION DOES NOT NECESSARILY REDUCE ACL LOADING

<sup>1</sup>Bing Yu, <sup>2</sup>William E. Garrett

<sup>1</sup>Center for Human Movement Science, Division of Physical Therapy, The University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; <sup>2</sup>Sports Medicine Center, Duke University; email: [byu@med.unc.edu](mailto:byu@med.unc.edu)

### INTRODUCTION

One of the risk factors of sustaining non-contact anterior cruciate ligament (ACL) injury proposed in literature is the strong quadriceps muscle contraction at a small knee flexion angle. Previous studies with cadaver testing show hamstring co-contraction significantly reduces ACL loading, and suggest that training for hamstring co-contraction assist in reducing the risk of sustaining non-contact ACL injuries. The results of reduced ACL loading with hamstring co-contraction, however, were obtained with reduced knee joint resultant extension moment. The purpose of this study was to investigate the effects of hamstring co-contraction on ACL loading in a stop-jump task using a computer simulation method with in-vivo lower extremity kinematic and kinetic data.

### METHODS

Twenty healthy recreational athletes (10 males and 10 females) with no known history of knee injuries or disorders were recruited to collect radiographic data of the knee. Side-view roentgenographic films of the knee were obtained for each subject at 0°, 15°, 30°, 45°, 60°, 75° and 90° knee flexion bearing 50% of the total body weight. Patella tendon-tibia shaft angles (PTTS) and actual knee flexion angles were measured from the roentgenographic films. Multiple regression analyses with dummy variables were performed to express the PTTS as a function of knee flexion angle and gender. Quadriceps and hamstring muscle moment arms and ACL elevation angles from the literature were also expressed as functions of knee flexion angle using regression analyses.

Sixty healthy recreational athletes (30 males and 30 females) without known history of knee injuries or disorders were recruited for kinematic and kinetic data collection. Three-dimensional (3D) kinematics and kinetics of the lower extremities were collected for each subject in a stop-jump task. Knee joint angles and joint resultants were estimated. Multiple regression analyses with dummy variables were performed to express each of the peak knee joint resultant extension moment and peak proximal tibia anterior shear force during landing of the stop-jump task as a function of the peak posterior and vertical ground reaction forces.

A biomechanical model of the knee was developed with the PTTS, quadriceps and hamstring moment arms, and ACL elevation angle as functions of knee flexion angle, and peak knee extension moment and proximal tibia anterior shear force as functions of peak posterior and vertical ground reaction forces. The hamstring tendon was considered as parallel to the femur. Peak posterior and vertical ground reaction forces and knee flexion angle at peak posterior ground reaction force were varied based on the variations of corresponding in-vivo data. Quadriceps and hamstring muscle forces were varied to satisfy the peak knee extension moment estimated from the

peak ground reaction forces. ACL loading were estimated from the peak proximal tibia anterior shear force, quadriceps and hamstring muscle forces, and ACL elevation angle.

### RESULTS AND DISCUSSION

ACL loading increased as the hamstring co-contraction increased when the knee flexion angle is smaller than 15 degrees for males and 20 degrees for females (Figures 1 and 2). Hamstring co-contraction effectively reduced ACL loading when the knee flexion angle is greater than 15 degrees for males and 20 degrees for females (Figures 1 and 2).

Knee flexion angle significantly affects the relationship between ACL loading and hamstring co-contraction. Quadriceps force has to be increased to satisfy the given knee extension moment due to external loading when hamstring co-contraction increases. The anterior shear force applied on the tibia by the quadriceps increases while the posterior shear force applied on the tibia by the hamstring decreases as the knee flexion angle decreases. The gender difference in the relationship between ACL loading and hamstring co-contraction is mainly due to the gender difference in PTTS.

## A COMPARISON OF VARIOUS DIGITAL FILTERING TECHNIQUES APPLIED ON PLANTAR SURFACE PRESSURE AND SHEAR DATA

Metin Yavuz, M.S., Brian L. Davis, Ph.D.

Department of Biomedical Engineering (ND20), Cleveland Clinic Foundation, 9500 Euclid Ave, Cleveland, OH 44195

E-mail: [davisb3@ccf.org](mailto:davisb3@ccf.org)

### Introduction

Occurrence of ulcers on the plantar surfaces of the diabetic patients' foot can lead to serious medical complications, including limb amputation. We have employed a transducer array to measure the plantar surface pressures and shear forces whose combination may give rise to diabetic foot ulceration. However data produced by the equipment includes noise that needs to be filtered in order to perform subsequent data analyses. The aim of this study is to investigate and compare the common spatial, temporal and wavelet signal denoising procedures on the plantar surface pressure and shear force data.

### Methods

The device (Figure 1) has 80 transducers that are based on strain gauge technology and capable of collecting all three force components (vertical, mediolateral and anteroposterior) simultaneously. It was designed in an 8 x 10 array architecture with 10 mm x 10 mm measuring transducers. Data were obtained at 50Hz for 2 seconds during steady state gait without adjusting step lengths prior to contact with the platform. To achieve spatial domain filtering the shear data were converted into an 8 x 10 pixel resolution 8-bit grayscale image. The median filter in Matlab's (MathWorks, Nattick, MA) image processing toolbox and a 2D Wiener filter were then employed on the spatial data. Two time domain filters, moving average and second order Butterworth, were also operated on the time series data. Cut-off frequency for Butterworth filter was calculated according to Wells *et al* (1). We utilized the Rice Wavelet Toolbox, an open source wavelet toolbox developed by the Digital Signal Processing Group at Rice University, to carry out wavelet filtering of the shear data (2).

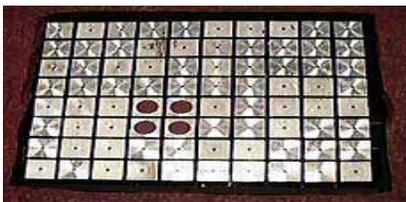

Figure 1. The transducer platform used to obtain pressure and shear data. The overall size is 14.2 cm by 11.4 cm

### Results and Discussion

In order to compare the performance of the methods employed, average signal-to-noise ratio (SNR) was calculated for each filtering process. The results of SNR calculations are given in Table 1. The SNR values indicate that the wavelet filtering yielded the best noise removal. Spatial filtering was found to be inappropriate with the shear data. Figure 2 shows a representative set of results for the five filtering techniques. Temporal filtering of the shear data produced intermediate noise elimination.

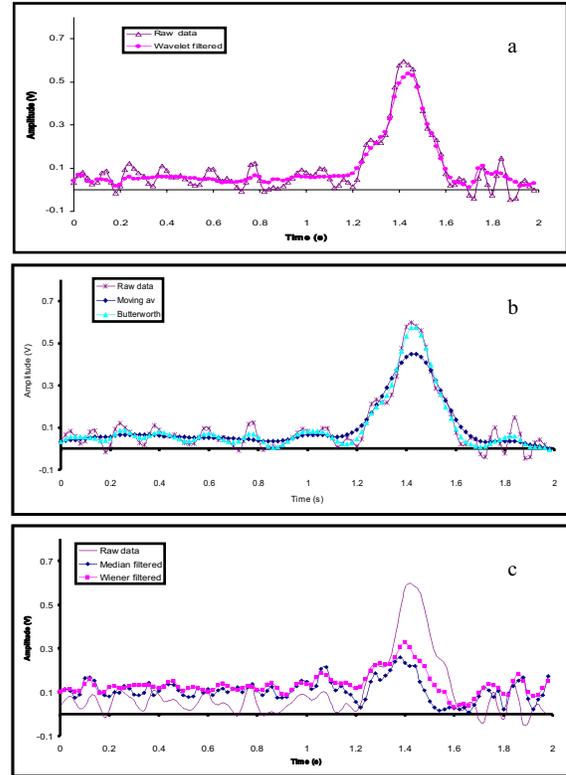

Figure 2. Results of a. wavelet filtering, b. time domain filtering, c. spatial filtering of shear data

Table 1. SNR values for each filtering process

Filter	SNR (dB)
Wavelet	8.97
Butterworth	7.13
Moving Average	4.96
Wiener	0.12
Median	-0.19

### Conclusions

Wavelets were observed to perform high quality shear data filtering due to their ability to analyze both spectral and temporal information in the data compared with other noise removal procedures. Spatial filtering did not perform well, most probably due to spatial resolution of the transducer array.

## THE ENERGETICS AND BIOMECHANICS OF TURTLE LOCOMOTION

<sup>1</sup> Peter A. Zani, <sup>1</sup> Rodger Kram, <sup>2</sup> Audrone R. Biknevičius, and <sup>2</sup> Stephen M. Reilly  
<sup>1</sup>University of Colorado, <sup>2</sup>Ohio University;  
email: [zani@colorado.edu](mailto:zani@colorado.edu), web: [www.colorado.edu/kines/research/locomotion.html](http://www.colorado.edu/kines/research/locomotion.html)

### INTRODUCTION

Tortoise muscle has been shown to be very efficient *in vitro*<sup>1</sup>. Likewise, a semi-aquatic turtle has been shown to walk with remarkable metabolic economy<sup>2</sup>. Yet, Galápagos tortoises do not conserve substantial mechanical energy during walking<sup>3</sup> calling into question the link between locomotor energetics and mechanics. We have begun to investigate if turtles in general are economical walkers and if so why.

### METHODS

We measured the metabolic cost of locomotion in 18 terrestrial box turtles, *Terrapene ornata*. We trained turtles to walk steadily on a treadmill for 10-20 minutes while wearing a mask (Figure 1). We then measured steady-state oxygen consumption for 5-10 trials of level walking as well as walking up a 24° incline. In addition, we collected ground-reaction forces for individuals walking across a force platform to determine whether economical walking in box turtles is due to the inverted-pendulum mechanism of energy conservation<sup>4</sup>.

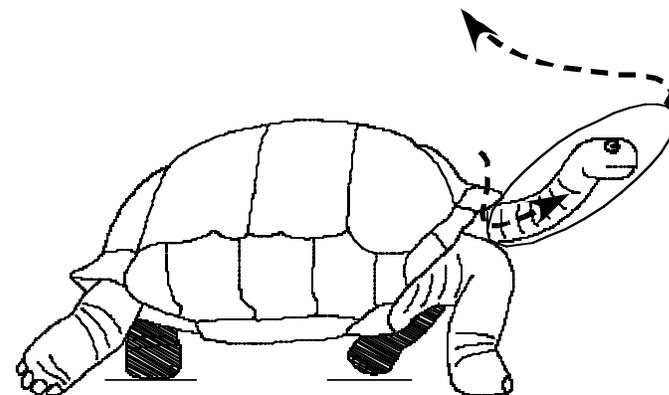

### RESULTS AND DISCUSSION

Minimum cost of transport for level walking ( $8.0 \pm 2.97$  J/kg/m) was roughly one-half the expected value ( $15.9 \pm 1.50$  J/kg/m) for animals of similar size (Figure 2). When walking up an incline turtles walked much slower ( $0.04 \pm 0.016$  m/s) and with a much higher cost of transport ( $15.0 \pm 7.10$  J/kg/m). By matching level and incline trials of similar speed we were able to calculate uphill efficiency ( $20.2 \pm 9.16$  %). This value is comparable to terrestrial mammals and birds of similar size. Thus, the low cost of transport during level walking does not appear to be due to high efficiency of turtle muscle.

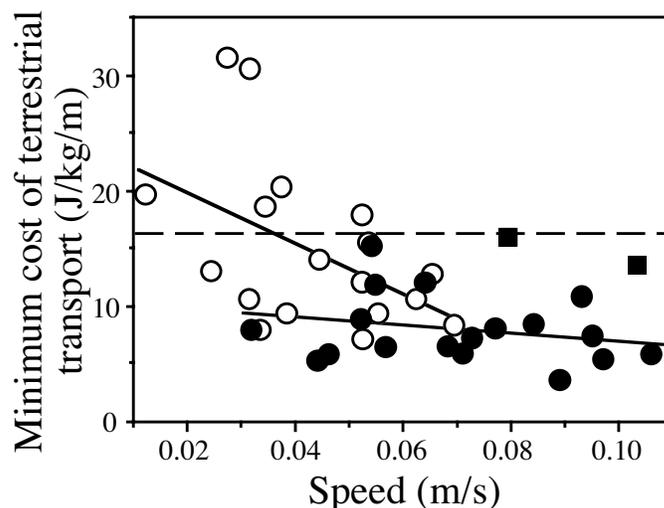

Examination of turtle mechanics indicates that the magnitude of kinetic-energy fluctuations ( $0.01 \pm 0.004$  J/stride) were only one-quarter of fluctuations in gravitational potential energy ( $0.04 \pm 0.017$  J/stride). These energies were only sporadically out of phase and thus, turtles recovered only  $25.2 \pm 3.83$  % of their mechanical energy per stride. Hence, it appears that economical level walking in turtles is not due to mechanical-energy conservation. We suggest that the low metabolic cost of turtle walking is related to their extremely slow muscles, consistent with the cost-of-generating-force hypothesis<sup>5</sup>.

### CONCLUSIONS

We studied the energetics and mechanics of turtle locomotion. Despite having poor mechanical-energy conservation (~25% energy recovery), turtles are very economical at level walking (half the expected metabolic cost). Yet, this does not appear to be due to extraordinary muscular efficiency (~21%). Thus, we suggest that economical walking in turtles in general is not dependent upon effective mechanical-energy recovery. Rather, the extremely slow muscles of turtles may account for their low metabolic expenditure during walking.

**Figure 1:** A walking turtle wearing an open-flow mask to collect respired air (flow direction indicated by arrows).

**Figure 2:** Minimum cost of transport vs. speed for level (filled symbols) and 24° incline (open symbols) walking in turtles. Dashed line is average expected level cost based on size.

### INTRODUCTION

Over the past several decades, *in vivo* research addressing non-contact ACL injury mechanisms has been unable to directly examine motion of the tibiofemoral joint and the strain on the ACL during high-risk activities. Cadaver studies have attempted to identify the loading patterns that strain the ACL during such activity, but these studies are limited by practical considerations such as cadaveric tissue breakdown and experimental setup limitations.

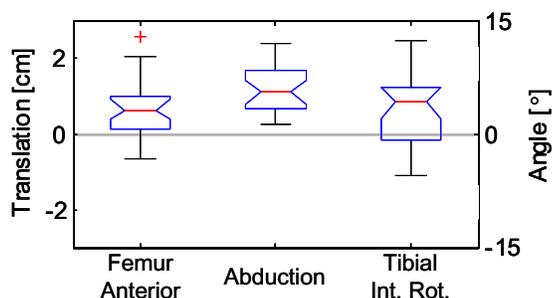

Recent advances in measuring *in vivo* kinematics using the Point Cluster Technique (PCT) [1] now allow much more detailed examinations of the knee loading patterns and tibiofemoral motions that occur *in vivo* during high risk activities [2], and simulations of the tibiofemoral joint can be used to examine consequences of such loading patterns for ACL injury [3]. This talk will discuss the results of these techniques in improving our understanding of the ACL injury mechanism.

### METHODS

Using the previously-described PCT we use an opto-electronic motion capture system to measure the 6 degree of freedom motion of the femur with respect to the tibia during activities of daily living. We have observed the anterior-posterior translation, internal-external rotation, and abduction/adduction of the knee joint during 90-degree sidestep cut and single-leg stopping maneuvers [2], as well as the net reaction forces and moments at the knee [4].

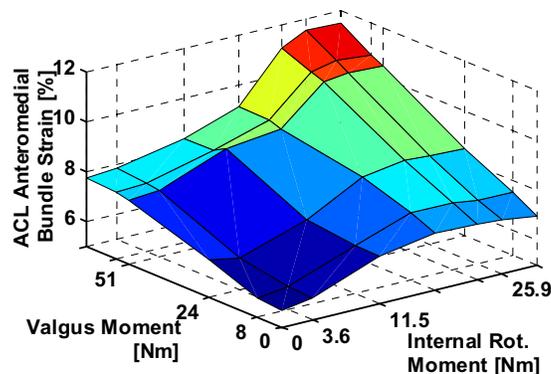

In addition, we have developed a specimen-specific simulation model of the knee built from MRI data and validated against experimental loading tests of cadaver specimens [3]. Using this model together with the physiologic loading observed during *in vivo* testing, we can estimate the strain in the bundles of the ACL to examine the relative importance of the different loading modes for the ACL injury [3,5,6].

### RESULTS AND DISCUSSION

**Figure 1.** *In vivo* knee tibiofemoral displacement during first 100ms after foot strike during a run-to-stop maneuver.

*In vivo* testing using the PCT shows that anterior translation of the tibia does not occur in most subjects during single-limb landing. However, abduction and tibial internal rotation do occur in most subjects, suggesting that a mechanism involving abduction and tibial internal rotation may be the most relevant in understanding the ACL injury mechanism during these deceleration and change-of-direction activities. Joint reaction loads at the knee further support these conclusions because the external reaction force at the knee acts to push the proximal tibia in a posterior direction, while the reaction moment acts to push the tibia into abduction and internal rotation.

**Figure 2.** Response of ACL anteromedial bundle strain to applied valgus, internal rotation, and combined moments.

Applying the loading patterns observed *in vivo* to our simulation model shows the direct effects of these loads on ACL strain. Increasing the posterior force from zero to the maximum physiologically observed values reduces ACL strain. **This reduction in strain occurs even while the force in the quadriceps increases, because the force in the quadriceps is merely a reaction to the externally applied force.** In contrast, externally applied abduction and internal rotation moments result in increased ACL strains. The individual moments themselves do not appear large enough to cause rupture of the ACL, but when acting together combined abduction and internal rotation loading cause increased ACL strains that may be large enough to damage the ACL.

## COUPLED BIOMECHANICAL-EPIDEMIOLOGICAL STUDIES FOR THE ASSESSMENT OF ACL INJURY RISK

<sup>1,2</sup> Timothy E. Hewett, <sup>1</sup>Gregory D. Myer and <sup>1</sup>Kevin R. Ford

<sup>1</sup>Cincinnati Children's Hospital Sports Medicine Biodynamics Center

<sup>2</sup>University of Cincinnati College of Medicine; email: [tim.hewett@cchmc.org](mailto:tim.hewett@cchmc.org), web: [www.cincinnatichildrens.org/sportsmed](http://www.cincinnatichildrens.org/sportsmed)

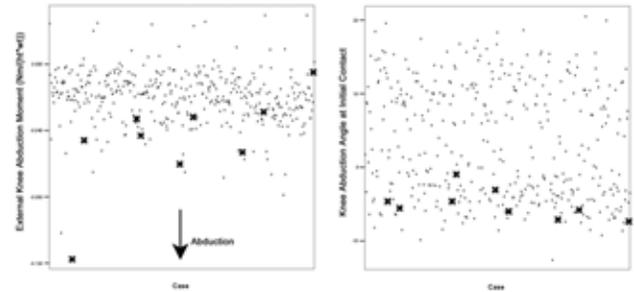

### INTRODUCTION

The goal of applied biomechanical and epidemiological research aimed at decreasing injuries in general and specifically anterior cruciate ligament (ACL) injuries in athletes must be to first determine the factors that make athletes susceptible to ACL injuries, second to develop screening tools to identify these factors in individual athletes and third to develop treatment modalities targeted to these factors in an attempt to prevent of these injuries. If preventive modalities such as dynamic neuromuscular training can reduce the incidence of knee injury by even a few percentage points, thousands of knee injuries can be prevented in high school and collegiate sports annually. In addition, with the ever increasing popularity of high-risk jumping and pivoting sports like soccer, volleyball, and basketball and the rapidly growing number of participants each year, even higher numbers of ACL and other injuries might be avoided in the future.

Neuromuscular control deficits that can be identified using kinematic and kinetic techniques may be responsible for decreased knee joint control and increased injury risk in female athletes.<sup>1</sup> Neuromuscular training may alter active knee joint control, decreasing ACL injury rates by correcting identified neuromuscular deficits.<sup>2</sup> Coupled biomechanical and epidemiologic techniques have shown the effects of growth and development on neuromuscular control deficits and on ACL injury risk and the effects of neuromuscular training on both dynamic knee control and ACL injury risk in young female athletes.<sup>2,3,4</sup> Coupled biomechanical and epidemiologic studies clearly demonstrate the ability not only to detect but to correct neuromuscular imbalances using biomechanical techniques. These biomechanical and epidemiologic studies provide strong evidence that biomechanical screening, computer modeling and neuromuscular training used in combination may provide an effective solution to the problem of gender inequity in knee and ACL injury.

The goal of these studies is to determine whether measured neuromuscular control deficits can predict ACL injury risk. A large-scale prospective coupled 3D biomechanical and epidemiological cohort study design was employed to determine whether prescreened athletes with decreased neuromuscular control and increased valgus joint loading had increased risk of ACL injury.<sup>3</sup> Prior to their competitive season, 205 female athletes in the high-risk sports of soccer, basketball, and volleyball were prospectively measured for neuromuscular control during landing using 3D kinematics and kinetics.

Nine athletes who subsequently during the following sports seasons suffered confirmed ACL ruptures had significantly different knee kinematics and kinetics than the 196 female athletes who did not go on to ACL rupture. The knee abduction valgus angle at landing was 8° greater in ACL-injured than uninjured athletes. ACL-injured athletes had a

**Figure 1:** Knee abduction moment and knee abduction angle prospectively measured in subsequently ACL Injured (X) and Non-Injured Subjects.

2.5-times greater knee abduction moment and 20% higher ground reaction force. The knee abduction moment predicted ACL injury status with 73% specificity and 78% sensitivity.

### CONCLUSIONS

Biomechanical and epidemiological findings demonstrate that decreased neuromuscular control, as evidenced by measures of knee abduction torque and knee abduction angle, can predict increased ACL injury risk in a high percentage of individuals.<sup>3</sup> Computer models show that valgus increases ACL loads.<sup>5</sup> A combination of computer modeling coupled with the above approach may provide the necessary answers to this problem. However, the question is whether it is possible to accurately and identify those individuals who display these potential causal factors. Effective screening programs need to be developed and put into practice that will enable identification of athletes at risk for ACL injury in order to channel them into custom-designed neuromuscular interventions.

## BIOMECHANICAL ANALYSIS OF OCCUPATIONAL HIGH EXERTION TASKS

Don B. Chaffin, PhD, CPE, PE

Center for Ergonomics, The University of Michigan

[dchaffin@umich.edu](mailto:dchaffin@umich.edu), <http://www.personal.engin.umich.edu/~dchaffin/>

Often extremely high levels of exertion are required in manual tasks in industry, and the preponderance of epidemiological evidence indicates that these tasks cause and precipitate excessive numbers of low back and other musculoskeletal pain and suffering for thousands of workers, along with high medical and compensation costs. This paper will explore the historic role that biomechanics has played in understanding these outcomes, as well as reviewing the basis for ergonomic prevention strategies used today.

The focus of the presentation will be on occupational low back pain. The discussion begins with the fundamental biomechanical reality; that the lumbar spine is often subjected to extremely large compression forces when one stoops to pick up an object, even if the object is of moderate weight. Biomechanics research has disclosed that such compression forces will cause premature vertebral disc fractures in many people. This information has provided a primary basis for the "Lifting Guideline" first proposed by NIOSH in 1981, which recommends the amount of load that can be lifted in various postures by most people. The paper will discuss this outcome of the research, as well as biomechanics research in the late 80s that lead to inclusion in 1994 of a torso twisting risk factor in the "Lifting Guideline." Much of the biomechanics research to be reviewed in this later regard focused on the role of torso muscle antagonism during lateral bending and twisting exertions.

During the 90s measurement methods and biomechanical models became available to begin to understand the affects on the lumbar spine of complex motions. The need for this knowledge was predicated on a growing awareness that the recommendations to keep heavy loads off the floor and close

to the body when being lifted was not sufficient to prevent all occupational low back pain incidents. The growing use of mechanical aids (hoists, articulated arms and conveyors) has done a great deal to alleviate high levels of low back stress while lifting, but too often these same devices require people to twist and push and pull objects. High torso muscle antagonistic actions and vertebral shear forces were being predicted in such activities, especially when fast motions were involved. Concern also over shoulder injuries was growing related to the use of these devices, leading to the need to develop and use models of whole body exertions in industry to understand the full complexity of the problems for various groups of people.

Recently some biomechanics research began to focus on another aspect of vertebral column function that makes it vulnerable to injury, particularly during fast motions with light loads. This vulnerability is due to the column's reliance on well coordinated torso muscle contractions to control its inherent dynamic instability. Such instability could explain why low back pain is often associated with performance of tasks when: 1) an occasional and possibly poorly planned motion takes place, 2) a sudden or unexpected motion (such as a foot slipping) takes place, or 3) when torso muscle fatigue is present.

This presentation reviews these matters and proposes that future prevention strategies will have to be much more sophisticated than is presently the case. It will propose the need for better biomechanical risk models, and will propose work cell design strategies that take advantage of newer digital human modeling CAD technologies.

## HISTORY AND FUTURE OF ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

Masahiro Kurosaka, MD  
Department of Orthopaedic Surgery  
Kobe University Graduate School of Medicine, Kobe, Japan

Primary repair of the anterior cruciate ligament used to be the standard treatment for the torn anterior cruciate ligament. However subsequent follow up of these patients have shown poor healing potential of the anterior cruciate ligament. Biomechanical studies have shown that the anterior cruciate ligament is the primary anterior stabilizer of the knee. Also different bundles of the anterior cruciate ligament have been shown to play different roles in different knee flexion angle against anterior and rotational load. From 1980's anterior cruciate ligament reconstruction with some type of the graft became standard treatment technique. Among the factors that influence the results of ACL reconstruction, selection of graft materials, tibial and femoral graft position placement, orientation of the drill holes, fixation and tensioning of a graft are known to be important intra-operative factors when performing ACL reconstruction surgery. Reconstructed anterior cruciate ligament grafts with an autogenous bone-patellar tendon-bone graft and a hamstrings graft have been shown to be revascularized and remodeled after the implantation and are therefore thought to be biologically suitable materials. Thus, the use of one of these graft materials has become a common procedure. The graft material, fixation technique, preconditioning, and tensioning will influence the early postoperative graft load. We have shown that interference fit type fixation provides better stability and advantageous mechanical properties of the reconstructed graft [1].

Regarding graft positioning, the recommended placement of the tibial graft placement has changed from an eccentric anterior medial position to a more posterior anatomic position. Theoretically more anatomically placed femoral graft

positioning will also provide better biomechanical function and clinical result. Currently we are trying to do two bundle ACL reconstruction through two femoral and tibial tunnels [2]. Femoral tunnels can be prepared through two tibial tunnels or far anterior medial arthroscopic portals. Femoral positioning of the posterolateral bundle should be more posterior and distal than conventional femoral drill hole placement. Damage of the posterior neurovascular bundle and breakage of the posterior wall of the drill hole can be a possible intraoperative complication. This problem can be avoided by making deeper knee flexion angle when creating a femoral drill hole. Once two bundle grafts are passed through drill holes created they can be tensioned and fixed separately. We fix a posterolateral bundle graft first in 15 degree knee flexion angle and then an anteromedial bundle graft is fixed in 70 degree knee flexion angle. Advantages and disadvantages and technical pitfalls of this procedure will be discussed both in basic and clinical aspects.

## BONE: THE ENGINEER'S ULTIMATE DREAM MATERIAL

Rik Huiskes

Department of Biomedical Engineering, Eindhoven University of Technology, The Netherlands

After cartilaginous bone tissue mineralizes in the embryo, the tissue is modeled to bone by bone-forming osteoblasts and bone-resorbing osteoclasts. This modeling process continues during growth, producing cortical shells and trabecular patterns that seem mechanically optimized in form, density and directionality, relative to the external forces. In maturity, bone is continuously remodeled through resorption and apposition of bone tissue at free trabecular surfaces and within the cortical shells, while maintaining structural optimality relative to external loads. Later in life trabeculae reduce in number and thickness, while cortices become thinner, when musculo-skeletal activities reduce.

The evident – though implicit – question for the scientific biomechanics community is whether effects of external forces on bones can be linked to local metabolism, so that they could be made predictable in a quantitative sense. From the mid-Eighties, several empiric theories to this end were proposed and used in computational models [1,2]. It was found, in serendipity, that the recursive formulas used in these models inherently cause trabeculation [3]. We put this to use in a new theory, by separation of ‘actor’ and ‘sensor’ functions [4]. Osteocytes within the trabeculae were considered as strain-energy-density (SED) sensors, signaling Basic Multicellular Units (BMU’s) of osteoclasts and osteoblasts at trabecular surfaces to add or remove net bone mass [4].

We refined and unified the theory to include the separate activities of osteoclasts and osteoblasts in modeling & adaptation and in remodeling of trabecular structure [5,6]. We use dynamic loading variables (SED-rate) that activate osteocytes in the bone matrix to transfer osteoblast bone-formation stimuli to trabecular surfaces, through the canalicular network. The stimulus received at the surface depends on osteocyte density, mechano-sensitivity and signal decay by distance. Bone is formed at the surface where and while the stimulus exceeds a threshold value. Concurrently, osteoclasts are assumed to resorb bone which is (micro)damaged, the sites of which are determined at random per iteration. Coupling between osteoclast and osteoblast activities in remodeling is governed implicitly by the mechanics, through SED concentrations around resorption cavities, due to a notching effect. Applied in an FEA computer simulation of a bone cube, the theory produces a mature trabecular structure, aligned to the external loads [6,7], with morphological parameters similar to reality [8].

Hence, the strain-related signaling processes producing trabecular morphology in accordance with optimal mechanical resistance can now be understood. We have discovered recently that this trabecular computational theory can be unified to also describe remodeling processes in the cortical shells. These theories can now be applied for the investigation of osteoporotic processes, in search for preventive and curative agents. A complication is still that only small bone cubes can be investigated, due to limitations in computational capacities, but we expect that these limitations can be reduced with time.

## EMERGENCE OF GAIT IN LEGGED SYSTEMS

Andre Seyfarth

Locomotion Laboratory, University of Jena  
email: [oas@uni-jena.de](mailto:oas@uni-jena.de), web: [www.lauflabor.de](http://www.lauflabor.de)

What is special about our legs such that we do use them daily without any effort? And what makes legged locomotion special compared to other types of locomotion?

One of the basic observations in human and animal locomotion is the existence of gaits, e.g. distinct movement patterns with characteristic curves of the joint kinematics and the corresponding ground reaction forces. In humans we observe just two gait patterns, walking and running, whereas in many animals a repertoire of different gaits can be found.

What are the common design and control principles of legged locomotion from which one could derive the individual gait patterns? To approach this issue, (1) we performed experiments on human locomotion, (2) we modeled the dynamics of legs in computer simulations and (3) we built a series of legged robots to explore the behavior of a physical model in a real-world environment.

In **experiments on human locomotion**, we found that during the push-off phase there was an *in-phase* relationship of knee and ankle extension in running but an *out-of-phase* relationship of knee flexion vs. ankle extension in walking. Hence, the knee joint is extending during running but bending during walking. The ankle joint, at the same time, is extending in both gaits.

In a **computer simulation model**, we found that walking could be understood as a sequence of single and double supports of a *pair of compliant legs* similar to the well-known spring-mass model (such as the pogo stick leg, figure A).

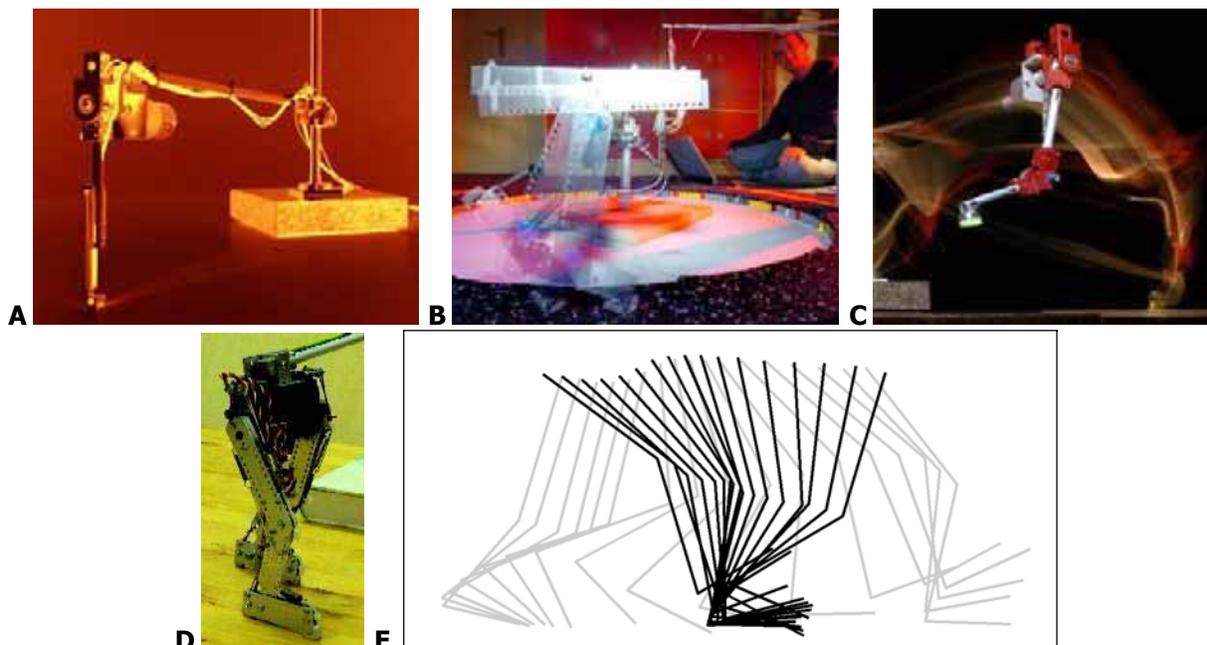

Gait changes from walking to running could then be considered as an energetically driven transition from a region where double support phases do occur to a second region where only single-support phases and flight phases are present (Geyer et al., this conference). However, such a simple representation of a leg seems not sufficient to explain the experimentally observed change in the coordination of the leg joints between walking and running.

This leads us to the **role of leg segmentation**. In a series of robots with segmented legs (figures B, C, D) we investigated the influence of leg segmentation and joint stiffness on the dynamics of locomotion. Here, the leg was actuated only at the hip joint by an electric motor introducing a sinusoidal joint kinematics.

For elastic two-segmented legs (figures B, C) we found forward or backward hopping depending on the hip control (frequency, leg orientation). In contrast, stable walking patterns could be observed in a bipedal robot with elastic three-segmented legs (figure D, E). Here, the **experimentally observed out-of-phase coordination** of knee and ankle joint was reproduced by attaching several springs to the purely passive leg. The control of the hip joint was kept identical to that of the hopping robot. Hence, elastic properties in a segmented leg could be responsible for the observed gait-specific leg kinematics.

## DEVELOPING TEXTILE BIOFEEDBACK TECHNOLOGY: FROM BRASSIERES TO NOISY KNEES

Julie R Steele

Biomechanics Research Laboratory, Department of Biomedical Science, University of Wollongong, NSW, Australia, 2522  
email: [julie\\_steele@uow.edu.au](mailto:julie_steele@uow.edu.au), web: [www.uow.edu.au/health/brl](http://www.uow.edu.au/health/brl)

### INTRODUCTION

A perpetual challenge confronting practitioners when they are evaluating and modifying human motion is to monitor the kinematics and/or kinetics characterizing human performance in the field and then to “feed” this information back to the performer in real-time so the performer can modify their motion to achieve the desired outcome. Although advances in technology have provided highly sophisticated equipment for biomechanical analyses of human performance, many of these items are unsuitable as biofeedback devices because they require extensive data processing before meaningful information can be relayed back to the performer. Other devices, particularly those attached to an individual’s body, are often inappropriate as they have rigid components that do not conform to the individual’s body shape, thereby interfering with their natural motion during performance of a movement and possibly posing a safety hazard.

Recent advances in polymer science, however, now enable inherently conducting polymers to be integrated into appropriate host fabrics, creating the opportunity to develop wearable sensors which offer novel biomonitoring options. These fabric sensors, with strain gauge-like properties that have a wide dynamic range, are ideal for biomonitoring applications as they can be integrated directly into existing clothing and equipment without changing the material properties or functions of these items and without interfering with normal human motion. When connected to appropriate electronic circuitry, these fabric sensors can also act as unique wearable systems capable of providing biofeedback to the wearer with respect to their joint motion. The purpose of this talk is to overview the development of these unique fabric sensors, from their initial application in monitoring breast motion to the development of an innovative fabric biofeedback system designed for use in landing training programs to reduce the rate of non-contact anterior cruciate ligament (ACL) ruptures.

### WHY MONITOR BREAST MOTION?

As female breasts have limited internal anatomical support, external support, such as a sports brassiere, is usually recommended to reduce breast motion and, in turn, exercise-induced breast pain, during vigorous activity. Breast motion is restricted by compressing the breasts tightly against the chest wall and by using relatively non-elastic materials in the vertical plane. Although effective in limiting breast motion and related breast pain, the straps of most current sports bras bear much of the load generated by breast motion during physical activity. Excessive brassiere strap loading can lead to a distinct set of symptoms including deep brassiere strap furrows, malpostures and paresthesias of the fifth digit [1]. Despite potential negative consequences associated with excessive strap pressure, no research was located quantifying

the loads borne by brassiere straps during physical activity. A novel method using inherently conducting polymers to directly measure dynamic brassiere strap loading during treadmill running was therefore developed and will be described.

### NOISY KNEES?

Non-contact rupture of the ACL is one of the most common disabling injuries an athlete can sustain. As ACL rupture frequently results from poor landing technique, it is postulated that learning to land correctly, particularly bending the knee

**Figure 1:** An early prototype of the Intelligent Knee Sleeve.

sufficiently, can help to protect athletes against non-contact ACL injury. The “Intelligent Knee Sleeve” (IKS) was developed, also using polymer technology, as an immediate biofeedback system to teach athletes how to land correctly. The IKS consists of a simple, inexpensive sleeve of Lycra-like material incorporating a disposable polymer coated fabric sensor that is placed over the patella. The fabric sensor, integrated into an

electronic circuit, acts as a fabric strain gauge whereby as the sensor is stretched when the wearer bends their knee, resistance within the sensor decreases. At a predetermined threshold resistance, which can be varied, an audible tone is emitted to alert the wearer that the desired knee flexion angle has been achieved. The knee sleeve has the advantage over other currently available feedback devices of providing immediate individualized feedback to the wearer, thereby increasing the objectivity, frequency, and speed of feedback. How the IKS was developed and how it is used as a biofeedback system to teach safe landing technique will be described. Future applications of fabric biofeedback systems in enhancing patient rehabilitation following total knee replacement surgery will also be presented.

## NOISE-ENHANCED SENSORIMOTOR FUNCTION

J.J. Collins

Department of Biomedical Engineering and Center for BioDynamics, Boston University;  
email: jcollins@bu.edu, web: www.bu.edu/abl

### INTRODUCTION

Traditionally, noise has been viewed as a detriment to signal detection and information transmission. Recently, however, it has been shown that noise can enhance the detection and transmission of weak signals in certain nonlinear systems, via a mechanism known as stochastic resonance (SR). In this talk, we describe studies wherein we demonstrate SR-type behavior in model neurons, rat cutaneous afferents, and human sensory and motor function. We show that input noise (mechanical and electrical) can enhance somatosensation in young subjects, older adults, and patients with sensory deficits. We also demonstrate that the application of sub-sensory mechanical noise to the soles of the feet via vibrating insoles improves balance control in healthy young subjects, older adults, patients with diabetic neuropathy, and patients with stroke. We discuss how noise-based techniques and devices might prove useful in overcoming age- and disease-related losses in sensorimotor function.

## SPINNING SPORTS BALLS

Mont Hubbard

Department of Mechanical and Aeronautical Engineering  
University of California, Davis, USA

email: mhubbard@ucdavis.edu , web: mae.ucdavis.edu/~biosport

### INTRODUCTION

Ball spin significantly affects how sports balls move. The production of spin, its evolution during impact and flight and its effects on the ball paths are discussed for two popular American ball sports; baseball and basketball. In baseball, the spin in flight is important because it generates substantial lift forces. These can add substantial range to that achievable with no spin and cause large lateral deviations of the path from the vertical plane. As a result a curve ball can be hit farther than a fastball, even though its pitched and batted speeds are less than those of the fastball. Furthermore, the effect of spin has implications on how different pitches should be batted optimally. In basketball free throws, aerodynamic forces are small compared to spin-generated friction contact forces that dominate. This talk examines the mechanics of spin generation and its effects on the two games.

### METHODS

Improved models for the pitch, batting impact, and post-impact flight phases of a baseball can be used in an optimal control context to find bat swing conditions that produce maximum range [1]. An improved batted flight model incorporates experimental aerodynamic lift and drag force profiles (including the drag crisis) and their dependence on spin and velocity. The rigid-body model for bat-ball impact includes the dependence of the coefficient of restitution on the approach relative velocity and the dependence of the incoming pitched ball angle on speed. Undercut distance and bat swing angle are chosen to maximize range of the batted ball. Post-impact conditions are found to be independent of the ball-bat coefficient of friction. The lift force is enhanced by spin produced by undercutting the ball during batting. Contrary to popular opinion, an optimally hit curve ball will travel farther than an optimally hit fastball or knuckleball as a result of increased lift during flight. Because the curve ball has pitched topspin, less undercut is required to produce optimal batted backspin, and smaller batted ball speed and launch angle penalties must be incurred to generate backspin than when hitting a fastball optimally. Changing spin during flight is likely not important since the characteristic spin decay time is of the order of 30 s [1]. The sensitivity of maximum range can be calculated for all model parameters including bat and ball speed, bat and ball spin, and wind speed.

In contrast, the flight of a basketball is much less affected by aerodynamics but spin is important during rim and backboard contact. Friction forces caused by spin-induced relative motion of the ball contact point are important and largely determine the ball path. A dynamic model [2] is discussed for basketball motion that may contact the rim, the backboard, the bridge between the rim and board, and possibly the board and

the bridge simultaneously. The model is used to investigate free throw success near the sagittal plane. Non-linear ordinary differential equations describe the ball angular velocity and ball center position. The model includes radial ball compliance and damping and contains sub-models describing slipping and non-slipping contact and purely gravitational flight. Switching between the sub-models depends on contact point velocity and friction forces. Interesting limiting dissipation-free families of trajectories allow the ball to enter and pass below the rim plane before being ejected rather than being captured. These rely importantly on continuously changing spin and precession of the consequent angular momentum by the contact forces. The dynamic models of basketball-rim and basketball-backboard interaction allow simulations for a single point ball-rim or ball-board contact, as well as the possibility of two-point contact on both board and bridge. The model can be used to study release angles, velocity, and angular velocity that maximize the probability of success. In basketball free throws in which contact forces dominate, backspin can scrub more energy from the ball in shots that hit the rim and can aid in capture, increasing the number of successful shots by about 10%, all other conditions held constant.

Generation of appropriate spin by the athlete during impact (baseball) or launch (basketball) relies on contact forces normal [3] and tangent [4] to the ball surface. Simple rigid-body models of the ball may not accurately predict post-impact spin. Although large normal compliance is obvious in high-speed images of batted balls, models including tangential compliance of the ball surface lead to two-degree-of freedom oscillations and predict significantly different post-impact spin and translational velocity than do models assuming rigid-body ball motion. Experimental measurements of baseball and basketball contact forces [5] show the possible influence of tangential compliance. Present research efforts search for the least complex model of the 1 ms baseball-bat and 11 ms basketball-rim impacts that can adequately describe these processes.

### CONCLUSIONS

Accurate description of the paths of sports balls must rely on a complete understanding of the aerodynamic and contact forces caused by the interaction of the spinning ball with its environment.

THE EVOLVING JOURNEY OF TENDON AND JOINT MECHANICS - CLINICAL IMPACTS FROM HUMBLE CONCEPTS

K. N. An, Ph.D.

Biomechanics Laboratory, Division of Orthopedic Research  
Mayo Clinic College of Medicine, Rochester, MN 55905 – E-mail: an@mayo.edu

As integral components of the musculoskeletal system, the primary function of tendons is transmission of muscle forces to the skeletal system. Proper excursion and gliding of the tendon will determine the efficiency of this function. Studies of the tendon and joint mechanics based on two simple mechanical concepts have resulted in several significant clinical implications.

### EXCURSION

A pulley-type constraint keeps the tendon path close to the bone when the tendon crosses a joint. In normal anatomy, there is an intimate relationship between tendon excursion and joint rotation that maintains the mechanical advantage of the tendon while preserving the passive and active muscle tension during joint motion. The instantaneous moment arm ( $r$ ) of a tendon can be related to the tendon excursion ( $E$ ) and the joint rotation ( $\phi$ ) as:

$$r = d E / d \phi.$$

This simple concept has been confirmed analytically for various scenarios of tendons crossing the joint [1]. Experimentally, the tendon excursion has been measured using linear or rotary potentiometers *in vitro* or ultrasound imaging *in vivo*. Joint rotations have been monitored using goniometers, magnetic tracking devices, and imaging systems. The moment arm-tendon excursion principle has been used to examine the importance of the pulley constraint and also to compare various surgical reconstructive procedures and the options for tendon transfer and tendon reattachment [2]. For joints with additional degrees of freedom or when the tendon crosses multiple joints, muscle recruitment depends on the resultant moment at the joint [3] or all of the joints that the muscle spans. For the postoperative treatment of flexor tendon injury, it has been demonstrated that synergistic wrist motion could eliminate tendon slackness in the palm and improve tendon excursion during passive finger joint motion [4]. This concept explained why the mechanism of co-contraction of quadriceps and hamstrings at the knee joint during closed-kinetic-chain exercises resulted in favorable tension in the anterior cruciate ligament after reconstruction [5]. Finally, tendon excursion influences the functional length of the muscle-tendon unit. Due to the length-tension interaction during muscle contraction, the potential tension generated by the muscle will be influenced by the joint position and tendon excursion.

### GLIDING

A tendon sliding through the pulley is analogous to a belt wrapped around a fixed mechanical pulley [6]. As the tendon moves proximally, the tensions in the tendon proximal and distal to the pulley ( $F_p$  and  $F_d$ ) are related to the angle ( $\theta$ ) of

the tendon segments across the pulley and the friction coefficient ( $\mu$ ):

$$F_p = F_d e^{\theta \mu}.$$

Based on this simple model, a system was developed that allows direct measurement of friction at the tendon-pulley interface as the difference between  $F_p$  and  $F_d$ . This relationship clearly demonstrated the importance of avoiding awkward joint postures in ergonomic consideration to reduce the repetitive injury of soft tissue. In-depth investigations of the mechanism of lubrication [7] associated with the tendon gliding provided insight related to the potential etiology of soft tissue disorders including carpal tunnel syndrome and tendonitis. Clinically, significant improvements have been made in the surgical and rehabilitation modalities for treating tendon injuries [8, 9].

## REHABILITATION AND BIOMECHANICS (DO THE LOCOMOTION)

Mary M. Rodgers

Department of Physical Therapy and Rehabilitation Science, University of Maryland School of Medicine  
Baltimore, MD; email: [MRodgers@UMaryland.edu](mailto:MRodgers@UMaryland.edu). web: [www.ptmaryland.edu](http://www.ptmaryland.edu)

Rehabilitation is defined by the Institute of Medicine as the restoration of “some or all of the patient's physical, sensory, and mental capabilities that were lost due to injury, illness, or disease.” Rehabilitation includes assisting the patient to compensate for deficits that cannot be reversed medically. It is prescribed after many types of injury, illness, or disease, including [amputations](#), arthritis, [cancer](#), cardiac disease, neurological problems, orthopedic injuries, spinal cord injuries, [stroke](#), and traumatic brain injuries. It has been estimated that as many as 14% of all Americans may be disabled in some way at any given time, and that nearly 1.5 million Americans have a disability that requires use of a manual wheelchair [1].

The achievement of functional independence for individuals with disability is a primary goal in rehabilitation. Because independent locomotion is essential to independent function, rehabilitation interventions are usually directed toward this goal for those individuals who desire independent function and for whom that goal is feasible.

Studies in rehabilitation science research have incorporated combinations of variables that are not likely to be studied in separate existing basic science, health professional or engineering disciplines. Models of disability have provided a framework for examining how rehabilitation research studies address the enabling-disabling continuum [2]. Within this framework, biomechanical measures and analyses play an

important role in quantifying disability related performance and factors affecting the enabling-disabling process.

This is illustrated, for example, by selected studies of walking gait and wheelchair propulsion. I will discuss how biomechanical performance measures have contributed to an understanding of disability and how rehabilitation interventions can be more individualized and effective.

### CONCLUSIONS

Future work that incorporates biomechanical performance measures in the framework of “enablement” would ensure that all of those who desire to do so would be able to independently “do the locomotion” [3].

### INTRODUCTION

What are the features of the human hand that enable dexterous manipulation functionality that transcends that of state-of-the-art robotic hands? Understanding and emulating the biologically evolved solutions to the manipulation problem in humans would empower both biomechanists and roboticists alike. In this interdisciplinary work, we present the computational foundations to simulate and predict the functional advantages of multi-finger grasps with a biomechanically realistic model of the human hand.

### METHODS

We translated the anatomical description of the “virtual five-link” thumb kinematics into a standard robotics notation (Denavit-Hartenberg (D-H)) using 3D geometry and D-H conventions [1]. We added musculoskeletal parameters (e.g., moment arms) to the kinematics, resulting in a 50-parameter robotics-based model capable of producing thumbtip forces and torques. We then used Markov Chain Monte Carlo simulations to find parameters that achieved a least squares best fit to experimental thumbtip forces [2].

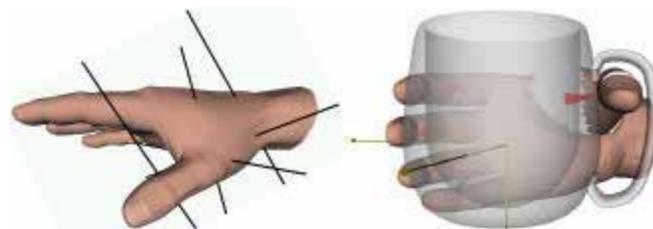

As a first approximation, we implemented these best fit D-H parameters for the thumb in *GraspIt!* [3], our visualization and simulation engine designed for the study of grasp planning in robotic hands. The other fingers were simulated using universal joints at the metacarpophalangeal joints, and simple hinges at the interphalangeal joints [4]. With this program, grasps of arbitrary objects can be dynamically simulated, optimized for grasp stability, and objectively quantified for feasibility and grasp quality.

To quantify grasp quality, we use a robotics-based mathematical representation of grasp that employs a “grasp matrix” to relate fingertip contact forces (and torques if using soft fingertips) to the effective force and torque on the grasped object (the grasp “wrench”). The rank of the grasp matrix, for given object geometry and friction characteristics, is affected by fingertip placement and the margin of error permitted by the friction cones associated with each fingertip contact force, and is a measure of how many degrees of freedom of the object can be controlled [5]. We evaluate the ability of a quasi-static grasp to reject disturbances by building the 6D space of forces and torques that can be applied by the grasp using convex hull theory. We propose the hyper-volume of this space as one possible measure of grasp quality, since a larger volume of this space means that the grasp is more efficient at rejecting force and torque perturbations [3].

### RESULTS AND DISCUSSION

The D-H representation of the anatomy-based, non-

intersecting, non-orthogonal axes of rotation for the thumb provides a new biomimetic direction for comparative kinematic studies of robotic and human hands, and may help elucidate whether and how these kinematic features enable dexterous manipulation in humans (Fig. 1). Traditionally, simple orthogonal axes of rotation are used to model thumb kinematics in robotic hands, but our work suggests these articulations cannot realistically predict 3D static thumbtip forces [6].

**Figure 1:** Left: The anatomy-based model represents more faithfully the thumb’s five non-orthogonal, non-intersecting joint axes. Right: The hand model grasps a mug.

We have adapted a computational environment to quantify grasp quality of biomimetic human hands. Our critical challenge now is to determine the level of model complexity that is necessary and sufficient for predicting realistic multi-finger manipulation function. We are currently investigating adaptive refinement finite element methods to account for finger pad compliance and skin deformation, tendon interconnections within and across fingers, and will use accurate skeletal geometry to constrain the innermost elements. This computational platform will allow us to investigate the relative contributions of passive anatomical elements and active neuromuscular elements to dexterous manipulation.

## ALTERED FOOT LOADING IN DIABETICS. THE ROLE OF ACHILLES TENDON AND PLANTAR FASCIA.

<sup>1</sup> Claudia Giacomozzi, <sup>2</sup> Emanuela D'Ambrogi <sup>2</sup>Luigi Uccioli, <sup>1</sup> Velio Macellari

<sup>1</sup>Dept. Technology and Health, Istituto Superiore di Sanità, Rome, Italy,

<sup>2</sup>Dept. Internal Med., Tor Vergata University, Rome, Italy; email: [c.giacomozzi@yahoo.com](mailto:c.giacomozzi@yahoo.com)

### INTRODUCTION

The diabetic foot often undergoes abnormal plantar pressures, changing in walking strategy, ulcerative processes. Neuropathy was frequently added as the main responsible for the alteration of foot loading pattern [1]. A different approach comes from the observation that the common sign of the distinct diabetic syndromes, hyperglycaemia, promotes glycosilation of proteins and the consequent accumulation of advanced end-products in most human tissues [2]. This means that muscles, cartilages, tendons, ligaments, all might experience structural changes even before the onset of diabetic neuropathy, and might then concur to alter the gait pattern.

The present study focuses on the effects that diabetes-induced alterations of Achilles tendon, plantar fascia and 1<sup>st</sup> metatarso-phalangeal joint – both anatomical and functional - may have on foot loading.

### METHODS

Sixty-one diabetic patients (27 without neuropathy, 19 with neuropathy, 15 with previous neuropathic ulcers), and 21 healthy volunteers were recruited. Thickness of Achilles tendon and plantar fascia was measured by ultrasound [3]. Flexion-extension of the 1<sup>st</sup> metatarso-phalangeal joint was measured passively by a long-arm mechanical goniometer [3]. Main biomechanic parameters of foot-floor interaction during gait were acquired by means of an integrated force/pressure device [3]. Among them, only vertical ground reaction (expressed as a percentage of body weight (b.w.)), force/time integral and relative loading time (expressed as a percentage of the whole stance phase) under the metatarsals were included in the present study. Piecewise linear regressions were applied to relate all the above measurements.

### RESULTS AND DISCUSSION

Plantar fascia and Achilles tendon were significantly thicker in diabetics with neuropathy than in controls, while flexion-extension of the 1<sup>st</sup> metatarso-phalangeal joint was significantly smaller. Load under the metatarsal heads significantly increased in diabetics with neuropathy in terms of both amplitude and duration, as proved by vertical forces and integrals data. Mean values and standard deviations of all the above parameters are reported in Table 1. The increase in the vertical force under the metatarsals strongly related

( $R=0.83$ , explained variance = 70.1%) with the changes in the three examined structural and functional parameters.

Thickening of plantar fascia and Achilles tendon in diabetics, more evident in the presence of neuropathy, concurs to develop a rigid foot, which poorly performs the physiological impact force absorption during landing. More generally, an overall alteration of the foot-ankle complex motion likely occurs throughout the whole gait cycle, which partly explains the abnormal loading under the forefoot.

### CONCLUSIONS

Even though neuropathy is still considered as the major responsible for the ulceration of the diabetic foot, we believe that several other factors should be investigated and monitored, in the attempt of preventing the formation of such severe wounds.

In the present study we observed structural alterations of the main tendinous and ligamentous structures of the foot-ankle complex in presence of mild-to-severe diabetic neuropathy. Range of motion of the 1<sup>st</sup> metatarso-phalangeal joint in the sagittal plane was also measured under passive conditions. Most important finding was that the thicker the Achilles tendon and plantar fascia become, and the more the 1<sup>st</sup> metatarso-phalangeal joint mobility is reduced, the more severe is the overall alteration of the foot loading during gait. More specifically, concurrent changes of the above factors accounted for 70.1% of the changes in metatarsals loading for all diabetics groups, with and without neuropathy. In presence of severe neuropathy only, the explained variance attained a value of 74.4%.

We do not claim the hereby measured alterations as the only factors which are responsible for the triggering of the neuropathic ulceration process. Further studies are needed to merge the contributions of the numerous structural and functional alterations of the diabetic foot, which concurrently take the forefoot plantar soft tissue under conditions of "potential damage" [4].

# EFFECTS OF LOW BAR AVOIDANCE AND GYMNAST SIZE ON HIGH BAR DISMOUNT PERFORMANCE

Alison Sheets, Mont Hubbard  
 University of California, Davis, USA  
 email: alsheets@ucdavis.edu , web: www.ucdavis.edu/biosport

## INTRODUCTION

Required maneuver difficulty on the uneven parallel bars has increased with the maximum allowed bar spacing. Computer modeling, simulation and optimization are used to quantify the low bar's detrimental effect on the maximal number of dismount revolutions a short and a tall gymnast can complete. Two optimal low bar avoidance strategies were calculated; 1) using only planar shoulder and hip movement (2D), and 2) using planar shoulder but three dimensional hip motion (3D).

## METHODS

A four-segment dynamic model of a female gymnast in a preparatory swing is optimized to maximize dismount revolutions at a specified landing height. The purpose is to quantify the low bar's effect on dismount performance and to calculate optimal joint motions for low bar avoidance resulting in minimum dismount performance decreases. Optimization constraints include maximal bar force, joint ranges of motion, and minimum landing distance. Joint torque models include angle, angular velocity, and isometric strength dependent factors. Torque activation time histories are approximated by cubic splines fit to ten nodes equally spaced throughout bar contact. Using the downhill simplex method, optimal joint torque activations and bar release time are calculated [1].

The optimal solution begins ( $t = 0$ ) with the gymnast in a handstand rotating about the deflected bar with an initial angular velocity of 1.8 rad/s [2]. It ends at bar release ( $T$ ), and results in maximal straight body revolutions during dismount:

$$J_o = (\omega(T)\Delta t + \gamma(T))/(2\pi) \quad (1)$$

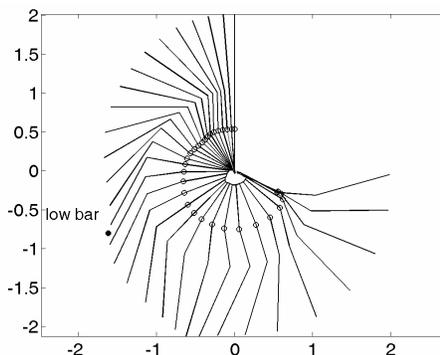

where  $\omega(T)$  is the gymnast release angular velocity,  $\Delta t$  is the flight time and  $\gamma(T)$  is the angle between the line from the deflected bar center to the gymnast mass center and vertical. Using the optimization criterion in eqn. (1) and constraints, three performances are calculated for two collegiate gymnasts: short=1.887m, 62.38 kg; tall=2.048 m, 69.30 kg.

## RESULTS AND DISCUSSION

Both athletes completed the most revolutions when no low bar was present (Table 1). Avoiding the low bar and restricting motion to 2D decreased dismount performance 1.22% and 3.59% for the short and tall gymnasts, respectively (Fig.1). By straddling her legs, the performance decrease is reduced to 0.45% and 2.00%, respectively. The taller athlete with 2D motion was most affected by the low bar because her optimal swing was most altered to avoid low bar contact.

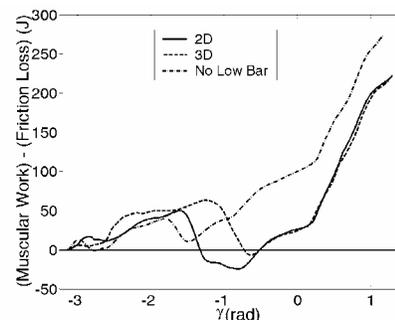

**Table 1: Number of dismount flight revolutions**

	No Low Bar		Low Bar	
		2D motion	3D motion	
<b>Short</b>	1.556	1.537	1.549	
<b>Tall</b>	1.503	1.449	1.473	

**Figure 1: Stick figure sequence- tall 2D case**

Absence of the low bar allowed more revolutions because joint torques applied during the swing added more energy to the system (Fig. 2). Avoiding the low bar required substantial negative work to resist hip joint extension after low bar clearance (Fig. 1), and decreased terminal system energy.

**Figure 2: Net energy change during swing- tall gymnast**

All performances were limited by the ability to maintain bar contact. Because the gymnast mass center cannot move instantaneously, fast joint angle flexion compresses the bar and exerts larger hand forces. Thus bar force constraints limit both joint angles and rates and, indirectly, ability to do muscular work.

In all cases, short athletes release with lower mass centers than tall ones. Short athletes minimize bar contact time because a larger percentage of initial energy is dissipated by bar friction (short-17%, tall-15%) reducing dismount performance capabilities. Frictional energy dissipation was relatively constant regardless of low bar presence. The short and tall athletes have largest release angles in the 2D case. Because of the time needed for joint extension after low bar avoidance, release is delayed to allow muscular work to be performed during bar contact.

## INTRODUCTION

Motions of the foot and tibia during locomotion, or their kinematic coupling, have been highlighted as a factor that may be important in the aetiology of lower limb injury [1]. Particularly, transference of excessive eversion motion of the rearfoot to internal rotation of the tibia through the subtalar joint has been linked to overuse injuries of the knee [2,3,4]. The relative timing of motions of the foot and shank during locomotion may also be an additional factor in injury predisposition [3]. Coupling of the foot and shank has been examined by the ratio of the range of angular motion of these adjacent segments [3], although [2] indicated that differences in the rates of rotation between the two adjoining segments might be a better indication. Continuous relative phase angles have also been used [5], although many of these studies have involved low subject numbers [6]. Rotations about the longitudinal axis of the shank have been difficult to quantify accurately, primarily due to motion of skin-mounted markers relative to the underlying bone [7]. Recently, a lightweight, custom-moulded plate contoured to the shape of each subject's tibia has been used to minimise this error and allow higher frequency aspects of the motion to be captured during locomotion [8]. The aim of this study was to assess movement coupling between the rearfoot and shank during the stance phase of barefoot running, utilising high-speed kinematic analysis and an evaluation of the relative movement rates, ranges of motion and timing of peak velocities. It was hypothesised that timing and magnitudes of angular velocities of rearfoot eversion and tibial internal rotation would be influenced by the inclusion of high frequency components in the displacement data, with velocities being greater than previously recorded [8,9].

## METHODS

Twenty-five healthy male subjects (mean age  $26 \pm 5.2$  years, height  $1.78 \pm 0.05$  m and mass of  $80.5 \pm 9.6$  kg) ran barefoot ( $3.35 \text{ m}\cdot\text{s}^{-1}$ ) along a runway whilst the landing kinematics of the right foot and shank on a large Kistler force platform were recorded by 8 ProReflex (Qualisys, Sweden) cameras at 1000 Hz. At least 15 dynamic running trials were collected per subject. An individually moulded plate was used to track rapid movements of the tibia [8] and foot movements were monitored using a multi-segment foot model so that eversion/inversion movements of the calcaneus segment with respect to the tibia could be calculated. Data was filtered using a standard low-pass Butterworth digital filter (cut-off freq. 40 Hz). Movement coupling was assessed by means of a coupling ratio of calcaneal eversion (EV) to tibial internal rotation (TIR) range of motion

(ROM), and by determining the ratio and timing of peak angular velocity of the calcaneus and tibia.

## RESULTS AND DISCUSSION

The range and velocity of EV motion of the rearfoot tended to be larger compared to the tibia, producing coupling ratios greater than 1.0 (Table 1). The ROMs and ROM coupling ratio values were similar to that found in the literature [3,4,10]. Peak ang. velocity of the tibia was more than double that previously reported [2,10], which can be explained by the maintenance of high frequency movement transients in the displacement data due to the high sample rate and marker attachment procedure used in this investigation [8]. TIR peak ang. velocities displayed greater differences to the literature than EV peak ang. velocities (4.6 times v 3.77 times greater) [10], suggesting that if a velocity ratio had been performed in that study they would have been different to that presented here. For 14 subjects (56%), peak internal rotation velocity of the tibia occurred before peak eversion velocity of the calcaneus, suggesting proximal motion control [2]. ROM ratio was significantly correlated to TIR ROM ( $-0.689$   $p=0.000$ ), but not EV ROM ( $-0.026$ ,  $p=0.901$ ) suggesting TIR excursions have more influence on this ratio despite being smaller in magnitude than EV excursions [6]. This highlights the importance of reducing marker displacement error during capture of tibial rotation data.

During the impact phase, when motions of the lower limb segments combine to transmit force and attenuate shock, the relative velocity of adjacent segments and the timing of velocity changes may be more important than excursion differences for the identification of factors associated with overuse injury. At lower sample frequencies, peak ang. velocity is underestimated to varying degrees for each segment, increasing the likelihood of a misinterpretation of the velocity coupling. The present investigation will be expanded to evaluate the influence of different foot types (static and dynamic) on the high frequency coupling parameters reported here.

## INTRODUCTION

Kinematic coupling of the foot and shank has been highlighted as a potential factor in lower limb overuse injury aetiology, particularly if excessive eversion motion of the rearfoot is transferred to rotation of the tibia [1,2]. It has been speculated that the height of the medial longitudinal arch of the foot may play a role in the amount of movement transfer present [2,3,4] and so researchers have attempted to classify foot type [5,6,7] in an attempt to understand the effects of foot structure on dynamic foot function. Recently, a foot posture index (FPI) was devised based on a number of observational tests during normal static stance to classify feet [8]. However, it has been suggested that traditional static measurements appear not to predict dynamic function accurately [7,9,10]. The aim of this study was to examine a number of simple static parameters of foot arch structure at three different loading conditions, and several dynamic measures of foot type obtained during barefoot running to characterise foot type, and examine the relationship to movement coupling of the foot and shank during running.

## METHODS

Using callipers and a ruler, repeated anthropometric measurements were recorded on the right foot of 27 healthy male subjects in static non weight bearing (NWB), normal partial weight bearing (PWB) and full weight bearing (FWB). They included truncated foot length (TFL), dorsum height (DH), and soft tissue arch height (AH). Retro-reflective markers were glued to anatomical landmarks on the foot (medial calcaneus (MED\_CALC), medial aspect of the navicular tubercle (NAV\_TUB), and medial aspect of the first metatarsal head (MTH1)) and tibia. At each weight-bearing condition, the Arch Ratio (AR) was calculated by DH/TFL [6]. Static relative arch deformation (SRAD) was calculated based on NWB and FWB measurements of soft tissue arch height [11]. Dynamically, min. vertical height of the NAV\_TUB marker during stance and average height at NWB stance were used. A further method of classification, Arch Deformation Ratio (ADR), was developed by combining SRAD and AR [12]. From marker position data average vertical height of the NAV\_TUB marker (NTMH), average Infra-Navicular Angle (INA) and navicular height (NH) [13] were calculated.

The subjects ran barefoot ( $3.35\text{ms}^{-1}$ ) whilst the landing kinematics of the right foot and shank were recorded by 8 ProReflex cameras (Qualisys, Sweden) at 1000Hz. An individually moulded plate was used to track rapid movements of the tibia [14], and foot pressure data was collected at 500Hz (RSscan Ltd., Belgium). For running trials, min. NTMH and NH, and max. INA during the stance phase were calculated (indicating the arch is at its flattest), along with the total deformation of the arch, and velocity of the deformation. Dynamic RAD (DRAD), Dynamic Arch Ratio (DAR) and Dynamic Arch Deformation Ratio (DADR) were calculated. A Dynamic Arch Index (DAI) (% midfoot contact) was

obtained from the pressure data. Ratios of the range of motion (ROM Ratio), peak angular velocity (VEL Ratio) and time to peak velocity (TIME Ratio) for rearfoot eversion and tibial internal rotation were used to characterise movement coupling. Pearson's correlations were used to identify any significant relationships.

## RESULTS AND DISCUSSION

There was no significant correlation between ROM Ratio and VEL ratio with any of the static or dynamic parameters. The DAI obtained from the pressure mat was negatively correlated with AH at all loading conditions (NWB = -0.576,  $p=0.002$ ; PWB = -0.546,  $p=0.004$ ; FWB = -0.563,  $p=0.003$ ). SRAD was not correlated at any loading condition to any AH or AR measure or to DRAD. Equally, DRAD was not correlated to DAR. In general, the static measures were not strongly correlated to any of the dynamic parameters, with the exceptions of INA at PWB was strongly correlated to max INA (0.952,  $p=0.012$ ) and min NH (-0.948,  $p=0.014$ ), NH at PWB was strongly correlated to DAR (0.889,  $p=0.044$ ), and NTMH at PWB was strongly correlated to DAR (0.895,  $p=0.040$ ), and min NTMH (0.944,  $p=0.016$ ).

Traditional static measurements do not predict dynamic function accurately [7,9,10], as observed in this study by the lack of correlation between static and dynamic parameters. It appears that static measures taken during PWB are the most accurate predictor of dynamic function, however some information about deformation of foot during locomotion is needed to improve classification of foot arch type [5,6].

Although both include valuable information about the foot, SRAD and Arch Ratio were not correlated. We must consider the amount of static deformation as well as the height of the MLA, as these may not be well correlated [15]. A more comprehensive categorisation of foot type may be achieved when static and dynamic measures are combined. This will be attempted in an extension of this study by combining the parameters measured into a single foot index.

**SOFT TISSUE COMPARTMENT RESPONSE TO AN UNEXPECTED SURFACE CHANGE.**

<sup>1</sup> Katherine A. Boyer, <sup>2</sup> Benno M. Nigg

Human Performance Laboratory, Departments of Mechanical Engineering<sup>1</sup> and Kinesiology<sup>2</sup> University of Calgary

**INTRODUCTION**

During locomotion, the body adapts to changes in surface or shoe sole properties by changing the GRF, kinematics, joint stiffness and/or muscle activity [1,2,3]. It has been speculated that one reason for these changes may be to limit vibrations of the soft tissue [4]. The amplification of the skeletal acceleration (input) for soft tissue vibrations depends on the magnitude, length and shape of the input signal. Resonance will occur when the input frequency equals the natural frequency of a given soft tissue compartment (Fig 1.). It has been shown that accelerations of soft tissue compartments remain constant and that EMG pre-activation changes with changing loading rate,  $G_z$  [5] when the input frequency is close to the natural frequency of a soft tissue compartment. Maintaining a constant acceleration level is possible if (a) damping in the soft tissue compartment is increased to reduce the accelerations [4] or (b) lower extremity kinematics are altered to change the skeletal acceleration transient rate. However, for an unexpected change of the input signal the muscle pre-activation should remain constant while the acceleration level should change. Thus, the purpose of this study was to compare the soft tissue vibrations for an expected and an unexpected excitation signal near its resonance vibration frequency. It is expected that this study will increase the understanding of the function of muscle pre-activation and the potential adaptations to changes in surface stiffness during running. The hypotheses tested were:

- H(1): Frequencies:  $f_{nat}(expected) \approx f_{nat}(unexpected)$ ,
- H(2): accelerations:  $a(expected) < a(unexpected/hard)$ ,
- H(3): EMG(preHS):  $EMG(expected) \approx EMG(unexpected)$

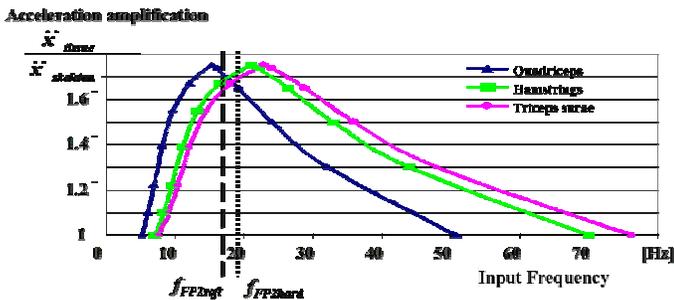

Figure 1: Theoretical response spectrum for the quadriceps, hamstrings and triceps surae soft tissue compartments, assuming a system with a simple mass and linear spring. Input is a versed sine pulse with magnitude and duration  $\tau$ ; thus  $f_{in} = 1/(2*\tau)$ .

**METHODS:**

Fourteen male subjects ran at 4.8 +/- 0.2 m/s on a 24 m long runway instrumented with 3 consecutive force platforms (Kistler, Type Z4852/C) while soft tissue accelerations and muscle activity [5] were measured. Overlying the runway were two different flooring surfaces to change the input signal. To hide the location of the surface change a thin carpet was placed on top of the flooring. The surfaces were arranged in two different ways (Fig. 2). The experimental conditions were presented in a randomized block sequence, ABBAAB. Data was collected for the following steps of running: (Control condition) FP1<sub>soft</sub>, FP2<sub>soft</sub>, FP3<sub>hard</sub>; (Test condition) FP1<sub>soft</sub>, FP2<sub>hard</sub> (unexpected), FP3<sub>hard</sub> (expected).

Peak acceleration and the frequency power spectra were determined for each accelerometer signal. The EMG intensity was summed for a 50 ms window prior to heel-strike to determine the pre-activation EMG intensity.  $F_z$  and  $G_z$  were determined from the GRF data. The time of peak leg acceleration was estimated from the  $F_z$  and  $G_z$  maximums. Each subject was examined independently to determine the relationship between EMG, input signal and soft tissue accelerations. Paired t-tests and repeated measures ANOVA ( $p < 0.05$ ) were used to determine group differences between the expected and unexpected conditions.

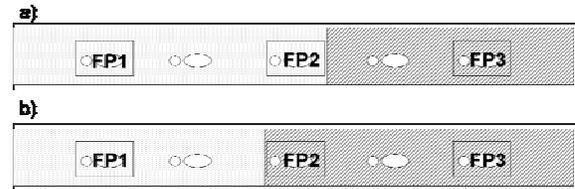

Figure 2: Experimental set-up. a) Control condition b) Test condition.

□ Surface 1: soft      ▨ Surface 2: hard

**RESULTS AND DISCUSSION:**

- (1) The natural frequencies of the soft tissue compartments were the same for the expected and the unexpected situation, indicating that the vibration characteristics have not been changed because the change was not expected.
- (2) The soft tissue accelerations were typically higher for the unexpected than for the expected condition. They were highest when the input frequency was close to the natural frequency of a soft tissue compartment.
- (3) The EMG intensities were the same for the expected and the unexpected situation since the subjects could not prepare.
- (4) EMG and GRF showed no systematic changes for the third step, which suggests that the expectations and/or the applied strategies were different for the different subjects. Specifically illustrated for subject P: The natural frequencies were estimated at 15.23 Hz, 20.95 Hz, and 22.85 Hz for the quadriceps, hamstrings and triceps surae, respectively. There was no change in the EMG pre-activation intensity between the unexpected (step FP2<sub>hard</sub>) and the expected surface condition (step FP2<sub>soft</sub>). There was an increase in the magnitude of the peak acceleration of 3%, 10% and 7% for the quadriceps, hamstrings and triceps surae. The input frequencies were estimate as 17.7 Hz for the soft expected and 19.0 Hz for the hard unexpected surface. As expected based on the theoretical response spectrum (Fig 1.) for a shift in the input frequency from 17.7 to 19 Hz the greatest increase in acceleration occurred in the hamstrings.

**CONCLUSIONS**

Increased soft tissue vibrations did occur when a runner experienced an unexpected impact with a frequency close to the natural frequency of a soft tissue compartment.

## A MATHEMATICAL DEFINITION OF FEASIBLE FINGER POSTURES AND MOVEMENTS

### INTRODUCTION

It is not well understood why or how neurological diseases or injuries so easily disrupt the delicate interactions among finger muscles that produce finger postures and slow movements. Thus, we lack clear therapeutic approaches to, say, shape the hand for grasp following stroke. A first-order dynamical systems approach is applicable to this neuromuscular control problem because finger postures are combinations of joint angles, and slow finger movements are damped during transitions between postures. Our long-term goal is to explicitly define the manifold of feasible finger postures in state-space as a function of the continuous muscle inputs that drive the fingers to various configurations during slow movements. As a first step, we develop here, the mathematical tools to find such manifolds and their stable points. While our approach is reminiscent of the *deformable membrane* analogy of the equilibrium-point hypothesis, our purpose is quite different: to determine whether first-order dynamical equations derived from basic biomechanical and muscle mechanics concepts can begin to explain experimental measurements of finger postures and slow movements.

### METHODS

To facilitate visualization of our methods, we present the example of a tendon-driven, 2-joint, planar finger with anatomically inspired tendon routing [1]. For quasi-static motions, muscles are modeled as simple force-length actuators with the resting lengths as parametric inputs and the tendons are modeled as elastic bands. Using geometrical constraints obtained from tendon routing, we obtain relationships between tendon stretch/excursions and joint angles (generalized coordinates). This relationship we obtain is called the transmission matrix  $G$ . For a given set of muscle resting length inputs, the potential energy of the system can be written as a non-linear function of tendon stretch/excursions and joint angles. This potential energy function is a high dimensional manifold in the generalized coordinate space whose maxima/minima give the equilibrium postures for the finger. These maxima/minima when plotted as a function of the muscle input parameters also give a manifold, the local and global properties of which determine if the system is controllable locally and/or globally. We use results from manifold theory to study such properties. For example, the Implicit Function Theorem lays down the sufficient conditions for a functional relationship to exist between the muscle inputs and the output generalized coordinates [2].

### RESULTS AND DISCUSSION

For the above example, we found that the transmission matrix  $G$  determines the controllability of the system. A necessary and sufficient condition for such a system to be controllable is that the rank of the matrix  $G$  should be equal to the number of joints (generalized coordinates). For two test cases, the results

are shown in Figure 2. We found that the cross-over tendon  $m_3$  shown in Figure 1 (analogous to the extensor mechanism of the fingers) plays a major role in determining this rank for  $G$ , hence showing the importance of anatomically faithful models.

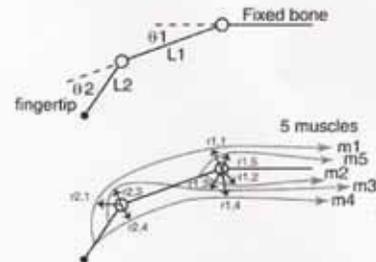

Figure 1: The tendon geometry for the 2-link 5-muscle finger.

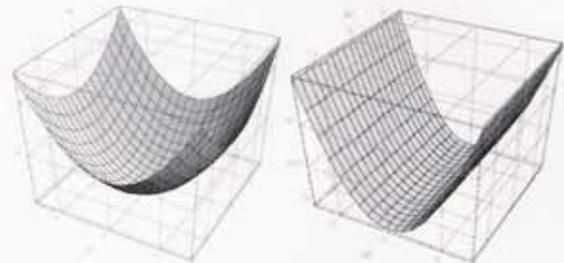

Figure 2: Left: The potential energy function manifold is a paraboloid in the joint angle space when rank ( $G$ ) = 2. The system is fully controllable along the two degrees of freedom. Right: The potential energy function manifold reduces to a parabolic cylinder when rank ( $G$ ) = 1. There is loss of controllability along the axis of this cylinder.

Having developed the ability to calculate the manifolds that predict stable finger postures and gradients for finger movement, our next step is to create anatomically faithful 3D models of the human finger with complex tendon geometry.
