The body is like an inverted pendulum during SL, and the elder females accommodate the temporal parameters, and the motion at proximal parts to complete the task. A decrease in maximal excursion of COM displacement in AP direction, and an increase in ML in elder group may suggest that as the elderly restrict the body motion in AP direction to prevent from confronting the risk of falls. Therefore, they need to increase body motion in transverse plane to advance to next step.

## BIOMECHANICAL ANALYSIS OF THE WALKING PATTERN IN HEALTHY SUBJECTS WITH AND WITHOUT ROLLATOR

<sup>1</sup>Tine Alkjaer, <sup>1</sup>Peter K. Larsen, <sup>1</sup>Gitte Pedersen, <sup>1</sup>Linda H. Nielsen and <sup>1</sup>Erik B. Simonsen  
<sup>1</sup>Institute of Medical Anatomy, The Panum Institute, University of Copenhagen, email: [t.alkjaer@mai.ku.dk](mailto:t.alkjaer@mai.ku.dk)

### INTRODUCTION

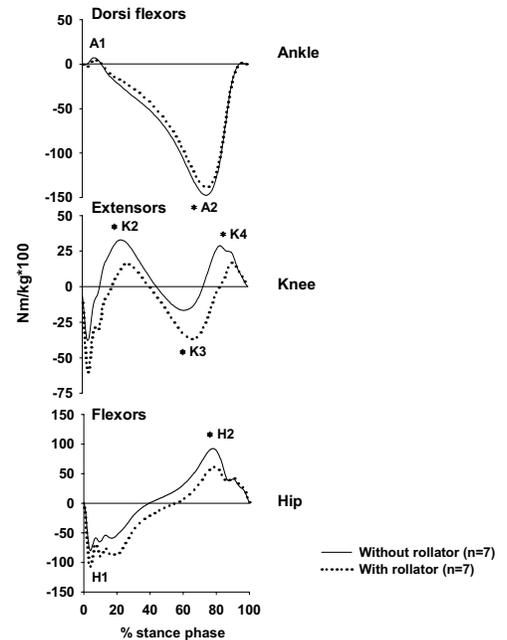

The rollator is a commonly used walking-aid in elderly and in disabled subjects. The purpose of using the rollator is to improve the walking performance and minimize the risk of falling. Studies have shown that the walking performance in elderly subjects measured as distance, cadence and velocity is improved when they walk with a rollator [1]. However, knowledge about the specific changes in the joint moment patterns of the ankle, knee and hip joint are limited. Thus, the purpose of the present study was to investigate the biomechanical effects of walking with a rollator on the walking pattern in healthy subjects.

### METHODS

Seven healthy women (age: 34.7 (range: 25-57) years, height: 1.70 (range: 1.64-1.78) m, weight: 64.7 (range: 55-75) kg) participated in the study, which was approved by the local ethics committee. The subjects were asked to walk across two force platforms (AMTI, OR6-5-1) both with and without a rollator (Dolomite Maxi 650, Dolomite AB, Anderstorp, Sweden) at a speed of 4.5 km/h. Fifteen small, reflecting spherical markers were placed on the subjects according to the marker set-up described by Vaughan et al. [2]. In addition, 14 markers were placed on the upper extremities and on the rollator.

Five video cameras (Panasonic WV-GL350) operating at 50 Hz were used to record the movements. The video signals and the force plate signals were synchronized electronically with a custom-built device. The device put a visual marker on one video field from all cameras and at the same time triggered the analogue-to-digital converter, which sampled the force plate signals at 1000 Hz. The subjects triggered the data sampling and synchronization when they passed the first pair of photocells. Three-dimensional coordinates were then reconstructed by direct linear transformation using the Ariel Performance Analysis System (APAS). Prior to the calculations, the position data were digitally lowpass filtered by a fourth-order Butterworth filter with a cut-off frequency of 6 Hz, and the 1000 Hz force plate signals were down sampled to 50 Hz to fit the video signals.

An inverse dynamics approach was used to calculate the kinematics and kinetics for flexion and extension. Six gait cycles were normalized and averaged for each subject and situation (with and without rollator, resp.). Normalization was performed by interpolating data points to form 500 samples for each gait cycle. Only the stance phase of the left leg was analyzed. A Student's t-test for paired data was used to identify statistically significant differences between walking with and without rollator in selected kinematic and kinetic variables of the walking patterns. The level of significance was set at 5%.

**Figure 1:** Average joint moments (Nm/kg\*100) of the left ankle, knee and hip. 0% indicates heel strike and 100% indicates toe off on the x-axis. \* indicates significant difference between walking with and without rollator.

### RESULTS AND DISCUSSION

The hip was significantly more flexed during the stance phase when walking with the rollator ( $p=0.007$ ). The peak ankle plantar flexor moment (A2,  $p=0.02$ ) and knee extensor moments (K2 + K4,  $p=0.01$ ) were significantly smaller during walking with rollator, while the peak knee flexor moment (K3,  $p=0.000$ ) was larger than without rollator (Figure 1). The peak hip flexor moment (H2) was smaller during walking with rollator than without ( $p=0.000$ ) (Figure 1).

### CONCLUSIONS

The results showed that walking with a rollator unloaded the plantar flexors and knee extensors. The hip was more flexed when walking with rollator because the trunk was leaned forward. This resulted in a smaller hip flexor moment during walking with rollator. However, the more flexed hip position should result in better conditions for the hip extensors to produce moment. Further investigation is needed to answer this question.

## SEGMENTAL DYNAMICS OF SOCCER INSTEP KICKING

<sup>1</sup>Hiroyuki Nunome, <sup>2</sup>Takeshi Asai and <sup>1</sup>Yasuo Ikegami  
<sup>1</sup>Nagoya Univ., Nagoya, Japan; e-mail: nunome@htc.nagoya-u.ac.jp  
<sup>2</sup>Yamagata Univ., Yamagata, Japan

### INTRODUCTION

An open kinetic chain model generally used for the detailed biomechanical analysis of the kicking leg motion allowed the moment due to muscular force input and other sources to be computed separately. Putman (1991) illustrated the actions of the resultant joint moment and motion-dependent interactive moment simultaneously during punt kicking. The procedure was applied by Dörge et al., (2002) to soccer instep kicking. However, as the integrated parameters were solely reported in their study, the time-series changes of the resultant joint moment and motion-dependent interactive moment during soccer instep kicking were still concealed.

The purpose of this study, therefore, was to reveal the detailed time-series actions of the resultant joint moment and motion-dependent interactive moment during soccer instep kicking

### METHODS

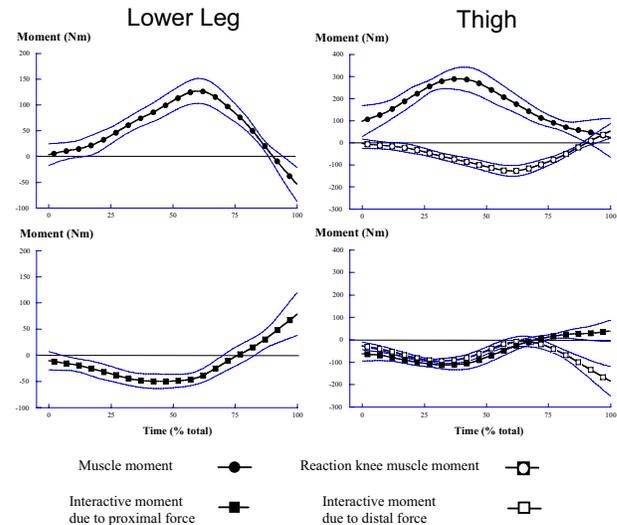

The kicking motions of five highly skilled club players (age: =  $16.8 \pm 0.4$  yrs; height: =  $176.2 \pm 6.1$  cm; mass: =  $70.6 \pm 7.2$  kg) were captured using a three-dimensional cinematographic technique at 200 Hz. The resultant joint moment (muscle moment) and the motion-dependent interactive moment (interactive moment) were computed using a two link kinetic chain composed of the thigh and lower leg (including shank and foot).

To avoid a systematic distortion of the data caused by ball impact, the moments were computed from unsmoothed coordinates until three frames before ball impact and then extrapolated for fifteen points by a linear regression line. The regression line was defined for each change. To resemble the final change of the data, the final eight to twelve data points were fitted to the linear regression line. For angular velocities, a quadric regression line was fitted to the unsmoothed data in the same manner. After these extrapolations, all parameters were digitally smoothed by a fourth-order Butterworth filter at 12.5 Hz, and then the extrapolated regions after ball impact were removed.

### RESULTS AND DISCUSSION

During the final phase of kicking, though the forward hip muscle moment rapidly decreased, its backward moment was rarely seen toward ball impact. This indicated that the backward hip muscle moment had no substantial influence to decelerate the thigh during kicking. As shown in Figure 1, it is obvious that the deceleration of the thigh was initiated by the reaction knee muscle moment and was later emphasized by the interactive moment due to the distal end force.

For the lower leg motion, as shown, the knee muscle moment dominates the lower leg motion until the final phase of kicking.

**Figure 1:** The average ( $\pm$ SD) changes of muscle moment and motion-dependent interactive moment acting on the lower leg and thigh.

After this, the knee muscle moment was rapidly inhibited. It is assumed that as the angular velocity of the lower leg exceeded the inherent force-velocity limitation of muscles immediately before ball impact, the muscular system related to the lower leg motion became incapable of generating any concentric force. Thus, it can be speculated that the backward knee muscle moment was mainly due to the resistance of the muscular system when it was forced to be stretched.

In contrast to the inhibition of the knee muscle moment, the interactive moment began to dominate the accelerative motion of the lower leg immediately before ball impact.

### CONCLUSIONS

Detailed time-series data of the muscle moment and interactive moment during soccer instep kicking was clearly illustrated. The deceleration of the thigh was initiated by the reaction knee muscle moment and was later emphasized by the interactive moment due to the distal end force.

The acceleration of the lower leg immediately before ball impact was dominated by the interactive moment due to the proximal end force.

## RELATIONSHIP BETWEEN FOOT PROGRESSION ANGLE AND EXERCISE-RELATED LOWER LEG PAIN

<sup>1</sup>Tine Willems, <sup>2</sup>Dirk De Clercq, <sup>2</sup>Anneleen De Cock, <sup>3</sup>Philip Roosen and <sup>1</sup>Erik Witvrouw

### INTRODUCTION

Exercise-related lower leg pain (ERLLP) is a common and enigmatic overuse problem in athletes and military populations [1]. Runners, track athletes and athletes participating in jumping sports are frequently diagnosed with ERLLP which is usually induced by repetitive tibial strain imposed by loading during intensive, weight bearing activities. Retrospective and prospective studies have identified a relationship between an increased subtalar eversion and ERLLP [2,3,4]. As highly potential risk factor, also an increased medial pressure distribution during the forefoot contact phase has been identified [4]. In clinical practice, an increased foot progression angle (abducted) is often linked with an increased eversion as it is suggested that the lower leg follows the direction of progression. Therefore, we hypothesize that ERLLP could be related to an increased foot progression angle which could relate to the increased eversion and the increased medial pressure distribution. However, to our knowledge, in the literature, the relationship between foot progression angle and ERLLP or the eversion excursion or the medio-lateral pressure distribution has not been investigated. Therefore, the purpose of this study was 1) to investigate the relationship between the foot progression angle and the amount of eversion and the medio-lateral pressure distribution and 2) subsequently gain insight in a potential underlying mechanism that might be implicated as precursor to ERLLP.

### METHODS

Subjects were 400 healthy undergraduate physical education students. 3D-gait kinematics combined with plantar pressure profiles were collected during barefoot running at a speed of 3.33m/s. The experimental set-up consisted of a 2m x 0.4m AMTI-force platform set into a 16.5m indoor running surface. Plantar pressure data were collected with a Footscan pressure plate (RsScan Int, 2m x 0.4m, 2 sensors/cm<sup>2</sup>, 480Hz, dynamic calibration with AMTI), mounted on top of the force platform. The foot progression angle was derived from the plantar pressure data and was defined as the angle between the direction of progression and the mid heel - head of metatarsal II axis. Kinematics were collected at 240Hz using 7 infrared cameras (Proreflex) and Qualisys software. Marker placement and modeling was based on that of McClay and Manal (1999). The eversion was calculated through positioning the rearfoot with respect to the lower leg and the excursion was measured around the sagittal axis through modeling with Visual3D (C-motion). Three valid right and three valid left stand phases were measured and analysed.

After the evaluation, all sports injuries were registered by the same sports physician during a certain period.

First, intrasubject variability of the foot progression angle of 30 healthy subjects was evaluated by means of Intraclass Correlation Coefficients (ICC) for three consecutive trials. Second, foot progression angle was correlated with the eversion excursion and the medio-lateral pressure distribution during the forefoot contact phase, which were both risk factors for ERLLP.

And third, Cox regression analysis was performed to test the effect of the foot progression angle on the hazard of injury.

### RESULTS AND DISCUSSION

Intraclass Correlation Coefficient showed low intrasubject variability (ICC=0.92), which demonstrates that positioning of the foot is very constant in barefoot running.

Pearson correlation showed no significant correlation between foot progression angle and the eversion excursion ( $R=.121$ ) and between foot progression and the medio-lateral pressure distribution during the forefoot contact phase ( $R=.116$ ).

During the follow-up period, 46 of the subjects developed ERLLP, of whom 29 subjects had bilateral complaints. So 75 symptomatic lower legs, 35 left and 40 right were classified into the ERLLP group. As control group, bilateral feet of 167 subjects who had no injuries at the lower extremities were selected. Cox regression analysis showed no significant differences between the foot progression angle between the uninjured and ERLLP group ( $P = .533$ ).

Our hypothesis that ERLLP could be related to an increased foot progression angle which related to the increased eversion and the increased medial pressure distribution can be rejected.

### CONCLUSIONS

Results of this study show that the foot progression angle is not a risk factor for ERLLP. In addition, the foot progression angle is not related to the amount of eversion or the medio-lateral pressure distribution during the forefoot contact phase. We therefore hypothesize that during the roll off, the lower leg is not following the direction of progression, but rather the direction of the foot axis. However, this should be investigated further.

**PLANTAR PRESSURE DISTRIBUTION PATTERNS USED AS BIOFEEDBACK INFORMATION IMPROVE TECHNICAL TRAINING AND PERFORMANCE IN IN-LINE SPEED-SKATING**

<sup>1</sup> Olaf Hoos, <sup>2</sup>Dieter Rosenbaum, <sup>2</sup>Eric Eils and <sup>3</sup>Kuno Hottenrott  
<sup>1</sup>University of Marburg, Institute of Sports Science, Marburg, Germany  
<sup>2</sup>University of Münster, Movement Analysis Lab, Münster, Germany,  
<sup>3</sup>University of Halle, Institute of Sports Science, Halle, Germany  
 email: [hoos@mail.uni-marburg.de](mailto:hoos@mail.uni-marburg.de)

**INTRODUCTION**

In-line speed-skating (ISS) is a rather new competitive discipline with biomechanical characteristics similar to ice speed-skating (3,4). In both disciplines knowledge and feedback of push-off mechanics appear essential for performance optimization (1,2). Therefore, the goal of the study was to evaluate whether plantar pressure distribution patterns are useful as biofeedback information to develop exercises for technical training that are beneficial for performance optimization in ISS.

**METHODS**

The study consisted of two parts. **Part 1:** Foot pressure distribution (Novel-Pedar, 50 Hz) was assessed for eight elite in-line speed skaters (age: 28±5 years, weight: 72±4 kg) skating 1000 m at 35 km/h behind a car on a smooth road track. All athletes skated the road track four times with different push-off conditions in randomized order: normal technique (N), focused on normal technique (F), push-off with the forefoot/toes (T) and push-off with the heel (H). For each condition, five consecutive steps were analyzed yielding contact time (CT), peak pressure (PP), maximum force (MF) and force-time-integrals (FTI) for 10 anatomical regions. Furthermore, all subjects completed a questionnaire about their experience and sensation concerning push-off mechanics for the different conditions. Pressure distribution patterns and the results of the questionnaire were used to extract main characteristics of push-off dynamics in elite ISS and a training program with specific push-off exercises was developed accordingly. **Part 2:** The developed program was evaluated in a 6 week trial of technical training with 69 recreational in-line speed-skaters, randomly separated in a training group (TG; n=39; age 37±10 years, weight 70±12 kg) and a control group (CG; n=39; age 38±9 years, weight 67±10 kg). Technical training volume was similar for both groups (once a week, 105 min) with the major focus on basic technical aspects of the ISS technique. While CG focused only on basic technical drills, TG additionally used the specific push-off exercises. The

effect on skating performance was evaluated by a 200 m sprint test before (PRE) and after (POST) the 6 week program.

**RESULTS AND DISCUSSION**

Table 1 shows the PP-values of the elite skaters. The plantar pressure values indicated that the major characteristics during push-off are a well-distributed load between heel and medial forefoot and a push-off with pronounced heel impulse. This specific pressure distribution pattern is only altered by the condition push-off with toes, which is further mentioned in the questionnaire as most ineffective and "unusual". The results had shown that for technical training in Part 2 of the study specific exercises for plantar sensation during skating and for pronounced sideways push-off with high-heel impulse had to be used.

The results of the 200m sprint test yielded a significant improvement for TG (pre: 35.1±4.5 s; post 33.9±4.0 s, p=0.0005) and no changes for CG (pre: 38.9±7.0 s; post: 39.1±6.3 s, n.s.), underlining the positive effect of the developed technical training program on skating performance.

**CONCLUSIONS**

Plantar pressure distribution patterns yield useful biofeedback information for coaches and athletes and may help to improve technical training programs and performance in ISS.

## COMPUTER SIMULATION OF A HUMAN SKI JUMPER - A COMPLETE TRIAL

<sup>1,2</sup> Syn Schmitt, <sup>1</sup> Helmut Mutschler, <sup>2</sup> Albert Gollhofer and <sup>1</sup> Hanns Ruder

<sup>1</sup>Section Biomechanics, Department of Astronomy and Astrophysics, University Tuebingen

<sup>2</sup>Department of Sport and Sport Science, University Freiburg; email: sschmitt@tat.physik.uni-tuebingen.de

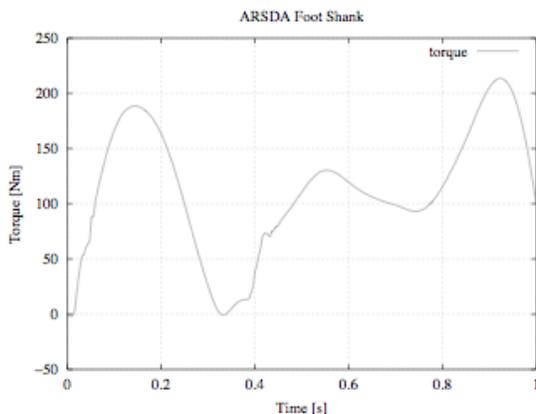

### INTRODUCTION

Recent computer simulation results make a good contribution to understanding human movements [2,4]. But the control algorithms used there, are very complex and numerically more expensive. The purpose of this contribution is to present a robust method to model and simulate a complex human movement with aerodynamic interaction. In detail the squat position control at start-up and the calculation of lift and drag forces during the complete ski jump are considered.

### METHODS

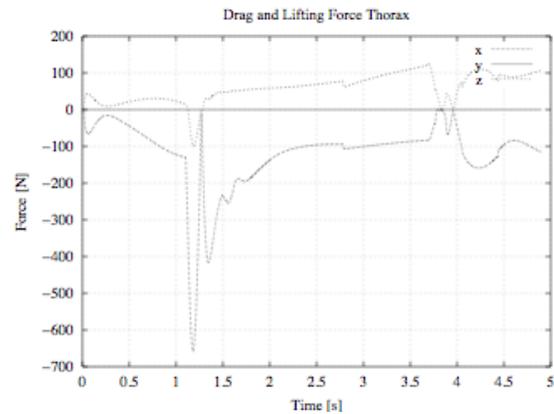

The ski jumper model was created on the bases of a HANAVAN [3] model (height: 1,78m, weight: 60kg) consisting of 17 rigid bodies. Each joint has a 1-dof rotational spring damper representing stiffness and elasticity of the real body joints except for the following joints: ankle, knee, hip, upper body, shoulder and neck. These joints are the actuators of the model. To create and solve the equations of motion we used DySim, a self-coded rigid body simulation package. The animation of the data was made with AniDySim also self-coded using OpenGL.

The actuators are built with 1-dof rotational spring dampers (ARSDA) with adaptable resting length. Therefore we created a control algorithm to switch between different states to adapt the resting length to the desired motion. The torque produced by the spring is directly transmitted to the body mechanics. In this presented simulation we used eight different angular configurations (states/resting lengths) for the complete trial.

**Figure 1:** Movement control of the foot-shank joint: The control algorithm switches between two states, one to bring the ski jumper more to the front and the other more to the back (positive and negative torque changes).

During the start-up and the landing phase the ground reaction forces were modeled with contact elements between the skis and the jumping hill. In the flight phase we used a newly written aerodynamic algorithm. Lift and drag forces were calculated separately with drag force  $F_D = 0.5 \cdot c_R \rho_A A_R v^2$  as a

**Figure 2:** Aerodynamic forces in x-, y-, z-direction. Where -x marks the drag direction and z marks the lift direction.

standard formula. The lift force, largely dependent on the variable aerodynamic conditions like position and surface conditions, was estimated by the modified formula  $F_L = 0.5 \cdot c_L \rho_A A_W v^2$ .

### RESULTS AND DISCUSSION

The result of this computer simulation is an entire ski jumping trial, encompassing the start-up and the landing including the calculated aerodynamic forces. Figure 1 displays the ankle torque for the movement control during the start-up phase. The swift-like regulation between forward and backward position is clearly observable. Figure 2 shows the lift and drag forces of the thorax body calculated for the entire trial. At  $t \sim 1,2s$  the takeoff of the jumping movement takes place, thus high drag forces are considerable.

This example of an entire and complex movement model on the basis of realistic physical constraints demonstrates a powerful tool for better understanding of complex biomechanical structures. However, the validation of the results is still in progress using detailed position and velocity data from real ski jumper collected with a GPS receiver.

### CONCLUSIONS

Even with this approach to model human movement we showed that a complex computer simulation could be done according to the  $\lambda$ -model [1]. Furthermore it is obvious that modeling of aerodynamics of a dynamic multibody system enables to identify the most critical flight phases in relation to optimize horizontal velocity.

## DOES COURSE OF A PRECEDING PITCH INFLUENCE BASEBALL BATTING AS THEY SAY?

<sup>1,2</sup>Chizuru Toriki, <sup>1</sup>Tomoyuki Matsuo, <sup>3</sup>Takayuki Shigetani, <sup>3</sup>Ryutaro Himeno, <sup>4</sup>Kazushi Tezuka, <sup>1</sup>Ken Hashizume

<sup>2</sup>Asahi Broadcasting Corporation

<sup>3</sup>Advanced Computer Center, The Institute of Physical and Chemical Research

<sup>4</sup>Beta-Endorphin; email: tmatsuo@skill.hss.osaka-u.ac.jp

### INTRODUCTION

It is generally believed that a certain combination of pitches influences the performance of baseball batting. However, it is difficult to elucidate it in real game situation, because several factors involve it (not only characteristics of pitches but also game situations). Gray (2002) ascertained, in his virtual batting study, that there were both the expectancy effect concerning the preceding pitch sequence and the pitch count effect [1]. He focused on change of pitch speed. In the current study, we focused on change of the course of pitch, especially whether the course of the preceding pitch individually influence the movement of batting the succeeding low-and-outside ball.

### METHODS

Eight experienced college-level baseball players voluntarily participated in this study. Their mean height was 1.75 m (SD = 0.06), mean body mass was 71.9 kg (SD = 25.4), mean age was 20.6 years (SD = 1.2), and mean number of years of playing experience was 12.3 years (SD = 2.5). After detailed explanation of the experiment and filling out an informed consent, they were provided sufficient amount of time for warm-up including bat swings.

Three reflective markers with 19 mm in diameter were put at the distal end of an aluminum bat. Its length was 0.85 m and its mass was 0.87 kg. Reflective markers were also put on the top of participant's head, both of lateral tip of the acromions, and both of anterior superior iliac spines. A four-camera ProReflex system (Qualisys) was used to collect the three-dimensional coordinates of the reflective markers with sampling frequency at 200 Hz during swings.

The task was to 'hit' a virtual ball, simulating an approaching baseball. The virtual pitch was displayed on a large display (2.1 m in vertical X 6 m in horizontal) with a pitcher (height was 1.78 m) in a baseball stadium. The

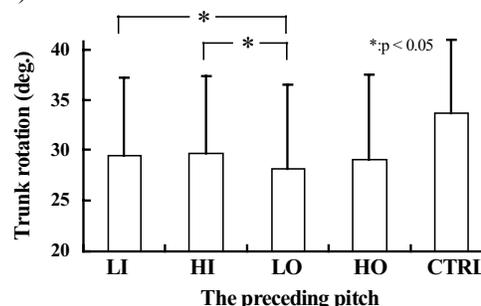

trajectories of pitches were computed based on the pitch velocity, the angle of incidence, air resistance, and spin of the ball (Himeno, 2001). The ball velocity at the instant of ball release was always set at 33.3 m/s. Each participant first swung in the control condition in which he was informed where the ball was thrown, then swung in the pseudo-random condition in which the course of pitch was strategically decided so as not to be noticed by the participants.

A block consisted of approximately 22 swings with a 20 sec. rest between swings, and eight blocks were performed with 2–10 min. rest between blocks.

Several kinematic variables concerning trunk and bat movements during swing for the pitch into low-and-outside corner of the strike zone were calculated and compared among the conditions of the course of the preceding pitch.

### RESULTS AND DISCUSSION

Although angle of trunk forward bending did not differ among conditions, both of maximum angles of the pelvis rotation and the upper trunk during backswing were significantly smaller in the condition where the preceding pitch was the low-and-outside pitch (pre-LO condition), than in the condition where the preceding pitch was high-and-inside (pre-IH condition) (Figure 1).

**Figure 1:** Maximum upper trunk rotation during backswing for the low-and-outside strike. LI, HI, LO, HO, CTRL stand for low-and-inside, high-and-inside, low-and-outside, high-and-outside, and pre-informed conditions, respectively.

Maximum angular velocity of the upper trunk during forward swing had a tendency to be slightly lower in the pre-OL condition than in the pre-IH condition.

From the above results, it is suggested that the participants expected that the probability of successive low-and-outside pitches was low and the probability of the low-and-outside pitch after high-and-inside pitch was high.

### CONCLUSIONS

From the results of the swings for the same course of the pitch but different course of the preceding pitch, it was found that even only the course of the preceding pitch influenced the trunk movement during batting for the low-and-outside ball.

## A FOOTTYPE CLASSIFICATION WITH CLUSTER ANALYSIS ON PLANTAR PRESSURE DISTRIBUTION DURING BAREFOOT JOGGING

<sup>1</sup> Anneleen De Cock, <sup>2</sup>Tine Willems, <sup>2</sup> Erik Witvrouw and <sup>1</sup> Dirk De Clercq

<sup>1</sup> Ghent University, Department of Movement and Sport Sciences, Belgium

<sup>2</sup> Ghent University, Department of Rehabilitation Sciences and Physiotherapy, Belgium

### INTRODUCTION

The foot provides stabilisation, shock absorption, balance and propulsion during stance phase, but how these functions are realised is still not fully understood<sup>1</sup>. Plantar pressure measurements have the potential to unravel the relations between foot structure and foot function. It is a common belief that different functional foot types exist, but a classification into functional foot types is mostly based on morphological characteristics, measured in a static position<sup>2,3</sup>. Dynamical measurements, linked to the functional behaviour of the foot, may provide a better basis for a classification system. The aim of the present study was to develop a foot type classification based upon dynamical plantar pressure measurements.

### METHODS

Plantar pressure data were collected from 215 healthy subjects (age:  $18.3 \pm 1$  years; 129 men and 86 women). A footscan pressure plate (RsScan Int., 2m x 0.4m x 0.02m, 10sensors/4cm<sup>2</sup>, dynamic calibration with AMTI force plate) was mounted in the middle of a 16.5m long running track. The subjects ran at a speed of 3.3m/s ( $\pm 0.17$ m/s). Three stance phases were measured for each side. For each trial, eight important anatomical areas (medial and lateral heel, metatarsal I-V and the hallux) were identified on the footprint. For each area descriptive statistics (mean, SD) were calculated for relative regional impulses (% of summed impulses of all subareas,  $RI_R$ ). To classify into foot types, a K-means clustering analysis was used, based on the relative regional impulses of the forefoot. A multivariate ANOVA with post-hoc Tukey test was used to study differences between the four clusters.

### RESULTS AND DISCUSSION

With the K-means cluster analysis, four clusters of pressure patterns were identified (figure 1): (a) Medial  $M_2$  pattern with large pressure loading underneath  $M_2$  (b) Central-lateral pattern with a more overall scattered pressure loading, (c) Central pattern with larger pressure loading underneath  $M_3$  and  $M_2$  and (d) Medial  $M_1$  pattern with a large pressure loading underneath  $M_1$ . Significant differences were found between the four clusters for peak pressures, regional impulses, relative regional impulses and some timing factors. In three of the four patterns and certainly in the  $M_2$  pattern,  $M_2$  sustains high impulses, since specific characteristics of this metatarsal make it a cantilever during push off. The forefoot contact phase (when meta's make contact) for the  $M_1$  pattern is significant shorter in duration compared to other foot types,

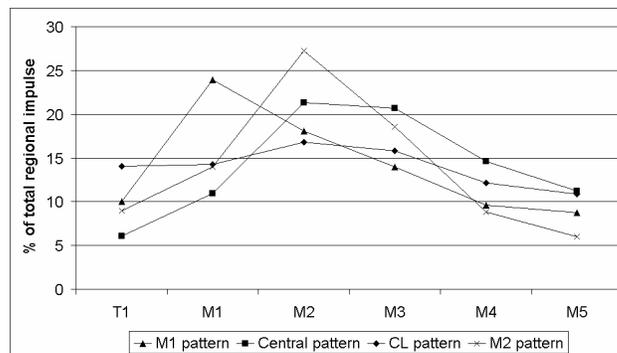

Figure 1: Relative regional impulses for the four loading patterns.

which could indicate a fast initial plantar flexion and initial eversion.<sup>4</sup> The high pressure loading on the first metatarsal might also arise from a rigid first ray, which then sustain almost all pressure loading during push off.

The pressure load patterns found in the present study are very similar to the pressure patterns found by Hughes et al (1993)<sup>5</sup>, which were based on peak plantar pressure underneath the forefoot of 100 adults in a walking condition. Although peak pressures and pressure-time integrals are higher in running, the distribution of the pressure over the foot is comparable to that of walking. This could indicate that in both locomotion forms, similar loading mechanisms exist.

### CONCLUSIONS

An interpretation of foot types was suggested by classifying four foot types on differences in dynamical plantar pressure distribution. Further research combining plantar pressure data with morphological measurements and 3D kinematic data is expected to get a better insight in the functional behaviour of the different foot types.

### INTRODUCTION

High and frequent loading during wheelchair ADL is a generally recognized factor contributing to the development of shoulder complaints. A previous study has shown that the external load on the shoulder in subjects with a spinal cord injury (SCI) is high (40 Nm) during weight relief lifting [1]. Simulation of internal load that includes the effect of (partial) muscle paralysis is likely to lead to higher glenohumeral contact forces and forces in the remaining muscles, when compared to a complete musculoskeletal system. The purpose of this study was to evaluate the effect of lesion level on the estimated glenohumeral contact force and muscle load.

### METHODS

Four subjects with tetraplegia (TP) and four able-bodied (AB) male subjects participated. Three-dimensional kinematics of the thorax, humerus, clavicle, scapula, forearm and hand were recorded with a 3-camera opto-electronic system (Optotrak, Canada) during 3 trials of weight relief lifting. External forces were recorded with an instrumented wheelchair (AMTI 6df; Quickie Triumph, The Netherlands). The orientation of the scapula was determined in a calibration measurement with a scapula-locator system. From this measurement and the orientation of the humerus during the tasks, the orientation of the scapula and clavicle were calculated using a regression model [2]. Position and force data were used as input for the Delft Shoulder and Elbow Model which calculates muscle forces and joint glenohumeral contact forces (GHCF). To simulate complete lesion levels, we made a classification of muscle force at each lesion level, based on muscle segment innervations as described in Gray [3], based on the assumption that the maximum relative force of each muscle was relative to the number of innervating segments above the lesion. By this method the model was modified to simulate lesions from C5 to T1, whereby a T1 lesion was equal to the complete, fully functional, shoulder-elbow model. All 24 input profiles (3 trials x 8 subjects) were used. This implied that the profiles of the AB subjects were used as input to a model with a SCI and vice-versa.

### RESULTS AND DISCUSSION

The peak GHCF (Figure 1) was higher for the TP profiles than for the AB profiles ( $P=0.037$ ) and for the TP profiles the peak GHRF was significantly higher for the first successful simulation (S1) compared to T1 ( $P=0.029$ ). For the T1 simulation, higher forces are calculated for the TP profiles in the serratus anterior, pectoralis major, deltoideus and in the rotator cuff compared to the AB profiles. However the muscle forces are not significantly higher for the TP profiles compared to the AB profiles ( $P=0.36$ ). The calculated forces for the biceps and triceps show much more predicted force in the triceps for the AB profiles compared to the TP profiles.

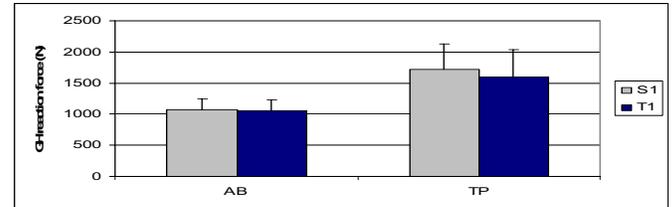

Figure 1: GHCF (mean + SD) for AB and TP profiles for the first successful (S1) and complete model simulation (T1).

Results show that it is possible to have a successful simulation of the performance of a weight relief lift with a complete C6 SCI but not with a C5 lesion, which appears indeed to be the case in real life. At the C6 lesion level, fewer successful AB profiles suggest an adaptation in the kinematics of the subjects with TP. The lesion modifications do have a small effect on the GHCF: T1 is 7.3 % higher than S1 for TP profiles. We expected the effect to be larger, but it is well likely that the adaptations in the TP kinematics already compensate for the loss of muscle force and the loss of muscle function by the use of different muscles.

A critical issue in this study is the question of whether the forces and particularly the forces of the triceps are correct. The predicted maximum triceps force for the TP profiles still 11 % of the maximum triceps force in the model. This percentage is close to the percentage measured by Needham-Shropshire [4]. They reported that subjects with a manual muscle test score of 3/5 for the elbow extension only had 9 % of the maximum voluntary force production of healthy controls. However, especially for TP subjects, the EMG intensity in terms of %MVC is of little value without information about the moment that can be generated at 100 % MVC. Information about muscle force instead of muscle activity is an important reason to use a biomechanical model.

### CONCLUSIONS

The higher GHCF found in our simulations was mainly due to a different task performance by the TP subjects. The model modifications had a minor effect on the calculated GHCF. Due to the higher load on the shoulder joint and shoulder muscles in subjects with tetraplegia, these subjects run a higher risk of muscle overload and damage to the shoulder joint.

## IMPEDANCE MODULATION WITH PRECISION DEMANDS IN DISCRETE MOVEMENTS

Luc P.J. Selen, Peter J. Beek and Jaap H. van Dieën

Institute for Fundamental and Clinical Human Movement Sciences, IFKB, Vrije Universiteit, van der Boechorststraat 9,  
1081 BT Amsterdam, The Netherlands; email:Luc.Selen@fbw.vu.nl

### INTRODUCTION

Human motor performance is intrinsically variable, but this variability is tuneable, as evidenced by the speed-accuracy trade-off. Recently, impedance modulation has been suggested as a means to decrease motor output variability [1,2]. Unlike previous studies, in which impedance was estimated from muscular (co)-activation, we conducted an experiment in which we estimated the impedance from mechanical perturbations.

### METHODS

Twelve subjects participated in the experiment. Their right forearm was cast (NobaCast) to a splint, which was attached to a torque controlled motor. Two targets were presented on a ledbow placed 1.5m in front of the subject. A laserpointer attached to the splint indicated the pointing direction of the arm on the ledbow. Three different targets (3, 6 and 9cm in width) were presented in blocks. Subjects were instructed to make discrete,  $35^\circ$ , target-to-target flexion movements, with a movement time between 270 and 330ms. After each trial, the performance was fed back to the subject. Each blok consisted of 165 flexion movements of which 20 were perturbed by a torque pulse of 5Nm and a duration of 70 ms duration.

For the unperturbed trials that matched the time and precision constraints we determined the trajectory variability. The perturbed trials were matched to the best fitting unperturbed trial [3] to find the trajectory deviation after perturbation. These trajectories were normalized to the maximum deviation in all trials of each subject individually. The maximum deviation was used as a first order estimate of the impedance. ANOVAs for repeated measures were performed on both the trajectory variability and the impedance changes.

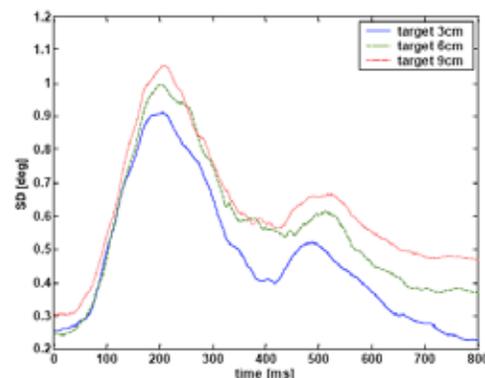

Figure 1: Kinematic variability over all subjects in the correct trials. The variability of the 3 cm target is different from the 6cm and 9cm target after 300ms

### RESULTS AND DISCUSSION

Figure 1 shows the standard deviation over all correct unperturbed trials for the different targets for all subjects. Trials were aligned to movement onset. Notice the decrease in variability when entering the target region (300-400ms) and the subsequent increase. This monotonic behavior was present in the correct trials of all subjects. Figure 2 shows the normalized maximum trajectory deviation after perturbation. Although overall the deviation increases with target width, the large standard deviations reflect that impedance modulation is not present in all subjects.

So far, only the maximum trajectory deviation was analyzed as an impedance estimate. In future work we will try to explicitly model the elbow joint as a second order system, resulting in quantitative measures of stiffness and damping.

### CONCLUSIONS

This study shows that impedance modulation and precision demands go hand in hand. Whether this impedance modulation is a strategy for reducing motor output variability in the face of precision constraints remains unclear. Osu et al. [1] presented a similar result, based on EMG activity. Although group averages indicate that impedance is modulated with precision demands, in single subjects this is not always the case. Apparently, other strategies to meet precision demands are available, even in single degree of freedom, time-constrained movements.

## GROUND REACTION FORCES IN PIGS DURING GAIT ON DRY AND GREASY FLOOR

<sup>1,2</sup>Vivi M. Thorup, <sup>2</sup>Frede A. Tøgersen and <sup>1</sup>Bente R. Jensen

<sup>1</sup>Institute of Exercise and Sport Sciences, University of Copenhagen, Denmark; email: [ViviM.Thorup@agrsci.dk](mailto:ViviM.Thorup@agrsci.dk),

### INTRODUCTION

Leg weakness, meaning clinical leg and claw disorders, joint diseases and locomotion disturbances, form a large welfare concern in modern pig production. Inappropriate flooring is a major contributor to these leg problems [1].

The dual purpose was to study the normal walk of slaughter pigs on solid (non-slatted) dry floor and to examine the effect of greasy floor condition on the gait.

### METHODS

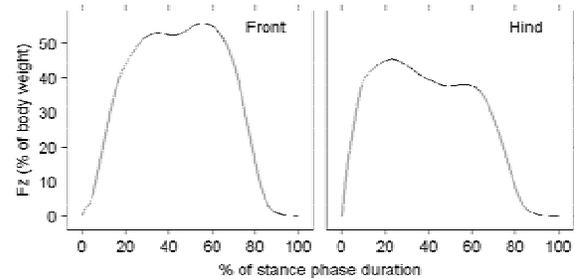

Kinetic data were collected from 12 healthy Danish crossbred slaughter pigs, with 6 pigs walking on dry and 6 on greasy concrete floor, respectively. Rape oil was used to make the floor greasy. Ground reaction forces were recorded at 1KHz from a force plate in the floor. Three to four trials were obtained for both right limbs. Vertical forces (Fz) were normalized to percentage body weight. For the stance phase vertical peak force (PeakFz), vertical mean force (MeanFz), horizontal craniocaudal peak (PeakFy) and minimum (MinFy) forces and stance phase duration were examined. Video recordings (50 Hz) were used to calculate walking speed.

Average vertical force curves were aligned according to a registering method [2]. Representatives of front and hind limb were chosen as templates. Then average of forces for each point of time was taken.

Results are reported as average (SD). Ratios are front/hind limb. Paired t-tests were used to compare limbs and unpaired t-tests to compare conditions. Level of significance was 5%.

### RESULTS AND DISCUSSION

Average weight of the pigs was 75 (6) kg. Average walking speed was 0.86 (0.12) m/s on dry and 0.75 (0.11) m/s on greasy floor, with pigs tending to move faster ( $P < 0.07$ ) on dry floor. Figure 1 shows the vertical force exerted by front and hind limbs on dry floor. Kinetic parameters are reported in Table 1. Front limb MeanFz was significantly higher than hind MeanFz for both conditions, with a mean ratio of 1.2, that is the front limb carried more weight. Correspondingly, front limb PeakFz was significantly higher for both floor conditions meaning that the front received higher vertical peak forces

**Figure 1:** Average vertical ground reaction force of walking pigs during stance phase on dry floor (n=6). Left: front limb (24 trials), right: hind limb (23 trials).

than the hind (mean ratio 1.3). Front PeakFy in dry condition tended ( $P < 0.06$ ) to be higher than for the hind limb (ratio 1.1), whereas for greasy condition it tended ( $P < 0.07$ ) to be lower than the hind PeakFy (ratio 0.9). Front limb MinFy tended ( $P < 0.09$ ) to be lower than hind for dry condition (ratio 0.8). Comparing conditions, front limb PeakFy was significantly higher for dry than greasy condition, whereas hind limb PeakFy for greasy condition tended ( $P < 0.06$ ) to be higher than for dry. MinFy for the front limb tended ( $P < 0.1$ ) to be larger for greasy condition. Regarding stance phase duration, front limb stance phase lasted significantly longer than hind for both conditions. Stance phase duration of the hind limb was significantly longer than the front for greasy condition.

### CONCLUSIONS

Pigs carry more weight on the front limb, and the front limb absorbs higher vertical peak force than the hind limb. Front limb peak horizontal force is higher on dry than on greasy floor. On dry floor horizontal peak force tends to be largest on the front limb and horizontal minimum force tends to be largest on the hind limb, however, on greasy floor the situation is reversed. Front limb stance phase lasts longer than hind for both dry and greasy floor. On greasy floor pigs have longer hind limb stance phases and tend to walk slower.

## KINEMATICS OF LATERAL TRANSFERS: A PILOT STUDY

<sup>1</sup> Sharon Eve Sonenblum, <sup>1</sup> Stephen Sprigle, <sup>2</sup> Leslie VanHiel, <sup>2</sup> Chris Maurer and <sup>1</sup> Eric Whittaker  
<sup>1</sup> CATEA, Georgia Institute of Technology, <sup>2</sup> Shepherd Center; email: Sharon@catea.org

### INTRODUCTION

People with spinal cord injuries (SCI) must transfer many times daily. Despite the importance of proper transfers, researchers have not completely described the kinematics of lateral transfers. Nyland *et al* identified transfer technique as a risk-factor for upper extremity degeneration and cited the need for quantitative measures of transfers and additional transfer research [1]. The purpose of this pilot study was to collect kinematic data on lateral transfers and identify different transfer strategies.

### METHODS

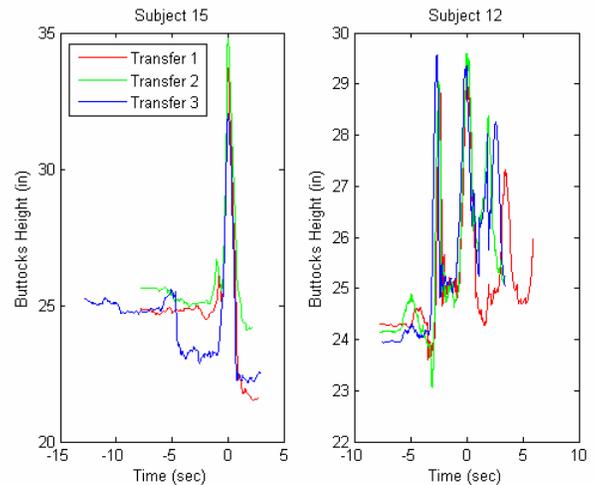

A convenience sample of 19 male adults was recruited from Shepherd Center (an acute SCI rehabilitation center) with IRB approval. Subjects had to be able to perform lateral transfers independently or with minimal assistance and could not have pressure sores or upper extremity orthopaedic conditions. Data was collected with a motion capture system from Motion Reality Inc. (Marietta, GA). We used eight 60Hz cameras and 41 markers on the body and 8 on the wheelchair. After providing written consent, subjects performed three lateral transfers to their stronger side between their own wheelchairs and a 20" high therapy mat. They were provided as much assistance as they generally used.

For each subject, two average values (transfer to the mat and transfer to the chair) were calculated for the following descriptors of transfers: **maximum buttock height, minimum head height, wrist spacing and torso angle**. Wrist spacing (the distance between the left and right wrist body segments) and torso angle (the angle between the projections of lines running through the shoulders and through the hips) were measured at the mid-transfer point. Time zero was set at the **mid-transfer point**, which was defined as the point where the buttocks reached a maximum height between the final lift-off from the chair (or mat) and the initial contact with the mat (or chair). Paired t-tests were used to compare maximum buttock height, minimum head height, wrist spacing and torso angle during transfers to and from the wheelchair.

### RESULTS AND DISCUSSION

Subjects elevated their buttocks an average of 11 inches above the therapy mat at mid-transfer (Table 1). They lowered their heads to approximately 21 inches above the mat. Subjects did not display a significant difference in buttock and head heights when transferring to the mat versus transferring to the wheelchair. On average mid-transfer (or maximum buttocks height) and minimum head height were separated by  $0.3 \pm 0.5$  seconds for transfers to the mat and  $0.1 \pm 0.6$  seconds for transfers to the wheelchair.

Subjects' wrists were spaced similarly at mid-transfer in transfers from the wheelchair (25.5") and transfers to the wheelchair (26.2"). The amount of torso rotation varied greatly between the subjects. The average angles formed by the shoulders and hips were nearly identical in transfers to and from the wheelchair (24° & 23°).

**Figure 1:** Two subjects' transfers to the mat are shown. Transfers to the wheelchair looked similar. Subject 15 (C6/7, Asia A) performed a smooth transfer with only one peak of buttock elevation while Subject 12 (T8, Asia C) used more buttock elevations to complete the transfer task.

A variety of transfer strategies were used by our subjects to complete the transfer task (Figure 1). The variation in buttock height within each subject's transfers was greater for transfers to the wheelchair than transfers to the mat ( $p=0.0335$ ).

### CONCLUSIONS

People with SCI use a variety of strategies to transfer between two surfaces. The different transfer strategies might be correlated to such factors as injury level, time since injury or body weight. Future work will cluster the transfer strategies in order to determine these relationships. Additionally, it is possible that the repeatability of the transfers might be related to upper extremity pain or safety of transfers. Further work with a greater number of subjects is needed to determine these relationships.

## DIFFERENTIAL EFFECT OF M. TIBIALIS ANTERIOR FATIGUE ON WALK-TO-RUN AND RUN-TO-WALK TRANSITION SPEED IN UNSTEADY STATE LOCOMOTION CONDITIONS

<sup>1</sup>Veerle Segers, <sup>2</sup>P. Aerts, <sup>1</sup>M. Lenoir and <sup>1</sup>D. De Clercq

<sup>2</sup>University of Antwerp (UA), Functional Morphology lab, Department of Biology, Belgium  
 veerle.segers@ugent.be

### INTRODUCTION

There are basically two forms of human locomotion, namely walking and running, kinematically distinguished from one to another by presence resp. absence of a double stance phase. When increasing resp. decreasing speed, a gait transition occurs at the point people intuitively feel that it is easier, more naturally to run resp. to walk even though it is possible to walk faster or run slower than the preferred transition speed. [1]. One of the most puzzling aspects of the transition-dilemma is to reveal the reason why gait transitions occur at that specific speed.

The purpose of the present study was to examine the role of the m. tibialis anterior -a possible trigger [2]- in a protocol with gradually changing speed before and after fatigue of the m. tibialis anterior. Our hypotheses are (1) that there is a relationship between the m. tibialis anterior and transition speed also in a protocol with gradually changing speed and (2) that within burst endurance rather than the strength is determinative for transition speed. Muscular fatigue of the dorsiflexors is therefore assumed to affect the transition speed.

### METHODS

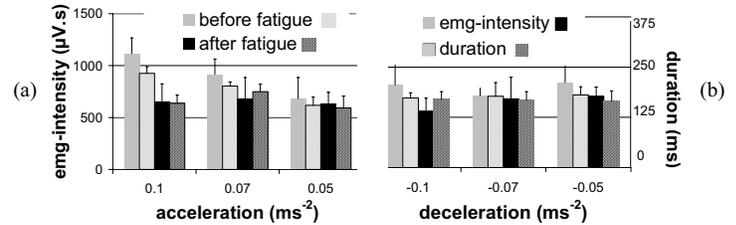

A group of 20 active female human subjects participated in the study after given informed consent. The WRT (walk-to-run transition) and RWT (run-to-walk transition) speed were determined on a treadmill in a protocol with gradually changing speed. The accelerations used in this research were 0.1 ms<sup>-2</sup>, 0.07 ms<sup>-2</sup>, 0.05m s<sup>-2</sup> for the WRT and -0.1 ms<sup>-2</sup>, -0.07 ms<sup>-2</sup> and -0.05m s<sup>-2</sup> for the RWT. WRT and RWT speed were determined using high speed video-images (200 Hz) before and after a fatigue protocol, in which the subjects performed submaximal dorsiflexions (ROM : 30°, ±75% 1RPM) until exhaustion was reached.

EMG of the m. tibialis anterior was obtained using bipolar electrodes and Daxon-software. The signal was rectified, filtered (bandpass 4-500 Hz) and integrated. EMG-intensity (integral) and duration of the first peak of the m. tibialis anterior (end swing- begin stance), being the most dominant activity in RWT and WRT, were calculated. A 2 (fatigue) x 3 (acceleration) ANOVA and with step number as factor and Post Hoc Tukey tests were used for WRT and RWT to find

**Table 1. Transition speed**

		Transition Speed (ms <sup>-1</sup> )

**Figure 1:** EMG-intensity and duration of energy burst of the m. tibialis anterior for the (a) WRT and (b) RWT

differences for transition speed, energy-intensity and duration of the burst of the m. tibialis anterior.

### RESULTS AND DISCUSSION

Transition speed is significantly changed after introducing muscular fatigue. After fatigue, WRT speeds are lower for all accelerations. RWT-speeds do not change, except for the intermediate deceleration (Table 1). The differential effect of fatigue of the m. tibialis anterior is in agreement with the findings of Prilutsky and Gregor [3]. They claim that WRT is triggered by the increased sense of effort due to the augmented activity in the muscles activated during swing (m. tibialis anterior, m. rectus femoris and hamstrings), and, on the other hand, that RWT would be triggered by the activity during stance (m. soleus, m. gastrocnemius and m. vastii). [3] Post hoc Tukey tests reveal that tibialis anterior EMG-intensity is higher in the steps around transition (step0) in both WRT and RWT. Therefore, EMG-intensity of the burst is averaged over 3 steps in the transition-zone (step-1 → step+1). In the WRT before fatigue EMG-intensity is higher, except for the lowest acceleration and duration is higher for the highest acceleration. In the RWT there is no significant effect, nor for duration nor for EMG-intensity. This might indicate that in the WRT the m. tibialis anterior is no longer capable of maintaining the desired muscle tension, a combination of both a loss in power and duration, resulting in a higher sense of effort [4] accompanied by a change in locomotion pattern[3].

### CONCLUSIONS

Walk-to-run transition speed is clearly affected by fatigue of the m. tibialis anterior. The increased sense of effort, due to the muscular fatigue, might explain this phenomenon. Further research is necessary since evolution of EMG-intensity on a step to step basis can provide meaningful information.

## A MULTIPLE MATERIAL PARAMETER FINITE ELEMENT MODEL OF HIP RESURFACING ARTHROPLASTY

<sup>1</sup>J P Little, <sup>2</sup>F Taddei M, <sup>2</sup>Viceconti and <sup>1</sup>H S Gill

<sup>1</sup>Oxford Orthopaedic Engineering Collaboration, University of Oxford, Oxford, UK,

<sup>2</sup>Instituti Ortopedici Rizzoli, Laboratorio di Tecnologia Medica, Bologna, Italy;

email: [paige.little@ndos.ox.ac.uk](mailto:paige.little@ndos.ox.ac.uk)

### INTRODUCTION

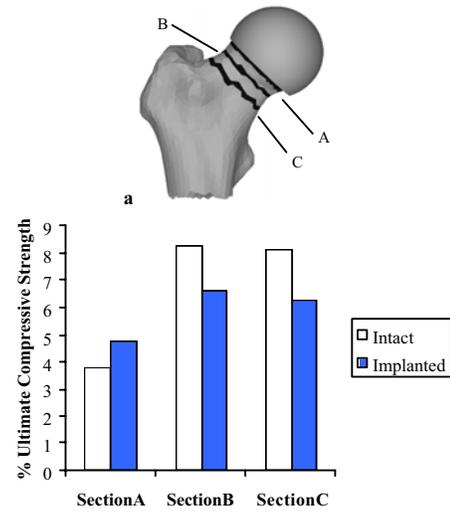

Hip resurfacing arthroplasty (HRA) is increasingly carried out as an alternative to total hip arthroplasty (THA) in young, active patients. The primary indication for this surgery is osteoarthritis. It is favoured over THA as it preserves bone stock and it is claimed not to cause stress shielding. However, fractures of the femoral neck result in short term failure of the procedure in approximately 2% of patients [1]. Previous finite element (FE) analyses have employed over-simplified material parameters to define the femoral bone and non-physiological loading conditions [2,3]. Furthermore, it is unclear from the literature whether the surface interaction between the implant and bone cement is a 'sticking/sliding' contact best represented using a Coulomb friction model or whether it is a 'glued' contact. In this study an experimentally validated FE model of a cadaveric femur pre- and post- HRA surgery was analysed to determine the change in mechanics. This model included physiological loading conditions and more accurate multiple material parameters represented nonhomogeneous bone distribution in the femur.

### METHODS

Material properties were assigned to the femoral bone using the data from a detailed CT of a cadaveric femur [4]. Intact and implanted FE models were validated using experimentally measured strains compared with model calculated strains. The surface interaction between the retro-surface of the implant and the underlying bone cement was represented using either a Coulomb friction model ( $\mu=0.3$ ) or as rigidly bonded ( $\mu=\infty$ ). A physiological load case representing the muscle and hip contact forces at an instant 10% through the level walking gait cycle was applied to the intact and implanted models. Von Mises stresses were compared in three cross-sections through the neck of the femur (Figure 1a) and in the femoral head. To determine the potential for femoral bone fracture under this physiological loading condition, a risk of fracture (RF) scalar was calculated as the ratio between the Von Mises stress and the ultimate strength of bone. A value greater than one indicated a potential failure.

### RESULTS AND DISCUSSION

It was found that the use of 381 separate material parameters to define the femoral bone was optimum. The correlation between the experimental and calculated strain values for the two material model had  $R^2=0.87$ , while in the model incorporating 381 materials  $R^2$  was 0.92. Von Mises stress in the femoral head was 0.8 to 3.2% higher when the implant and bone cement were rigidly bonded; however, Von Mises stress in the femoral neck was the same in both the implanted models. Therefore, only results for the Coulomb friction model are considered. For this physiological load case the

**Figure 1:** a. Cross-sections in the femoral neck; b. Peak Von Mises stress in femoral neck as a percentage of ultimate compressive strength

change in maximum Von Mises stress after resurfacing, expressed as a percentage of the reported ultimate compressive strength of cortical bone (193MPa) ranged from -1.8% to 1.0% (Figure 1b). Of the 47,984 elements in the implanted model, 72 had an RF value greater than 1. As these elements were remote from one another and it was unlikely that localized volumes of bone would be sites of fracture, the fracture risk post-HRA surgery was assessed to be low.

### CONCLUSIONS

A multiple material property model more closely simulates real bone mechanical properties than a 2 material model. This is the first fully validated FE model of a femur implanted with an HRA. These results indicate that the geometry and direction of loading on the implant result in implant-cement interface stresses that are transmitted to the underlying bone as if these two materials were rigidly bonded. Analysis of the intact and implanted FE models under physiological loading conditions appears to support the claims that HRA does not result in stress shielding in the femoral neck. Furthermore, the calculated bone stress in the femoral neck was not sufficient to be a potential cause of fracture.

## DYNAMIC LOWER LIMB ALIGNMENT AND KNEE JOINT LOAD DURING GAIT IN PATIENTS WITH KNEE OSTEOARTHRITIS

<sup>1</sup>Michael A. Hunt, <sup>1</sup>Trevor B. Birmingham, <sup>1</sup>Ian C. Jones, <sup>1</sup>J. Robert Giffin and <sup>1</sup>Thomas R. Jenkyn

 email: tjenkyn@eng.uwo.ca

### INTRODUCTION

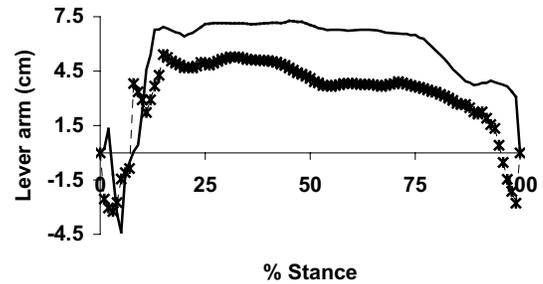

Factors suggested to be associated with the development and progression of osteoarthritis (OA) of the knee include lower limb malalignment and high dynamic knee joint loads. Due to the high, repetitive knee joint loads associated with walking, gait analysis has become an important tool in the evaluation of OA in patients. The peak external knee joint adduction moment (EKAM) has been the most commonly reported variable in the gait literature for patients with OA of the knee due to its hypothesized association with medial compartment knee joint load during walking [1]. The EKAM is calculated as the product of the frontal plane lever arm (FPLA) and the frontal plane ground reaction force (GRF). While numerous studies have reported GRF data, no previous studies have reported data pertaining to the FPLA in patients with OA. Since the FPLA can be thought of as a dynamic measure of alignment, it would be beneficial to understand how lower limb alignment contributes to knee joint load during gait. The purpose of the present study was to examine the inter- and intra-limb relationships between the peak EKAM, peak FPLA, and peak frontal plane GRF during gait in patients with knee OA.

### METHODS

Prior to medial opening wedge high tibial osteotomy, gait analyses were performed on 125 patients (98 males, 27 females; mean age = 46.8 +/- 10.5 yrs.) with knee joint OA primarily affecting the medial compartment. Patients walked across the laboratory at a self-selected velocity while three-dimensional kinetic and kinematic data were collected bilaterally. These data were combined to calculate the EKAM and the FPLA – defined as the perpendicular distance from the GRF to the knee joint centre of rotation (Figure 1). Inter-limb comparisons (operative vs. non-operative) were made among the peak values during stance for the following dependent variables: EKAM, FPLA, and frontal plane GRF. Pearson product moment correlations were computed to assess the magnitude of the intra-limb relationships between variables. Lastly, intra-limb comparisons were made regarding the time during stance (% stance) where the peak value of each variable occurred.

### RESULTS AND DISCUSSION

Compared to non-operative limbs, the peak EKAM and peak FPLA magnitudes were significantly greater in the operative limbs (Table 1). In contrast, peak frontal plane GRF magnitudes were significantly larger in the non-operative

**Figure 1:** Frontal plane lever arm values for a single patient during stance. Solid line indicates operative limb while dashed line indicates non-operative limb.

limbs. The peak EKAM was more highly correlated with the peak FPLA ( $r=0.77$ ) than the peak frontal plane GRF ( $r=0.18$ ). Within limbs, the positions during the gait cycle where the peak values occurred were significantly different among all variables (Table 1).

These results indicate that although the peak magnitude of the frontal plane GRF was greater in non-operative limbs, the peak magnitude of the EKAM was larger in operative limbs mainly due to an increased lever arm length. The increased dependency of the EKAM on the lever arm magnitude was further highlighted by a higher correlation with the FPLA than with the frontal plane GRF.

### CONCLUSIONS

Results from this study support the claim that knees affected with OA experience higher dynamic medial compartment knee joint loads during walking. However, this is the first study to report data pertaining to the FPLA during stance in this patient population. Given the hypothesized association between lower limb alignment and OA development and progression [2] and the finding of a high association between EKAM and FPLA peak magnitudes, the FPLA appears to be an important biomechanical measure of dynamic lower limb alignment in the study of knee joint OA.

## A THREE-DIMENSIONAL WHOLE-BODY WALKING MODEL BASED ONLY ON GAIT KINEMATICS

Lei Ren, Richard Jones and David Howard  
Centre for Rehabilitation and Human Performance Research, Salford University,  
Salford, United Kingdom; email: d.howard@salford.ac.uk

### INTRODUCTION

Biomechanical investigations of human movement often involve a simplified mechanical model of the human body, consisting of a collection of articulated rigid segments subject to external forces and moments. Many models only focus on a portion of the body, whereas whole body models have been used for activities involving both lower extremities and the upper body, such as balance control [1], weight lifting [2] and load carriage [3].

This paper presents a 3D whole body multi-segment model for gait analysis studies, where inverse dynamics analysis over a whole gait cycle is based only on kinematic data. It differs from the conventional application of inverse dynamics used in gait laboratory studies, where the calculations start from measured ground reactions. This is useful for test conditions where force plates are not suitable (e.g. outdoor gait trials or traversing obstacles). Whole body gait measurements using a multi-camera motion analysis system have been used to validate the model. The predicted ground reaction forces and moments on each foot were compared with force plate data.

### METHODS

The human body was modeled as a dynamic coupled multi-segment system, which includes 13 rigid body segments: the head, torso, pelvis, right and left forearms, right and left humeri, and both legs (thighs, shanks and feet). Anthropometric data for each body segment are based on de Leva [4], but modified for the forearm and torso due to the different definitions used. A set of bone-embedded local coordinate systems based on anatomical landmarks are defined for each body segment [5].

An inverse dynamics method is employed to calculate the joint kinetics during walking based only on segmental motions. From the sum of the translational equations of motion of all the body segments, the sum of the ground reaction forces (GRFs) can be derived. In single stance, the GRFs on the supporting foot can be obtained directly. For double support, a "Smooth Transition Assumption" (STA) is used to solve the indeterminacy problem. The ground reaction forces and moments acting on the trailing foot move smoothly towards zero by following simple mathematical functions. Thereby, the GRFs on each supporting foot can be calculated, and then the forces at each joint derived by applying inverse dynamics segment by segment.

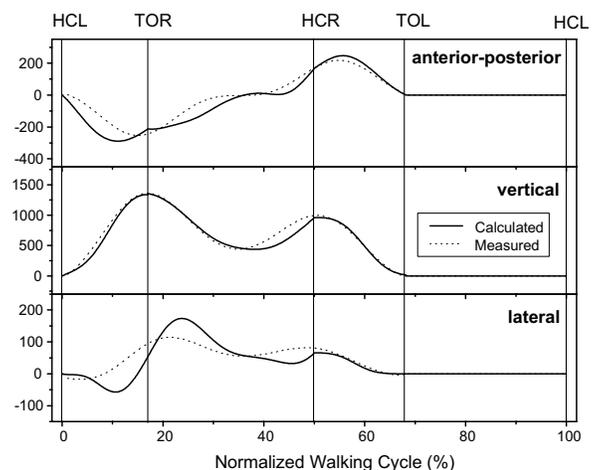

Similarly, from the sum of the rotational equations of motion of all the body segments, the sum of the ground reaction moments (GRMs) can be derived from the segmental motions and joint forces. Thereby, the GRMs on the supporting foot in single stance can be obtained directly. In double support, the STA assumption is used to calculate the GRMs on each foot.

Thereafter the net muscle moments at each joint can be calculated by applying inverse dynamics segment by segment.

Whole body gait measurements were conducted to validate the model [5], using a set of specially designed plastic plates carrying marker clusters and a set of calibration procedures based on the CAST technique. Four male subjects walked along a walkway at two speeds, normal and fast. The motion data was collected at 100 Hz using a 6-camera Qualisys motion analysis system. Two Kistler force plates were used to record ground reactions. The raw marker data was processed by a MATLAB software package SMAS (Salford Motion Analysis Software), which was developed for 3D kinematic and kinetic analysis of general multi-body systems. The processed segmental motion data were then input into the whole body model, which was validated by comparing the calculated GRFs and GRMs with measured data.

### RESULTS AND DISCUSSION

For all subjects, the calculated GRFs and GRMs at each foot were compared with force plate data. The results show that the calculated GRFs are in good agreement with the measured values. Figure 1 shows a typical result for one subject (38 yrs, 101.7 Kg). However, the estimated GRMs are larger than the measured data, and this problem needs further investigations.

**Figure 1:** Calculated and measured ground reaction forces on left foot over a whole gait cycle (walking velocity: 2.11 m/s)

## VARIABILITY OF GLENOHUMERAL EXTERNAL ROTATOR MUSCLE MOMENT ARMS

<sup>1</sup>Joseph E. Langenderfer, <sup>1</sup>Cameron Patthanacharoenphon, <sup>2</sup>James E. Carpenter, and <sup>1,2</sup>Richard E. Hughes

### INTRODUCTION

Glenohumeral rotator muscle moment arms have been determined in previous studies [1,2,3]. These studies did not examine the interaction between portions of the rotator cuff, or between sub-regions of cuff tendons. This study's purpose was to empirically determine rotation moment arms for sub-regions of supraspinatus, infraspinatus, and for teres minor. There were 2 hypotheses: 1) that muscles and their sub-regions possess differences in moment arm due to joint angle, and 2) that sub-regions of the cuff tendons increase their effective moment arms through connections to other sub-regions.

### METHODS

Data were collected from 10 normal cadaver specimens for supraspinatus (SSP), infraspinatus (INF), and teres minor (TM). SSP and INF were divided into 3 and 4 sub-regions, respectively. The change in tendon excursion relative to humeral head rotation was measured with a custom instrument. The instrument has demonstrated error less than 0.5 mm. Data were collected for the full range of external rotation at 10° and 60° abduction in the scapular plane. Two conditions were tested: 1) tendon divided just up to musculotendinous junction (intact cuff), and 2) tendon divided all the way to the insertion to bone (divided cuff). Three trials were recorded for each abduction angle - tendon condition combination. Polynomials were fit to the tendon excursion vs. rotation angle data. Moment arm was determined at one degree increments as the derivative of the tendon excursion versus joint angle relationship [4]. Moment arm data were analyzed with an ANOVA model.

### RESULTS AND DISCUSSION

Rotation moment arms were dependent upon abduction angle, rotation angle, cuff condition and muscle sub-region, and demonstrated significant inter-specimen variability (Figures 1&2) (Mean±S.D.). Moment arms for INF were significantly greater at 10° abduction ( $p<0.001$ ). Moment arms of SSP ( $p<0.05$ ) and teres minor ( $p<0.001$ ) were significantly greater at 60° abduction. Moment arms of sub-regions of INF ( $p<0.001$ ) and SSP ( $p<0.001$ ) were significantly different. Moment arms of INF ( $p<0.001$ ) and SSP ( $p<0.001$ ) were significantly greater with an intact rotator cuff. TM moment arm was not significantly affected by cuff condition ( $p=0.46$ ).

### CONCLUSIONS

Moment arm differences between muscle sub-regions and for different cuff conditions have possible clinical implications. At neutral rotation the SSP has a very small rotation moment arm suggesting it contributes little to external rotation strength. Some loss of strength seen clinically with isolated SSP tears is likely due to muscle inhibition or pain.

Additionally, the results of interaction between cuff regions have potential for explaining why some subjects retain strength after small cuff tear. This finding also helps explain why a partial cuff repair may be beneficial when a complete repair is not possible. Such data can help differentiate between cuff tear cases which would benefit from cuff repair and cases for which cuff repair might not be as favorable.

## VARIABILITY IN ISOMETRIC FORCE AND TORQUE GENERATING CAPACITY OF GLENOHUMERAL EXTERNAL ROTATOR MUSCLES

<sup>1</sup>Joseph E. Langenderfer, <sup>1</sup>Cameron Patthanacharoenphon, <sup>2</sup>James E. Carpenter, and <sup>1,2</sup>Richard E. Hughes

### INTRODUCTION

Glenohumeral external rotator muscles possess varying ability for generating forces and torques due to differences in muscle architecture, moment arm, and the interaction of these two factors. Previous authors have measured muscle architecture [1], and moment arms [2,3] at the shoulder. Due to parameter covariance, it is advantageous to utilize parameters from a unique dataset rather than from disparate sources. This study's purpose was to determine a complete dataset of parameters for predicting the length-tension (L-T) dependence and torque generating capacity of infraspinatus, supraspinatus and teres minor for shoulder external rotation.

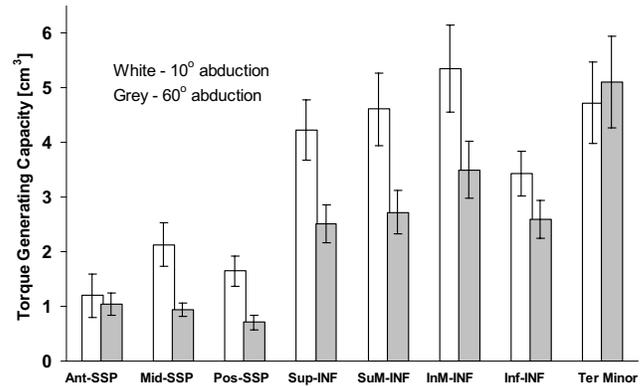

### METHODS

Data were collected from 10 normal cadaver specimens for supraspinatus (SSP), infraspinatus (INF), and teres minor (TM) muscles. SSP and INF were divided into 3 and 4 sub-regions respectively. Muscle-tendon units were dissected from the specimens. Tendon length, muscle belly length and muscle fascicle length were measured with a digital caliper. Muscle volume was measured via water immersion. Pennation angle was measured with a goniometer. After muscle fixation, fascicles were dissected and sarcomere lengths measured via laser diffraction. Tendon area, PCSA, optimal muscle length and optimal fascicle length were determined from empirical data. Tendon excursion relative to humeral head rotation was measured with a custom instrument from 45° internal to 45° external rotation with the humerus at 10° abduction. Muscle moment arms were determined as the derivative of tendon excursion versus rotation angle [4]. Inelastic tendon was assumed, and fascicle excursion as a function of joint angle was calculated from tendon excursion and pennation angle. Rigor was assumed to develop with the humerus in neutral rotation and abduction. Length-tension relationships were determined by normalizing fascicle excursion to optimal fascicle length [5]. Maximum isometric rotation torque generating capacity was estimated as the product of PCSA, maximum moment arm, and cosine of pennation angle, at 10° and 60° abduction. ANOVA models were used to determine if muscle sub-regions were operating on different portions of the length-tension relationship, and to test the effect of abduction angle, cuff condition and muscle sub-region on maximum torque capacity.

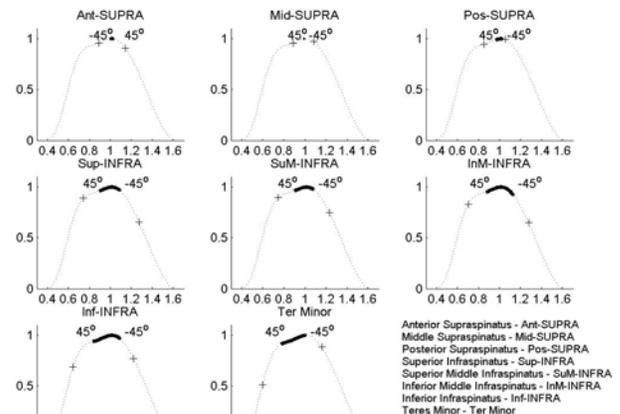

### RESULTS AND DISCUSSION

The muscles demonstrated differences in their maximum isometric torque capacities (Figure 1), and length tension relationships (Figure 2). Abduction angle ( $p < 0.001$ ) and muscle sub-region ( $p < 0.01$ ) had a significant effect on maximum isometric torque capacity. Cuff condition did not have a significant effect on maximum torque capacity. Sub-regions of INF were operating on different portions of the L-T

relationship ( $p < 0.001$ ), but SSP was operating over the same L-T region ( $p = 0.49$ ).

**Figure 1:** Maximum isometric rotation torque generating capacity (mean±standard error).

**Figure 2:** Normalized force versus normalized fascicle length. (Mean (+) S.D.) [5].

### CONCLUSIONS

Functional capabilities of these muscles depend on muscle architecture and moment arm and their combined effects. Significant variability was detected between specimens. Parameter covariance can be determined from this unique dataset and is important for probabilistic modeling.

## TRUNK MUSCLE ACTIVATION PATTERNS COMPARING CABLE PRESS AND BODY-BLADE® EXERCISES

Janice M. Flynn, Francisco J. Vera-Garcia, Stephen H.M. Brown, Stuart M. McGill  
 Spine Biomechanics Laboratory, Department of Kinesiology, University of Waterloo, Canada  
 Email: jflynn@uwaterloo.ca

### INTRODUCTION

Rehabilitation professionals often rely on intuition and subjective observation to choose treatment techniques. Our objective is to provide some quantitative information to assist decision-making. The Body-blade®, a 122 cm, .68 kg flexible rod with a resonance frequency of 4.5 Hz. is frequently used for recruiting the stabilizing muscles of the trunk and shoulder girdle, yet no in-depth analysis has been undertaken to justify this treatment choice. The purpose of this study was to compare the electromyographic (EMG) amplitudes and recruitment patterns of the trunk muscles during simple cable presses and compare them with various exercises using the Body-blade®.

### METHODS

Fourteen recreationally trained men (age =  $28.14 \pm 8.33$  yr, height =  $1.78 \pm 0.05$  m, mass =  $77.78 \pm 10.41$  kg) were recruited from the university population. All subjects were right-handed and healthy, without current back or shoulder pain. Superficial EMG was measured of the right anterior deltoid (AD) and pectoralis major (PM), bilateral rectus abdominis (RA), external oblique (EO), internal oblique (IO), latissimus dorsi (LD), and erector spinae at 3 levels (EST9, ESL3, ESL5), while subjects performed standing cable press and Body-blade® exercises.

The EMG was A/D converted at 12 bit resolution at 1024Hz. Signals were full wave rectified and low pass filtered (single pass Butterworth) at 2.5 Hz, and then normalized to maximal voluntary contraction (MVC) amplitudes. The normalized muscle activity corresponding to a 2-second window of coordinated Body-blade® or cable press use was then averaged over the 14 subjects for each exercise.

### RESULTS AND DISCUSSION

Cable presses resulted in high levels of EMG activation in the shoulder muscles, followed by the left IO and LD. Large amplitude Body-blade® oscillations, with the blade in a vertical orientation and oscillations in a medial/lateral direction, produced large increases bilaterally in the IO amplitude, as well as moderate bilateral EO activity. When oriented horizontally (vertical oscillations), the highest muscle activity was seen in the back muscles: LD and UES, as well as RAD (Figure 1).

Vertical orientation of the Body-blade® resulted in the greatest activation levels of the IO (avg 48% MVC bilaterally) and EO (avg 26% MVC) muscles, thought to be critical contributors to lumbar spine stability [1]. Previous research has demonstrated that IO surface electrodes adequately represent Transverse Abdominis (TA) activation within 15% RMS difference [2], suggesting that TA is equally trained with this exercise.

Horizontal orientation of the blade resulted in very little EO or IO activity.

### CONCLUSIONS

The Body-blade® is a superior exercise modality for recruitment of the IO and EO muscles, when used in a vertical orientation. As such, it could be a valuable asset to exercise programs aimed at optimizing muscle recruitment patterns, which are known to stabilize and support the lumbar spine.

## EFFECT OF RECOVERY RESTRICTIONS ON THE THRESHOLD OF BALANCE RECOVERY PRELIMINARY RESULTS

Marc-André Cyr, Kodjo E Moglo and Cécile Smeesters

Research Center on Aging, Sherbrooke Geriatric University Institute, Sherbrooke, QC, Canada

Department of Mechanical Engineering, Université de Sherbrooke, Sherbrooke, QC, Canada

email: [Cecile.Smeesters@USherbrooke.ca](mailto:Cecile.Smeesters@USherbrooke.ca)

web: [www.cdvr.ca](http://www.cdvr.ca)

### INTRODUCTION

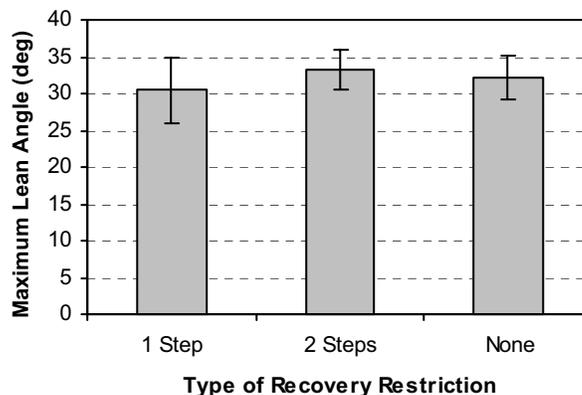

It is only recently that studies have focused on postural perturbations at the threshold of balance recovery, i.e., postural perturbations large enough that balance recovery is not always possible and a fall can occur. The knowledge at the threshold of balance recovery is thus very limited. In particular, the effect of recovery restrictions on the threshold of balance recovery has not been quantified, despite evidence of its importance during small and medium postural perturbations [1-4]. Therefore, the purpose of this study is to quantify the effect of recovery restrictions on the threshold of balance recovery.

### METHODS

Balance recovery following sudden release from an initial forward lean was performed by six healthy younger adults, three males and three females ( $23.3 \pm 2.3$  yrs,  $1.74 \pm 0.07$  m,  $67.1 \pm 11.5$  kg). The maximum forward lean angle that these younger adults could be released from and still recover balance was determined using i) only a single step, ii) no more than 2 steps and iii) no recovery restriction. The forward lean angle was sequentially increased until the subjects failed to recover balance twice at a given angle and the types of recovery restrictions were randomly ordered. Forward lean angles, reaction times, weight transfer times, first step times, first step lengths and first step velocities were measured using force platforms (AMTI, Newton, MA) and an Optotrak motion measurement system (NDI, Waterloo, ON). One-way analyses of variance with repeated measures were used to determine the effect of the type of recovery restriction.

### RESULTS AND DISCUSSION

The type of recovery restriction did not significantly affect maximum forward lean angles that younger adults could be released from and still recover balance (Figure 1 and Table 1). Moreover, at the maximum forward lean angles, the type of recovery restriction did not significantly affect reaction times, weight transfer times, first step times and first step velocities (Table 1). However, at the maximum forward lean angles, the type of recovery restriction significantly affected first step lengths (Table 1). Specifically, first step lengths using only a single step were significantly longer than those using no more than 2 steps ( $p = 0.008$ ).

**Figure 1:** Effect of the type of recovery restriction on the maximum forward lean angle that younger adults could be released from and still recover balance ( $p = 0.156$ ).

### CONCLUSIONS

Preliminary results have shown that, despite possibly lengthening the first step, restricting balance recovery to only a single step does not significantly decrease the postural disturbance younger adults could sustain. Therefore, recovery restrictions do not seem to affect the threshold of balance recovery. Further experiments are needed to confirm these preliminary results in a larger sample of younger adults and, more importantly, in a sample of older adults.

### INTRODUCTION

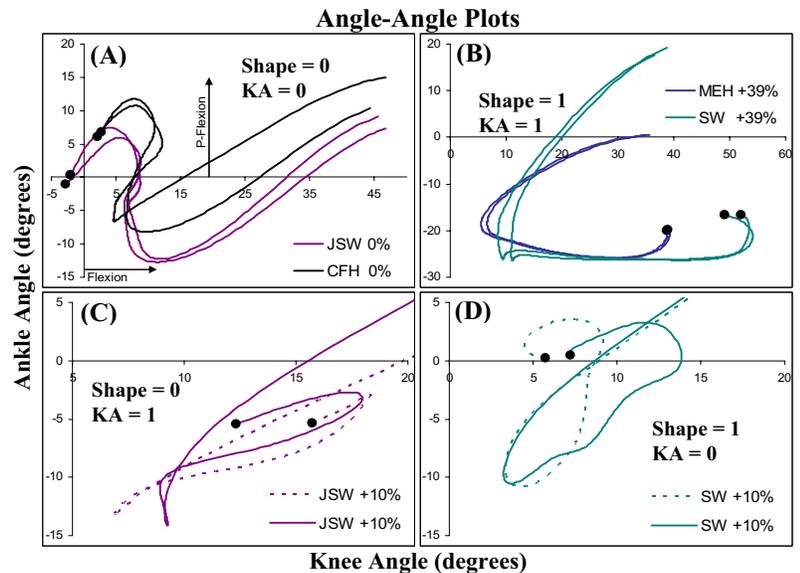

Investigations of slope walking in quadrupeds have revealed motor programs (control strategies) for up and downslope walking different from that for level walking [1]. Similar results would be expected in humans during slope walking based on the changes in biomechanics and muscle activity [2; 3]. One interesting question that then follows is at what grade does the nervous system switch from the level walking strategy to the slope walking strategy? For the first step of upslope walking, a transition grade has been suggested to exist between 6° and 9° (11% and 16%) [4]. Although the question of transition grades has not been addressed in detail for slope walking, it has been studied for the similar task of stepping on a wedge [5]. Based on kinematic and EMG patterns, the authors identified two distinct control strategies, with a transition grade at 15° (27%) [5]. The goal of this study was to investigate kinematic patterns during upslope walking in order to identify common control strategies, and potentially identify a transition grade between control strategies.

### METHODS

Five healthy volunteers (4M, 1F, mean age = 28 yrs) gave their informed consent and then were fitted with fifteen retroreflective markers (Helen Hayes system) and walked at five different grades (0%, +10%, +15%, +25%, +39%) on a modified LifeFitness treadmill. Each participant selected a comfortable pace at +39% and maintained this speed for all trials. After participants adjusted to each condition data were collected for two 10 second trials. Kinematic data were captured at 60 Hz using a six camera Peak 3D Optical Capture system and were exported to in-house software to calculate joint angles. Joint angle data from each leg (L and R) were normalized to 300 points for every stride (200 stance, 100 swing) and then ensemble averaged across all strides for each trial. Ankle-knee angle-angle plots of the stance phase were used to classify the control strategies [5]. Each plot was given a shape score (s-shaped = 0, c-shaped = 1) and a knee angle (KA) score for the value of the knee angle during mid to late stance at the same ankle angle as at heel strike (HS) (larger angle than at HS = 0, smaller angle than at HS = 1). The sum of the two scores was used to classify each plot.

### RESULTS AND DISCUSSION

Sample ankle-knee angle-angle plots and their scores are presented in Figure 1. Because of the similarity between the three highest grades, only data from +39% is shown (Fig 1B). All 0% plots (n=18) received a cumulative score of 0 (Fig 1A), and all +15%, +25%, and +39% plots (n=20 for each) received a total score of 2. These findings suggest that a different control strategy is being used for the steeper grades than for level [5]. In contrast, the 10% (n=18) plots received

**Figure 1:** Representative angle-angle plots for stance (● = HS). Knee flexion and ankle p-flexion are indicated in (A). The scales of (C) and (D) are expanded to show the shapes.

mixed scores: 4 received a total score of 0, 9 received a total score of 1 (Fig 1C and 1D), and 5 received a cumulative 2. A cumulative score of 1 indicates a mixed control strategy, and therefore a possible transition grade. The four plots that received a total score of 0 were from one subject (2L and 2R), who used only the level walking form. Another subject used only the mixed strategy shown in Fig 1C, and the remaining three subjects used both pure and mixed strategies. These data suggest the presence of a 10% transition grade for upslope walking. This transition grade is lower than that observed during wedge stepping (27%) [5] and than that predicted for the first step of upslope walking (11-16%) [4]. It is possible that the level walking strategy may be sufficient for a single step on a grade above 10%, but inadequate when sustained walking is required. In light of these findings we expect that for grades of less than 10% the level walking control strategy will prevail. Exploration of this idea, as well as its extension to downslope walking, warrants future research.

## ANALYSIS OF INTER-SEGMENT SPINE KINEMATICS DURING TRUNK MOTION

JoAnne Resig, Sam Augsburger, Hank White, Donna Oeffinger, Chester Tylkowski  
Shriners Hospitals for Children, Lexington, KY.  
Email: saugsburger@shrinenet.org

### INTRODUCTION

The purpose of this study is to develop a technique that models the spine as a multi-segment system and determines kinematic patterns in multiple planes. Past studies have used motion analysis systems to examine the lumbar spine with respect to the pelvis [1,2,3] and total spinal segment range of motion in scoliosis [4,5]. However, these studies did not report kinematics of the spine segments while moving in all three planes. The method described here has the potential to document changes in dynamic spine motions following therapeutic interventions for spinal pathologies.

### METHODS

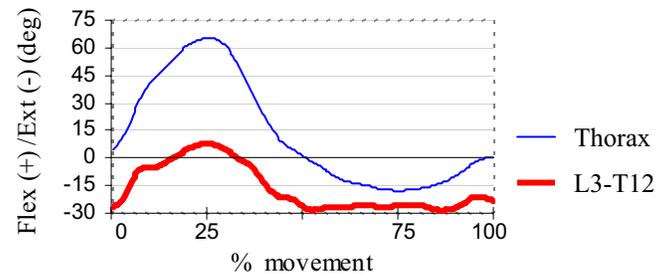

Eight reflective skin markers were placed over the following anatomical landmarks: sternum, the spinous processes of 3 thoracic vertebrae (T1, T8, T12), 1 lumbar vertebra (L3), sacrum (Vs), and both anterior superior iliac spines (L.ASIS, R.ASIS). Each participant performed four trunk motion tasks while standing: flexion/extension, lateral bending, axial twist, and a cone (moving trunk through a continuous maximum circular motion, starting with flexion, then lateral bending, extension, opposite lateral bending, and ending with flexion). Using custom software, seven segments were created for analyses of the trunk motions: thorax (T1, T8, Sternum), pelvis (L.ASIS, R.ASIS, Vs), total spine (Vs-T1), and 4 spine segments: (Vs-L3), (L3-T12), (T12-T8), and (T8-T1).

For the first three movement tasks, a transformation matrix was determined from the pelvis coordinate system. Spine segment angles were calculated in the frontal and sagittal planes based on the pelvis coordinate system. Inter-segmental angles were calculated between adjacent spine segments and angular data were normalized based on the position of the T1 marker at four events within each motion: 0% = onset of motion; 25% = change in direction of motion (i.e. end flexion); 75% = change in opposite direction of motion (i.e. end extension); and 100% = end of motion.

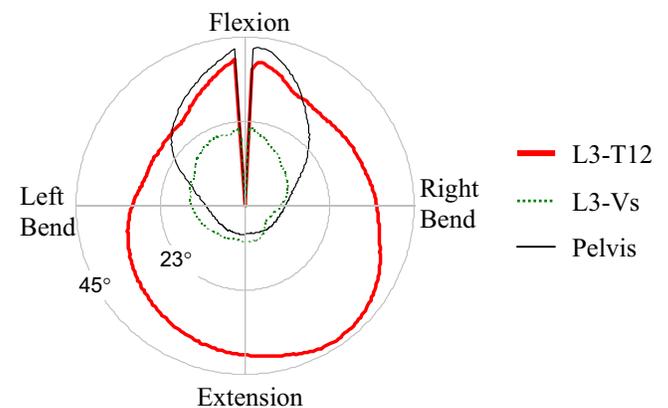

For the multi-planar cone motion, segment angles (Z-angles) were found with respect to the vertical axis, which was defined by the pelvis coordinate system. Data were normalized based on the angular location of the T1-Vs segment as a 360° arc was created in space during the motion.

### RESULTS AND DISCUSSION

Figure 1 shows sagittal plane flexion/extension angles for one person. Motion of the L3-T12 segment with respect to the Vs-L3 segment contributed to over half of the thorax flexion motion, but this segment had little contribution in extension. For this person, minimal motion occurred in the frontal plane during flexion/extension (data not shown). Figure 2 shows the Z-angle of the pelvis with respect to the room and the lumbar segments with respect to the pelvis. Circular gridlines

**Figure 1:** Sagittal plane angles for the Thorax segment with respect to Pelvis and the L3-T12 segment with respect to Vs-L3 during trunk flexion-extension (mean of 3 trials).

**Figure 2:** Z-angles during cone movement for the Pelvis with respect to room vertical and L3-Vs and L3-T12 segments with respect to Pelvis vertical (mean of 3 trials).

represent the angular value. For this participant, flexion at the beginning of the cone movement occurred almost equally with tilting of the pelvis and bending of the L3-T12 segment. However, as the person rotated the trunk towards the right and extension, most of the motion of the trunk occurred in the lumbar region with the L3-T12 segment.

### CONCLUSIONS

One advantage of this technique is that the contributions of different spine segments to total motion are quantified. Trunk motion can be compared within a subject or between subjects to determine differences in flexibility at certain spinal segments. Limitations of the model include marker obstruction and/or coalescence during extreme motions and skin motion artifact. A database for comparison of normal and pathological spine kinematics is under development.

## CO-CONTRACTION IN ACL DEFICIENT SUBJECTS

<sup>1</sup>Sietske Aalbersberg, <sup>1</sup>Idsart Kingma, <sup>2</sup>Leendert Blankevoort and <sup>1</sup>Jaap H. van Dieën

Institute for Fundamental and Clinical Human Movement Sciences; <sup>1</sup>Vrije Universiteit Amsterdam;

<sup>2</sup>Academic Medical Center, University of Amsterdam, Amsterdam, the Netherlands; email: [s.aalbersberg@fbw.vu.nl](mailto:s.aalbersberg@fbw.vu.nl)

### INTRODUCTION

Co-contraction of the Hamstrings muscles is proposed in the literature as one of the strategies that anterior cruciate ligament deficient (ACL D) subjects can use to compensate the loss of ACL function. This study examined the response of ACL D and control subjects to shear forces in isometric knee extensions.

### METHODS

Twelve chronic ACL D and 10 control subjects performed submaximal isometric knee extensions. The task was a positioning task with knee flexion target angles ranging from 5° to 45° with two external flexion moments both applied at two distances on the lower leg in a custom made chair (Figure 1). The shear force was controlled by changing the moment arm without changing the moment. A more proximal placement of a resistance pad will decrease the tibiofemoral displacement [1] and will thus lead to less force on the ACL [2]. Subjects received real-time position feedback about their knee joint angle (Optotrak). The subject was asked to extend the knee to one of the six target angle and hold it there for 5 seconds. Electromyographic data were collected from three Quadriceps and three Hamstring muscles. All EMG signals were normalized to the average EMG during a reference positioning task (30 Nm extension moment for extensors and 25 Nm flexion moment for flexors).

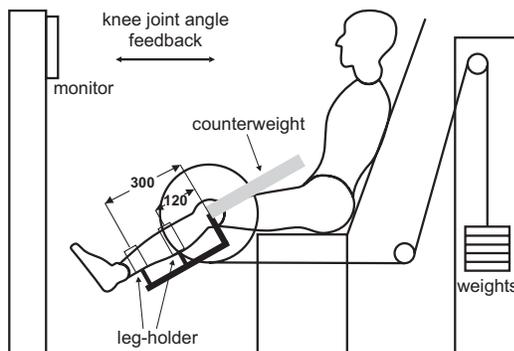

Figure 1: Experimental set-up

### RESULTS AND DISCUSSION

The EMG of four muscles during positioning tasks is shown in Figure 2. In the analysis of variance, no significant effect of subject group was found in positioning across all muscles ( $p$ -values > 0.2). There was a significant interaction between knee angle and subject group for the Biceps Femoris, but this effect was very small and will not have a great impact on the resulting shear forces.

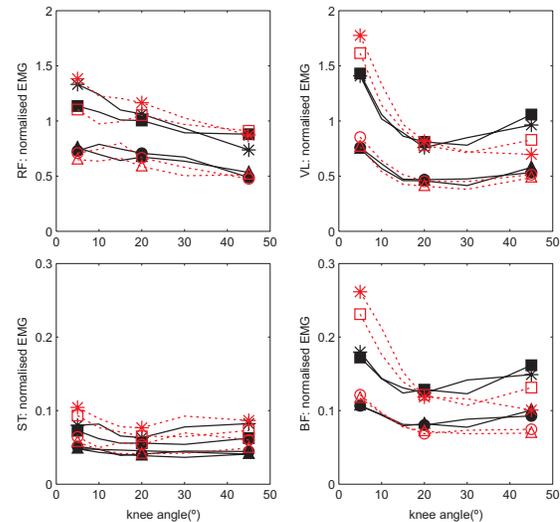

Figure 2: Normalized EMG of four muscles during positioning tasks for control (dashed red line) and ACLD group (solid black line). \* = 30 Nm at 120 mm, □/■ = 30 Nm at 300 mm, ○/● = 15 Nm at 120 mm, ▲/△ = 15 Nm at 300 mm, RF = Rectus Femoris, VL = Vastus Lateralis, ST = Semitendinosus, BF = Biceps Femoris.

Interestingly, neither moment arm nor moment arm x knee angle interacted with subject group, indicating a comparable strategy between the control group and the ACLD group in response to shear force challenges to the knee joint.

### CONCLUSIONS

The hypothesis that ACLD subjects increase co-contraction in situations with an increased shear load in sub-maximal isometric knee extensions was rejected.

**PREVALENCE OF BACK PAIN IN SEVEN SPORTS BASED ON SELF-REPORTING  
 BY A SAMPLE OF 2268, 8-to-18 YEAR OLD ADOLESCENT ATHLETES**

Paul J. Moga

College of Osteopathic Medicine, Michigan State University,  
 East Lansing, MI U.S.A. email: [moga@msu.edu](mailto:moga@msu.edu)

**INTRODUCTION**

Pediatric back pain is an important problem for at least two reasons. First, it may restrict activity [e.g. 1]. Second, it has been associated with back pain later in life [e.g. 2]. This study is aimed at identifying back pain prevalence in youngsters, both by gender and by sport. This information may be helpful in the development of preventative measures.

**METHODS**

Data from the study of Wojtys, et al. [3] were used for this post-hoc analysis. That study was originally designed to investigate the relation between athletic training and thoracic kyphosis angle. Part of the original data were collected using written survey instruments that were completed by each of the nearly 2300 adolescent athlete participants.

The original survey instruments included questions regarding general health and injury history, sport participation, and the presence of back pain. Those subjects who experienced back pain were asked to identify which area of the spine was involved: cervical, cervico-thoracic, thoracic, thoracolumbar, or lumbar, or combinations thereof.

Back pain prevalence was then calculated with subjects divided by gender and by primary sport. The primary sports of volleyball, wrestling, swimming, football, gymnastics, and ice hockey were grouped according to the gender predominance of the participants.

**RESULTS AND DISCUSSION**

There were 2268 respondents to the backache question--406 females [mean age 13.8 (± 2.3) years] and 1862 males [mean age 14.8 (± 2.0) years]. The overall prevalence of pain in one or more spine areas was about the same for both genders (females: 27.3%; males: 27.9%).

Table 1 lists back pain prevalence by spine region for each of seven sports. Of these sports, only male athletes reported having cervical pain (<1.5%), while more female swimmers reported cervicothoracic pain (1.8%). Male ice hockey players reported having the most thoracic pain (2.7%). Thoracolumbar pain had a prevalence of at least twice that of thoracic pain in female volleyball players (5.8%), male swimmers (5.7%), and male ice hockey players (5.3%). Finally, the prevalence of lumbar pain was the largest for each sport, most notably in female gymnasts (about 37%) and male football players (about 29%).

**CONCLUSIONS**

Of five spine regions, lumbar pain was the most prevalent, as reported by our sample of 2268 adolescent athletes, ages 8 to 18 years. This finding holds true for participants of female volleyball, swimming, and gymnastics, as well as male wrestling, swimming, football, and ice hockey. These findings should be considered by those involved in designing training programs for adolescent athletes.

## OPTIMAL EXTRA WEIGHT ON HANDS ENHANCE STANDING JUMP PERFORMANCE

Chenfu Huang, Hung-ying Chen and Hsiente Peng  
 National Taiwan Normal University, Taipei, Taiwan; [email:t08001@cc.ntnu.edu.tw](mailto:t08001@cc.ntnu.edu.tw)

### INTRODUCTION

Standing long jump is one of events in ancient Olympic game and in the eighteenth ancient Olympiad in 708BC; extra weights (halteres) were used either to make the challenge more difficult or to enhance the jumping performance. Minetti et al. [1] used computer simulation to determine the optimal extra weights that would be needed to maximally increase a jumping distance. They suggested that the extra mass 2-9 kg would increase a 3-meter jump by at least 17 cm. However, they only asked subjects to perform the vertical jump with halteres instead of standing long jump. Huang et al [2] suggested optional extra weight for extending distance is 6-12% of body mass. However, their subjects dropped the extra weights in the air which may gain more distance during jumping. The purpose of this study was to investigate the effect of different levels of extra weights on standing long jump performance.

### METHODS

Twelve male athletes (age  $21.8 \pm 1.7$ yr, height  $175 \pm 5$ cm, body mass  $67.8 \pm 12.0$ kg) served as subjects for this study. Each subject performed maximal standing long jump while loaded with one pair of handbell that ranged from zero (unloaded) to 10 kg of total extra weights. The extra weights were defined as four loading levels: zero, low (2kg or 4kg), middle (6kg or 8 kg), and high weight (10kg). Each subject was randomly assigned one weight on both low and middle levels. Each subject performed two trials for each level. Four best jumps from each subject (one unloaded and three loaded trials) were selected for analysis. A Redlake camera (125Hz) was synchronized with a Kistler force platform (9287B, 1250Hz) to collect standing jump data. Nine body landmarks (ear, shoulder, elbow, wrist, hip, knee, ankle, toe and heel) were digitized by Kwon 3D software. Dempster's study [3] was used to calculate body segment parameters.

### RESULTS AND DISCUSSION

Figure 1 shows the effect of different extra weights on jumping distance. Average values of the best jumps for each loads (handbell weight / BW) are shown as a fraction of the

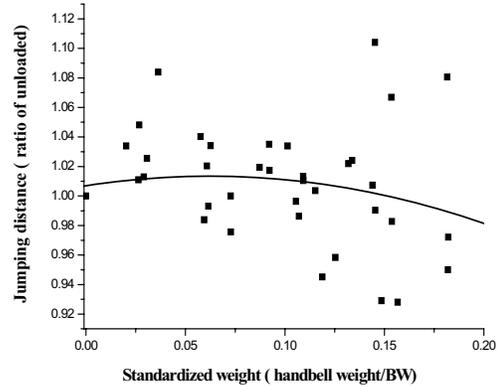

Figure 1: Effect of different weights on jumping performance.

value for an unload jump. Curve is best-fit by using second-degree polynomial regression. For the average mass of subjects in this study, the optimal extra weight for enhancing performance is 4.24 kg or 6.25% of body mass. The results of selected variables were listed in Table 1. The vertical velocity of body CG and body CG angle at takeoff were reduced as extra weights increased during the jumps. The results showed a longer time to peak horizontal force (T max) and a greater horizontal impulse (H Impulse) as extra weights increased. In addition, the peak vertical power (Max  $V_p$ ) decreased as extra weights increased. Minetti suggested that 5-6 kg of extra weight is optimal for extending jumping distance. This study indicated that 4.24 kg or 6.25% BW of extra weight is optimal for extending jumping distance.

## COMPARISON OF UPPER LIMB KINEMATICS COLLECTED BY ELECTROMAGNETIC TRACKING VERSUS DIGITAL CAMERA SYSTEMS IN A GAIT ANALYSIS LAB

<sup>1,2</sup> Elizabeth Hassan, <sup>1,2</sup> Thomas Jenkyn, PhD, PEng and <sup>1</sup> Cynthia E. Dunning, PhD, PEng

<sup>1</sup>Department of Mechanical and Materials Engineering, University of Western Ontario, London Ontario, Canada,

<sup>2</sup>Wolf Orthopaedic Biomechanics Lab, Fowler-Kennedy Sports Medicine Clinic, London, Ontario, Canada

### INTRODUCTION

The purpose of this study is to dynamically quantify the accuracy of kinematics measured by an electromagnetic tracking device compared to a digital optical motion analysis system for applications in the upper limb. Unlike lower limb motion, there is currently no standardized marker set for collecting upper limb kinematic data. [1] Complicating upper limb kinematic are joint motion pathways with fewer biomechanical constraints, smaller segments, and larger skin movement errors. These factors make collecting accurate and reliable in vivo data of the upper limb difficult. [2] However, innovations in motion analysis technology combined with optimized marker set design and placement could allow investigators to study upper limb kinematics in a gait analysis lab as an alternative to electromagnetic tracking systems.

### METHODS

All of experiments were performed in the Wolf Orthopaedic Biomechanics Lab (WOBL) at the University of Western Ontario, which is equipped with an 8 camera Eagle Digital Motion Capture System (Motion Analysis Corp., Santa Monica, CA, USA). Rigid clusters of spherical reflective markers and electromagnetic sensors were attached to a mechanical articulator that mimicked elbow motion (Fig. 1).[3] Kinematic data were collected simultaneously using the camera system and an electromagnetic tracking system (Flock of Birds, Ascension Technologies, Burlington VT, USA) while the mechanical 'elbow' was moved through known ranges of flexion (i.e. 1, 2, 3, 5, 20, 110°), with and without coupled varus-valgus and/or internal-external rotations.

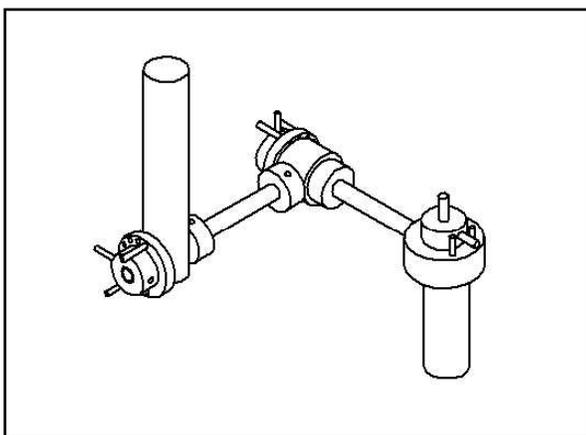

Figure 1 – Mechanical Articulator

### RESULTS AND DISCUSSION

Compared to the known magnitudes, both the electromagnetic system and the optical system tended to overestimate the motion with mean differences of 0.96° and 3.28°, respectively (confidence intervals from 0.67°-1.24° and 2.55°- 4.06°, respectively). Two-way ANOVA analysis showed that for large (110°) flexion arcs, there is no effect of adding coupled motions ( $p=0.53$ ) and no significant difference between systems ( $p=0.09$ ). Both systems are able to accurately describe upper limb motion (Fig. 2), although they tended to overestimate the magnitude of the motion. This appeared to be more pronounced for the optical system, but optimization of the marker cluster design may improve these results.

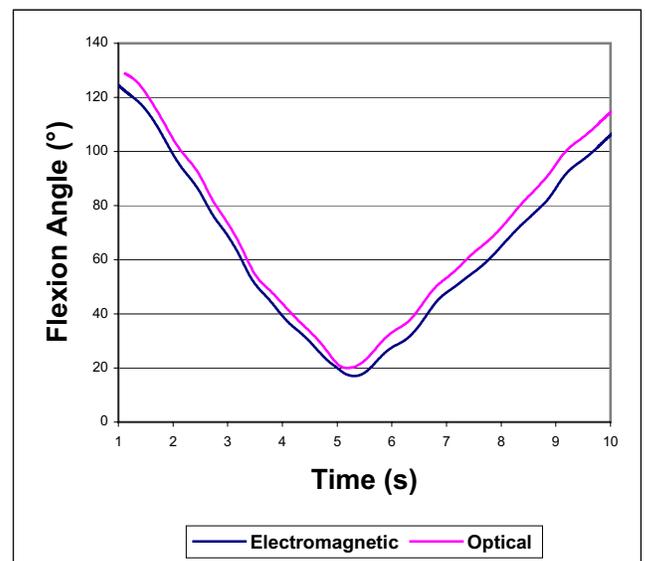

Figure2 – Reported Flexion Angle for Both Systems as a Function of Time.

### INTRODUCTION

Foot pressure data is frequently collected during gait analysis. Analysis of this data is typically done by dividing the foot pressure into regions with a mask that is not customized to the shape of the individual foot. Previous studies have successfully used these generic foot masks to evaluate varus and valgus foot deformities [1]. The effect of posterior tibialis [2] and anterior tibialis [3] dysfunction on foot pressure data has also been examined in vitro. This study examined average peak foot pressure on patients with a strength imbalance between a major evertor and invertor of the foot.

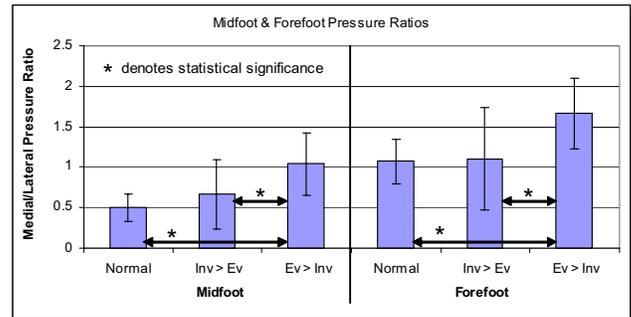

### METHODS

Five able-bodied subjects (ten limbs; mean age = 11.8 yrs) and 15 patients with a mean age of 10.5 yrs (12 cerebral palsy, 1 pdd, 1 lipoma, and 1 clubfoot) were included. The same physical therapist measured all patients' muscle strengths. A minimum difference in muscle strength grade of 1 (on the 0 to 5 scale) between the peroneus brevis (evertor) and the posterior tibialis (invertor) was observed for inclusion. The patients were divided into 2 groups. Group 1 (n=7 limbs) showed greater posterior tibialis strength. Group 2 (n=10 limbs) showed greater peroneus brevis strength.

**Figure 1:** Foot pressure overlay with plantar surface picture

Barefoot pedobarograph data was collected for all subjects using a Tekscan, Inc. FMAT pressure mat. A static photo of the plantar surface of the foot was taken for each subject while in bilateral self selected weight bearing. The peak foot pressure data was overlaid on the static image of each patient's foot as seen in Figure 1. This facilitated a more thorough evaluation by displaying the peak pressure relative to the individual shape, size and anatomical landmarks of the foot. Simultaneous gait analysis data was collected on select subjects (as needed) to verify that the foot progression angle of the image matched the foot progression angle of the foot pressure. The long axis of the foot, from the center of the heel to the 2<sup>nd</sup> interspace was rotated to vertical and used to create the medial/lateral division. The foot was then divided at 32.9% and 62.3% of the overall foot length from the posterior aspect to give the midfoot and forefoot sections. The four regions evaluated were the medial midfoot, medial forefoot, lateral midfoot, and lateral forefoot. The average (over the area) peak pressure of each region was normalized to the maximum peak pressure of the entire foot. The ratio of

**Figure 2:** Medial/lateral pressure ratios for the midfoot and forefoot.

medial to lateral average peak pressure was examined for the midfoot and for the forefoot.

### RESULTS AND DISCUSSION

Group 1 (Inv. > Ev.) showed an average posterior tibialis strength of 3+/- and an average peroneus brevis strength of 2+. Group 2 (Ev. > Inv.) showed an average peroneus brevis strength of 3 and an average posterior tibialis strength of 2-.

Figure 2 shows that the medial to lateral ratio was not statistically different between the normal group and the Inv. > Ev. group, for both the midfoot (p = 0.38) and the forefoot (p = 0.91). The normal ratio is approximately 0.5 for the midfoot (the medial midfoot shows approximately half the mean peak pressure as the lateral midfoot), and approximately 1.0 for the forefoot (same mean peak pressure for both medial forefoot and lateral forefoot). The Ev. > Inv. group showed significantly increased mean peak medial pressure for both the midfoot (p = 0.001) and the forefoot (p = 0.002).

### CONCLUSIONS

The overlaid image of the plantar surface of the foot is a useful tool in orthotic fabrication, foot pressure analysis and research. These results show that a foot evertor/invertor strength imbalance can have a significant effect on foot pressure data. In subjects where the posterior tibialis is significantly stronger than the peroneus brevis, the pressure ratio is not significantly affected; however, when the posterior tibialis is significantly weaker than the peroneus brevis, there is a significant shift of pressure towards the medial aspect of the forefoot and midfoot. This may be an important factor when considering the implications of a surgery that may weaken the posterior tibialis. Future studies will focus on the effects of an imbalance between other muscle groups.

## ASSESSING REGULARITY IN VOLUNTARY MOTOR ACTIVITY WITH APPROXIMATE ENTROPY

Oliver Wirth and Israel R. Hall  
National Institute for Occupational Safety and Health  
email: owirth@cdc.gov

### INTRODUCTION

The objectives of the present study were to: 1) extend the use and analysis of the regularity statistic *approximate entropy* (ApEn) [2] to voluntary motor performances of rats, and 2) describe how ApEn changes as a function of other biomechanical measures of motor performance including pull force and power spectral density. Because previous studies have shown that vibration affects muscle activity [1], we also attempted to determine how a mechanical stressor (i.e., vibration) affects motor activity and thus ApEn.

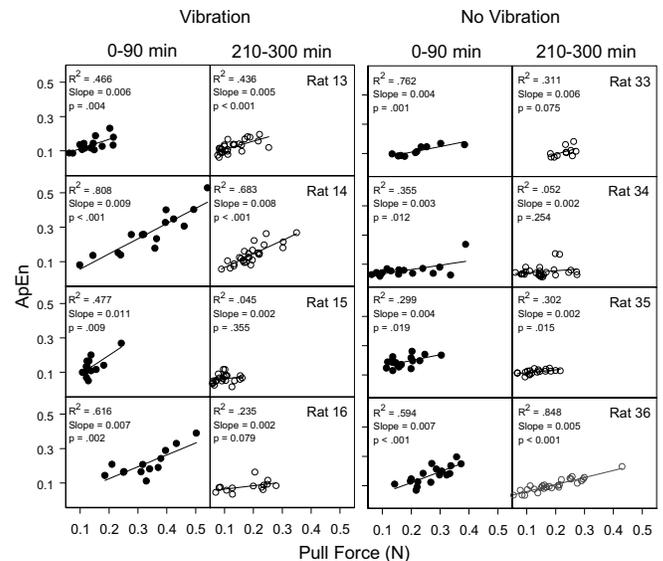

### METHODS

Eight rats were trained with operant conditioning techniques to perform a voluntary and repetitive bar-pulling response [3]. After training, a single 5-hr exposure session was conducted in which food rewards were earned for performing pull-bar responses of at least 1-s duration and 0.1 N peak force. For one half of the rats, a vibration stimulus (125 Hz, 49 m/s<sup>2</sup>) was applied to the pull bar with every response. Because thousands of bar-pull responses were performed by each rat, 4 to 7 bar pulls of at least 2-s duration were sampled at 1000 Hz in each successive 30-min time bin of the session. To eliminate any signal noise from the vibration stimulus, the vibration was turned off briefly during the recording of those forces.

Among the record responses, several time-domain measures were computed, including peak force, mean force, and standard deviation of the force-time series. In addition, a Matlab routine was developed to calculate ApEn for each response on the basis of an algorithm previously published [2]. The force-time series for each response was truncated, and only the middle 1024 data points were used in the calculation of ApEn. In addition, the power spectral density (PSD) was computed to obtain the total power of the force-time series of each response. The total power of the spectrum was calculated as the integral of the PSD between 5 Hz and 40 Hz – the range often associated with physiological force tremor. The modal frequency also was determined from that range. ApEn and the other time-domain measures were compared and plotted as a function of exposure group and session time.

### RESULTS AND DISCUSSION

All rats were trained successfully to perform repetitive bar pulls for food rewards with or without vibration. 3-5 thousand bar-pulling responses were generated in the 300-min session with each rat with and without the vibration stimulus. Global measures of performance, including peak force, mean force, and standard deviation of the force-time series, total power, the modal frequency, and ApEn, when averaged across the recorded pull-bar responses, revealed no significant differences between the vibration and no vibration groups. In both groups, however, there was a significant decrease in pull

**Figure 1.** ApEn for the vibration and no vibration groups in the first and last 90-min periods of the session plotted as a function of pull force.

force, total power, and ApEn. Furthermore, orderly relations were found when ApEn was compared with other measures. For example, Figure 1 shows significant positive correlations between ApEn and pull force and, in the vibration group only, the slopes of the functions that describe the relation between ApEn and force significantly decreased across session time. Additional results (not shown) indicated similar relations between total power and force. Increases in ApEn were associated with increases in total power; however, the relation between ApEn and total power did not change across session time. The time-dependent decreases in ApEn and changes in the functions relating ApEn to force and total power in the vibration group indicate that regularity in each force-time record increased with increased exposure to the repetitive task and that vibration may have exacerbated this change. It is tempting to speculate that a physiological response such as tremor or fatigue might have played a role.

### CONCLUSIONS

The present study demonstrated that high-gain force records obtained from voluntary bar-pull activity of rats revealed systematic changes in ApEn, total power, and other measures of performance. In addition, vibration may have had direct motor effects contributing to changes in force output, and that the regularity statistic ApEn was sensitive to those changes.

### INTRODUCTION

Diseases like osteoarthritis and repetitive strain injuries lead to changes in coordination that develop slowly over time. It is important, but often very difficult, to track the progression of these disease processes. By contrast, changes in movement coordination patterns can be easily measured. Our goal is to develop methods to track changes in underlying (i.e. “hidden”) disease states from easily obtainable biomechanical data.

### METHODS

We borrowed a method for tracking similar hidden damage processes in mechanical systems [1,2]. We assume our system can be modeled as a hierarchical dynamic system of the form:

$$\dot{x} = f(x, \mu(\phi)), \quad \dot{\phi} = \varepsilon g(\phi, x) \quad (1a, 1b)$$

where  $x \equiv$  the *observable* states of the fast-time-scale system,  $\phi \equiv$  the *hidden* slowly-varying dynamics,  $0 < \varepsilon \ll 1$ , and  $\mu(\phi) \equiv$  the parameters in (1a). If  $\varepsilon = 0$ ,  $\mu(\phi)$  would be constant. We form a topologically valid state space from a single measured time series,  $x(n)$ , using delay embedding (Figure 1A):

$$y(n) = [x(n), x(n + \tau), \dots, x(n + (d - 1)\tau)] \quad (2)$$

where  $\tau$  is a time delay and  $d$  is the embedding dimension [3]. Data from the unperturbed system are used to build a locally linear model of the system behavior (Figure 1B). Drift in  $\phi$  leads to “errors” ( $\mathbf{E}_k$ ) between actual and predicted behavior. If our model is good, the model error ( $\mathbf{E}_k^M$ ) will be small and  $\mathbf{E}_k \approx \mathbf{E}_k \equiv$  the true error or drift in the system dynamics.  $\mathbf{E}_k$  can then be used to define the following *tracking metric*:

$$\varphi = \langle F \| \mathbf{E}_k(y(n), \phi) \| \rangle \approx \langle \| \varepsilon_k(y(n), \phi) \| \rangle \quad (3)$$

where  $\langle \cdot \rangle \equiv$  the RMS over the index  $n$  and  $F$  is an appropriate filter [2]. Thus, this metric essentially tracks the average error, over time, in the predicted fast-time-scale dynamics that is introduced by the slow-time-scale dynamics.

Five healthy subjects walked on a motorized treadmill at their self-selected pace. The treadmill incline was increased from  $0^\circ$  to  $+8^\circ$  slowly over 25 minutes. Kinematic data were recorded (Vicon-612, Oxford Metrics, Oxford, UK) continuously at 60 Hz to obtain sagittal plane hip, knee and ankle angles. These joint kinematics defined  $x(n)$ , the fast-time-scale dynamics. Tracking metrics ( $\varphi$ ) were computed from joint angle data and regression analyses were used to determine how well these metrics tracked the “hidden” treadmill incline angle.

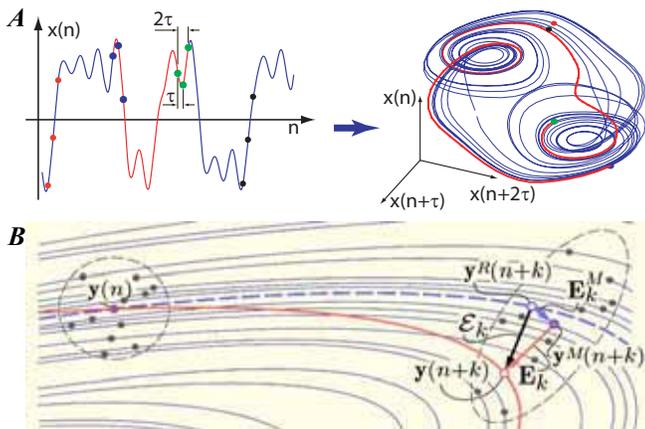

### RESULTS AND DISCUSSION

Basic patterns of joint kinematics changed little across trials. Tracking metrics ( $\varphi$ ) generally increased with treadmill angle (Fig. 2). Regressions yielded  $\text{adj-}r^2$  of 86% to 98%. Although these predictions were not perfect, no attempt was made to adjust or alter the original algorithm of [2]. By accounting for additional features specific to biological systems (e.g. noise, multiple time scales, etc.), better results may be obtained.

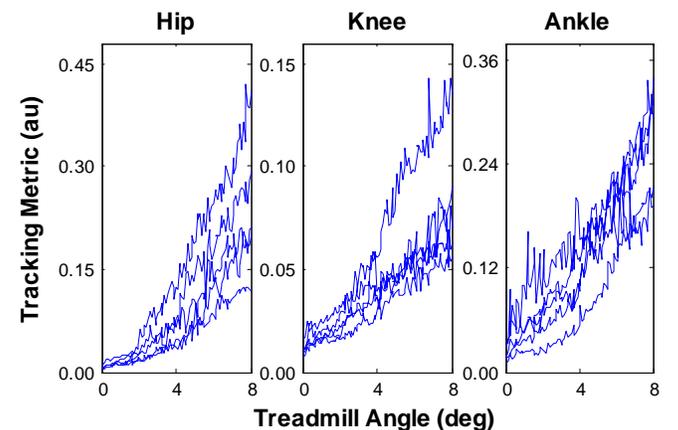

By using a state space formulation, the proposed method yields valid measures of slow-time-scale dynamics, without the need for “guessing” or for highly detailed first-principles models of system dynamics [2]. We anticipate this approach can be used to track other “hidden” biological processes like muscle fatigue, repetitive strain injury, or disease progression.

## KINETIC EVALUATION OF RIGHT SHOULDER AND ELBOW DURING SPICCATO TECHNIQUE VIOLIN BOWING

Luke Wooldridge, Peter Visentin<sup>1</sup>, Gongbing Shan<sup>1</sup>  
<sup>1</sup>University of Lethbridge  
email: [Luke.Wooldridge@uleth.ca](mailto:Luke.Wooldridge@uleth.ca)

### INTRODUCTION

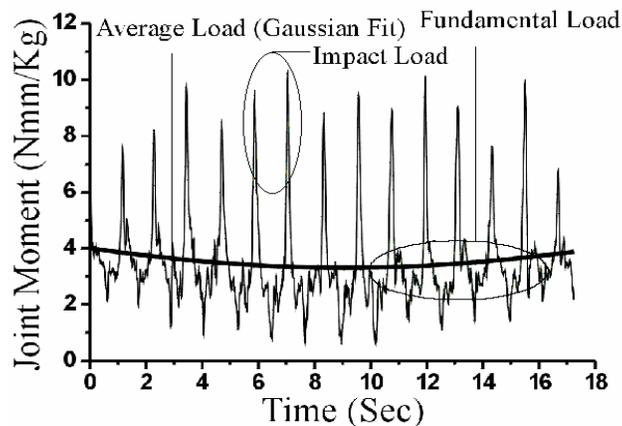

Musicians are a group particularly susceptible to overuse syndrome (OS), with up to 65% of professionals afflicted [1]. Violinists are at particularly high levels of risk for developing OS, due to the repetitive nature of the movements they use. Of 227 music students surveyed, string players reported shoulder pain more often than any other group at any other injury site [2]. Previous work has provided biomechanical descriptions of the legato (smooth bowing) technique during violin performance. It was discovered that kinetic considerations for risk of OS include the type and quantity of loading [3]. The current study examines the right shoulder (RS) and right elbow (RE) for the spiccato (bounced bow) technique.

### METHODS

3-D motion capture using a nine-camera VICON v8i system (<0.76mm accuracy) was used to collect kinematic data. Inverse dynamic modeling technique was applied to capture data for obtaining joint kinetics. A ten-segment biomechanical model (upper body, violin and bow) designed for the capture was utilized. Subjects consisted of eight professional violinists. The protocol had the performers play G major scale cycles covering all four stings of the violin from the lateral G-string to the medial E-string and back at different tempi (varying bowing speeds) using the spiccato technique.

### RESULTS AND DISCUSSION

Violin play can be described by two types of muscle load, the fundamental load from the process of moving the arm during a stroke, and the impact load resulting from overcoming the inertial forces of string crossings and bow direction changes (Fig. 1). In legato bowing it was found that fundamental loads dominated total joint moments at lower tempi, gradually giving way to impact loads at higher tempi [3].

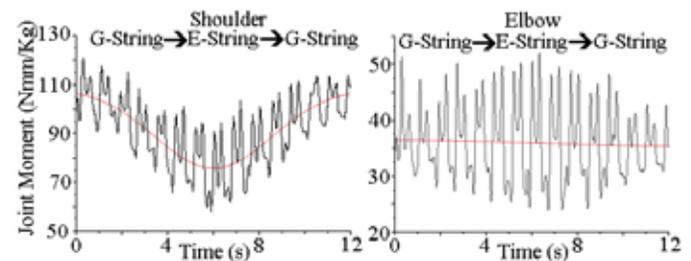

**Figure 1:** Wrist moment representative of legato bowing during the cycle of the scale at a low tempo.

Figure 2 shows spiccato bowing to produce a moment curve composed solely of impact load. Thus, playing spiccato even at low tempos exposes the muscles to loading patterns similar to those experienced during high tempo legato bowing. Impact

loads have been identified as a significant factor in the cause of OS, and results suggest that spiccato bowing carries a higher risk for the development of OS than legato [4].

Kinetic analysis of spiccato bowing revealed that string played had a large effect on RS loads. RS moment is greatest when the G-string is played (88.9 Nmm/kg +/-SD 11.03) and lowest on E (64.2 Nmm/kg +/-SD 10.48). In contrast to the RS, the RE moment is greater for E than G-string bowing, although the difference is much smaller (31.13 Nmm/Kg +/-SD 5.05 vs. 29.97 Nmm/Kg +/- 4.61 respectively)

The height of the oscillations in Figure 2 gives an indication of the effect of string on moment range. Large ranges of moment indicate a more dynamic movement, while small ranges are indicative of quasi-static movement. There are some indications that static loads may increase risk of injury relative to more dynamic loads [3]. Moment ranges are larger when playing the E-string than G for both RS (41.44 Nmm/Kg vs. 34.68 Nmm/Kg) and RE (26.05 Nmm/Kg vs. 19.84 Nmm/Kg respectively).

**Figure 2:** RS and RE joint moments at 144 bows/min during the cycle of a scale.

### CONCLUSIONS

The current study reveals that playing on the G-string for extended periods using the spiccato technique increases risk of injury in the right shoulder, due to the higher overall loads and the narrower load range (approaching quasi-static conditions) experienced under these conditions. It follows that apportioning practice time with consideration of the factors identified should reduce the risk of RS injury due to overuse.

### INTRODUCTION

Uni-compartmental replacement of the knee is recognized as a suitable treatment for localized damage of the tibiofemoral joint, whilst often allowing for later revision to a total knee replacement <sup>[1]</sup>. Several clinical studies have followed the progress of this implant device, however to date there have been very few computational studies <sup>[2]</sup>. The purpose of this project is the development of a Finite Element testing suite for the uni-compartmental knee, and its validation against existing clinical data. This paper will consider the steps involved in the development of such a model.

### METHODS AND MATERIALS

Loading of the knee has been applied using data gathered from the Kansas Knee Simulator. This device uses five axes of dynamic control to apply loads to the components of the total knee replacement during activities such as walking and squatting. The loading profile consists of a vertical component applied to the centre of rotation of the hip, a prescribed rotation of the femur during walking (12-37° flexion), an applied quadriceps loading, tibial torque and abduction-adduction of the tibia. An FE model of one of the tested component sets was developed from CAD data (Fig. 1). The femur, tibia and patella were modeled as rigid bodies for this analysis, with the quadriceps modeled as a 2D membrane. Following successful application of the Explicit Finite Element time-stepping scheme to the analysis of total knee kinematics with the Stanmore simulator <sup>[3]</sup>, all analyses were conducted in the Explicit FE solver PAMCRASH (ESI Software). The femur was free to rotate and translate relative to the vertical axis. The tibia was permitted to rotate around the ankle centre, but not to translate in the vertical axis. The resulting unconstrained movement of the knee components was recorded during these different activities and compared to the experimental findings.

**Figure 1** – FE models of TKR used to validate loading configuration.

Using the software package AMIRA (TGS Software) it is possible to extract surface representations of the anatomy of the lower extremity. Surface meshes of the osseous geometry have been developed from this data (Fig. 2), and in the first instance a model of the intact knee has been developed, inclusive of cartilage and ligaments. Following successful modeling of this configuration, a uni-compartmental knee device will be developed from CAD data and introduced to the lateral and medial compartments in separate analyses.

**Figure 2** – Surface meshes of femur, tibia and patella developed from CT

### RESULTS AND DISCUSSION

Displacements of the patella, tibia and femur were recorded during loading and compared with experimental data. The FE model managed to reproduce predicted kinematics to within 8% for all three components. Time-step size was not found to influence kinematics, however due to the large range of movement in the unconstrained knee system mass and inertial forces were found to be of critical relevance. The model was extremely sensitive to misalignment of the components.

The surface meshes of the tibia, femur and patella have been introduced to the finite element model of the total knee replacement. Initial results suggest that precise positioning of these osseous geometries and the inclusion of accurate inertial qualities of the mesh will influence the kinematics of the intact knee.

## KINETIC CHARACTERISTICS OF THE GAIT IN CHILDREN, ADULTS AND ELDERLY

Jansen Atier Estrázulas, Roberta Pires, Diego Murilo dos Santos, Lígia Raquel O. G. Stolt and Sebastião Iberes Lopes Melo.  
Santa Catarina University State – UDESC – Brazil – email: jansenef@hotmail.com

### INTRODUCTION

The gait is a simple activity of daily life and one of the main abilities of the human, that starts to develop the gait in the first years of life, and in agreement with Delisa (1992), the bipede gait standard is acquired in infancy for around 7 or 8 years old, where the sensory-motor system becomes suitable automatically to generate a repetitive set of motor control commands to allow a person to walk without conscientious effort. In adults, for being a daily movement, the gait pattern is characteristic of each person and well defined. In the elderly, in general way, one of the biggest functional limitations is the fall, or the fear of it, that implies in diminished levels of activities with subsequent loss of the muscular function, joint tissue and information processing.

Studies have been carried through in the search for characterizing the gait in these cited populations above, however, one can find little comparison between them. Thus, the search for a bigger understanding of kinetic characteristics of the gait was objectified in this study comparing children, adults and elders, trying to identify a possible difference between these populations.

### METHODS

This diagnostic descriptive study was carried through in the Laboratory of Biomechanics of the Center of Physical Education, Physiotherapy and Sports of UDESC. There were as population children, adults and elders of the city of Florianópolis – SC - Brazil.

The sample was constituted by individuals of the feminine sex, being 34 children (G1) with age between 10 and 12 years old, 24 adults (G2) with age between 18 and 41 years old, and 12 elders (G3), with age between 64 and 74 years old. The sample was intentional type. One selected only subjects that had not presented any type of pathology or disfunction.

As measure instrument one used an ergometric treadmill Kistler-Gaitway 9810SI, with two force platforms of piezoelectric crystals connected to their bases that register the ground reaction force. The data processing was made through the instrument software.

For data collection, it was initially did a period of adaptation to the equipment and weightning for the data normalization by the corporal weight (CW). Finally, one collected data with sampling frequency of 600 Hz and acquisition with 12s, speed average for the citizens of 4,0km/h. The average value of both sides of the sample was used. One used descriptive statistics in the characterization of the variáveis (média and standard deviation) and to comparison used ANOVA One-Way and the Scheffe Post Hoc test. The level of significance adopted was of 95%.

In this study some kinetic variables related to the vertical component of the ground reaction force had been analyzed: First Force Peak (FFP), Second Force Peak (SFP), Force of Medium Support (FMS), Tax of Weight Acceptance (TWA).

### RESULTS AND DISCUSSION

The results show that the groups that had participated of this study had presented the First Force Peak with a statistically significant difference between the groups, and when applied the Scheffe Post-hoc test one did not find where this difference occurred, being able to have been influenced by the size of the sample. However, analyzing the results, it can be verified that the average value for the G1 (1,08CW), was greater than the average values of G2 and G3 (1,05 CW).

The variable Second Force Peak occurs in the phase of propulsion of the foot to stimulate it for the following step during the gait. The groups of this study had differed in this variable, having the G3 the lesser value (1,00 CW) and the G1 the greater (1.11 CW).

The Medium Support Force was the only kinetic variable that did not present significant difference statistically. This can be explained by this variable occur in the phase of transition of the weight of the citizen on the support foot, not happening many variations from a citizen to the other.

The Tax of Weight Acceptance consists in the form the citizen is cushioning the first impact in the phase of weight reception. In this study, the citizens of G2 had differed from G1 and G3, presenting lesser values for this variable, what demonstrates a less harmful gait for health.

### CONCLUSIONS

With results and the theoretical referencial this study conclude that: The FFP was bigger for the children, what it demonstrates the lack of maturation for the protection of the locomotive device during walking of this group. The SFP was lesser for the elderly, that it tells to the lesser force used for this population for the translation of the step. The children and the elderly group had presented a bigger TWA compared with the adults. The two groups execute the gait with lesser protection of the locomotive device, for the lack of maturation (children) and degenerative deficiency of the advanced age (elderly). For in such a way, it can even be concluded that these groups possess distinct characteristics of locomotion, although some variables present similarities.

## AN ANALYSIS OF UNCERTAINTIES IN INVERSE DYNAMICS SOLUTIONS FOR GAIT

Raziel Riemer, Elizabeth T. Hsiao-Wecksler, and Xudong Zhang

Department of Mechanical and Industrial Engineering, University of Illinois at Urbana-Champaign, Urbana, IL 61801, USA  
 E-mail: [xudong@uiuc.edu](mailto:xudong@uiuc.edu)

### INTRODUCTION

Inverse dynamics is a powerful tool for analysis of human movement [1], but is subject to error from various sources; these include estimates of segmental properties [2], skin artifacts [3], inaccuracies in center of pressure (COP) locations [4], and inherent noise in instrumentation. Previous studies have focused on the effect of only one or two error sources [2, 3, 4]. The combined effect of all sources of error on the calculated joint torques has not been investigated. A comprehensive analysis can provide a thorough understanding of uncertainties in inverse dynamics solutions. It can also lead to more effective error controls and improved algorithms for error correction such as the variance-weighted least-squares method [5].

This study seeks to provide a comprehensive analysis of most sources of error in inverse dynamics and their effects on computed lower extremity joint torques during gait.

### METHODS

A three-segment linkage (foot, shank and thigh) represented the human leg, and served as the basis for Newton-Euler equations incorporating ground reaction force measurements (bottom up). An inverse dynamics solution was then computed for the joint torques at the ankle, knee and hip.

The magnitudes of the uncertainties in the leg joint torques are determined using an error analysis method [6]

$$E = \sqrt{\left(\frac{d\tau}{dx_1} \Delta x_1\right)^2 + \left(\frac{d\tau}{dx_2} \Delta x_2\right)^2 + \dots + \left(\frac{d\tau}{dx_n} \Delta x_n\right)^2} \quad (1)$$

where  $\tau$  is the torque at a given joint, and  $\Delta x_i$  are estimated inaccuracies associated with the input variables in the equation of motion of interest. The uncertainty,  $E$ , is a statistical representation of the possible  $3\sigma$ -error in the torque value. The magnitudes of the inaccuracies ( $\Delta x_i$ ) were derived from literature data [2, 3, 4] and our own experimental studies. Since the reported values for  $\Delta x_i$  varied across the studies, and because different systems and methods were used to determine input parameters to the equations of motion, two sets of  $\Delta x_i$  were used to represent the range of values: Set 1 (small  $\Delta x_i$ ) and Set 2 (large  $\Delta x_i$ ).

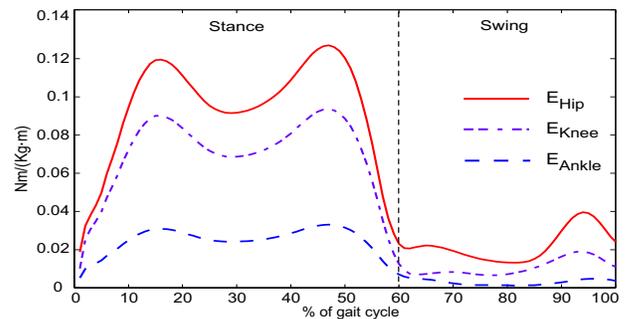

Five males and five females (weight:  $75.98 \pm 14.74$  kg; height:  $1.69 \pm 0.06$  m) walked at their normal speed, with the right foot landing on a force plate (AMTI) while motion capture system (Vicon) recorded their movements. These measurements, the estimated segment parameters, and  $\Delta x_i$  were then input into Equation 1 to estimate the uncertainties in each joint torque.

### RESULTS AND DISCUSSION

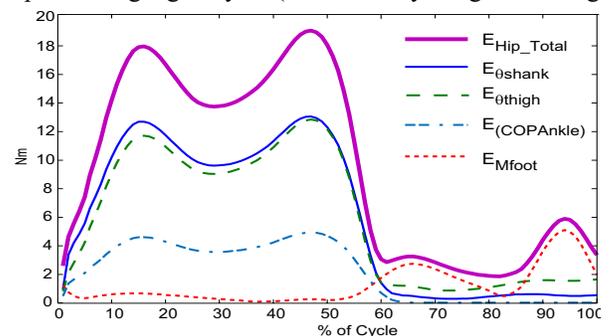

The magnitudes of the uncertainties changed over time (Fig. 1) and show temporal resemblance to the vertical ground

reaction force profiles during stance, but not at all to the torque profiles. Similar trends were observed for both sets of  $\Delta x_i$ . The values of estimated uncertainties relative to peak joint torque for the ankle, knee and hip are: 4 %, 29 %, 56 %, respectively, when using Set 1, and are 7 %, 70 % and 140 %, respectively, for Set 2. This suggests that the difference between the inverse dynamics results and the true joint torque at knee and hip can be substantial.

The main contributors to the uncertainty in the joint torques are the inaccuracies in the segment angles, the distance from the COP to the ankle center of rotation, and the foot mass (Fig. 2). Other studies have suggested that inaccuracy in the joint torques is closely related to the quality of the acceleration estimation [7]. Our findings, however, indicate such is not the case for the leg joint torques at least during normal gait.

**Figure 1:** Estimated uncertainties (Set 1) in calculated joints torques during a gait cycle (normalize by weight and height).

**Figure 2:** Main contributors for estimated uncertainty in hip joint torque for a 1.8 m and 80 kg subject in one cycle (Set 1).

## REPRESENTATION AND ANALYSIS OF SOCCER PLAYERS' TRAJECTORIES

Milton Shoiti Misuta, Rafael Pombo Menezes, Pascual Jovino Figueroa, Sergio Augusto Cunha,  
 Ricardo Machado Leite de Barros

Laboratório de Instrumentação para Biomecânica – Faculdade de Educação Física, Universidade Estadual de Campinas,  
 Campinas (SP), Brazil; e-mail: [misuta@fef.unicamp.br](mailto:misuta@fef.unicamp.br)

### INTRODUCTION

The increasing interest in quantifying variables related to the athlete's performance has been stimulated the development of systems to collect data. In [1], we proposed an automatic method of tracking soccer players from video sequences. This kind of method provides a great amount of data to be summarised and interpreted. In this paper, we propose and evaluate two ways of representation and analysis of players' trajectories.

### METHODS

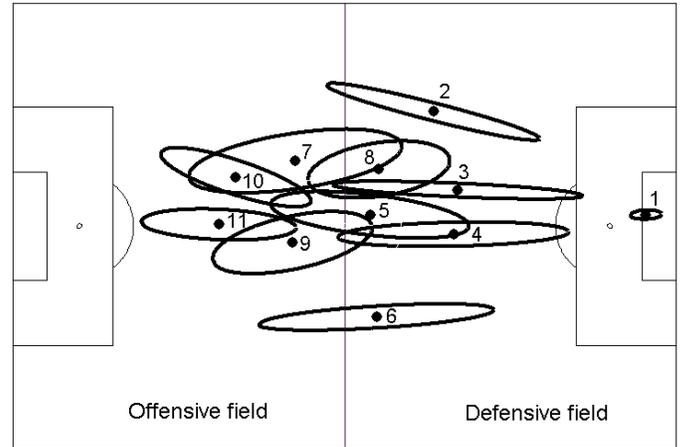

A first division Brazilian championship game was recorded using four stationary digital video cameras. Applying [1], the 90 minutes players' positions were obtained (sampled at 7.5 Hz). To each player's position data set, linear regression of the covered distance in function of time was performed and the slope of the best fit regression line ( $\alpha$ ) was determined. This parameter was used to characterise the physical performance of each player. Principal components analysis (PCA) was performed to model the regions more visited by the players. In the Figure 1, the ellipses are centred in the player's median position. The ellipse's major axis has his direction driven by the eigenvector associated to the largest eigenvalue. The lengths of the axes are one standard deviation long symmetrically to the origin. The slope of the major axis related to the longitudinal axis of the field was also calculated ( $\theta$ ). To evaluate the stability of the proposed variables, the variations of slopes ( $\Delta\alpha$ ) and ( $\Delta\theta$ ) were analysed increasing the time of sampling from 2 to 90 minutes (2 minutes step). In this evaluation, the trajectories of just 14 players were considered, excluding therefore the goalkeepers and the players replaced during the game.

### RESULTS AND DISCUSSION

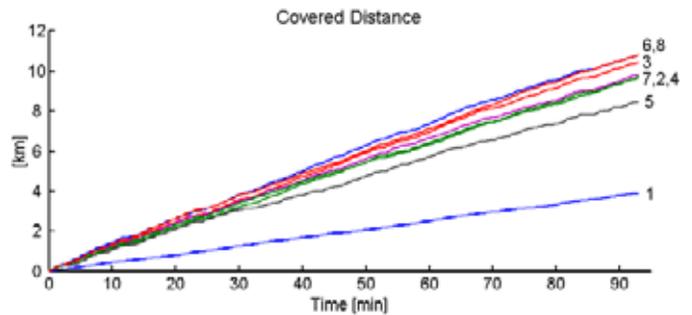

An individual analysis of the PCA can be used to distinguish the players' characteristics of moving, as shown in the Figure 1. Considering that the PCA is obtained *a posteriori*, the representation can be associated to the tactical organization of the team. The Figure 2 exemplifies the players' covered distances at any time interval for 8 players. Furthermore, it is remarkable that the curves seem to be characteristic to each player. The Figure 3 shows the tendency of stabilization of the mean value and standard deviation of ( $\Delta\alpha$ ) and ( $\Delta\theta$ ) for the 14 players with the increment of the time interval used to determine the variables. This result suggests that it is not necessary to analyse the full time game to determine, at a given error level, the variables proposed. In conclusion, the proposed variables showed to be useful to represent and analyse important aspects of the soccer players' performance.

### INTRODUCTION

When compared to other forms of mechanical testing of articular cartilage, triaxial testing holds the unique advantage of accommodating independent modulation of physiologically relevant shear stress states within the matrix, by varying the axial and radial (transverse) applied loads. However, owing to the proximity of loading/constraint boundaries, stress heterogeneities may confound the interpretation of *in situ* experiments performed in this configuration. A poroelastic finite element (FE) model of a cartilage specimen in cyclic triaxial compression testing was developed in order to investigate the effect of variation in loading conditions, geometry and material properties.

### METHODS

A baseline FE model of a cartilage explant (4 mm diameter, 1.5 mm thick) and containment sheath (0.0254 mm thick) was created to mimic triaxial testing conditions [1]. The specimen was modeled using axisymmetric, poroelastic elements. In the radial (*r-z*) plane, the specimen was discretized into 150 8-noded bi-quadratic elements. The sheath was modeled using 100 2-noded axisymmetric shell elements. The experimentally measured modulus of the containment sheath was 5.5 GPa and Poisson's ratio  $\nu = 0.4$ . The cartilage had an initial void ratio (volumetric ratio of fluid to solid) of  $e = 4.0$ ,  $\nu = 0.1667$ , a depth-dependent modulus ranging from 10 MPa in the superficial zone to 20 MPa in the deep zone, and void ratio-dependent permeability [2].

The cartilage explant was compressed between two rigid porous platens (diameter = 4 mm). Consequently, the interstitial fluid was free to flow in and out of the surfaces adjacent to the platens (Fig 1a). Transverse fluid flow was assumed to be restricted by the impermeable containment sheath. Six hundred cycles of trapezoidally-modulated loading were applied at a frequency of 1 Hz (Fig 1b); axial and transverse load magnitudes were 0.2 to 2.0 MPa.

Parametric testing was performed by independently modifying model attributes from the baseline model. The series included the cartilage radius, thickness, modulus, Poisson's ratio, and initial void ratio, as well as load magnitude, rate, and frequency. For the purpose of this abstract, only the results from the thickness and void ratio parametric series are shown.

In all cases, data were collected at the centroid of each element. The thickness was decreased from the 1.5 mm baseline case to 0.75 mm and 0.375 mm. In the void ratio series, three models were run in addition to the baseline case ( $e = 4.0$ ) in which the initial void ratio was 2.0, 8.0, and 16.0.

### RESULTS AND DISCUSSION

Throughout the 600 cycles, the cartilage peak-to-peak axial strain range decreased and total strain increased for all cases (Fig 2). As the thickness decreased from the baseline, peak-to-peak strain increased, in addition to the maximum strain for each cycle.

The pore pressure is shown (Fig 3) at 0.1 mm off the symmetry axis of the cartilage at time  $t^*$  (Fig 1b) for the 1<sup>st</sup> and 600<sup>th</sup> cycles of loading. At the onset of loading, pore pressures were higher compared to 600 cycles, where the effect of the different void ratios was seen.

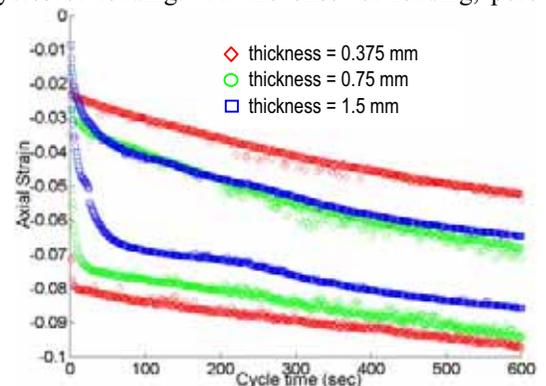

Figure 2. Peak-to-peak axial strain.

This FE model is a powerful tool to explore cartilage behavior for a wide range of physiological conditions.

Additionally, changes in thickness, water content, permeability, stiffness, etc. are commonly associated with cartilage degradation [3], and can therefore be simulated to better understand these pathological conditions.

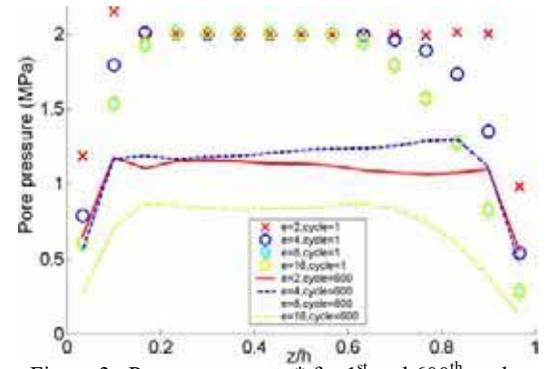

Figure 3. Pore pressure at  $t^*$  for 1<sup>st</sup> and 600<sup>th</sup> cycles.

## SOLDIERS' LOADS AFFECT RANDOM WALK OF CENTER OF PRESSURE AND EMG ACTIVATION DURING POSTURAL SWAY

Jeffrey M. Schiffman, Carolyn K. Bensel, Leif Hasselquist, Karen Norton, and Louis Piscitelle  
U.S. Army Natick Soldier Center, Natick, MA, 01760, USA  
Email: Jeffrey.Schiffman@natick.army.mil

### INTRODUCTION

Carrying loads may contribute to poor balance resulting in falls when soldiers perform marches, negotiate obstacles, and maneuver during operations. We investigated the effects of carrying loads on soldiers' center of pressure trajectories during postural sway using a general stochastic model; we also examined EMG activity changes as a function of load carried.

### METHODS

Fourteen Army enlisted men (mean: 19.6 yr, 1.75 m, 74.11 kg) participated after giving informed consent. We tested the soldiers under three load weight configurations: 6, 16, and 40 kg. At the heaviest load, soldiers wore/carried: M16A1 rifle, boots, minimal clothing (6 kg), plus a helmet and armor vest with ammo, grenades, and canteen (+10 kg), plus a backpack containing a 20-kg steel block (+24 kg). The 20-kg block was located either high on the back and close to the shoulders (h&c) or low on the back and away from the body (l&a) to create two unique backpack center of mass positions.

We recorded postural sway as the volunteers stood comfortably on a force plate for ten trials of 30-s each. Foot placement on the force plate was controlled. The presentation order of the load configurations was based on a Latin square. Force plate outputs were recorded and converted to physical units (mm). From a stabilogram diffusion analysis (SDA), we determined Hurst scaling exponents for short-term and long-term regions for axial and planar movements [1]. Percent of EMG on-time activation for 8 bilateral muscle pairs (Tibialis Anterior, Vastus Lateralis, Rectus Femoris, Gluteus Medius, Biceps Femoris, Erector Spinae, Upper Trapezius, Paraspinals) was calculated as described elsewhere [2].

For each configuration, each measure was averaged over the ten trials. A one-way repeated measures ANOVA with three levels was run on each averaged measure to determine the effects of weight (6 kg, 16 kg, 40 kg h&c). A significant ANOVA finding was followed up with a trend analysis using a within-subjects polynomial contrast. A paired samples t-test was used to determine the effects of load position (h&c vs. l&a) on the measures. Alpha was set at .05 and we corrected for multiple comparisons.

### RESULTS AND DISCUSSION

**SDA**--For the medio-lateral Hurst exponent over the short-term time intervals, a significant linear trend for weight was found, with the heaviest load being the least random with values ranging from 0.81 to 0.85. The l&a load position was significantly less random than the h&c position, 0.84 vs. 0.85. For both the planar and anterior-posterior Hurst values (both with similar means) over the long-term time intervals, a significant linear trend for weight was found (Figure 1): The lightest load was the most random. Also, the l&a position was significantly more random than the h&c position, about 0.20 vs. about 0.12.

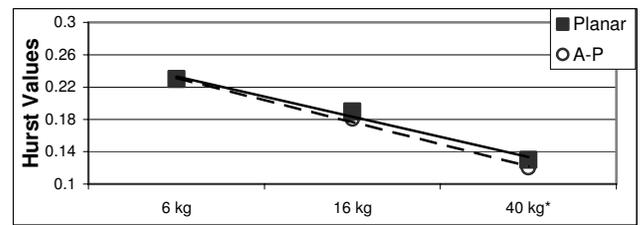

Figure 1: A-P and planar long-term mean Hurst values results. ( $H < 0.5$ , correlated anti-persistent motion)

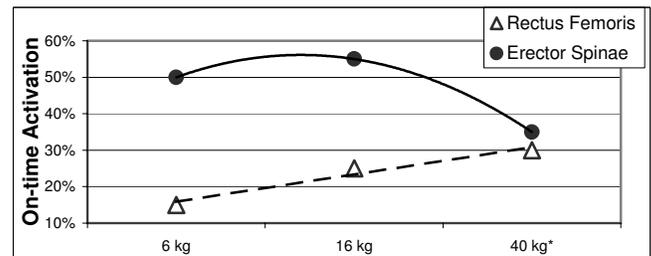

Figure 2: Rectus Femoris and Erectors Spinae mean on-time activation results.

\*40 kg load includes pack with block in h&c position.

**EMG**--For bilateral Rectus Femoris, a significant linear trend was found: On-time percentage increased with an increase in load weight from 15% mean on time at 6 kg to 20% at 16 kg to 30% for 40 kg (Figure 2). For Erector Spinae, a significant quadratic trend was found: on-time percentage increased with an increase in load carried from 50% at 6 kg to 55% at 16 kg, but then decreased to 35% at 40 kg (Figure 2). The Paraspinals increased significantly in on-time percentage as a function of load position, from 65% for h&c to 80% average on-time for the l&a position.

Postural sway became less random as load weight increased. However, as the load position was changed from high and close to low and away from the body at the heaviest load, postural behavior became less structured. Thus, a load placed low and away in the backpack may be quite difficult for a load carrier to control precisely. In contrast, a load placed close and high on the back required more control to balance, but was easier and more predictable to manage.

At the heaviest load, Rectus Femoris activity continued to increase while Erector Spinae activity decreased. These muscular changes at the heaviest load may be attributable to forward lean of the trunk when the backpack was worn. The changes may reduce the efficiency of the muscular control scheme, which aims to maintain posture while minimizing fatigue.

## SCAPHOID AND LUNATE ROTATIONS ARE MINIMIZED WITH WRIST MOTION ALONG THE DART THROWER'S PATH: IMPLICATIONS FOR STABILITY IN HIGH-DEMAND TASKS

<sup>1</sup> Joseph J. Crisco, <sup>1</sup> James C. Coburn, <sup>1</sup> Douglas C. Moore and <sup>2</sup> Scott W. Wolfe

email: [joseph\\_crisco@brown.edu](mailto:joseph_crisco@brown.edu), web: [brownbiomechanics.org](http://brownbiomechanics.org)

### INTRODUCTION

The radiocarpal joint (radio-scapho-lunate articulation) is responsible for as much as 85% of overall wrist motion, depending on direction the wrist is moved in [3]. However, there appear to be directions of wrist motion where radiocarpal motion is significantly reduced [2,4]. An interesting example is the "dart thrower's" motion, which involves movement of the wrist from a position of combined extension and radial deviation (radial extension) to a position of combined flexion and ulnar deviation (ulnar flexion). The dart thrower's motion is used for activities that require fine control, such as fly casting, as well as high-demand activities that require maximal grip and stability, such as hammering. This study was performed to explore possible motion minima in the 3-D kinematics of the radiocarpal joint *in vivo*, throughout the entire range of wrist motion.

### METHODS

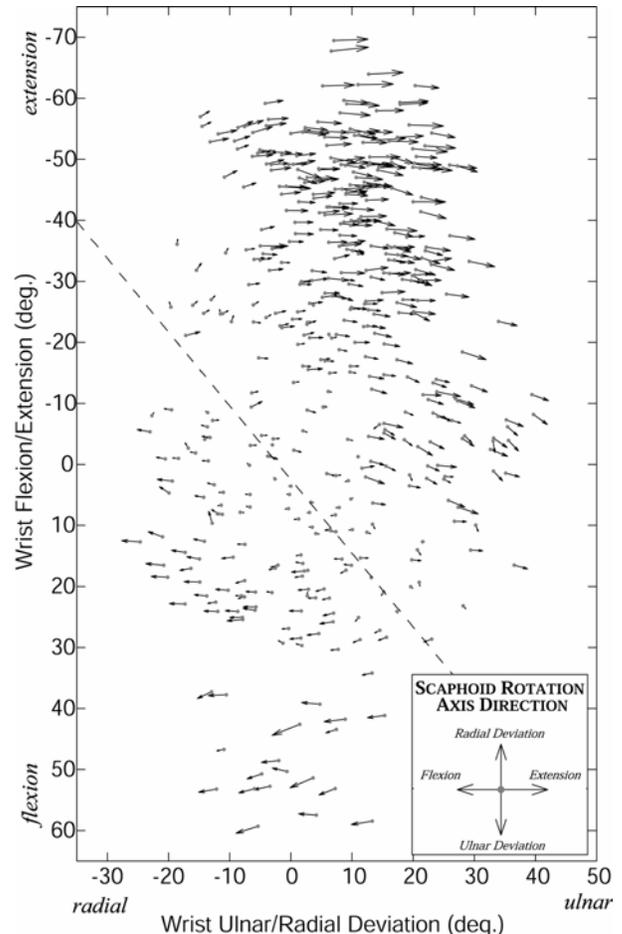

The 3-D kinematics of the capitate, scaphoid and lunate were measured *in vivo* in both wrists of 14 male (25.6 years; range 22-34), and 14 female (23.6 years; range 21-28) healthy volunteers using CT volume images of 481 static wrist positions and established segmentation and registration procedures for markerless bone tracking [1]. This study was approved by the IRB and all volunteers were enrolled after informed consent. Carpal kinematics were calculated relative to the radius, with respect to the neutral wrist position, and described using helical axis of motion variables. Multiple linear regression was used to analyze carpal rotation as a function of wrist position.

### RESULTS AND DISCUSSION

For all wrist positions, regardless of direction, the scaphoid (Fig. 1) and lunate rotated primarily in flexion or in extension. Scaphoid and lunate rotations and translations were minimized *only* at wrist positions along the path of the dart thrower's motion (Fig. 1, dashed line). This behavior was independent of gender and was consistent across all subjects (RMS errors of scaphoid and lunate rotation as a function of wrist rotation were 6.6° and 6.9°). The scaphoid and lunate translated radially  $1.5 \pm 0.9$  mm and  $1.3 \pm 0.9$  mm when they extended, but only  $0.5 \pm 0.4$  mm and  $0.5 \pm 0.4$  mm when they flexed.

### CONCLUSIONS

Using the largest database of subjects and wrist positions to date, we found that the kinematics of the radiocarpal joint is dominated by flexion and extension rotations of the scaphoid and lunate, regardless of the direction of wrist motion. We also found that radiocarpal motion was *uniquely* minimal only along the path of the dart thrower's motion. It is unclear why wrist motion along this path is shifted to the midcarpal joint

**Figure 1:** The scaphoid rotation axes (see legend) were almost exclusively in the flexion-extension direction for all wrist positions. The dart thrower's path of motion (dashed line) differentiated wrist positions at which the scaphoid flexed from those at which it extended. Scaphoid rotation values near this path approached zero (the length of each vector is a measure of the magnitude of scaphoid rotation).

(esp. scaphocapitate and lunocapitate), but it is consistent with the unique functional importance of this motion which is used for both low and high demand activities that require exquisite control and stability.

## DO MECHANICAL PROPERTIES OF CHEST PROTECTORS CORRELATE WITH THE INCIDENCE OF VENTRICULAR FIBRILLATION IN A SUDDEN DEATH (COMMOTIO CORDIS) SWINE MODEL?

<sup>1</sup> Elizabeth Drewniak, <sup>1</sup>David B. Spenciner and <sup>1</sup>Joseph J. Crisco  
<sup>1</sup>Department of Orthopaedics, Brown Medical School/Rhode Island Hospital  
email: [joseph\\_crisco@brown.edu](mailto:joseph_crisco@brown.edu), web: [brownbiomechanics.org](http://brownbiomechanics.org)

### INTRODUCTION

For young healthy athletes, Commotio cordis is the second leading cause of death is commotio cordis. Commotio cordis (CC) is the sudden death (or aborted sudden death) due to a non-penetrating chest wall impact that, in the absence of injury to the ribs, sternum and heart, occurs in a vulnerable window on the T-wave of the cardiac cycle (10 to 30 ms prior to the T-peak) and results in ventricle fibrillation (VF). The fatal impact mostly occurs to the left chest wall in the region of the cardiac silhouette by a projectile (ball or puck) traveling at speeds consistent with youth play. Despite increases in the use of protective gear, to date, 7 young athletes (3 lacrosse goalies, 2 baseball catchers, and 2 hockey goalies), all wearing chest protectors, have died from commotio cordis [1].

We hypothesized that the efficacy of chest protectors could be predicted from quasi-static compression testing. The purpose of this study was to determine if a correlation existed between the incidence of VF [2] and three quasi-static mechanical properties, displacement, stiffness, and pressure distribution, for various baseball and lacrosse chest protectors.

### METHODS

Quasi-static compression testing was performed on eleven models of lacrosse and baseball chest protectors evaluated in a previous animal model of CC [2]. Each model was placed on a rigid plate and a compressive load was applied by a rigid spherical object positioned on each chest protector using a servo hydraulic material tester (Instron Corp., Canton, MA). The spherical object was a hardwood ball with a diameter of 6.35 cm and 7.62 cm for the lacrosse and baseball chest protectors, respectively. A preload of 10 N was applied and then cycled up to 6000 N five times at 1 Hz. Load and actuator position data were collected at 100 Hz.

During the quasi-static compression testing, displacement, stiffness, and pressure distribution were measured. Displacement was defined as the difference from the minimally and maximally compressed positions of each model. Stiffness was calculated from load-displacement measurements, first for the region of low stiffness between 0 and 400 N and second for the region of high stiffness between 2400 and 5000 N. A pressure sensitive film (Ultra Super Low Fuji Film, Fuji Photo, Co., Ltd., Tokyo, Japan) was used to measure the distribution of applied pressure.

Linear regression (SigmaStat3.1, Systat, Point Richmond, CA) was used to examine correlations between these mechanical properties and the incidence of VF, which was determined for the same chest protector models in a previous animal model

[2]. We computed the  $R^2$  and P values for the regression equation. A significance value of  $P < 0.05$  was set *a priori*.

### RESULTS AND DISCUSSION

The displacement of each model ranged from 7.09 to 21.03 mm. There was a trend of increasing displacement with decreasing incidence of VF, but no significant linear correlation was found ( $R^2 = 0.14$ ,  $P = 0.06$ ).

The compression testing revealed a highly nonlinear load-displacement behavior in all chest protector models. There was an initial range of very low stiffness (10.88 to 48.24 N/mm), then a transition region, followed by a region of high stiffness (2425.42 to 7335.44 N/mm) that was assumed to be associated with the bottoming out of the chest protector. Neither the low stiffness region ( $R^2 = 0.1$ ,  $P = 0.12$ ) nor the high stiffness region ( $R^2 = 0.05$ ,  $P = 0.25$ ) demonstrated a linear correlation with the occurrence of VF.

The area of the pressure distribution ranged in shape from circular to rectangular. Grouping all models together, we found that there was a significant ( $P = 0.01$ ) decrease in the incidence of VF as the area of the pressure distribution increased.

This study was performed to determine if quasi-static compression testing could explain the variance in the incidence of VF. While none of the models significantly increased or decreased the risk of VF in the previous study [2], we did find that the incidence of VF significantly decreased as the pressure distribution increased. While this finding seems logical and intuitive, it is still surprising considering the complexity and the dynamic nature of CC.

### CONCLUSIONS

The goal of this experiment was to develop an experimental protocol that could be incorporated into performance standard test protocols for chest protectors to ensure that all models meet a minimal standard performance requirement. Surprisingly, we found that increases in quasi-static pressure distribution were associated with a significant decrease in the incidence of VF. It remains to be demonstrated that chest protectors constructed using these findings as design criteria can significantly reduce the incidence of VF.

**BIOMECHANICAL ANALYSIS OF THE FORCE APPLIED IN AQUATIC GAIT OF HUMANS IMMERSSED AT THE STERNUM LEVEL**

SOUZA, Patricia Vieira de<sup>1</sup>, HAUPENTHAL, Alessandro<sup>1</sup>, SCHUTZ, Gustavo Ricardo<sup>1</sup>, & ROESLER, Helio<sup>1</sup>  
 1- Santa Catarina State University – UDESC – Brazil – email: patricia@posturall.com.br

**INTRODUCTION**

The human gait is one of the most studied movements in terrestrial environment [1,2,3], but this fact does not occur in the aquatic environment [4]. Despite of the aquatic environment be a lot utilized for training and rehabilitation, there are few works about the aquatic gait.

This study analyzed the Ground Reaction Force (GRF) vertical component during the aquatic gait. For so much, the objectives of this work were: 1) Verify the maximum value of the GRF vertical component; 2) Compare the GRF inside and outside the water.

**METHODS**

This diagnostic descriptive study was carried through in the Laboratory of Aquatic Biomechanics Research of UDESC. One invited to participate of this study individuals that possessed stature from 1,60 to 1,85m and no gait disorders. With these criteria, 63 subjects (31 female and 32 male) carried out the experiment. The average ages were 23±5 years old. The average height was 1,70±0,15 m. The water depth was 1,30m. Although that depth of immersion corresponds to a level for each subject, they all had the water reaching their sternum.

In the bottom of a thermal swimming pool (30±1oC) one had put a footbridge of 6,15 m of length containing two underwater force platforms [5] (A and B). One acquired the GRF in the vertical components (Fy) in a rate of sample of 600hz. One has used the acquisition system SAD 32 version 3.0 [6].

Each subject carried out four passages in the footbridge at the maximum speed they could obtain. The average speed was 0,55± 0,05 m/s.

To analyse the reduction in the GRF vertical component in the aquatic gait, their values have been compared to the land gait values. The value used to calculate the force reduction was 1,2N/BW [1,2,3]. For data analysis one utilized descriptive statistics through the program Microsoft Excel.

**RESULTS AND DISCUSSION**

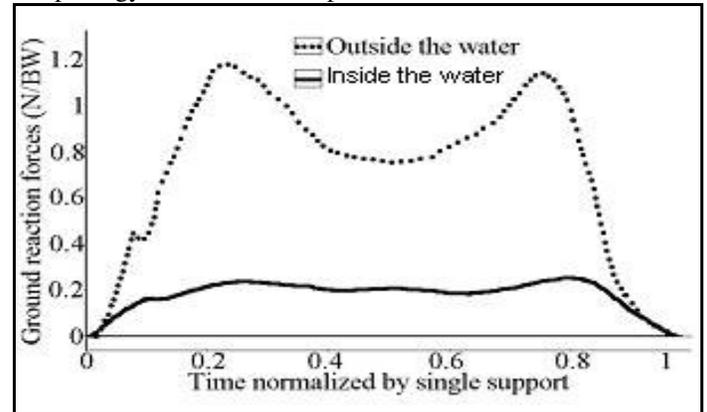

In the vertical component the forces had varied 59% of the subjects' corporal weights., as one can see in Table 1 .

**Table 1:** Maximum Force in Fy e Fx (N/BW) and reduction compared to land gait values (%).

	<b>FyA</b>	<b>FyB</b>
(N/BW)	<b>0,59±0,09</b>	<b>0,58±0,08</b>
(%)	<b>51±8</b>	<b>52±7</b>

For a better understanding of the alteration that occurs in the underwater gait, a forcetime curve for GRF vertical component at the sternum level is compared to a GRF curve outside the water. One can visualize that occurs a curve rectification, the peaks are next to deflection and the load absorption happens in a larger time until the first force peak

(Figure 1). The “M” look curve common in the outside water gait [2,3] is not characterized inside the water and the curve morphology is similar to a trapezium.

**Figure 1:** Comparing the forcetime curves for GRF vertical component outside the water and aquatic gait.

The found values in this study for maximum force in the GRF vertical component are inferior to the ones previously reported by Harrison et al [7]. The BW reduction values are similar to the ones found by Brito [8], in wich study the immersion level was at the hip and the speed was smaller.

**CONCLUSIONS**

One can conclude that at the sternum immersion level the GRF vertical component can be altered in significant values. The curve shape is similar to a trapezium, differently from the land curve.

This work values point out that submmiting the individual to an exercise inside the water at this immersion level can bring benefits when it comes to reducing the resultant load. Knowing these values and their relations to other immersion levels is crucial to activities prescription in aquatic environment.

**DYNAMOMETRIC ANALYSIS OF THE ANTEROPOSTERIOR FORCE APPLIED IN AQUATIC HUMAN GAIT**

SCHUTZ, Gustavo Ricardo<sup>1</sup>, SOUZA, Patricia Vieira de<sup>1</sup>, HAUPENTHAL, Alessandro<sup>1</sup>, & ROESLER, Helio<sup>1</sup>.

1- Santa Catarina State University – UDESC – Brazil – e-mail: patricia@posturall.com.br

**INTRODUCTION**

Walking in water is a major rehabilitation therapy for patients with orthopedic disorders. However, data about kinetic variables while walking in water is still unclear [1]. It is important to the professionals who work with rehabilitation to know informations as the ground reaction force components during gait in water. According to Brito et al[2], few works exist about the subject, and also there aren't knew studies about the behavior of the anteroposterior component during walking in water. This work had the objective to analyze the anteroposterior component of the ground reaction force (GRF) during the aquatic gait and the influence of the speed and the upper limb position on the GRF anteroposterior component values.

**METHODS**

This study took place at the swimming pool and Aquatic Biomechanics Research Laboratory of Santa Catarina State University.

The sample was composed by 60 individuals that possessed stature from 1,6 to 1,85m and no gait disorders. The water depth was 1,30m. One opted for dividing the sample in three groups, according to their levels of immersion: (1) manubrium sterni, (2) medial point between the manubrium sterni and xiphoid process sterni distance (3) Xiphoid process sterni.

Two underwater force platforms [3] were set on the bottom of a thermal swimming pool (30±1oC), in a footbridge of 6,15 m of length. One acquired the GRF in the anteroposterior component in a rate of sample of 600hz. One has also used the acquisition system SAD 32 version 3.0 [4]. The subjects were supposed to walk along the footbridge in two speeds (Slow and Quick) and two different upper limb positions (Inside and Outside the water). The four situations imposed for the three groups in this study are described on Table 1.

**Table 1:** Aquatic Gait Situations

	Gait Situation	Speed
ISG	Slow gait with the upper member inside the water beside the body slow gait with the upper member inside the water beside the body - named inside slow gait	0,42 m/s
OSG	Slow gait with the upper member outside the water - outside slow gait	0,42 m/s
IQG	Gait with the upper member inside the water the fastest speed the subject obtained - inside quick gait	0,55 m/s
OQG	Gait outside the water the fastest speed the subject obtained - outside quick gait	0,66 m/s

**RESULTS AND DISCUSSION**

The GRF anteroposterior maximum force reduction for aquatic gait compared to the reference values for land gait [5](Table 2).

**Table 2:** Maximum force reduction of the GRF anteroposterior component for aquatic gait compared to the reference values for land gait (%).

	Group 1	Group 2	Group 3
ISG	55	55	55
OSG	50	50	50
IQG	45	35	15
OQG	30	20	5

Comparing each group separately in different speed situations (slow and quick), one can realize that the values raise as the speed raises, with statistic significance for all the three groups. Comparing the upper limb inside and outside the water gait situation, the values do not raise significantly.

In the slow situations the values had been cut off to half the values outside the water. Indeed, in the quick situations, there wasn't such a significant reduction, specially when it comes to group 3 OQG, where the values are very close to land gait values, despite of a slower speed in the water. The alteration of immersion level does not increase the maximum force in this component.

The Fx curve has a negative peak in land gait, related to the movement breakdown, and a positive peak, due to acceleration [5]. For the positive peak, one can observe that the maximum force increases significantly with the aquatic gait speed upgrade.

**CONCLUSIONS**

This work values point out that an increase in the gait speed results an increase in the anteroposterior component. This is very important for underwater exercise prescription. For instance, if the treatment goal is to train gait of a subject not so functionally injured, the aquatic gait that most approximates to land gait is in the xiphoid process immersion level, upper limb outside the water and the fastest speed the subject can carry out. An alteration in the curve pattern also can be confirmed: it looks like a triangle.

### INTRODUCTION

Back injuries still affect many workers. There is evidence that bending and twisting of the trunk and lifting at work are risk factors for back pain. Various methods are available for assessing bending and twisting of the trunk within a job. Recently, new types of instrumentation have been developed which combine different sensors. Backmann (2000) developed such a system consisting of a gyroscope, a magnetometer and a linear accelerometer. The data of each sensors are processed into a filter and produces orientation estimates. However, their system has not been validated exhaustively with human subjects. The purpose of this study was to evaluate a dosimeter composed of two sensors each including accelerometers, magnetometers and gyroscopes for the three-dimensional (3D) measurement of trunk motion.

### METHODS

The instrument (dosimeter) consisted of two three-dimensional inertial tracking sensors (Micro Strain 3DM-G. Burlington) linked by a flexible rod with a potentiometer (figure 1). The two sensors were used to measure the orientation of the thorax relative to the pelvis. Each sensor comprised of three orthogonal gyroscopes which measured the angular rate of rotation, three orthogonal accelerometers which sensed the gravitational acceleration and three orthogonal magnetometers which are sensitive to earth magnetic field. The signals from the two sensors were transmitted to a computer (Casiopeia Five 230 MZ; Casio). The sample frequency was set to 76 Hz.

Figure 1. Illustration of the dosimeter

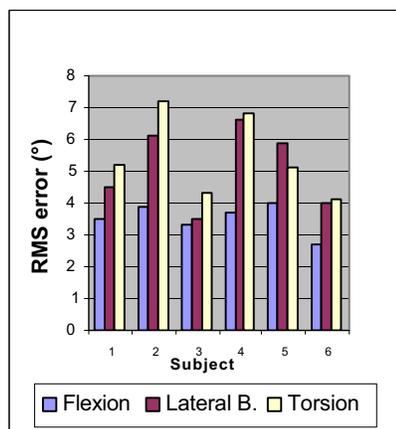

Figure 2. RMS errors during the long trial (30 min)

The data from the gyroscope were adjusted with the accelerometer and magnetometer estimates using a complementary filter [1]. The data of each sensors were processed into the filter which produced orientation estimates

in quaternion form. These outputs were transformed into direction cosines where the three orthopaedic angles of Grood & Suntay [2] were computed: flexion-extension (angle  $\alpha$ ), lateral bending (angle  $\beta$ ) and torsion (angle  $\gamma$ ).

To validate the dosimeter, six male subjects were asked to perform manual handling tasks with empty boxes. They had to adopt different static postures (20) as well as to perform slow, moderate and fast lifts over a short period of time (30 sec) and, finally, to transfer boxes during 30 minutes. The task forced the subjects to exert large amplitude back motions. The dosimeter was tested by comparing the orientation as calculated by the complementary filter to the orientation that was obtained from a 3D optoelectronic system (Optotrak 3020 with four bars, Northern Digital Inc). The sensor orientation was obtained from six active markers attached securely to each sensor box. The root mean square difference (RMS) between the dosimeter and the Optotrak system was calculated for the three orthopaedic angles ( $\alpha$ ,  $\beta$ ,  $\gamma$ )

### RESULTS

Figure 2 illustrates the RMS errors for the three orthopaedic angles between the thorax and the pelvis during the long dynamic trials (30 minutes). RMS errors varied between 3 and 7° and were generally higher for the torsion angle ( $\gamma$ ). Coefficient of multiple correlation was found to be higher than 0.90 for most of the long trials. Static and short dynamic trials resulted in smaller errors than the long trials, with the torsion angles having the highest level of errors (5°). Maximal errors were generally below 16° for the short trials. Speed of movement had a significant effect on the level of error but only in the order of 1 to 2°.

### DISCUSSION AND CONCLUSION

Errors about the torsion angle ( $\gamma$ ) can be explained by small disturbances from local magnetic field which affect the magnetic sensor. Gyroscopes also drift over time and the accelerometers used as inclinometer are influenced by quick motions. The filter worked well to overcome these sources of error, particularly during the long duration task. The results of this study indicates that the dosimeter is a valid system for the three-dimensional measurement of trunk motion. Future work should focus on obtaining more accurate data from long duration tasks .

## NEUROMODULATION CHANGES THE BIOMECHANICS AND CAPABILITIES OF THE *APLYSIA* FEEDING MUSCLE I2

<sup>1</sup>Gregory Sutton, <sup>2</sup>Bryan Higashikubo and <sup>2,3,4</sup>Hillel Chiel  
Case Western Reserve University, Departments of <sup>1</sup>Mechanical Engineering,  
<sup>2</sup>Biology, <sup>3</sup>Biomedical Engineering, and <sup>3</sup>Neurosciences

### INTRODUCTION

Neuromodulation is often used by the nervous system to change a muscle's response to nervous system stimulation. Invertebrate preparations are well suited for study of neuromodulation because of their experimentally tractable nervous systems and biomechanics. The *Aplysia* smooth muscle I2 is a good model for neuromodulation because it is a muscle with known behavioral correlates [1], and it responds to serotonergic neuromodulation [2]. During two feeding behaviors, biting and swallowing, I2 moves the grasping structure toward the jaws [1]. During swallowing behaviors, the I2 muscle is sufficiently strong to move the grasper throughout the grasper's full range of motion, but, during biting, an unmodulated I2 is insufficiently strong to generate the full motion of the grasper [3]. We used *in vitro* studies of I2's response to serotonin to show that serotonergic neuromodulation can sufficiently strengthen I2 to allow the I2 to generate biting behaviors.

### METHODS

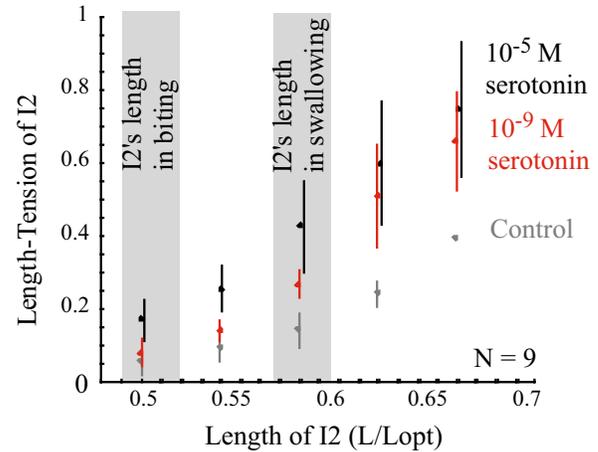

*Aplysia californica* were anesthetized by injection of 60% body mass of 333 mM MgCl<sub>2</sub> and the feeding apparatus (the buccal mass) was removed. The I2 was dissected out of the buccal mass, and the I2 nerve was suctioned and attached to a stimulus isolation unit (WPI A360). I2's length was controlled by a servomotor system (Aurora Scientific, 300B-LR).

In order to characterize how I2's mechanical properties would change in response to serotonergic neuromodulation, we measured the descending limb of I2's length-tension curve in response to increasing concentrations of serotonin. I2's maximum contractile force and rate of contraction were both recorded.

The changes in I2's contractile properties were then programmed into a kinetic model of the feeding apparatus [3] to predict whether these changes in biomechanics were sufficient to allow the I2 to produce biting behaviors.

### RESULTS AND DISCUSSION

In response to serotonin application, I2's maximal contractile force increased as a function of serotonin concentration and length (3 concentrations are shown in **Figure 1**). At longer lengths, both lower and higher concentrations of serotonin caused a near doubling of I2's maximum contractile strength. In contrast, at shorter lengths, lower concentrations of serotonin had little effect, while higher concentrations of serotonin caused a tripling of I2's maximum contractile force. Serotonin did not cause a significant change in the speed of I2 activation (data not shown).

**Figure 1:** I2's length-tension curve in response to different concentrations of serotonin

It has been previously shown that tripling of I2's maximal contractile force is sufficient to allow I2 to generate biting behaviors [3]. To achieve this increase of I2's contractile force, however, the serotonin concentration had to be quite high (10<sup>-5</sup> M). In a different *Aplysia* feeding muscle (I5), stimulation of a serotonergic neuron (the metacerebral cell) has been observed to cause the same change in muscle contraction as application 10<sup>-9</sup> M serotonin [4], suggesting that, while serotonergic neuromodulation can strengthen I2 sufficiently to allow I2 to generate biting behaviors, the amount of serotonin needed to do so is greater than the concentration that is biologically observed.

When this change in contractile strength is programmed into the kinetic model of the feeding apparatus, the model predicts that 10<sup>-5</sup> M serotonin would be required to strengthen the I2 sufficiently to generate biting behaviors.

### CONCLUSIONS

Serotonergic neuromodulation is sufficient to strengthen the I2 enough to allow I2 to generate biting behaviors. This does, however, require the nervous system to apply a very large amount of serotonin to the muscle. Serotonergic strengthening of a muscle represents a concrete example of a neuromodulating neuron (the metacerebral cell) acting to change the biomechanics of a muscle (I2). It is probable that another mechanism assists I2 with moving the grasper. These data are consistent with a complimentary hypothesis that another muscle (I1/I3) assists I2 with moving the grasper [3].

## NEUROMUSCULAR GENDER DIFFERENCES EXIST DURING UNANTICIPATED RUNNING AND CUTTING MANEUVERS WITHIN AN ELITE ADOLESCENT SOCCER POPULATION

### INTRODUCTION

The anterior cruciate ligament (ACL) is an extremely important ligament for knee joint stability and proper function, particularly during sporting activities that involve running, jumping and cutting. Injury to the ACL can be detrimental to an athlete's career, with approximately 70-80% of these injuries being non-contact in nature [1,2] and females being 2-8 times more likely of sustaining an ACL injury than males [3]. The non-contact mechanism of this injury most often involves landing from a jump or cutting to change directions during activities such as basketball or soccer. The purpose of this study was to identify gender related neuromuscular differences of the lower limb in unanticipated running and cutting maneuvers within an elite soccer population.

### METHODS

20 elite male and 20 elite female adolescent soccer players underwent a complete 3D kinematic, kinetic and electromyographic (EMG) analysis of the lower limb, with only the EMG findings being discussed in this abstract. Subjects were required to run at 3.5±0.2 m/s down the laboratory runway and just prior to the right foot landing on the force plate, a light system randomly cued the individuals to either 1) cut to the left (side-cut), 2) continue running straight or 3) cut to the right (cross-cut). For the stance portion of the maneuver, muscle activation patterns of the rectus femoris, vastus medialis and lateralis, lateral and medial hamstring and medial and lateral gastrocnemius were normalized to maximum voluntary isometric contractions (MVIC). All cuts were made at 35°-60° from the direction of travel and all waveforms were analyzed for gender differences using principal component analysis (PCA) [4].

### RESULTS AND DISCUSSION

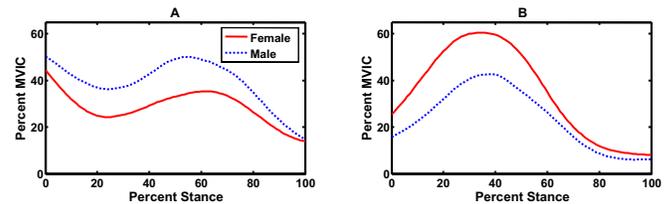

While all subjects were free from injury at the time of testing, many reported minor lower limb injuries previously in their soccer careers (Male=62%, Female=86%). The most common injuries included ankle sprains and muscle strains of the hip flexors, quadriceps, adductors and hamstrings. Descriptives comparing the male and female subject groups indicated that the only group differences were that males were taller and heavier than the females (Table 1).

**Table 1:** Descriptives for male and female subject groups. \* indicates stat. sign. (p<0.05). Values are mean (STD).

	Males	Females
Age (yrs)	17.2 (0.8)	16.9 (1.0)
Weight (kg) *	69.6 (6.6)	60.8 (5.5)
Height (m) *	1.8 (0.1)	1.6 (0.1)
BMI (kg/m <sup>2</sup> )	22.1 (1.7)	22.4 (1.8)
Soccer (yrs)	10.7 (1.7)	9.8 (2.1)

Using PCA to compare the EMG waveforms between males and females, it was determined that females had on average

higher lateral gastrocnemius activation magnitudes than their male counterparts during the side-cut, cross-cut and straight run (p<0.05) throughout stance. The overall activation magnitude of the rectus femoris in females was also larger than males during the both the cross-cut (Figure 1B) and straight run (p<0.01). For the lateral hamstring, however, females generated a smaller overall activation magnitude than the male soccer players (Figure 1A) (p<0.01) and this difference was only evident for the cross-cut maneuver.

**Figure 1:** (A) Lateral hamstring and (B) rectus femoris activation patterns for males and females during the stance phase of the cross-cut, normalized to % MVIC and % stance.

Comparing only peak stance activation levels between gender, females had an approximate 30% larger activation level for their lateral gastrocnemius for the run and two cutting maneuvers. For the cross-cut only, females had a 40% smaller lateral hamstring peak activation level and an approximate 40% larger peak activation compared to males.

These results confirm that athletic females tend to be more quadriceps dominant and do not use their hamstrings to the same degree as males [5] during cutting and running tasks. Having the higher rectus femoris and lateral gastrocnemius activity may also potentially expose females to earlier fatigue onset and may thereby result in reduced knee joint stabilization. Proper muscle function is crucial in preventing knee injuries while landing from a jump and/or cutting to change direction during activities like soccer and basketball.

### CONCLUSIONS

Neuromuscular differences between genders were most evident in the unanticipated cross-cut maneuver. The higher rectus femoris and lower lateral hamstring activity in females, in combination with specific knee joint loading patterns, appears to play a significant role in predisposing females to higher non-contact ACL injury rates.

## OBSTACLE COURSE PERFORMANCE: COMPARISON OF THE C-LEG TO TWO CONVENTIONAL KNEES

<sup>1</sup>Margrit-R. Meier, <sup>1</sup>Andrew H. Hansen <sup>1,2</sup>Steven A. Gard, and <sup>1,2</sup>Dudley S. Childress

<sup>1</sup>Northwestern University Prosthetics Research Laboratory and Rehabilitation Engineering Research Program,

<sup>2</sup>Jesse Brown VA Medical Center, Chicago, Illinois; email: [m-meier@northwestern.edu](mailto:m-meier@northwestern.edu)

### INTRODUCTION

Previous investigations of some microprocessor-controlled (MC) knee joints have produced conflicting results, indicating clear benefits for amputees while others suggested there were no differences compared to conventional knee mechanisms [1-4]. Further quantitative analyses are needed to determine if it is beneficial to prescribe expensive MC knee mechanisms over passive knee units that cost significantly less.

The specific objectives of this study were to: (1) examine participants' walking performances while walking over an obstacle course (OC), and (2) test the influence of mental loading (ML) while walking over the OC using three different knee units.

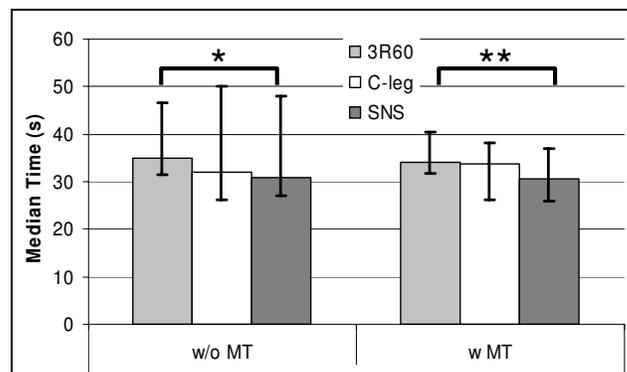

### METHODS

**General:** In a crossover study design, participants wore each prosthetic knee joint—Otto Bock C-leg, Otto Bock 3R60 and Mauch SNS—for a period of four weeks. Test prostheses were fabricated using a duplication of the participant's current prosthetic socket and each participant was fitted with a Dynamic Plus foot to reduce variability. **Participants:** Persons with unilateral transfemoral amputation, aged between 40 and 60 years, with a body-weight less than 125 kg, were included if they: presented with no serious complications that interfered with their walking ability; had six or more months of experience with a definitive prosthesis; and were able to walk unassisted at a comfortable speed without undue fatigue and without health risk. **Protocol:** The OC was set up in the VA Chicago Motion Analysis Research Laboratory. It consisted of a foam section (3m long, 1m wide (3x1), 20 durometer on a shore A scale), narrow slaloms around three chairs, a vacuumized bean-bag section (3x1) simulating sand, a rock section (3x1), a short downward sloping ramp (1.5x1.4), a 90-degree left turn, and a final stair step (height: 12cm). The ML test consisted of an arithmetic calculation task where the participant had to count aloud backwards in 3-step increments (1<sup>st</sup> visit), in 7-step increments (2<sup>nd</sup> visit) and in 3-step increments (3<sup>rd</sup> visit). Participants completed the OC twice, once without and once with ML. No familiarization run was allowed. Time was measured from a videotape recording of participants navigating the OC. **Statistical Analysis:** Friedman Test assessed the overall performance of the three knee joints. If a variable reached significance level, Wilcoxon Signed Rank Test was used to determine differences between each knee joint. A Bonferroni correction was applied to account for multiple testing, lowering the significance level to 0.016.

### RESULTS

Data from 2 women and 9 men were analyzed. Their mean age was 45.8 ± 9.5 years, mean height was 175 ± 9 cm, and mean weight was 81.8 ± 14.1 kg. They were all established walkers with their amputation having occurred 20.1 ± 14.2 years ago.

The median time taken to complete the OS with the 3R60 knee was 34.9 seconds (s). Adding the ML altered the time minimally: 34.2s. For the C-leg, the total time without ML (32.1s) was slightly lower when compared to the 3R60 knee but increased with ML to 33.9s. The difference between the 3R60 and the C-leg was non-significant for both conditions (without ML:  $p=0.169$ ; with ML:  $p=0.045$ ). Participants performed best on the OC when fitted with the SNS unit: total median time without ML was 30.9s, with ML 32s. The difference between the SNS and the 3R60 was significant for both conditions. However, the difference between the C-leg and the SNS knee joint was not significant (without ML:  $p=0.674$ ; with ML  $p=0.678$ ) (Figure 1).

**Figure 1:** Total time taken (in sec) to complete the obstacle course for each prosthetic knee joint. w/o MT: without Mental Task \* SNS-3R60:  $p=0.011$  w MT: with Mental Task \*\* SNS-3R60:  $p=0.005$

### DISCUSSION AND CONCLUSIONS

The participants completed the OC in the shortest time when fitted with the SNS unit, followed by the C-leg, and they were slowest with the 3R60 knee regardless if ML was administered or not. The more mechanically complex (3R60) and the more sophisticated (C-leg) knee joints performed less favorably in this context. These two knees may require more time and training to take full advantage of their characteristics than the given 4-week accommodation period. However, it could also mean that for soft or uneven walking surfaces, a simpler knee (like a SNS unit) simply performs better, as participants may have a quicker and direct impact on its behavior.

## CROSS-MODAL EFFECT OF DAMAGE ON CORTICAL BONE STRENGTH

<sup>1</sup> Won Joo, <sup>1</sup>Dwight T. Davy  
<sup>1</sup>Case Western Reserve University, email: [dtd@cwru.edu](mailto:dtd@cwru.edu)

### INTRODUCTION

Bone is a complex biological material which continually undergoes damage accumulation and repair in-vivo [1]. The effects of damage are often studied in terms of the mechanical property degradation in the loading mode (e.g. tension, torsion, etc.) in which damage was accumulated [2]. However, in-vivo loading is more complex, and it is important to understand how damage accumulated in one loading mode affects mechanical properties in other loading mode. Our previous studies demonstrated complex cross-modal effects of damage on viscoelastic properties [3]. The purpose of this study was to determine how monotonic strength in each of three loading modes (tension, compression or torsion) is affected by damage mode and magnitude.

### METHODS

Cortical bone samples were machined from the mid-diaphyses of 18 human femurs (7 females and 11 males, 38-55 years old age). The final machined samples had a reduced diameter section (4 mm diameter x 18mm long) with the axis along the nominal bone axis. During all machining and testing, specimens were kept wet and testing was performed at 37°C. Samples were randomly assigned to experimental and control groups. For control groups, 10 undamaged specimens were tested under strain control in each loading mode (Tension (T), Compression (C), Rotation (R)). Loading rates of ±1 %/s or 8 degree/s were used. The results from control group were used as undamaged measures and the yield strain of each loading mode used to prescribe the damage cycle magnitudes shown in Figure 1.

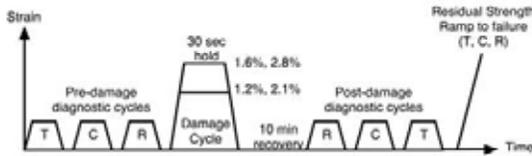

Figure 1. The protocol for strength degradation test.

Before and after the damage cycle, diagnostic cycles in three modes were performed to measure the change of viscoelastic properties by damage (Data shown in [3]). Damage was induced in one of three loading modes (T, C, or R) during damage cycle with two different magnitudes for each mode, which for tension were 1.2% and 1.6% (150% and 200% tension yield), compression were 1.2% and 1.6% (120% and 160% compression yield) and torsion were 2.1% and 2.8% (150% and 200% rotation yield). Following the damage cycle, 10 minutes recovery time was allowed at zero-stress (zero-torque) hold condition. After the recovery period, each specimen was monotonically loaded to failure in one of the three modes. Six specimens were tested for each test group. For the torsional tests, the following equation [4] was used to calculate shear stress.

$$\gamma = \theta \frac{a}{l}, \quad \tau = \frac{1}{2\pi r^3} \left[ \theta \frac{dT}{d\theta} + 3T \right]$$

Changes in properties due to damage were compared using 1-way ANOVA (with Tukey's pairwise comparisons) and paired t-tests (p<0.05).

**Table 1:** Measured parameters from monotonic failure test after damage. All values are normalized to mean values of control group (mean±SD).

Damage mode	failure mode	Damage strain	Yield strain, $\epsilon_y$	Yield stress, $\sigma_y$	Failure stress, $\sigma_f$

	C	2.1%	1.05±0.06	0.90±0.03	0.94±0.04
		2.8%	1.00±0.07	0.89±0.07	0.97±0.13
	R	2.1%	0.88±0.03	0.79±0.04	0.97±0.06
		2.8%	0.80±0.04	0.65±0.06	0.87±0.08

### RESULTS AND DISCUSSION

There were significant and mode dependent inter-modal damage effects on monotonic strength of human cortical bone. Axial (compressive and tensile) damage reduced tensile and compressive yield strain and stress (Table 1). Higher damage strains tended to produce greater property degradation, although not all differences were significant. Compression damage of -1.6% strain induced more degradation than tensile damage of 1.6% strain on tension and compression strengths. Axial damage modes affected torsion properties far less than axial properties. Conversely, shear (torsion) damage induced small degradations in tension and compression compared to shear strength degradation. The failure stresses showed significant decreases but smaller magnitudes of degradation than yield stress and strain (Table 1).

The un-coupling between axial and rotation damage modes is consistent with our earlier observations on viscoelastic properties [3]. They also are consistent with the qualitative differences in damage morphologies that have been observed [2,5]. Work in histological measurements of damage is ongoing to further explore the relationship between the observed cross-modal mechanical property changes due to damage and the morphological nature of the damage in each mode.

## COMPARISON OF THE BIOMECHANICAL RESPONSE OF A LUMBAR MOTION SEGMENT TO LOADING AND UNLOADING WHEN LOADS ARE APPLIED SUDDENLY AND AT NORMAL LIFTING SPEEDS

<sup>1</sup>Jamie Williams, <sup>1,2</sup>Raghu Natarajan and <sup>1</sup>Gunnar Andersson

<sup>1</sup>Department of Orthopedic Surgery, Rush University Medical Center, Chicago, Illinois,

<sup>2</sup>Department of Bioengineering, University of Illinois at Chicago, Chicago, Illinois; email: Jamie\_Williams@rush.edu

### INTRODUCTION

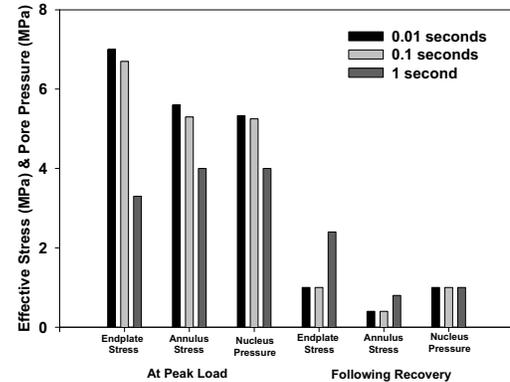

Repetitive lifting and sudden or unexpected loading have been attributed to the development of back injuries. Experimental studies have considered the response of the spinal musculature under both types of loading conditions. While it is important to understand how the muscles surrounding the spine react in these situations, it is equally important to understand how the spine itself reacts, specifically how the intervertebral disc behaves, under such conditions. However, studying the response of the various disc tissues to these types of loading conditions is difficult using standard experimental techniques. Therefore, the purpose of this study was to use a previously validated poroelastic finite element model (PEFEM) to compare the biomechanical response of a lumbar motion segment when subjected to physiological loading conditions when applied suddenly and under normal lifting speeds.

### METHODS

A previously validated three-dimensional PEFEM of an L4-L5 motion segment in which biological parameters such as swelling pressure and strain dependent permeability and porosity had been included, was used as the basis for this investigation [1]. The loads, compression, AP shear and lateral shear, were determined for a lifting activity in which a box was lifted from elbow height on the right side and placed at elbow height on the left side. This activity was found to have a significant AP shear component (818N) and lateral shear component (1489N) that occur at approximately the same time as the peak compressive load (5083N). While these loads were measured at normal lifting speed, for the sake of comparison the same load magnitudes were assumed for the suddenly applied load analyses. The peak loads were applied using a triangular waveform with the time taken to reach the peak load equal to 0.01sec, 0.1sec to simulate suddenly applied loads and 1sec to simulate the normal lifting speed. In all three analyses, following the release of the peak load a recovery period of 5 sec was modeled in which a constant 400N compressive load was applied.

### RESULTS AND DISCUSSION

Figure 1 shows the maximum effective stress in the endplates and annulus and the maximum pore pressure in the nucleus pulposus both when the peak load was applied and following the recovery period. The magnitude of the maximum effective stresses in the endplates and annulus for the two suddenly applied loading cases were very similar when the peak load was applied. When the loads were applied at a normal lifting speed, over 1sec, the magnitudes of these stresses were reduced. A similar effect was observed with respect to the maximum pore pressure in the nucleus. The loss of disc height was greatest when the loads were applied in 1sec (5.06mm), as

**Figure 1:** Maximum effective stress in endplates and annulus and maximum nucleus pore pressure at peak load and following the 5 second recovery.

compared to when the loads were applied in 0.01sec (3.61mm) and 0.01sec (3.62mm). Following the recovery period the maximum stresses and maximum pore pressure in the nucleus were greatly reduced as compared to when the loads were applied at a normal lifting speed. Also, the original disc height was restored following the recovery period in the two suddenly applied loading analyses; however, at a normal lifting speed only 90% was recovered.

### CONCLUSIONS

The results of the current study support that suddenly applied loads do create circumstances that can result in failure of disc tissues, particularly when the peak load is applied. The PEFEM results also suggest that the disc is able to quickly recover from such loads. When the same loads were applied at a rate representative of normal lifting, the stresses in the disc tissues were significantly less when the peak load was applied however, they remained elevated and the total disc height loss was not completely recovered at the end of the recovery period. If this were a repetitive lifting situation, additional fluid would be lost with each subsequent lift. Therefore, the disc tissues must resist more of the applied load in turn resulting in higher stresses in these tissues. Hence, without appropriate time to recover between bouts of lifting, normal lifting speeds also put the disc at risk of injury.

## SEX BASED DIFFERENCES IN TENSILE PROPERTIES OF HUMAN ANTERIOR CRUCIATE LIGAMENT

<sup>1</sup> Naveen Chandrashekar, <sup>1</sup>Javad Hashemi and <sup>2</sup>James R Slauterbeck

<sup>1</sup>Texas tech University, Lubbock, TX-79415

<sup>2</sup>University of Vermont, Burlington, VT-05405 email: jhashemi@coe.ttu.edu

### INTRODUCTION

Females participating in athletic events injure their ACL more frequently than males [1]. The disparity may be due to a smaller ACL size or inferior ACL tensile properties in females among other cited reasons. Any sex differences in the mechanical properties of the ACL might reflect a difference in the internal ACL structure. Therefore it is important to investigate how the tensile properties of ACL vary by sex. We hypothesize that male ACLs have superior structural properties than female ACL even after considering the size of the ACL as a covariant indicating a sex-based difference in the mechanical properties.

### METHODS

Seventeen fresh-frozen unpaired knees (8 male and 9 female) were thawed and dissected. The average length of the ACL was measured using a vernier caliper and the minimum cross-sectional area and volume of the ACL were measured using a 3D Scanner[2]. The femur and tibia were tested in tension at 100%/s along the ligamental axis. The structural properties\* were calculated and multivariate regression analysis, with age and body mass index (BMI) as covariants, was performed. To test for existence of a sex difference in mechanical properties\*\* of the ACL, the size variables of the ACL were added as covariants and the regression analysis was repeated.

### RESULTS AND DISCUSSION

As shown in Table 1, the structural properties of the male ACL are superior to those of the female ACL when age and donor body mass index (BMI) were considered as covariants. The male ACL showed a significantly higher load at failure, stiffness and absorbed energy before failure. This was expected as the female ACL (minimum area =  $57.32 \pm 15.7$ , volume =  $1996 \pm 530$ ) was significantly smaller than the male ACL (minimum area =  $72.9 \pm 18.9$ , volume =  $2772 \pm 706$ ) [3]. In order to test if any sex based differences in mechanical properties of the ACL existed, the size of the ACL was added as a covariant and the regression analysis was performed again. ACL length, cross-sectional area, area per unit length, and volume of the ACL were added as a covariate for regression analysis with displacement, load, stiffness and energy absorbed, respectively. Still, the male ACL was found to have superior tensile properties. This indicates that the female ACL is not weaker just because it is smaller [3] but also of lower mechanical quality. This might significantly contribute towards greater incidence in ACL tear rate in females. A lower torsional stiffness of female knees has also been cited as a potential reason for this disparity [5]. In our study, we found the female ACL to have lower stiffness and elastic modulus when compared to male ACL. Since ACL is the primary restraint for the internal rotation of the knee, decreased stiffness of the ACL might be a major contributor for lesser rotational knee stiffness in females. Though the

reason for inferior mechanical properties of the female ACL is unclear, the influence of sex hormones can be one of the possibilities. For instance, estrogen is known to lower the failure of rabbit ACL [6] but this could be species dependant and tissue specific. Ultrastructural studies are needed to support such theories. This study also emphasizes the need for considering sex as a variable while testing mechanical properties of human ACL. One limitation of this study is that the activity levels of the donors were unknown and therefore its impact on the results could not be assessed.

\* Structural properties are not normalized to geometrical variables of the tissue and include load at failure, linear stiffness, energy at failure, and elongation at failure.

\*\* Mechanical properties are structural properties normalized based on the corresponding geometrical variables of the tissue and include Failure strength, modulus of elasticity, strain energy density, and strain at failure.

**EFFECTS OF SEX AND MASS DENSITY ON THE MECHANICAL PROPERTIES OF THE HUMAN PATELLAR TENDON**

<sup>1</sup>Javad Hashemi, <sup>1</sup>Naveen Chandrashekar and <sup>2</sup>James R Slauterbeck

<sup>1</sup>Texas Tech University, Lubbock, TX-79415; <sup>2</sup>University of Vermont, Burlington, VT-05405 email: jhashemi@coe.ttu.edu

**INTRODUCTION**

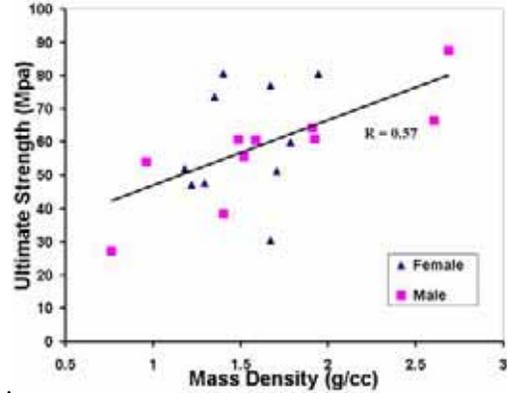

A diverse range of values for the mechanical properties of the human patellar tendon has been reported in the literature. These discrepancies persist even though similar test environments and specimen cross-sectional areas are used [1,2,3]. Since patellar tendon is used as an autogenous graft for ACL reconstruction, it is important from a clinical point of view to know the reasons for the variations in the reported properties. Donor age has been excluded as a factor that causes this disparity; at least in the age range below 50 years [2,3]. Since sex and collagen content are known to affect mechanical properties of some connective tissues [4,5], it is reasonable to believe these factors might be causing variability in the properties of patellar tendon. In this study, we hypothesize that 1) female patellar tendons have inherently inferior mechanical properties as compared to male patellar tendons and 2) the mechanical properties of the patellar tendon are correlated to its mass density.

**METHODS**

Twenty patellar tendons were harvested along with their bony attachments from unpaired knees (10 male and 10 female). The mean age of male donors was 39 years (range 26-50) and that of female donors was 37.7 years (range 17-50). The central portion of patellar tendon (average width of about 5mm) was trimmed. Its length, average width and thickness were measured using a caliper. The patellar tendon was tested to failure at a strain rate of 100%/s in a tensile testing apparatus. After the test, the tendons were carefully removed from their attachment sites and weighed accurately. The mass density of patellar tendon was calculated. The PT was kept moist by 0.1N saline solution throughout the experiment. Statistical tests were performed to compare mechanical properties of male and female patellar tendons. Correlation analysis was performed to test the correlation between the mass density of the tendon and mechanical properties.

**RESULTS AND DISCUSSION**

As shown in Table 1, no evidence of a sex-based difference in mechanical properties of human patellar tendon was found. The results revealed a diverse range of mass densities extending from a low of 0.76 g/cm<sup>3</sup> to a high of 2.68 g/cm<sup>3</sup> (250% difference) and the same was true with mechanical properties. The ultimate strength (Figure 1), elastic modulus

**Figure 1. Correlation between mass density and ultimate strength**

and toughness of patellar tendons were found to be correlated to the mass density. The tensile strength and elastic modulus were significantly higher for those patellar tendons having a mass density greater than 1.67 g/cm<sup>3</sup>. Sex does not seem to affect the mechanical properties of patellar tendon and hence the effect of sex might be tissue specific. The ranges in mass density and mechanical properties highlight the need for considering the quality of autograft before ACL reconstruction. Based on our findings, it is evident that mass density can be used as a predictor of mechanical properties of human patellar tendon. The need for such predictors is highlighted by some researchers [6]. Modern imaging techniques such as CT scans can be used to find the mass density of the patellar tendon to assess its suitability for use as a graft. Higher mass density might reflect higher amount of collagen and hence reflect better tissue quality [5]. Biochemical and histological studies are needed to verify our results.

**EFFECT OF PERTURBATION DIRECTION ON THE THRESHOLD OF BALANCE RECOVERY  
 PRELIMINARY RESULTS**

Alessandro Telonio, Marc-André Cyr, Kodjo E Moglo and Cécile Smeesters

 Department of Mechanical Engineering, Université de Sherbrooke, Sherbrooke, QC, Canada  
 email: [Cecile.Smeesters@USherbrooke.ca](mailto:Cecile.Smeesters@USherbrooke.ca) web: [www.cdvr.ca](http://www.cdvr.ca)

**INTRODUCTION**

It is only recently that studies have focused on postural perturbations at the threshold of balance recovery, i.e., postural perturbations large enough that balance recovery is not always possible and a fall can occur. The knowledge at the threshold of balance recovery is thus very limited. In particular, the effect of perturbation direction on the threshold of balance recovery has not been quantified, despite evidence of its importance during small and medium postural perturbations [e.g.: 1-2]. Moreover, understanding the effect of perturbation direction is particularly important given that case controlled studies have shown that sideways falls, compared to other fall directions, increases hip fracture risk [e.g.: 3-5]. Therefore, the purpose of this study is to quantify the effect of perturbation direction on the threshold of balance recovery.

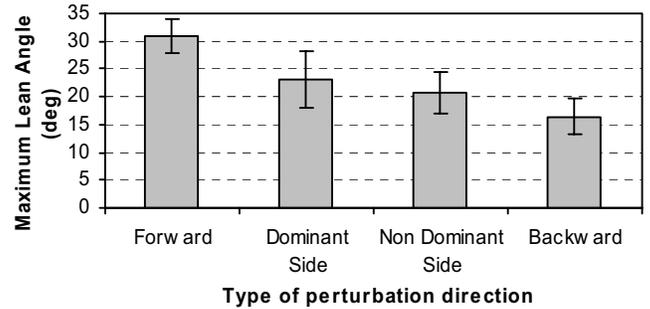

**METHODS**

Balance recovery following sudden release from an initial lean was performed by six healthy younger adults, three males and three females (23.3 ± 2.3 yrs, 1.74 ± 0.07 m, 67.1 ± 11.5 kg). The maximum lean angle that these younger adults could be released from and still recover balance using a single step was determined for i) forward, ii) dominant side, iii) non-dominant side and iv) backward leans. The lean angle was sequentially increased until the subjects failed twice at a given angle and the lean directions were randomly ordered. Lean angles, reaction times, step times, step lengths and step velocities were measured using force platforms (AMTI, Newton, MA) and an Optotrak motion measurement system (NDI, Waterloo, ON). One-way analyses of variance with repeated measures were used to determine the effect of the lean direction.

**RESULTS AND DISCUSSION**

Since there were no significant differences between dominant and non dominant side results, non dominant side results were not considered in the analyses of variance. The lean direction significantly affected the maximum lean angles that younger adults could be released from and still recover balance using a single step (Figure 1 and Table 1). Moreover, at the maximum lean angles, the lean direction significantly affected reaction times, step times, step lengths and maximum step velocities (Table 1). Specifically, forward results were different from dominant side and backward results (p < 0.034) but dominant

side and backward results were not different (p > 0.452). On the other hand, at the maximum lean angles, the lean direction did not significantly affect mean step velocity (Table 1).

**Figure 1:** Effect of the lean direction on the maximum lean angle that younger adults could be released from and still recover balance (p = 0.018).

**CONCLUSIONS**

Preliminary results have shown that the perturbation direction significantly affects the postural disturbance younger adults could sustain. It is thus conceivable that different mechanisms could be responsible for balance recovery in different directions. Further experiments are needed to confirm these preliminary results in a larger sample of younger adults and, more importantly, in a sample of older adults.

### INTRODUCTION

High and low arches have been reported to be predisposing factors for an increased injury risk (Kaufman et al., 1999) Running shoes have been designed to decrease this injury risk. Motion control shoes help to reduce excessive motion in low arch (LA) feet and cushioning shoes assist in attenuating impacts in high arched (HA) rigid feet. Recent data suggest that running in the recommended running shoe for a given foot type reduces injury rates (Knapik et al., 2001). However, the biomechanical changes that occur when running in the recommended shoe have not been evaluated.

Coupling variability, as it relates to injury, has received recent attention in the literature (Hamill et al., 1999) although no inferences have been made to joint variability. Two studies have examined how footwear influences joint variability. Kurz et al., (2003, 2004) reported no difference in frontal and sagittal plane variability of the ankle joint when running in motion control and cushioning shoes. However, variability should also be examined amidst the fatigue that is typical of a prolonged run, when most overuse running injuries are thought to occur. It was reported that the variability of foot position placement on the treadmill increased when subjects became fatigued during a prolonged run (Verkerke et al., 1998). These changes in variability may be a function of arch type, and may be influenced by footwear.

Therefore, the purpose of this paper was to examine changes in lower extremity joint variability when low and high arched individuals run in motion control and cushioning shoes over the course of a prolonged run. It is possible that the shoes may have a greater effect on variability at the end of a prolonged run when the runner is in an exerted state. Since the motion control shoe is more rigid than the cushioning shoe, it was hypothesized that it will reduce variability compared to the cushioning shoe in low arched runners. It was expected the more flexible cushioning shoe will increase variability compared to the motion control shoe in high arched runners during the prolonged run.

### METHODS

Subjects for the study included twelve LA and twelve HA recreational runners (>10mpw). These subjects were classified as LA or HA by being at least 1.5 sd below or above, respectively, a mean arch height index value of a reference population of 60 healthy individuals. The average arch height index was 0.273 for the LA runners and 0.390 for the HA runners. The motion control shoe used was the New Balance 1021 and the cushioning shoe was the New Balance 1022. Subjects were given a 5 minute warm-up jog before starting a prolonged run at their self-selected average training pace. Data were collected 5 min into the prolonged run and just prior to the termination of the run. The run was terminated when the subject exceeded a "hard physical activity intensity" as defined by the American College of Sports Medicine (>85% age specific HR max or the rate of perceived exertion >16).

The variables of interest were the average variability during stance for sagittal plane motion of the knee and ankle,

tibial internal rotation and rearfoot eversion. Average variability was determined by calculating the point by point standard deviation of 5 trials for each subject and averaging across the trial. A two-way repeated measures (shoe, time) ANOVA for each arch type was used to analyze the data. Interactions and main effects were analyzed using a significance level of  $p < 0.05$ .

### RESULTS AND DISCUSSION

A significant interaction in the HA runners for tibial rotation variability was found (Fig. 1). A similar trend was observed for tibial rotation in LA runners. No other interactions or main effects were observed

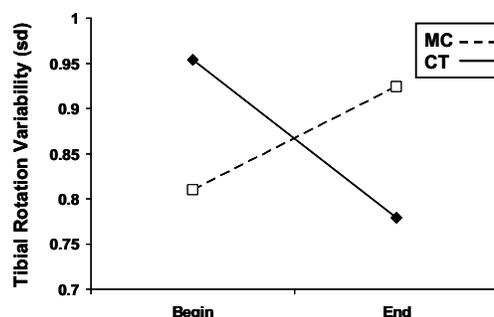

Figure 1. Interaction of footwear and time in High Arched runners (MC=motion control, CT=cushioning shoe)

The hypothesis that the cushioning shoe would increase variability in high arched runners and the motion control shoes would reduce variability in low arched runners over the course of the run was not supported. In fact, the single significant interaction was in the opposite direction of the expectation. Tibial internal rotation variability, while higher at the beginning of the run in the cushioning shoe, increased in the motion control shoe and decreased in the cushioning shoe over the course of the run. A similar trend was observed in the LA runners although not significant ( $p=0.16$ ). While we observed a shoe-related difference in variability, the benefits of this effect in injury prevention remain theoretical and require further study.

### CONCLUSION

High arched runners increased tibial rotation variability in motion control shoes and decreased tibial rotation variability in cushioning shoes over a prolonged run.

**Arm abduction angle and contraction intensity effects on deltoid and scapular rotator muscle recruitment during scapular plane isometric contractions**

Mark K. Timmons, Staci M. Stevens, Danny M. Pincivero  
 Email: mark.timmons@utoledo.edu

Human Performance and Fatigue Laboratory, Department of Kinesiology  
 The University of Toledo, Toledo, OH

**Purpose:** To investigate the effects of arm elevation angle and voluntary isometric contraction intensity on deltoid and scapular rotator muscle recruitment.

**Methods:** Nine healthy, young adults (5 men, 4 women) performed maximal and sub-maximal isometric arm abduction contractions in the scapular plane on a Biodex isokinetic dynamometer. The subject's right arm was secured to the resistance arm of the dynamometer immediately proximal to the wrist. The arm was positioned in the plane of the scapula in an abducted position. Subjects performed five isometric maximal voluntary abduction contractions (MVCs), followed by randomly ordered ten-second sub-maximal contractions at 10-90% MVC (10% increments) (CI), at the following arm abduction angles (AA): 15, 30, 45, 60, 75 and 90 degrees.

During each contraction electromyograms (EMG) were obtained from the deltoid (DEL), upper trapezium (UT), lower trapezium (LT) and serratus anterior (SA) muscles. EMG signals were collected at 2000 Hz, bandpass filtered (20-500 Hz) and fullwave rectified. A 3 second analysis window was chosen during the point of maximal torque for the MVC's and during the point at which the subject was producing the target torque. The integrated EMG (IEMG) value was calculated for each analysis window, and were expressed in absolute (ABS) and normalized to the MVC (NORM) units.

**Results and Discussion:** The MVC torque (TOR) decreased significantly ( $F_{5,40} = 7.44, p < 0.001$ ) as AA increased (Table 1). Absolute IEMG demonstrated significant main effects for AA ( $F_{5,160} = 15.82, p < 0.001$ ) and CI ( $F_{9,288} = 171.79, p < 0.001$ ).

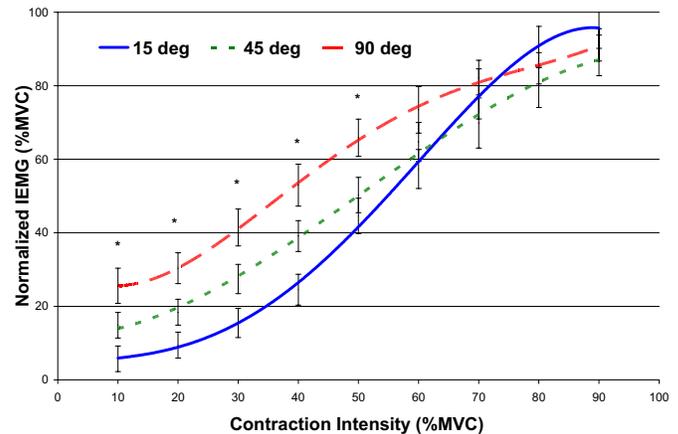

Analysis of the NORM IEMG demonstrated significant main effects for both AA ( $F_{5,160} = 15.18, p < 0.001$ ) and CI ( $F_{8,256} = 637.15, p < 0.001$ ), and an AA by CI interaction ( $F_{40,128} = 5.82, p < 0.001$ ). The lower AA levels (15, 30, and 45 deg) were each significantly different from the higher AA levels (60, 75, and 90 deg). No significant muscle main effect or interaction effects were observed to be significant. Figure 1 displays the normalized IEMG as a function of CI for the DEL muscle (only the 15, 45 and 90 deg levels are shown for clarity). A similar pattern of higher NORM IEMG, plotted as a function of CI, was shown for the UT, LT and SA muscles.

The results of this investigation agree with the results from previously reported studies. Lawrence and DeLuca (2) reported

**Table 1.** MVC torque and IEMG.

	15 deg	30 deg	45 deg	60 deg	75 deg	90 deg
<b>Torque (N•m)</b>	55.2 (7.7)	54.1 (7.5)	49.9 (6.7)	48.1 (7.0)	45.4 (6.9)	45.7 (8.3)
<b>Deltoid (V•s)</b>	3.468	3.45	3.611	3.884	3.862	3.78
<b>Upper Trapezium (V•s)</b>	1.903	2.775	2.558	2.988	3.199	3.165
<b>Lower Trapezium (V•s)</b>	1.914	1.92	1.719	1.75	1.95	1.867
<b>Serratus Anterior (V•s)</b>	0.84	0.783	0.967	1.102	0.906	1.117

a nonlinear increase in EMG intensity with increasing CI. Coury et al (1) reported an increase in deltoid EMG and a decrease in deltoid force with increasing shoulder flexion. Ringelberg (3) reported that normalized IEMG increased during sub-maximal isometric contractions, as a function of increasing AA. EMG from the upper trapezius has been shown to display a linear increase with increasing CI; however the rate of EMG increase was greater during higher force contraction, 50-90% MVC than lower force contractions (4).

**Figure 1.** Normalized deltoid muscle IEMG vs. CI, 15°, 45° and 90° AA (\* $p < 0.05$ ).

**Conclusions:** The results of this investigation demonstrate that the recruitment of the shoulder muscles during isometric abduction contractions is dependant upon the position of the shoulder, as well as the intensity of the contraction. The increased muscular recruitment that is exhibited at higher AA during relatively low CI is possibly explained by changes in muscle length produced by altering orientations of the bony components of the shoulder girdle.

## EFFECTS OF PROPRIOCEPTION AND STRENGTH TRAINING ON INJURY PREVENTION IN ADOLESCENT AND YOUNG ADULT FEMALE DANCERS

Carla Murgia

Exercise Science, Kean University

Biomechanics & Kinesiology; email: docmurg@aol.com, web: www.kean.edu

### INTRODUCTION

The positive effects of strength and proprioceptive training in the rehabilitative process of the injured athlete are well documented in the literature [1,2,3]. It has been suggested that deficits in neuromuscular pathways associated with injuries have a detrimental effect on joint position sense, protective and defensive mechanisms of the injured joint, balance, and delay of return to activity [4,5]. As a result, progressive strength and proprioception training have been incorporated early into the rehabilitation protocol of injured athletes to restore joint stability and a quicker return to functional performance activity levels [6,7]. The purpose of this study was to examine the effects of strength and proprioception conditioning in the prevention of injuries in female dancers.

### METHODS

One hundred subjects were randomly selected from professional dance studio advanced classes. Female subjects, aged 13 to 21 years of age, were cross trained in dance forms. Subjects were randomly assigned to four treatment groups: strength and proprioceptive conditioning (group 1); strength conditioning and relaxed static stretching (group 2); proprioceptive conditioning and relaxed static stretching (group 3); and static stretching (group 4). Progressive strength protocols for the knee and ankle included use of Thera-Band (silver strength) resisted motion and specialized weight training of the inferior extremity. Proprioception protocol consisted of a regimen commonly used in ankle and knee injury rehabilitation regimens. Stretch protocol incorporated the use of relaxed focused static stretch positioning. Positions were held for 30 seconds. All groups trained in front of a mirrored wall 3 times per week for 10 weeks. Pre and post-tests were compared for ankle and knee stability, kinesthesia, and postural sway. Pre and post treatment surveys were used to determine occurrence and severity of knee and ankle joint injury. Ankle stability was assessed using the anterior draw and tilt tests. Knee stability was assessed using varus-valgus, Lachman, and a-p drawer tests. Active and passive joint position sense for the knee and ankle were evaluated using isokinetic instrumentation. Postural sway was measured by identifying center of mass using a 3D automatic digitizing video system and a force platform. Subjects were required to maintain a flat-foot and demi-pointe one-foot stance for 30 seconds on the platform. Postural sway was determined by measuring the amount of center of gravity excursion in the frontal and sagittal planes. Quantity of sway in each plane was summed to determine total center of gravity excursion. A one-way ANOVA with repeated measures was used to analyze the data. Scheffe' post hoc tests were used to analyze the nature of the differences when significance was found.

### RESULTS AND DISCUSSION

Groups that participated in any combination of strength and/proprioceptive conditioning (groups 1, 2 & 3) had significantly ( $p < .01$ ) greater ankle and knee joint stability and less postural sway than the controls (group 4). When combination protocol (group 1) and the two combination relaxation protocols (groups 2 & 3) were compared for joint stability and postural sway, positive effects were found, although not significant. Joint position sense scores significantly increased ( $p < .01$ ) in the two proprioception training groups (1, 3). In addition, dancers who participated in any combination of strength and proprioceptive training sustained fewer leg injuries of lesser severity ( $p < .05$ ) and when injured, returned to full activity sooner than the controls. Anecdotally, surveys administered at the end of the study revealed that general complaints of discomfort about the knee and ankle joints decreased in number and severity ( $p < .01$ ).

### CONCLUSIONS

The results indicate that stronger muscles in proper strength ratios and educated sensory receptors produce stable joints that are more proficient in the identification of joint position and correction of sudden abnormal positions. The lack of significance between "treatment" regimens 1 and 2 or 3 does not necessarily indicate that all three treatment groups are equally effective. It may reflect the restorative effect of relaxed focused stretching. Dancers do not usually take the time to rest. They work through fatigue and minor injuries despite symptoms of pain and paresthesia, which result in poor movement mechanics, as evidenced by "harder" landings from jumps and leaps, "sagging ankles" in releve' and foot pronation in turn-out. The results of this study clearly demonstrate the positive effects of strength and proprioceptive conditioning when included in training cycle of the dancer. Inclusion of these components is recommended for enhancement of the quality of the performance life of the dancer.

## THREE-DIMENSIONAL IN VIVO ROTATION OF FUSED AND ADJACENT LUMBAR VERTEBRAE

William Anderst and Scott Tashman

Motion Analysis Lab, Bone and Joint Center, Henry Ford Health System, Detroit, MI 48202; email: anderst@bjc.hfh.edu

### INTRODUCTION

Over 300,000 spinal fusion operations were performed in the United States in 2001 and the frequency is increasing [1]. Vertebral motion is three-dimensional (3D) and dependent upon bone, ligament and disc constraints in addition to active musculature. To understand normal vertebral motion and the effects of surgical procedures on spine function, in vivo 3D studies must be performed during muscle driven activities.

Previous in vivo 3D lumbar vertebrae motion studies have included only static measurements [2-4], while dynamic motion has been studied only in 2D [5]. The present pilot study investigated the in vivo 3D motion of lumbar vertebrae during movement. The purpose was to measure the relative rotation between fused and unfused vertebral segments.

### METHODS

Five lumbar fusion surgery patients served as subjects ( $44 \pm 12$  yrs). Informed consent was received prior to surgery. Three to five tantalum beads were implanted into each of the fused vertebrae and the vertebrae adjacent to them. Subjects were tested 2, 3 and 6 months after surgery. Implanted beads were tracked (accuracy  $\pm 0.10$  mm [6]) in biplane x-ray images (50 fps, 100 kV, 100 mA) to determine 3D vertebral kinematics. Subjects performed six motions: forward and backward bending, lateral bending to both sides and axial twisting in both directions. Data collection began with the subject seated upright and continued for 1.0 s per movement. Subjects moved until they reached the end of their range of motion. Reflective markers placed on the shoulders, C7, suprasternal notch, ASIS and PSIS tracked trunk rotation.

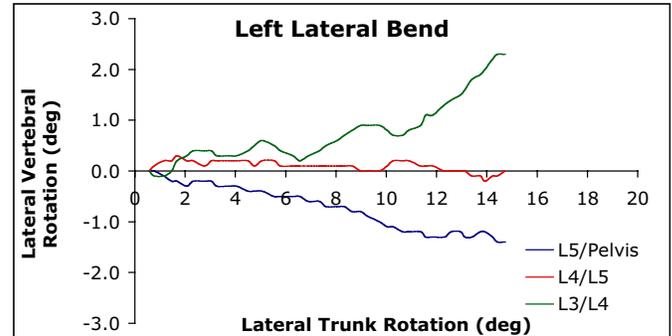

Vertebrae were CT scanned and reconstructed into 3D surface models [7]. Relative rotations between adjacent vertebrae (e.g. L3/L4 means "L3 relative to L4") were calculated by body-fixed, ordered rotations about vertebral body anatomical axes (defined by CT reconstructions) in the order flexion/extension, axial (twist), and lateral bending.

### RESULTS AND DISCUSSION

Data collected 2 and 3-months post surgery showed less than  $2^\circ$  of relative motion between vertebrae for all subjects, likely because their range of motion was still limited. Patient mobility increased six months post surgery. Between subject variation (fusion site, number of vertebrae fused, type of fusion) was wide ranging and grouping results was inappropriate. Thus, results from one patient 6 months post surgery are presented here. This subject had an L4-L5 fusion. Rotation of L5/Pelvis (inferior to fusion), L4/L5 (fused site) and L3/L4 (superior to fusion) were calculated.

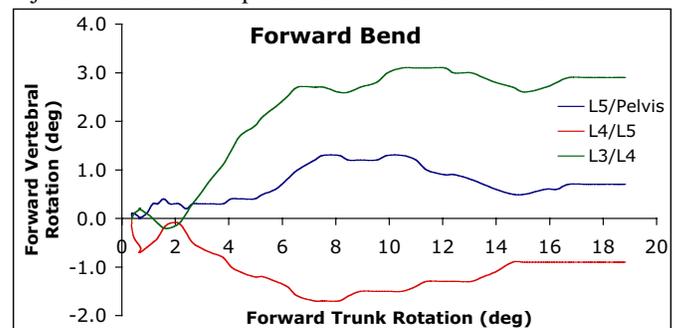

In the left lateral bend (Figure 1), there was less than  $0.3^\circ$  of rotation between fused vertebrae. The vertebra inferior to the fusion had a relative rotation opposite the trunk rotation and the vertebra superior to the fusion had a relative rotation in the direction of trunk rotation. The relative rotation between vertebrae did not necessarily change linearly with trunk

rotation, as there was little movement in L3/L4 until after the trunk rotated  $10^\circ$  (Figure 1). Conversely, L5/Pelvis varied more linearly with trunk rotation.

**Figure 1:** Relative vertebrae rotation during a left lateral bend. Positive values are in the direction of trunk rotation.

Forward bending induced relative motion between the fused vertebrae (Figure 2). Also, relative motion between vertebrae occurred near the initiation of trunk rotation. After  $7^\circ$  of trunk rotation, there was little change in relative rotation between adjacent vertebrae in spite of continued trunk flexion.

**Figure 2:** Relative vertebrae rotation during a forward bend. Note relative motion of fused vertebrae (L4/L5). Note also the non-linear relationship between trunk rotation and relative rotation between vertebrae.

### CONCLUSIONS

The primary findings were: 1) relative rotation between adjacent vertebrae was not always linearly related to trunk motion; 2) motion in different planes should be studied to investigate relative motion between fused vertebrae, and 3) relative rotation of the vertebra superior to the fused site tended to be in the same direction as the trunk, however relative rotation of the vertebra inferior to the fused site was often in the direction opposite of trunk rotation.

## THE EFFECTS OF WRIST SPLINTING ON MUSCLE ACTIVITY DURING A HAND GRIP TASK

Jennifer Di Domizio & Peter J. Keir Ph.D.\*

School of Kinesiology and Health Science, York University, Toronto, Canada M3J 1P3

\*email: pjkeir@yorku.ca

### INTRODUCTION

Wrist splints are commonly used in the rehabilitation of carpal tunnel syndrome and other wrist disorders. While they are usually prescribed for night use, they have become common for both day and workplace use. Theoretically, splinting of the wrist should lower muscle activity by stabilizing the wrist and reducing the need for co-contraction. However, the effectiveness of decreasing muscle activity through wrist restraint is inconclusive [1, 2]. The purpose of the study was to examine the relationship between forearm muscle activity and splinting during grip force production.

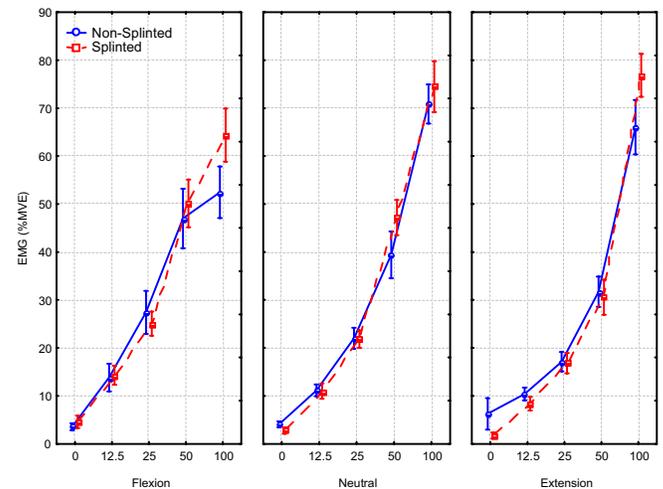

### METHODS

Ten healthy volunteers (5 male, 5 female) participated. Forearm muscle activity was examined during four grip force exertion levels (12.5, 25, 50 and 100% Grip<sub>max</sub>) in three wrist postures, with and without a wrist splint. EMG was recorded from flexors carpi radialis (FCR) and ulnaris (FCU), flexor digitorum superficialis (FDS), extensors carpi radialis (ECR) and ulnaris (ECU) and extensor digitorum communis (EDC). Plexiglass splints were affixed to the dorsal aspect of the right forearm and hand with tape for each posture (0°, 30° flexion, 30° extension). Experimental set up and procedures followed a previous study [3]. A grip dynamometer (MIE Medical Research Ltd., Leeds, UK) was used with a 5 cm grip span and was not supported, while the forearm rested on a platform. An oscilloscope provided visual feedback with the instantaneous grip force overlaid on the target grip force. Differential raw EMG and grip force data were collected at 1000 Hz, with EMG digitally linear enveloped at 3 Hz. Each trial lasted 10 s and was initiated with a "pre-exertion" (zero force) phase lasting a minimum of 1.5 s, followed by an increase to the desired target force, which was maintained for a minimum of three seconds. Average EMG (AEMG) was calculated for "pre-exertion" and target force phases.

### RESULTS AND DISCUSSION

No significant differences in activity were observed between splinted and non-splinted conditions for any muscle during low to moderate target forces (12.5, 25, 50%). However, the use of a splint significantly increased muscle activity for ECR, ECU, EDC, FCR and FCU during maximal efforts (100% Grip<sub>max</sub>) at postures specific to each muscle (all  $F < 3.6$ , all  $p < 0.044$ ). These increases ranged from 7.3%MVE for FDS to 28.2%MVE for FCU. The largest difference was observed for FDS (39.1%MVE), but it was not statistically significant. During pre-exertion (0% Grip<sub>max</sub>), wrist splinting appeared to support the wrist, as evidenced by lower AEMG for ECR and FDS (all  $F > 6.1$ ,  $p < 0.036$ ). ECU, EDC and FCR also exhibited lower activity, but did not attain significance. However, this finding may be explained by lower grip forces required to hold the dynamometer in the pre-exertion phase when splinted (approx. 0.6 N less). Figure 1 illustrates the

general result that AEMG was generally lower at zero grip force, similar from low to moderate target forces (12.5, 25, 50%) and higher at maximal (or near maximal) grip exertions. True maximal grip force was not attained by most participants, especially in the flexed wrist posture; however, there was no difference with or without splinting. While the splints created for this study are not representative of most commercially available products, these data indicate that the effectiveness of splinting may be governed by force level and wrist posture. These data also suggest that industrial wrist bracing to reduce operator effort with power hand tool use, such as with power screwdrivers [4], may require further assessment using EMG.

**Figure 1.** Mean ECU muscle activity (%MVE) versus grip force (%Grip<sub>max</sub>) for the three wrist postures in splinted (dashed line) and non-splinted (solid line) conditions.

### CONCLUSIONS

At low to moderate grip effort levels, muscle activity was not altered by using a wrist splint, however, at maximal effort, AEMG increased with the splint. It would appear that a dorsal wrist splint does not reduce muscular effort in what might be considered "active" use. In addition, under the conditions tested, dorsal wrist splints did not reduce co-contraction. Thus, the increasingly common use of wrist splints during daily activities should be reconsidered, if the intent is to reduce wrist loading by decreased muscle activity.

## THE FORCE-LENGTH CURVE OF THE HUMAN GASTROCNEMIUS IN VIVO.

Samantha Winter and John H. Challis  
Biomechanics Laboratory, The Pennsylvania State University, USA  
email: [slw294@psu.edu](mailto:slw294@psu.edu), [jhc10@psu.edu](mailto:jhc10@psu.edu)

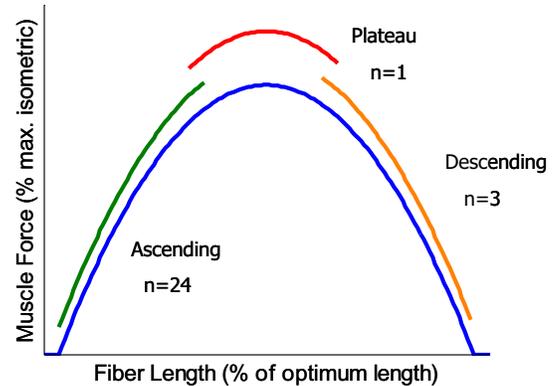

### INTRODUCTION

The variation in isometric force produced with changing muscle length has been investigated extensively and ascending, plateau and descending limbs of this force-length relationship have been explained in terms of the cross bridge theory [1]. However, in vivo different skeletal muscles may operate over all or only part of the force-length curve, and for a given muscle, different individuals may be adapted to operate on different parts of the curve. The purpose of this study was to determine the force-length relationship for the gastrocnemius, which has not been reported previously in vivo for humans. A modified method based on the algorithm of Herzog & ter Keurs [2] was used to reconstruct the force-length curves of the muscle.

### METHODS

Fourteen male and fourteen female subjects aged between 18 to 27 years performed maximal isometric plantar flexions in a Biodex dynamometer (females: mass  $60.9 \text{ kg} \pm 10.0$ , height  $1.66 \text{ m} \pm 0.02$ ; males: mass  $86.1 \text{ kg} \pm 11.9$ , height  $1.81 \text{ m} \pm 0.07$ ). Plantar flexion moments were recorded at five ankle angles: -15, 0, 15, 30 and 40 degrees, with negative angles defined as dorsi-flexion. These measurements were repeated for four different randomly ordered knee angles (0, 50, 90, 115 degrees of flexion) over two testing sessions four to ten days apart.

The change in normalised gastrocnemius muscle length was computed as a change from the reference position, defined as full knee extension and a 0 degree (neutral) ankle angle. The force in the Achilles tendon was computed from the active moment and the ankle moment arm [3]. The ankle moment arm was scaled according to the shank length of the subject. Robust regression techniques [4] were used to fit first and second order polynomials to each set of four forces measured at the same ankle angle, but at different knee angles. The second order equation was selected as long as it produced a monotonic relationship. This step produced five curves corresponding to different sections of the gastrocnemius force-length curve. The curves were separated along the vertical force axis by the monoarticular force contribution, but they overlapped in terms of the length change on the horizontal axis. The entire length change represented the length change produced by all of the various experimental joint configurations. In order to subtract out the mono-articular contribution from each data set, the polynomial equation of the first data set was used to predict the force value of the first data point in the second set, and the force difference was then subtracted from all the data points in this second set. This procedure was repeated for all subsequent sets. Points were then normalised to the maximum force, and second and first order polynomials were fitted to the entire normalised data set.

**Figure 1:** Number of subjects operating over each portion of the force-length curve.

### RESULTS AND DISCUSSION

The majority of the 28 subjects operated over the ascending limb; however, three subjects operated over the descending limb, and one subject operated over the plateau region (Figure 1).

Sensitivity analyses indicated that the reconstructions of the force-length curves were robust to changes in the moment arm and maximal tendon stretch parameters used.

Previous work has also determined that there is variation in the portion of the force-length relationship that the rectus femoris operates over [5]. There was, however, a higher degree of consistency in the portion operated over for the gastrocnemius. This might be reflective of more consistent functional demands placed on the gastrocnemius.

### CONCLUSIONS

In vivo variation exists, for the gastrocnemius, in the portion of the force-length curve operated over. The source of this variation, that is, whether it arises as a result of genetic expression or as a result of functional adaptation, is unknown, but the variation should be recognised when conducting modelling studies or when performing surgery.

## THE CONTRIBUTION OF ARTICULAR SURFACE GEOMETRY TO ANKLE STABILIZATION

Yuki Tochigi, M. James Rudert, Charles L. Saltzman, Annunziato Amendola, and Thomas D. Brown  
University of Iowa, Department of Orthopaedics and Rehabilitation  
Email: [yuki-tochigi@uiowa.edu](mailto:yuki-tochigi@uiowa.edu), web: <http://poppy.obrl.uiowa.edu/>

### INTRODUCTION

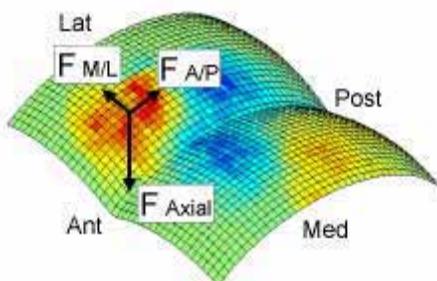

Passive stability of the ankle under weight-bearing conditions is thought to rely substantially on the role of the articular surfaces[1,2]. Ligament-sectioning paradigms previously utilized to study the relative contribution of ligamentous vs. articular restraints have not allowed direct study of the mechanism by which surface resistance contributes to ankle stabilization. This study hypothesized that ankle stabilization by surface resistance involves specific contact stress changes that plausibly explain the contribution of articular surface geometry to passive ankle stability.

### METHODS

Six cadaver ankles with the significant peri-ankle ligaments intact were subjected to an experiment to explore articular contact pressure changes associated with various external loads. The loads were anterior/posterior (A/P) shear forces (40 and 80 N), inversion/eversion torques (150 and 300 N-cm), and internal/external rotation (IR/ER) torques (150 and 300 N-cm); these magnitudes are similar to those occurring during gait. An MTS-based custom fixture held a specimen at a predetermined ankle position (15° dorsiflexion, neutral, 15° plantar flexion, or 30° plantar flexion) under 600N axial force. At each position, one of the three external loads was applied for all load increments, while motion associated with the two remaining loads was unconstrained.

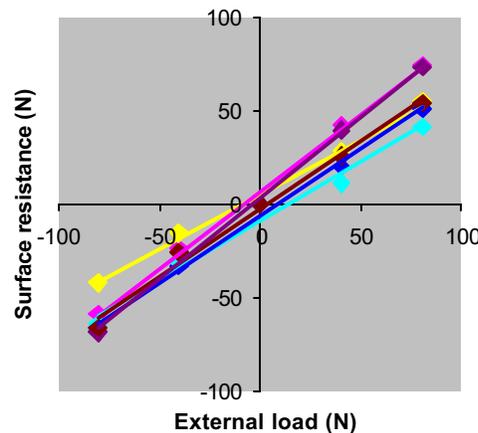

Contact stress on the superior tibial plafond surface was recorded by a purpose-designed transient stress transducer (Tekscan Inc., Boston, MA, USA), which reported local stress at each of the 1472 (32x46) sensing units (sensels). For each load/position, the pressure changes due to the applied external load were calculated from the recorded pressure map by subtracting the corresponding axial-load-only map obtained at that position, on a sensel-by-sensel basis.

Plafond geometry was modeled as two adjacent spherical sectors (Fig.1). The force at each sensel, assumed to act normal to the surface, was resolved into three components: axial, A/P, and medial/lateral (M/L). The sum of the A/P components was assumed to represent the surface resistance to the applied external A/P load. Version and IR/ER torques about the zero-load center of pressure were calculated from the appropriate force components and were assumed to represent the surface resistance to the corresponding external loads. Frictional forces were assumed negligible.

**Fig.1** Ankle geometric model with a pressure change map (external load = 300 N-cm IR torque). The plafond geometry consists of two partial spheres (radius = 25mm, separation b/w centers = 20mm). The force is regarded as applied from the tibia to the talus. Pressure change is converted to the corresponding force perpendicular to the sensel surface. The axial, A/P, and M/L components of the force are utilized to estimate the magnitude of the surface resistance associated with the external load.

For each of the three external loading conditions, and at each position, the resisting force/torque was linearly regressed against the magnitude of the externally applied force/torque (Fig.2). The slope was considered to represent the contribution of the measured pressure changes to restraining the ankle. (A slope of 1.0 would indicate that articular surface engagement provided 100% of the resistance). This analysis was individually applied to each specimen.

**Fig.2** External load vs. surface resistance in the A/P force test at the neutral position (n=6). Each specimen has five data points (plotted for the four external-load magnitudes and the axial-load-only condition) and a trend line based on linear regression. In this case, correlation coefficient (R) is greater than 0.99 in every specimen, and the slopes range from 0.61 to 0.98.

### RESULTS AND DISCUSSION

In the neutral position, the pressure changes on the tibial plafond accounted for  $73 \pm 11\%$  (average  $\pm$  standard deviation) of the external AP force,  $39 \pm 14\%$  of the version torque, and  $30 \pm 14\%$  for the IR-ER torque. Significant effect of ankle position was revealed only in the version test ( $p = 0.01$ , single factor ANOVA), in which the contribution linearly decreased in the plantar-flexed positions.

The results indicate that the superior-inferior tibial-talar surfaces play the primary role in A/P stabilization under weight-bearing conditions. Contribution of these surfaces in helping to resist version and IR-ER torque was also evident, even without counting the effect of the lateral and medial ankle “gutter” surfaces (a subject inviting future investigation).

### CONCLUSION

Ankle stability under weight-bearing conditions appears to be substantially dictated by the ankle surface geometry.

## AN INVESTIGATION OF THE CONGRUITY IN GEOMETRY OF THE GLENOHUMERAL JOINT ON THE MAXIMUM ACCEPTABLE LOAD DURING PUSHING

Krystyna Gielo-Perczak

Liberty Mutual Research Institute for Safety and Health, Hopkinton, MA U.S.A.

email: [Krystyna.Gielo-Perczak@LibertyMutual.com](mailto:Krystyna.Gielo-Perczak@LibertyMutual.com) web: [www.libertymutual.com/research/](http://www.libertymutual.com/research/)

### INTRODUCTION

Occupational ergonomics and safety analyses of the human body require a new biomechanical approach that combines the geometric complex nature of the human joints with the requirements of the workplace in order to explain the mechanism of musculoskeletal disorders. Recent analyses of the glenohumeral joint have not focused on the contribution of geometric parameters like the radii of the glenoid fossa of scapula and the humerus, and their functional relationship to strength. However, Saha (1961) pointed out the variance of shoulder anatomy relating to the congruity of the glenoid and humeral head. In the general population we can distinguish the three most common characteristic shoulder joints: 1) Type A, the glenoid with a radius that is larger than that of the humerus, 2) Type B, the glenoid and the humerus with the same radius, 3) Type C, the glenoid with a smaller radius than that of the humerus [1]. The purpose of the current study was to answer to question is the strength used in one-handed pushing related to the congruity of the glenoid and humeral head?

### METHODS

The coefficient of congruity (conformity) ( $R/r$ ) was defined as a ratio of the humerus radius ( $R$ ) and radius of the glenoid fossa of the scapula ( $r$ ) curvature. This coefficient for type A was defined as  $\leq 0.75$ , where components were with unequal radii of curvature (glenoid larger) nonconforming articulation; for type B as  $< 0.75; 1.25 >$ , as a conforming articulation where humeral and glenoid components were almost equal and for type C as  $\geq 1.25$ , nonconforming articulation with glenoid radius smaller than the humerus.

Frontal MRI images of the glenohumeral joint of the right arm were obtained from 12 healthy men who had never experienced chronic shoulder pain, stress fracture, or joint injury. Data were recorded by using a 1,5-T Sigma system (GE Medical Systems). The subject lay in an MRI tube in a prone position with his arm in  $0^\circ$  of adduction. The elbow was flexed to  $90^\circ$  with the forearm lying on the chest. The magnetic resonance images were taken at the same arm positions for all subjects.

The same 12 subjects performed a series of simulated pushing tasks in laboratory conditions. A special constrained framework was designed with twelve force sensors. Subjects exerted maximum push force during maximum voluntary contraction (MVC) on a handle in a sidewise direction. The subjects were asked to push on the handle and MVC loads were recorded when the arm was abducted from 5 to 30 degrees in the frontal plane. Over a two-week period, each subject performed two and four repetitions of constraint range upper-limb abduction and adduction at six different randomized angles while standing. For each repetition, participants were instructed to gradually increase their effort

to what they felt was an acceptable maximum force. Once the maximum force was reached, subjects sustained MVC on the instrumented handle for three seconds.

Subject	R/r	Type
1	1.41	C
2	0.72	A
3	0.70	A
4	0.69	A
5	1.13	B
6	0.77	B
7	0.86	B
8	0.70	A
9	1.39	C
10	0.47	A
11	1.05	B
12	1.38	C
Mean	0.71	

**Table 1:** The coefficient of congruity ( $R/r$ ) and type of joint for 12 participants.

### RESULTS AND DISCUSSION

The participants' mean age and standard deviation was  $40.5 \pm 8.7$  years, with an average height of  $178 \pm 7.08$  cm and body weight of  $81.5 \pm 14.9$  kg. The coefficient of congruity and related type of joint for the 12 participants are presented in Table 1. The three most common types of shoulder joint congruity among 12 subjects do not correlate with mean forces recorded at the handle during maximum voluntary contraction when arm was abducted from 5 to  $30^\circ$ .

The results from study [2] relating to one-handed pushing showed that the maximum forces exerted were higher than in the current study, but the subjects had free movement and were not constrained. Perhaps the constrained position of participants in the current experiment was a very unique factor which was never before considered during the strength measurements.

### CONCLUSIONS

The investigation didn't reveal the influence of the coefficient of congruity on the maximum acceptable load applied to the hand during pushing. However, the study confirmed that the relation of different geometric parameters of glenohumeral joint should be analyzed which have an influence on the strength of the subject.

**BIOMECHANICAL ANALYSIS OF EMG ACTIVITY BETWEEN  
 BADMINTON SMASH AND DROP SHOT**

Chien-Lu Tsai<sup>1</sup>, Huang, Kwei-Shu<sup>1</sup>, and Shaw-Shiun Chang<sup>2</sup>  
<sup>1</sup>National Taiwan Normal University, <sup>2</sup>National Taiwan Ocean University  
 email: [cltsai@cc.ntnu.edu.tw](mailto:cltsai@cc.ntnu.edu.tw)

**INTRODUCTION**

The forehand overhead stroke is one of the most typical and powerful badminton techniques. It can be divided into several types of stroke. Previous studies related to badminton skills had been conducted by several researchers, Gowitzke and Waddell, 1979, they used 2D model to describe the smash strokes. Tsai, et al, 1996, they used 3D model to analyze the smash strokes. Tsai, et al, 2001 used the inverse dynamic to investigate the upper extremities of Taiwan elite badminton players, they found the wrist joint exerted the greatest velocity and power value in both kinds of strokes than the elbow and shoulder, the extensor muscles of wrist were performing the eccentric contraction around contact. The purpose of this study was to analyze the kinematics and the surface EMG methods on the upper extremities of the elite badminton players when they were performing smash and drop shots.

**METHODS**

Four elite badminton players (age 21yrs, high 175cm, weight 68kg) in Taiwan were served as the subjects. The patterns of the shuttle in this study were divided into two different trajectories. While the players were performing the smash, the target of the shuttle was on the ground of opponent's middle court. The drop shot was landing on the opponent's frontal court. The upper extremity of the subject was separated into three segments. The segments were estimated by using the Dempster's parameter. Two Redlake 1000 high-speed digital cameras (Motion Scope, San Diego, USA, 250Hz) were used to record the 3D kinematics data, one Biovision EMG system was used to record the raw EMG signals of upper limb muscles, such as flexor carpi ulnaris, extensor carpi radialis, biceps brachii, triceps brachii, deltoid and pectoralis major. A dependent-paired t-test was used to test the selected variables at .05 significant levels.

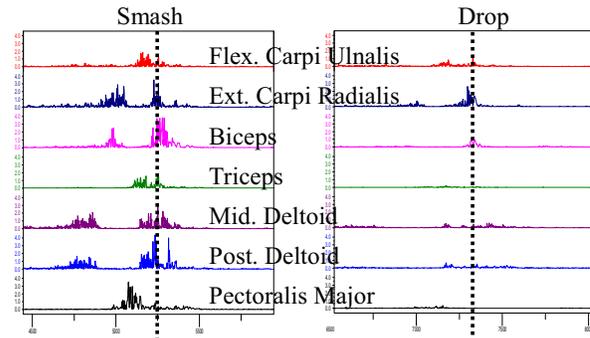

**RESULTS AND DISCUSSION**

**Table 1:** The Kinematics Variables of the Smash and Drop Strokes

Variables	Smash	Drop	Sig.
Time of Contact (sec)	0.004	0.008	*
Shuttle Velocity(m/s)	75	27	*
Shuttle Angle (deg)	-7	-2	
Shoulder Angle (deg)	169	147	
Elbow Angle (deg)	189	164	*
Wrist Angle (deg)	187	185	
Shoulder Ang Vel..(deg/s)	-709	-302	
Elbow Ang. Vel.(deg/s)	-678	-404	
Wrist Ang. Vel..(deg/s)	-2040	-498	*

\*  $p < .05$

Table 1 shows the kinematical data of the smash and drop shots at the contact point. There were significant differences between the smash and drop shots in shuttle velocity, the contact duration time, the elbow angle at the contact point and the wrist angular velocity. contact.

**Figure 1:** The EMG Signals of the Smash and Drop Shots

Figure 1 shows the raw surface EMG signal patterns of smash and drop strokes around contact. From the EMG patterns, we found the sequence of smash and drop shots were similar. The surface EMG activity of smash stroke was stronger than the drop shot. The Deltoids were acting in the very first period of the movement to raise the upper arm. Then the Ext. Carpi Radialis and Biceps to backward and downward the racket to prepare swing the racket upward. The Pectoralis Major acted to move the upper arm swing the arm upward. Before contact, the Triceps and the Flex. Carpi Ulnalis contracted to swing up the racket. The Biceps, the Ext. Carpi Radialis and the Deltoid acted to stable the upper extremities. Tsai, et al in 2001 had deduced that the Ext. Carpi Radialis and Biceps might be engaged in the eccentric contraction during the contact phase in the smash stroke. In this study, we verified that not only the extensor muscles of wrist but also the biceps were suffering the eccentric contraction around contact.

**CONCLUSIONS**

The results showed that there were significant differences in initial flight angle, contact duration time and initial shuttle velocity between the smash and the drop shots. The surface EMG activity of smash stroke was stronger than that of drop shot. The sequence of the movement of smash and drop were very similar. The EMG signal of smash was significant greater than that of drop shot. In this study, we verified the biceps and the wrist extensor were performing the eccentric contraction at the contact point.

## EVALUATION OF OSMOSIS-INDUCED DEFORMATION OF ARTICULAR CARTILAGE USING ULTRASOUND BIOMICROSCOPY IMAGING

Qing Wang and Yongping Zheng

Rehabilitation Engineering Centre, The Hong Kong Polytechnic University  
email: [03900369r@polyu.edu.hk](mailto:03900369r@polyu.edu.hk)

### INTRODUCTION

Articular cartilage, a biological connective tissue, covers the bony ends of articulating joints. It has been found that the unique composition and multilayered structure of articular cartilage contribute to its intrinsic biomechanical properties.

In recent years, ultrasound has been utilized to measure not only the acoustic properties but also the mechanical properties of cartilage combined with compression and indentation methods. This study introduced an ultrasound biomicroscopy imaging method to evaluate the osmosis-induced deformation of artilage cartilage and its mechanical properties.

### METHODS

The ultrasound biomicroscopy system consisted of a computer-controlled stepper-motor, 3-D translating device and the signal acquirement system (Figure 1). Ultrasound transducer could be moved vertically and horizontally in the  $x$ ,  $y$  and  $z$  directions to obtain the maximum echoes from the tissue. Using the custom-made software, the digitalized A-mode ultrasound signals and B-mode images were stored for the offline analysis.

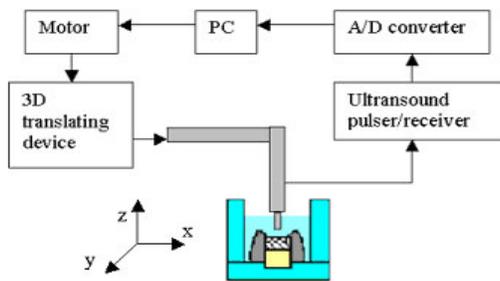

Figure 1: Schematic of the ultrasound system.

Cartilage-bone plugs ( $n = 5$ ) with a diameter of 6.35 mm and the cartilage thickness ranged from 1.39 mm to 1.70 mm were prepared from the proximal-lateral side of bovine patellae. Specimen was fixed on the bottom of the container and equilibrated for one hour in physiological saline solution (0.15 M NaCl), and then the solution was immediately replaced by the hypertonic saline (2 M NaCl). The deformation of cartilage under the osmotic loading was monitored by the ultrasound biomicroscopy imaging system.

### RESULTS AND DISCUSSION

The section (full-thickness of cartilage  $\times$  1.5mm) of the central portion of specimen was scanned (Figure 2). From the deformation of cartilage specimens under the osmotic loading due to the increase of the concentration of the external saline bath, the compressive strains were measured from 0.003 to 0.025 for the five samples. The mean ultrasound speeds in 2 M saline and in cartilage immersed in 0.15 M saline were 1646 m/s and 1652 m/s, respectively, measured using a noncontact method reported earlier [1].

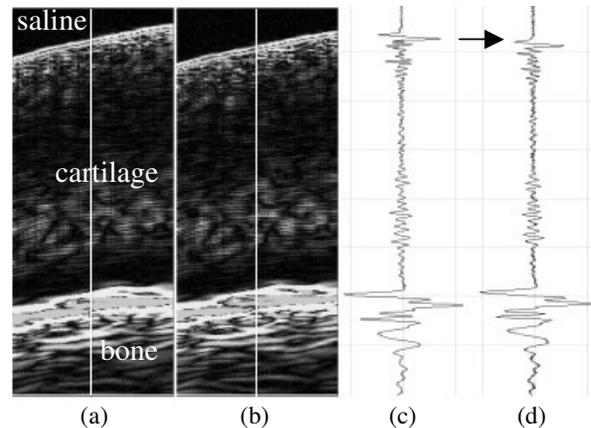

Figure 2: B-mode ultrasound images of one specimen equilibrated (a) in physiological saline and (b) in hypertonic saline. Ultrasound beam propagated along the thickness direction. The grey levels of the image linearly represent the amplitudes of the RF signals. RF signals in (c) and (d) correspond to the positions indicated by the white solid lines in (a) and (b), respectively. The black arrow indicated that the echoes reflected from cartilage surface shifted slightly due to the alteration of the saline concentration.

Swelling behavior is thought to be important for the overall mechanical properties and functions of cartilage and provides a high resistance to compressive loads. Most of previous studies reported the swelling-induced strains of cartilage, but not along a cross-section *in situ* [2-4]. The present study investigated the transient response of cartilage to the osmotic loading *in situ*. The results showed that the ultrasound biomicroscopy scanning technique could be feasible to assess the fine deformation of cartilage of both large and small animals.

### CONCLUSIONS

In comparison with traditional mechanical methods and optical methods, this method is potential to be applied for *in-vivo* applications due to the capacity of recording the transient deformation of the intact tissue nondestructively.

## THE RELATIONSHIP BETWEEN PELVIC FLOOR AND ABDOMINAL MUSCLE ACTIVATION AND THE GENERATION OF INTRAVAGINAL PRESSURE IN HEALTHY CONTINENT WOMEN

Stéphanie J. Madill and Linda McLean

School of Rehabilitation Therapy, Queens University, Kingston, Ontario, Canada

### INTRODUCTION

Stress urinary incontinence (SUI) is “the complaint of involuntary leakage [of urine] on effort or exertion, or on sneezing or coughing”[1]. It affects 26% of women aged 30 to 59, peaking in the 40 to 49 year age group[2]. It is caused by the failure of the pelvic floor muscles (PFM) and the urethral sphincters to resist increases in intra-abdominal pressure[3], however, the mechanism by which the PFM and abdominal muscles work together to maintain continence is not well understood.

### METHODS

PFM electromyography (EMG) data were acquired using a Femiscan™ probe seated in the vagina[4]. The probe had two pairs of bipolar bar electrodes mounted laterally, and was modified by mounting a pressure transducer in a hole cut through its posterior surface. Surface EMG data were recorded from rectus abdominis (RA), transversus abdominis (TA), internal obliques (IO) and external obliques (EO) using Meditrace™ 133 surface Ag-AgCl adhesive electrodes. All EMG data were amplified using Bortec AMT-8 amplifiers, and both EMG and pressure data were acquired at 1kHz using a 16-bit Analog to Digital Converter and Labview v. 6.1.

Resting data were recorded first, with each subject positioned in supine and asked to relax their PFM and abdominal muscles. After a period of instruction to familiarize subjects with the proper performance of a PFM contraction, volunteers performed three repetitions of a maximum voluntary contraction of their PFM while EMG and pressure data were recorded simultaneously from all sensors.

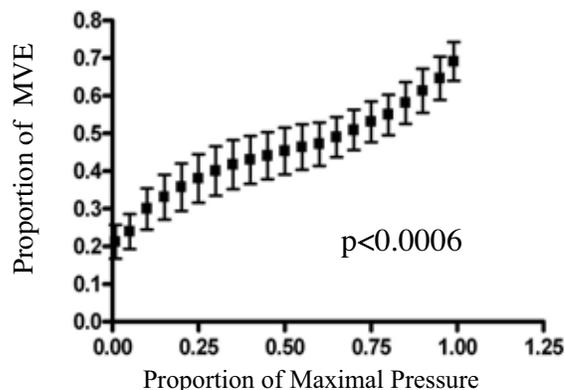

All pressure and EMG data were smoothed by computing the root mean square (RMS) value using a moving window of 20ms across the contraction time, less the resting RMS value. The data were then normalized based on the maximum smoothed pressure or EMG amplitude achieved during each contraction. The normalized pressure vs. EMG curves were ensemble averaged, and the equations of these curves were computed and tested ( $p < 0.05$ ). Significant curves were used to model the EMG vs. pressure relationship.

### RESULTS AND DISCUSSION

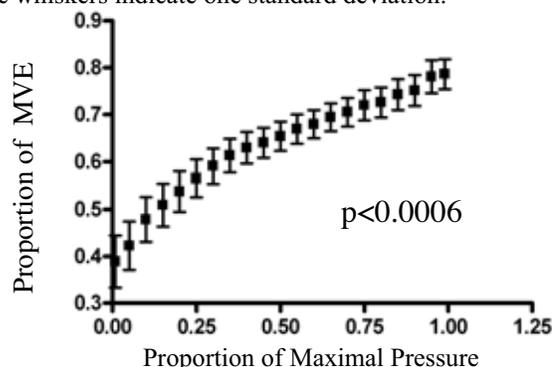

Thirteen urinary continent women, mean age  $36.3 \pm 9.9$  years (10 nulliparous, three parous) participated in the study. Since the EMG amplitudes from the two sides of the PFM were highly correlated in all cases (cross-correlation coefficient 0.90, 95% confidence interval 0.89-0.92), the side with the larger EMG amplitude was used in the analysis for each subject and each contraction.

The ensemble average EMG vs pressure curves for three of the abdominal muscles (RA, TA and IO) were “S” shaped (See Figure 1), whereas that for the PFM showed a steep initial rise followed by a leveling off. (Figure 2) The EO versus pressure curve did not produce any predictable pattern ( $p > 0.09$ ). All of the curves, except that for RA, were best

defined by second order polynomial equations ( $p < 0.05$ ). RA was best defined by a third order polynomial equation.

**Figure 1.** Ensemble average curve ( $n=13$ ) for normalized IO EMG versus lower vaginal pressure. Squares indicate the mean proportion of MVE for each pressure increment while the whiskers indicate one standard deviation.

**Figure 2.** Ensemble average curve ( $n=13$ ) for normalized PFM EMG versus normalized vaginal pressure. Squares indicate the mean percent MVE for each pressure increment while the whiskers indicate one standard deviation.

In voluntary PFM contractions, lower intravaginal pressure in urinary continent women is not solely the product of PFM activation; it receives significant contributions from TA, RA and IO. The EO muscles did not appear to have a predictable pattern of activation in response to a voluntary PFM contraction and are therefore thought to contribute minimally to the generation of lower intravaginal pressure.

## A Comparison of Isokinetic Leg Flexion and Extension Strength in Elite Adolescent Male Track and Field Athletes

Lee Shuei-Pi, Tsai Yeh-Jung, Gu Guo-Hong  
 National Taiwan Normal University  
 Email: koftp@yam.com

### INTRODUCTION

The characters of muscle could be specific to different kinds of sports events after long-time training, such as sprinters may perform better in power, poor in endurance, and marathonian may have reversed results. The isokinetic peak torque and torque ratio are important parameters to evaluate the athletic performance or to prevent knee injury (Costill, et al, 1968). So the purpose of this study was to investigate the differences among young male sprinters, jumpers and throwers in the two parameters. We hope the results could be benefit to the information for coaches or athletes in muscular training.

### METHODS

Three groups of well trained, adolescent male athletes were subjects in this study. One group consisted of 17 short-distance runners (<400m, age:17.8±1.4 yrs, weight:65.3±4.41 kg). Another group consisted of 10 long or high-jumping jumpers (long and high jumping, age:17.5±1.4 yrs, weight:64.0±6.4 kg). The last one consisted of 12 throwers (javelin, shot-put, discus, age:17.4±1.7 yrs, weight:91.7±16.8kg). They were asked to stop training at least one day, and signed informed consent for the information about basic procedures before experiment.

Quadriceps and hamstring were analyzed in this study. The measurement was mainly divided into three portions. First is the peak torque of quadriceps (QUAD PT) during concentric (QUAD con) and eccentric (QUAD ecc) periods. Second is the peak torque of hamstring (HAM PT) during the concentric (HAM con) and eccentric (HAM ecc) periods. The peak torque was maximum torque within certain period in dominant leg and measured by using a Cybex-6000 isokinetic dynamometer. The concentric data were collected at angular velocity of 180°/sec for 4 consecutive contractions, and eccentric ones were at angular velocity of 120°/sec for 4 consecutive contractions. The relative peak values (divided by

body weight) were also analyzed. Last is the ratio of H/Q (HAM PT / QUAD PT) during their concentric period. SPSS one-way ANOVA was used to compare the difference in peak torques of the three groups. The significant value was set at .05, and Scheffe method was used for post-hoc comparisons.

### RESULTS AND DISCUSSION

Table 1 and 2 showed that the throwers' absolute peak torques were significantly higher than sprinters' and jumpers' during both types of quadriceps' contractions (P< .05). The hamstrings' absolute values were similar to quadriceps', although without significant difference among the three groups. However, reversed results that the sprinters' and jumpers' relative peak torques were higher than throwers', but without significant difference among them, could be seen during both types of contractions in the two muscles. It indicates that runner and jumper may need faster movement than thrower do, so the influence of body weight should be taken into consideration.

The mean H/Q ratios of sprinters, jumpers and throwers were 0.61, 0.58 and 0.56 respectively, and there was not much difference among the three groups. The values were similar to those observed in young basketball players in Gerodimos et al.

### CONCLUSIONS

In healthy adult, the H/Q ratios ranges between 0.56~0.8. If the athlete value lower than those, the training in hamstring should be increased for maintaining muscular balance.

## Biomechanical Analysis of Punching Different Targets in Chinese Martial Arts

<sup>1</sup>Long-Ren Chuang, <sup>2</sup>Wei-Hua Ho, <sup>1</sup>Yu Liu, <sup>2</sup>Tyzz-Yuang Shiang

<sup>1</sup> Department of Chinese Martial Arts, Chinese Culture University, e-mail: allen@faculty.pccu.edu.tw

<sup>2</sup> Institute of Sports Equipment Technology, Taipei Physical Education College

### INTRODUCTION

The research of punching motion in martial arts was focus on different gloves type, skill levels and styles of punching (Smith, 1986, Powell, 1989, Whiting, 1988). Only Yoshihuku [1] has compared the punching motion with target and none. So far, no one has done a thorough study to determine the difference among punching different targets. Our hypothesis was the martial arts athletes' punching motion would be affected by different material and mass of targets. The difference will show on kinematics of the upper extremity and muscle moment calculated by inverse dynamics. The results will help us to understand the coordination of upper extremity when punch different targets.

### METHODS

Nine healthy Chinese martial arts athletes of Chinese Culture University aged 18-24 years, weight  $70.1 \pm 4.2$  kg and height  $168 \pm 4.9$  cm volunteered to participate in the experiment. They have to punch three different targets that include cardboard (0.2kg), small punching bag (9.2kg) and big punching bag (29.2kg). We used a Sony PD150 digital camera and Peak Motus 6.0 motion analysis system (60Hz) to catch the kinematics data of upper extremity. Then we applied the intersegmental dynamics formula that developed by Zernicke & Smith [2] to calculate the joint moment, muscle moment and interaction between the segments. One-way repeated-measures ANOVA were carried out for each of the dependent variables in the study. The probability level was set at  $P < .05$ .

### RESULTS AND DISCUSSION

The fist peak velocity was significantly different when punching three different targets ( $P < .05$ ). The fastest velocity of fist was punching the cardboard target ( $6.98 \pm 0.72$  m/s), then was punching the small bag ( $6.06 \pm 0.68$  m/s), and the lowest velocity was punching the big bag ( $5.43 \pm 0.82$  m/s). The contact time was significantly different when punching different targets, too. The shortest contact time was found in punching the cardboard ( $0.03 \pm 0.00$  sec), then the small bag ( $0.10 \pm 0.01$  sec), and the longest contact time was found in punching the big bag ( $0.14 \pm 0.05$  sec). The kinematics results are similar to Yoshihuku's [1] study.

Figure 1 shows similar trend of elbow and shoulder moment curve when subjects punched three different targets. The results of elbow and shoulder moment were similar with penetrating strike in previous study [3]. In all moments, only the maximum shoulder flexion moment in the cardboard ( $156.51 \pm 42.22$  Nm), small bag ( $90.29 \pm 64.09$  Nm) and big bag ( $61.16 \pm 40.58$  Nm) were significantly different ( $P < .05$ ).

The shoulder muscle flexion moment was larger when subjects punch the cardboard target than small and big targets

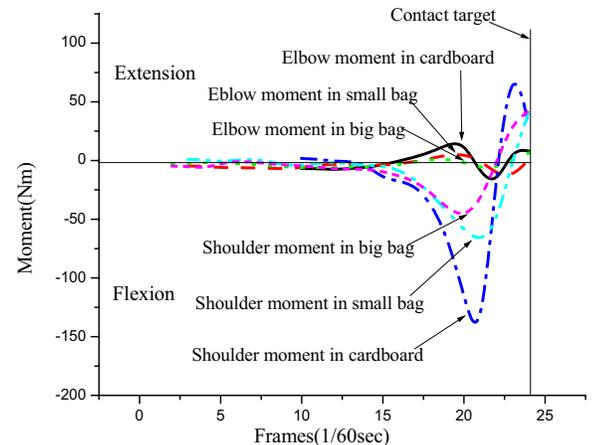

Figure 1. The subject 7 punched the different targets. The curve displayed the muscle moment of elbow and shoulder before contact

which indicated shoulder joint can fully flexion that make the fist velocity faster. On the contrary, the subjects wanted to recruit more muscle fibers and to raise the effective mass to participate when punching the heavy target. This phenomenon causes the shoulder muscle flexion moment and fist velocity decrease when punching the heavy target. The results agree with the principle of muscle loading and contraction velocity.

### CONCLUSIONS

Different target mass will affect punching motion of subject's upper extremity. These results showed differences in the fist peak velocity, contact time and the maximum flexion shoulder muscle moment which could provide useful information for the athletes and coaches.

## BIOMECHANICALLY DESIGNED SCIENTIFICALLY APPROPRIATE DIABETIC FOOTWEAR

Gautham Gopalakrishna, Mohamed Sadiq, Bhabendra Nath Das, Gnanasundaram Saraswathy  
 Shoe Design and Development Centre, Central Leather Research Institute, Chennai.India  
 email: [gautham@clrim.org](mailto:gautham@clrim.org)

### INTRODUCTION

Mechanical factors play an important role in the etiology of a majority of foot ulcers. The stress and strain experienced by the diabetic foot is significantly different from that of the non-diabetic foot. This is because of the biomechanical abnormalities in the foot as a consequence of diabetic neuropathy. This paper looks at the factors responsible for the abnormal stresses and also examines the vital role of the footwear which is designed after the biomechanical analysis of the diabetic foot. Many foot complications due to external sources are prevented only by footwear and it is illustrated in this paper that prescription of footwear is a pre-requisite for the diabetic foot along with medical treatment.

The paper also highlights the use of biomechanical principles in designing the correct footwear and details criteria and materials for satisfying the requirements of a scientifically appropriate footwear for diabetics which is designed to provide for better shock absorption, reduced friction, better comfort and wear properties and most importantly helps in redistributing pressure uniformly on the plantar surface of the foot.

### METHODS

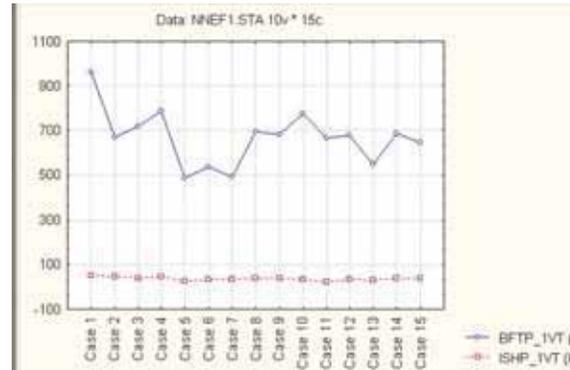

- A careful selection of patients was made and an adjusted sandal was fabricated for them. The footwear were fabricated with specially derived Rocker bottomed soles[1], to relieve biomechanical stresses
- This was tested for its pressure reduction using an optical pedobarograph [2]
- Pressure reduction was analysed
- Wear trials was carried out and Wear pattern assessed

### RESULTS AND DISCUSSION

From the pressure contours generated the significant changes in the pressure pattern as compared to the barefoot is evident. The pressure has been well distributed and reduced.

Sl. No	Bare foot Press. (KPa)	Inshoe Press. (KPa)	Sl. No	BFTP (KPa)	ISHP (KPa)	Sl. No	BFTP (KPa)	ISHP (KPa)
	BFTP	ISHP						
1.	960	52	6.	534	33	11.	665	21
2.	670	45	7.	491	33	12.	676	35
3.	717	38	8.	694	40	13.	546	32
4.	786	45	9.	680	38	14.	684	40
5.	486	26	10	773	33	15.	645	37

**Table 1:** Plantar pressure readings - Barefoot Vs Specially designed footwear

**Figure 1 :** Graphical representation of plantar pressures : Barefoot Vs Specially designed Footwear (BFTP = Barefoot Pressures; ISHP = Inshoe Pressure after wearing special footwear)

Table 1 and Figure 1 highlight the Barefoot pressures as well as the Inshoe pressures of subjects measured after wearing the specially designed footwear. As is amply demonstrated from the table, the underfoot pressures have reduced drastically on wearing the new footwear. On some of the patients, a follow-up study was done after three months and while there have been no drastic reduction in pressures in the follow up period as compared to the time when the initial pressures were measured on wearing the new footwear, in most of the cases the plantar pressures have either reduced or have remained unchanged.

The tabulated results clearly demonstrate that the design methodology adopted, selection of last and materials for the specially designed footwear have proven to be efficacious in minimizing underfoot pressures resulting in more comfort to the wearer.

The developed footwear targets specific high pressure areas particularly susceptible to neuropathic ulceration [3] and with the right combination of lasts, materials and design markedly reduces the pressures in these areas. The pedorthic therapeutic footwear, through use of specially designed rocker bottomed soles and custom moulded footbeds, relieves underfoot biomechanical pressures to a very large extent.

### INTRODUCTION

Low back pain (LBP) is a major health and socioeconomic problem and is frequently associated with a change in the mobility of the lumbar spine and hips [1], resulting in various forms of functional disabilities. Many back pain patients complain of aggravation of their back pain during activities of daily living. However, there is a paucity of information on the coordination of movements between lumbar spine and hips during activities of daily living especially for those pathological spines. This study was to examine differences in the kinematics and joint coordination of the lumbar spine and hips when putting on a sock in asymptomatic subjects and patients with sub-acute low back pain.

### METHODS

Subacute (with symptoms between 1 and 12 weeks) back pain subjects with (n=30) or without (n=30) straight leg raise (SLR) signs and normal asymptomatic subjects (n=20) were recruited. A three-dimensional electromagnetic tracking device was used for measuring movements of the lumbar spine and hips. Kinematic data was captured while each subject put on a sock from a sitting position and each subject was asked to put on the sock on legs of both the painful side (PS) and non-painful side (NP). The kinematic patterns of lumbar spine and hips were analyzed. Coordination between the two joints was studied by cross-correlation. This identifies the strength of correlation and phase lag of the two movements.

### RESULTS AND DISCUSSION

The results generally showed that LBP has altered the lumbar-hip coordination accordingly (Table 1). It is interesting to note

that when putting on a sock on the painful side (PS), there were marked alteration in the strength of cross-correlation between lumbar spine and hip. In groups 2 and 3, there was a significant decrease in the strength of correlation between flexion of the lumbar spine and hip. However, there were significant increases in the strength of the cross-correlation in other planes of motion. It is suggested that subacute back pain patients developed well-coordinated compensatory responses in performing activities of daily living.

It was also found that when back pain subjects putting on a sock with positive SLR sign there was altered lumbar-hip coordination in regard to the phase lag. When putting sock on the painful side, the lumbar spine flexed much earlier than hip in subjects with limited SLR when compared to normal subjects (phase lag = 0s, 0s and 2s for Groups 1, 2 and 3). Moreover, the coordinated activity with different planes of hip movements was affected by the presence of SLR sign. This further suggests that joint coordination is markedly influenced by the presence of SLR sign while putting on a sock with a positive SLR sign.

### CONCLUSIONS

Our study showed that low back pain will affect not only the lumbar-hip coordination but also the coordination within the hip joint. Assessment of back pain patients should include kinematic analysis of the spine as well as hips.

## CONTRIBUTIONS OF LOWER LIMB JOINTS TO SUPPORT THE BODY IN UNEXPECTED STEP-DOWN WALKING

<sup>1</sup> Sungjae Hwang, <sup>1</sup> Seongsik Myeong, <sup>1,2</sup> Hansung Kim and <sup>1,2</sup> Youngho Kim

<sup>1</sup>Dept of Biomedical Engineering, Yonsei University, Korea,

<sup>2</sup>Institute of Medical Engineering, Yonsei University, Korea;

email: yhkim@dragon.yonsei.ac.kr, web: biomecha.yonsei.ac.kr

### INTRODUCTION

The generation of the forward movement and the stable support of the upper body are two important roles of the lower limb in walking [1]. The function of the body support has been recently received much attention. The concept of the support moment, defined as the sum of all joint moments in the lower limb, has been used to determine the relative contribution of the lower limb joint moments to prevent the collapse [2].

Falling is a serious problem among the elderly population, frequently resulting in physical injuries. The unexpected walking is one of the most probable cause of falling in the elderly [3]. However, the postural recovery mechanism based on the support moment in the unexpected walking has not been clearly defined yet.

In this study, dynamic simulations were performed to analyze contributions of the lower limb joints for the support moment in the unexpected step-down walking based on 3-D motion analysis data.

### METHODS

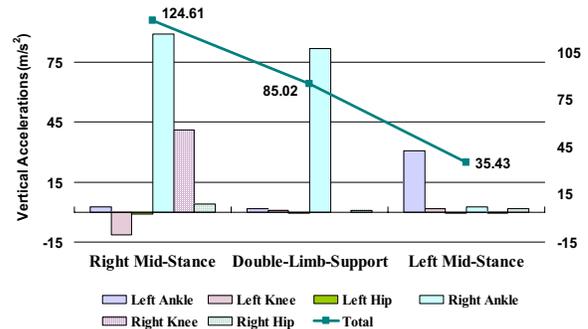

A 27 year-old male subject (height: 170cm, weight: 68kg), with no gait problems in gait, participated in the 3D motion analysis. Six infrared cameras (Vicon 612, USA) were used to capture movements of sixteen reflective markers based on the Davis protocol for the gait analysis of the lower extremity [4]. For the unexpected step-down walking, a movable platform was designed to provide vertical perturbations during gait. Computer simulations were performed using Lifemode (Biomechanics Research Group, USA). A 3D virtual skeletal model for the simulation was composed of seven segments. Gait simulations were performed by translational and rotational motion capture data. Motion capture data obtained by the 3D motion analysis system were imported to the generated skeletal model. The model for this study calculated the vertical acceleration of the upper body, which was produced by the support moment estimated at each joint. In order to calculate joint moments for the support in walking, gait phases were divided into right mid-stance, double limb support, and left mid-stance (Figure 1).

**Figure 1:** Simulation results from the forward dynamics in unexpected step-down walking.

### RESULTS AND DISCUSSION

Figure 2 shows vertical accelerations of the pelvic center in the unexpected step-down walking. In the unexpected step-down walking, the right ankle joint was the most primary contributor for vertical accelerations. In the unexpected step-down walking, the vertical acceleration at right mid-stance, contributed by the right ankle and knee joints, was very large. Since in the unexpected step-down walking, no roll-over mechanism of the foot exists, at first the forefoot contacted to the ground and then progressed to double-limb-support. At left mid-stance phase, the subject kept his balance for repositioning of the over-advanced COG through that the subject stepped left foot forcefully. This caused the left ankle moment large during left mid-stance.

**Figure 2:** Vertical accelerations of the pelvic center in unexpected step-down walking.

### CONCLUSIONS

In the unexpected step-down walking, the important contributors during single-limb-support are not only ankle plantar flexors but also knee extensors.

This study, analyzing the relative contributions of the lower limb joint moments for the body support would be helpful to understand many unexpected walking and compensatory mechanisms for various pathological gaits.

## Dynamical Analysis of Indoor Eight People Make Tug of War Attack Movements- “European Back-Step” and “Japanese Back-Step”

Fong-Wei Wang and Chien-Lu Tsai  
 Nation Taiwan Normal University  
 Email : s08048@yahoo.com.tw

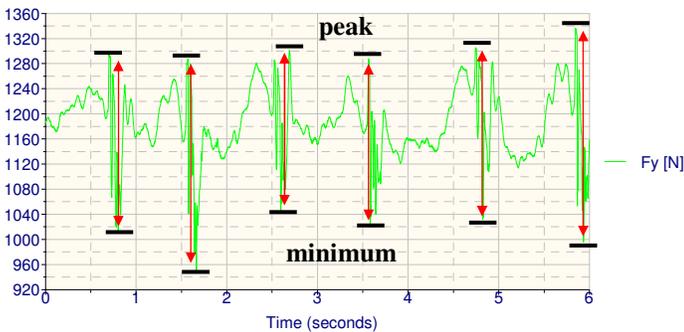

### INTRODUCTION

The “European Back-Step” Indoor Tug of War attack movement has been developed for more than one hundred years, and it is the most popular movement style in Europe. The “Japanese Back-Step” Indoor Tug of War attack movement is new technique from Japan. Both of the techniques have their own supporters. The purposes of this study were to investigate the kinetics parameters of Indoor Eight People Make Tug-of-War “European Back-Step” and “Japanese Back-Step” attack movements. We would like to find out which movement style is more powerful and more efficient.

### METHODS

The subjects were 8 Taiwan Indoor Tug-of-War national team pullers (174.1±3.6cm, 72.7±2.4kg, 22.1±2.4 year). Two Redlake High-Speed video cameras (60Hz) and a Kistler (9287) Force Platform (600Hz) were used to collect the 3D kinematical data and the ground reaction force of the subjects. The 3D data were analyzed by Kwon3D motion analysis system and the 6-second duration time of ground reaction force were analyzed by Bioware software. A Paired-samples t-test was used to compare the differences between “European” & “Japanese” back-step attack movements. The level of significance was  $\alpha = .05$  in this study, and the statistical software was SPSS 12.0 version.

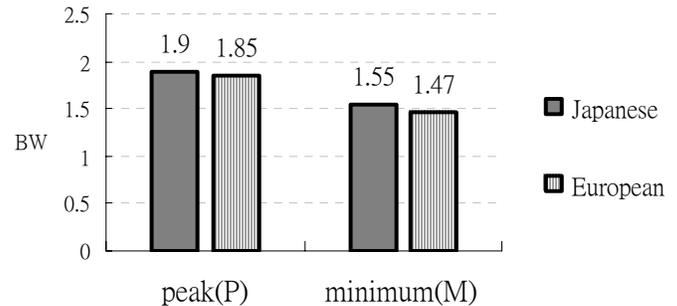

### RESULTS AND DISCUSSION

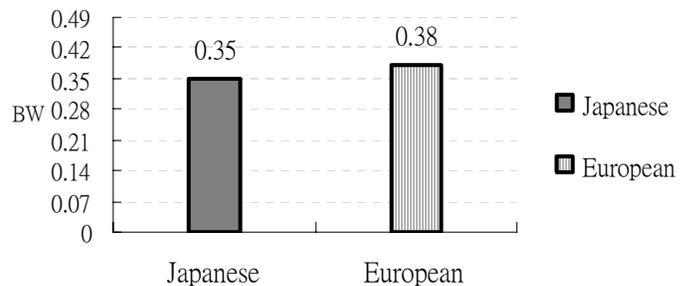

**Figure 1:** The curve of the peak and minimum backward ground reaction force (GRF)

We found that there were several cycles with peak and minimum backward ground reaction force (GRF) in the duration time in figure 1. The athletes should increase both the peak and minimum GRF in the competition. From the figure 2, we found there was a greater peak backward GRF in “Japanese Back-Step” (1.9bw) than “European Back-Step” (1.85bw). And there was a greater minimum backward GRF value in “Japanese Back-Step”(1.55bw) than the value of “European Back-Step”(1.47bw) ( $P < .05$ ). That meant the

“Japanese Back-Step” was more powerful than the European style both in the peak and the minimum GRF.

**Figure 2:** The peak and the minimum backward GRF of “European Back-Step” and “Japanese Back-Step”

**Figure 3:** The value between the peak and minimum backward GRF

From the figure 3, the value between the peak and the minimum backward GRF of “Japanese Back-Step” (0.35bw) attack movement was less than that of “European Back-Step” (0.38bw) ( $p < .05$ ). That meant the “Japanese Back-Step” was more constant than the European style. As the results, there was better performance in the “Japanese Back-Step” than that in the “European Back-Step” in the kinetics parameters.

### CONCLUSIONS

As result showed, there were greater the peak, the minimum and the less value between peak and minimum backward ground reaction force of the “Japanese Back-Step” than those value of the “European Back-Step”. That meant the “Japanese Back-Step” was more powerful and more efficient than the European Back-Step style. It is recommended that athletes should practice the Japanese Back-Step attack movement in the future.

### INTRODUCTION

Previous studies have shown that novice and highly trained cyclists use different patterns of leg muscle recruitment when cycling [1, 2]. Novice cyclists are characterized by greater individual variance, greater population variance, longer durations of muscle activity, more extensive and more variable muscle coactivation, and less modulation of muscle activity. The data also show that modulation of muscle activity decreases with increasing cadence in novice cyclists but is not influenced by cadence in highly trained cyclists. However, kinematics were not controlled in these studies of cycling so differences in leg muscle recruitment between novice and highly trained cyclists may relate to kinematic variations. The purpose of this study was to determine if kinematic variations are likely to account for differences in leg muscle recruitment between novice and highly trained cyclists.

### METHODS

Participants were ten novice and ten highly trained cyclists. Four experimental conditions of cycling at 55-60, 75-80 and 90-95 rpm and preferred cadence were investigated in random order. Three dimensional kinematics of the pelvis and lower limbs and orientation of the bicycle crank arms were measured. Coordinates of 14 mm reflective markers were sampled at 250 HZ using a VICON 620 eight-camera motion analysis system (Oxford Metrics Ltd, Oxford, England). Marker trajectories were filtered using a GCVSPL algorithm to remove low frequency movement artifact and three dimensional kinematics were calculated using the Plug in Gait® model which has been described and validated previously (Version 1.8, Oxford Metrics Ltd: Oxford, England). Electromyographic (EMG) activity of leg muscles was also measured using methodology previously described [1] in three novice and two highly trained cyclists to confirm comparisons were of novice and highly trained cyclists in whom muscle activity varied as previously reported.

### RESULTS AND DISCUSSION

The comparison of EMG data was consistent with previous findings of varied muscle activity between novice and highly trained cyclists. Patterns of movement (i.e. time series kinematic data) did not vary between novice and highly trained cyclists, but the absolute range of sagittal plane motion of the ankle was significantly less in novice cyclists ( $13.2 \pm 7.7^\circ$ ) than in highly trained cyclists ( $21.5 \pm 9.0^\circ$ ). Absolute ranges of motion of the pelvis, hip and knee was not different between groups. Cadence did not influence kinematics of the pelvis, hip, knee or ankle in either group.

Sagittal plane motion of the hip and ankle (i.e. hip flexion-extension and ankle dorsiflexion-plantarflexion) and knee and

ankle (i.e. knee flexion-extension and ankle dorsiflexion-plantarflexion) were more coordinated in highly trained cyclists ( $r = 0.85 \pm 0.07$  and  $0.76 \pm 0.08$ ) than novice cyclists ( $r = 0.65 \pm 0.10$  and  $0.53 \pm 0.08$ ). Sagittal plane motion of the hip and ankle, and knee and ankle, were also more consistently coordinated (i.e. the degree of coordination between these movements varied less between pedal strokes) in highly trained cyclists ( $0.04 \pm 0.02$  and  $0.05 \pm 0.02$ ) than in novice cyclists ( $0.09 \pm 0.03$  and  $0.11 \pm 0.02$ ). Coordination and variability of coordination of sagittal plane hip and knee motion did not vary between groups.

Individual variance (i.e. variability of movement patterns between pedal strokes) did not vary between groups. Population variance (i.e. variability of movement patterns between cyclists) of flexion-extension of the hip was greater in novice cyclists ( $8.0 \pm 1.6^\circ$ ) than in highly trained cyclists ( $4.2 \pm 1.8^\circ$ ), but population variance of frontal motion of the knee was greater for highly trained cyclists ( $7.1 \pm 1.1^\circ$ ) than novice cyclists ( $4.4 \pm 1.2^\circ$ ). Population variance of other joint motions was not different between groups.

### CONCLUSIONS

This study suggests that kinematics of the pelvis, hip, and knee do not vary between novice and highly trained cyclists. Differences in leg muscle recruitment between novice and trained cyclists may be explained in part by kinematic variations at the ankle. However, kinematic variations between novice and highly trained cyclists revealed in this study are unlikely to explain all aspects of varied leg muscle activity (e.g. longer durations and less modulation of muscle activity in novice cyclists). Greater coordination of motion between the hip and ankle and knee and ankle joints may reflect more skilled control of movement in highly trained cyclists. Furthermore, differences in the response of leg muscle recruitment to altered cadence in novice cyclists and highly trained, in whom decreased modulation of muscle activity with increased cadence was seen, are not likely to be associated with kinematic variations as cadence did not influence kinematics.

**THE VIBRATION AND COEFFICIENT OF RESTITUTION ANALYSIS IN TENNIS RACKETS  
 VARIED WITH MATERIAL COMPOSITION AND FIBER ARRANGEMENT**

**INTRODUCTION**

The increase in power of modern tennis could be attributed to stronger, better conditioned players, but the major reason was the modern racket of the consistent power making it possible (Groppe, 1992). However, there are strong indications that impact shock and post-impact vibration transfer in tennis racquet may lead to the epicondylitis humeri syndrome. This study was to investigate how the vibration on wrist joint of the player and rebounding velocity of the ball from each racket were affected by the vibration of various tennis rackets which were composed by the mixture of carbon fiber and glass fiber.

**METHODS**

There were eight different kinds of tennis racket, composed by mixing carbon fiber and glass fiber in the ratio of 1 to 0, 6 to 1, 5 to 2, and 4 to 3. The angles of the fiber were arranged in 22 degrees and 30 degrees with respect to the longitudinal axis.

The experiment 1 was to monitor the vibration on the wrist joint of participant and to find the logarithmic decrement ratio of vibration. Accelerometer was attached to participant's wrist joint to acquire the vibratory signals. The logarithmic decrement ratio,  $\delta$ , was calculated using,

$$\delta = \ln\left(\frac{X_m}{X_{m+k}}\right)$$

where  $X_m$  and  $X_{m+k}$  are the amplitudes of vibratory wave between  $k$  periods.

For experiment 2, Peak Motus system with one high-speed video camera was used to record the kinematics data and to calculate the coefficient of restitution. The coefficient of restitution,  $e$ , was calculated using,

$$e = -\frac{V'}{V}$$

**Figure:** The accelerometer ( attached to the wrist joint of participant) measuring chain.

where  $V$  and  $V'$  were the pre-impact and post-impact ball velocities.

**RESULTS AND DISCUSSION**

The results of the vibration logarithmic decrement ratio on wrist indicated that the pure carbon fiber made racket at 22 degrees had a higher value, and the value was significantly increasing as the content of carbon fiber in the racket was increasing. On the other hand, pure carbon fiber made racket had higher stiffness that its coefficient of restitution was higher than glass fiber made racket. This phenomenon indicated that the wrist joint would absorb more vibratory energy from racket made by pure carbon fiber.

**CONCLUSIONS**

By increasing the content of glass fiber in the racket, it might be decreasing the load in the tennis player's arm on center or off-center impact. But it would affect the performance on ball rebound. On the other hand, the rackets with fiber angle at 22 degrees had lower vibration than that at 30 degrees.

### INTRODUCTION

Previous studies have revealed differences of muscle responses between translational and rotational platform perturbation [1,2]. The differences in the organization of postural responses were ascribed to the different mechanical demands of the perturbations. Regulation of the body center of mass (COM) seemed to be the main function of postural control. No kinematic data including COM trajectory were collected to test the effects of all four of the platform displacements (forward/backward translation, F/B and toe-up/toe-down rotation, U/D), perform at same velocity, on the same subjects. Allum et al (2001) used combinations of support surface rotation and backward translation (BU and BD) to induce balance corrections [3]. It seemed to increase task difficulty. Two additional types of combination of support surface rotation and forward translation (FU and FD) were not studied in the literature. Therefore, the purpose of this study was to investigate the differences of COM trajectories under various types of support surface perturbations including uni-axial (F, B, U and D) and bi-axial (BU, BD, FU and FD) perturbations.

### METHODS

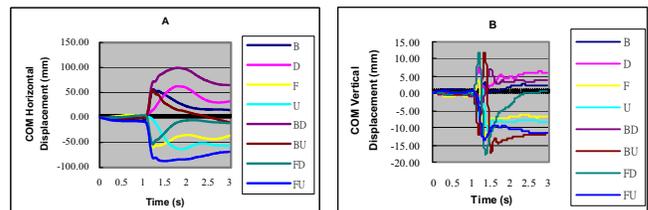

Six healthy subjects (4 males, 2 females; ages 19-22 years) consented to participate in the study. A tri-axial postural perturbation platform was used to provide both uni-axial and bi-axial support surface perturbation. The velocity and amplitude of platform movement was 50 mm/s for 70mm or 50 degree/s for 7 degrees, respectively. All subjects were tested under eight types of perturbations with 3 trials of each perturbation. These perturbations were delivered in a random sequence and commenced 1 second after the start of the data collection. A six-camera video-tracking motion analysis system (Motion Analysis Corp., CA, USA) was used to collect three-dimensional kinematic data with thirty-nine retro-reflective spherical markers fixed over the whole body of the subjects. The data was collected at 200Hz for 3seconds. The 13-segment model was used to calculate the total body COM. We divided the COM trajectories into two phases: a passive imposed postural sway and an active automatic postural reaction phases. The maximal horizontal (anterior/posterior, A/P), vertical and medial-lateral displacement of the body COM with respect to support surface in two phases was measured respectively.

### RESULTS AND DISCUSSION

**Table 1:** Mean of the maximal horizontal and vertical displacement of the body COM during the passive imposed sway and active postural reaction phases in eight types of support surface perturbation

Displacement (mm)	Horizontal								Vertical							
	B	D	F	U	BD	BU	FD	FU	B	D	F	U	BD	BU	FD	FU
<b>Imposed Sway</b>	63.25	53.06	-66.97	-63.98	91.31	71.89	-69.69	-89.3	-8.25	12.88	4.56	-9.47	4.31	-15.89	18.05	-9.24
<b>Postural Reaction</b>	-65.46	-23.41	55.89	23.66	-55.30	-74.93	68.92	32.38	13.6	8.45	9.57	12.52	14.74	32.34	-21.48	10.26

There were no differences of the maximal medial-lateral COM displacement among various types of perturbation, and the means were range from 10 to 20 mm. Table 1 presents the COM displacement and Figure 1 shows the COM trajectories in A/P horizontal and vertical directions. During uni-axial perturbation, all the four types of perturbation induced quite a large horizontal COM displacement, while the forward translation induced larger displacement than the others. Platform rotation (U and D) induced more vertical COM displacement than translation. All the bi-axial perturbation induced more horizontal displacement than uni-axial perturbation. The BD and FU tests demonstrated the adding effects of the imposed sway. However, the vertical displacement conformed to the expected adding and counterbalanced effects. In automatic postural reaction phase, translational tests recovered more displacement than rotational tests. Because rotational tests changed the end COM position by bringing the COM forward in D test and backward in U test. During bi-axial BU and FD test, the subjects recovered larger displacement in horizontal and vertical directions than BD and FU tests. It was assumed that the “enhanced” ankle input of BU and FD generated agonist stretch reflex that stabilizes the posture. Whereas the “nulled” ankle input of BD and FU tests produced weaker balance-reaction responses regardless of the greater imposed postural disturbance. It was presumed that BD and FU tests are the more challenge tests for balance control.

**Figure 1:** The horizontal trajectory (A) and the vertical trajectory (B) of the body COM of eight types of support surface perturbation.

## ARREST OF FORWARD FALLS ONTO OUTSTRETCHED HANDS IN HEALTHY YOUNG WOMEN

<sup>1,2</sup>Lisa Case, <sup>1</sup>Jia-Hsuan Lo, <sup>1,2</sup>James Ashton-Miller

<sup>1</sup>University of Michigan, Department of Mechanical Engineering

### INTRODUCTION

Fall-related injuries are projected to cost the United States \$85 billion per annum by the year 2020 [1]. Some 60% of all falls in older adults are in the forward direction [2]. Past studies have examined the biomechanics of forward fall arrests from different heights, onto different surfaces, and using different strategies. These studies, however, involved men; none address how forward falls are arrested by women. This is surprising since elderly women have 1.2 to 2.2 higher rates of falls [3], and are 1.8 to 2.2 times more likely to sustain an injury in a fall [4], than men. We first quantified how a group of healthy young women use their upper extremities to arrest standardized forward falls from three different heights, one of which was similar to that used in a two-height test protocol developed for men [5]. We tested the null hypothesis in women that fall height would not affect the magnitude of the ground reaction force, pre- and post-impact arm kinematics, or arm muscle EMG patterns. Finally, by comparing these results with the published male data [5] obtained using similar methods, we tested the hypothesis that there is no effect of gender on these parameters.

### METHODS

Ten healthy young women [mean (SD): age: 24.5 (2.1) yrs, body weight: 585 (61) N; height: 163.7 (4.3) cm] volunteered for this study. Kinematic markers were affixed to the subjects on both upper arms and forearms, left side of the head, neck and left thigh, as well as the left malleolus to collect kinematic data at 200 Hz with an Optotrak 3020 motion-tracking system. Three AMTI force plates were used to collect force and moment data at 2 kHz using the following protocol. RMS surface EMG was measured at 1 kHz in the left triceps, biceps, deltoid, pectoralis, neck extensor, and serratus anterior and a 50 ms window analyzed just prior to impact. Subjects were leaned 20° forward from vertical and held with a tether. The subject was then asked to bend at the waist with her arms out toward the force plates in front of her. The subject was then released, at the count of three, to arrest the fall, with each hand landing on a force plate. Two falls were performed from a neck marker height of 70 cm, followed by two falls from 80cm and three falls from 90 cm. Subjects were asked to fall naturally using only their arms. Because the fall heights were 75 and 100 cm in the male study and since the women's data appeared linear across fall heights, linearly-interpolated male values at 80 and 90 cm were used in the gender comparisons. Repeated measures analysis of variance (rm-ANOVA) were used to test the hypotheses (using  $p < 0.05$  for significance).

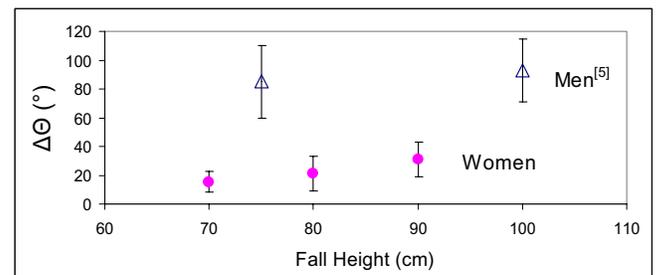

### RESULTS AND DISCUSSION

In the women, the peak ground reaction force, F1, normalized by body weight, increased with fall height (Table 1, rm-ANOVA,  $p < 0.05$ ). Their elbow flexion angle at impact,  $\Theta$ , did not vary significantly across the fall heights ( $p > 0.10$ ). The

increase in elbow flexion from impact through the first 500 ms of the fall arrest,  $\Delta\Theta$ , however, did increase with fall height ( $p = 0.003$ ), leading us to reject the first hypothesis. Pre-impact triceps activation,  $EMG_{tri}$ , shown as a percentage of a maximum triceps contraction, did not vary with fall height ( $p > 0.05$ ). Comparing these parameters with published results for men [5], no gender difference was found in F1 after normalization by body weight ( $p = 0.376$ ). There was also no difference in the elbow flexion at impact ( $p = 0.177$ ) or in pre-impact triceps activation ( $p > 0.05$ ). The remarkable finding was the significant, almost 4-fold difference, in the post-impact increase in elbow angle ( $p = 0.039$ ; Figure 1). Therefore, we rejected the null hypothesis of no gender differences in the forward fall arrest strategy under these test conditions. We speculate that these healthy young women may have limited post-impact elbow flexion to reduce the risks of elbow buckling and, thereby, head impact.

**Table 1:** Mean (SD) initial elbow angle ( $\Theta$ ) at impact, post-impact increase in elbow angle ( $\Delta\Theta$ ), maximum impact force (F1), and triceps EMG ( $EMG_{tri}$ , % max) for the women. [ $\Theta = 180^\circ =$  full arm extension]

Fall Ht.	$\Theta$ (°)	$\Delta\Theta$ (°)	F1 (N)	$EMG_{tri}$ (%)
70 cm	166 (6)	15 (7)	482 (75)	66 (30)
80 cm	169 (7)	22 (12)	584 (79)	67 (34)
90 cm	168 (7)	31 (12)	648 (90)	70 (31)

**Figure 1:** A 4-fold gender difference in the mean post-impact change in elbow flexion ( $\Delta\Theta$ ) was found. Bars denote SD.

### CONCLUSIONS

- In healthy young women, increasing fall height:
  - Did not affect elbow flexion angle at impact
  - Did increase normalized impact forces
  - Did increase post-impact elbow flexion.
- Healthy young women permit significantly smaller increases in post-impact elbow flexion than men.

### INTRODUCTION

The human upper extremity plays an important role in activities of daily living. Knowledge of the kinematics of the joints of the upper limb is helpful for the understanding of its normal function. Most published kinematic models of the upper extremity oversimplified the shoulder complex and forearm due to their great complexity and huge skin movements [1,2]. These simplifications may lead to erroneous results that can be further magnified by skin movement artefacts, limiting their clinical applications. No quantitative validation was offered for these models. Measurement of the scapular kinematics presents another problem due to its large relative movement underneath the skin.

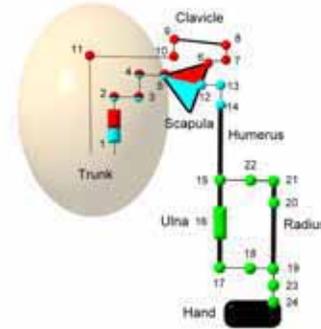

In motion analysis, segmental positions and orientations were mostly calculated without joint constraints, leading to errors in calculated joint motion and artifactual joint dislocations[3]. This problem can be resolved by the global optimization method (GOM) [3]. The purpose of the study was to develop an upper extremity model considering all the bones and joints, and to use the GOM to reduce skin movement artefacts. The model was validated with skeletal marker data of the scapula.

### METHODS

The human upper extremity was modelled as a series of 25 rigid links connected by 24 single-degree-of-freedom (SDOF) joints. The shoulder complex was modeled as a spatial mechanism with 14 rigid links, including the trunk, clavicle, scapula and humerus. The scapulothoracic (ST) joint was modelled as a 5-DOF joint; sternoclavicular (SC) joint as a 3-DOF joint; acromioclavicular (AC) as a 3-DOF joint; and glenohumeral (GH) joint as a 3-DOF joint. The forearm was modeled as a mechanism with 11 rigid links, including the ulna, radius and hand. The distal and proximal radioulnar joints were each modelled as 3-DOF joints, the elbow joint as 1-DOF and wrist as 2-DOF joints.

These multi-DOF lower-pair joints were modelled as a series of SDOF joints connected by virtual links and described following the Denavit-Hartenberg notation [4]. There were a total of 12 DOFs in this upper limb mechanism, Fig. 1. These 12 independent variables (IV) were obtained using measured data and the other dependent variables (DV) obtained by solving loop equations at the shoulder and forearm. Minimization of the skin movement artefacts was achieved with the GOM.

For the validation of the model, scapular kinematic data from 5 healthy male subjects implanted with bone pins were

**Figure 1:** The mechanism of the upper extremity model. Prismatic joints are represented as rectangles and revolute joints circles.

obtained by a 7-camera motion analysis system (Vicon 370, Oxford Metrics, U.K.) during humeral elevation (HE) in the scapular plane, forward reaching and manual wheelchair propulsion (MWP). The measured skin marker data were input into the model and the predicted scapular kinematics were compared with those measured with the skeletal markers.

### RESULTS AND DISCUSSION

The root mean squared errors (RMSE) of the model-predicted scapular protraction, rotation and tilt during HE were 4.61°, 1.54° and 4.14°, respectively. The corresponding values were 3.21°, 2.90° and 3.07° for reaching and 2.20°, 2.96° and 1.70° for MWP. The RMSEs of translation were all within 8mm.

A three-dimensional kinematic model of the human upper extremity was developed, allowing the prediction of the scapular orientation and position as well as all other joints during dynamic movements using skin markers with GOM to minimize the skin movement artefacts. Comparisons of the model predicted scapular kinematics with those measured with skeletal markers provided a direct and quantitative validation of the model. The model will be useful for the study of the function and biomechanics of the upper extremity and with further development to include the kinetic analysis of the upper extremities.

### INTRODUCTION

Muscle-actuated forward dynamic simulations of self-selected and slow walking speeds have shown that the ankle plantarflexors are supplemented by the uniarticular knee extensors to provide body weight support in midstance [1,2]. Patients with severe ankle plantarflexor weakness show reduced walking speed and compensatory strategies related to the strength of hip and knee extensors [3]. This case study presents the first muscle-actuated forward dynamic simulation of post-stroke hemiparetic gait over the entire gait cycle and demonstrates one way that post-stroke muscle contributions to support differ from those of neurologically healthy older adults.

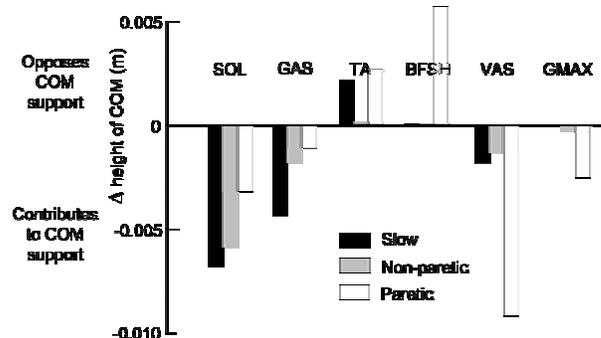

### METHODS

Two forward dynamic simulations of slow gait (0.3 m/s) were developed based on the walking patterns of healthy older adults [4] and an individual with post-stroke hemiparesis who walked with his paretic knee abnormally flexed during midstance. A 2D musculoskeletal model consisting of a trunk, pelvis and two legs was developed using SIMM [5] and actuated by 15 Hill-type muscle-tendon units per leg, including the soleus (SOL), gastrocnemius (GAS), vasti (VAS), tibialis anterior (TA), gluteus maximus (GMAX) and biceps femoris short head (BFSH). Muscle excitation patterns (i.e., onset, offset, magnitude) were assumed symmetric for healthy slow gait, and asymmetric for post-stroke gait. Dynamic optimization was used to find the appropriate muscle excitation patterns that best emulated the experimental kinematics and kinetics during slow and post-stroke hemiparetic gait. To assess the contribution of each muscle to support of the center of mass (COM), individual muscle forces were reduced to zero during midstance (i.e., middle third of the total stance duration) while all other muscle forces remained unchanged. The effect of each muscle force perturbation on vertical position of the COM was quantified 0.06 seconds later.

### RESULTS AND DISCUSSION

Experimental kinematics and vertical ground reaction forces were reproduced by the simulations of slow and post-stroke hemiparetic gait. Muscle excitations agreed reasonably well with EMG [6]. Compared to healthy slow gait, peak excitation of the paretic and non-paretic plantarflexors were unaltered, paretic TA and BFSH excitations prolonged and increased, and paretic and non-paretic VAS excitations shortened.

In midstance, on the non-paretic side, SOL, GAS and VAS contributed less to support than in speed-matched healthy older adults (Figure 1) due to reduced contributions to extension of the ankle, knee and hip by SOL and GAS. The

**Figure 1:** Contributions of key muscles to midstance support of COM in slow and post-stroke hemiparetic gait.

non-paretic TA no longer opposed COM support, thus less effort was required by the plantarflexors.

On the paretic side, the plantarflexor contributions were reduced even further (Figure 1), with compensation to COM support provided by VAS, GMAX and other muscles not shown. Although paretic TA and BFSH midstance activity may enhance ankle and knee stability, respectively, these muscle actions opposed COM support. Because the model used in the analysis was 2D, the hip abductor contributions to COM support have been neglected and may be significant [7].

### CONCLUSIONS

These simulations represent the first muscle-actuated forward dynamic simulations of healthy slow and post-stroke hemiparetic gait, characterized by a flexed paretic stance knee posture. Despite reorganization of paretic and non-paretic muscle coordination patterns with respect to that of speed-matched healthy older adults, adequate body weight support was provided by altered muscle contributions.

**INTRODUCTION**

Stress shielding at the proximity of total knee replacement (TKR) implants can cause of aseptic loosening and weakened implant fixation. Reduction of stress shielding is therefore a focus of current TKR design. A finite element (FE) tool was recently developed, improving upon the state of the art for stress analysis of the tibia. It addresses deficiencies of past FE models by giving special consideration to the incorporation of realistic geometry, material properties, and loading to provide improved analysis of bone stress states. A better representation of stress states in the post-TKR tibia will allow for better implant design. This paper presents a parametric analysis of the effects of TKR tibial component design on stress shielding.

**METHODS**

A 3D tibia, incorporating orthotropic and heterogeneous bone properties mapped directly from experimental data, was used. Loading representative of the stance phase of gait was applied. Tibiofemoral and patellofemoral surfaces were loaded with non-uniform distributed compressive forces while 4 ligament (ACL, PCL, MCL, LCL) and 6 muscle (gracilis, sartorius, semitendinosus, semimembranosus, popliteus, iliotibial tract) forces were distributed over experimentally determined attachment areas. The ACL and PCL were each divided into anterior and posterior bands; the MCL was divided into deep and superficial bands. The lines of action for each ligament and muscle were assigned for various intervals of the gait cycle. This realistic approach to incorporating loading conditions is rarely done in FE models.

The tibial TKR component, modeled after a commercially available implant, consisted of a metal tray, a polyethylene insert, and a post fixed to the tibia by bone cement. Three FE tibia implant models were created featuring a Ti6Al4V tray (E=117 MPa, v=0.3), a CoCrM tray (E=220 MPa, v=0.3), and a stainless steel (AISI 316 L) tray (E=200 MPa, v=0.3). Cement-bone interface forces were examined for the models at 3 locations: beneath the tray, around the periphery of the post, and beneath the post. Stresses were compared with those from a model representing the natural tibia (with identical loading conditions) to examine the stress changes associated with introduction of an implant. Stress shielding was assessed by examining global changes in stress distribution and stress

**Figure 1:** Stress in cancellous bone posterior to implant post from the proximal end to the distal end of the post.

changes in the cancellous bone immediately surrounding the post.

**RESULTS AND DISCUSSION**

Introduction of a metal post generally reduced stress in the surrounding cancellous bone at the more proximal portion of the post and increased stress in the more distal portion (Fig 1). High stress increases were observed in the bone directly beneath the post. Globally, bone stress was seen to decrease in both cortical and cancellous bone (except in the proximal anterior bone). Inserting an implant into the tibia greatly reduced bone stress; the type of metal composing the tray component slightly affected stress levels in the cancellous bone. In addition, the interface forces between the bone and the cement used to secure the implant were not affected by the material composition of the implant (Table 1). In a previous work, it was found that the shape of the post had a noticeable influence on interface forces [1]. The presentation will discuss the influence of different post shapes and different implant materials on cement-bone interface forces and stresses distribution in the tibia.

**CONCLUSIONS**

While inserting a metal implant significantly alters the stress fields, the material composition appears to have only a slight effect.

## EVIDENCE OF MOVEMENT CONTROL ADAPTATION IN A LOWER EXTREMITY MOTOR TASK

<sup>1</sup> Shih-Chiao Tseng and <sup>2</sup> Steven J. Stanhope

<sup>1</sup>Department of Physical Therapy and Rehabilitation Science, University of Maryland, School of Medicine

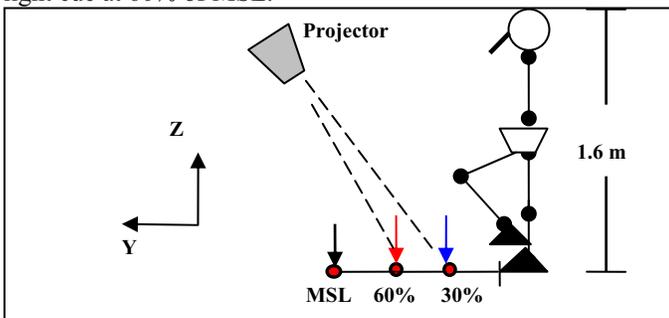

<sup>2</sup>Physical Disabilities Branch, National Institutes of Health; email: [tsengs@cc.nih.gov](mailto:tsengs@cc.nih.gov), web: [pdb.cc.nih.gov](http://pdb.cc.nih.gov)

### INTRODUCTION

Movement control adaptation (MCA) is designed to optimize dynamical characteristics of movement (such as effort, power, joint torque, or muscle force) in response to a change in the physical demands of movement. [1-3]. Results from previous studies on movement adaptation for upper extremities suggest that a delay in the onset or poor execution of movements in response to environmental change would form the basis of impaired MCA. The purpose of this study was to develop a method for measuring MCA in a more complex, functional lower extremity motor task. We hypothesized that MCA will begin in the motor preparatory phase and continue in the motor execution phase.

### METHODS

Data from one healthy young subject are presented. The tests consisted of training an individual to react to a light cue by stepping forward as fast as possible to the light target, a distance equaling to 30% of maximal step length (MSL). Following the training period, an MCA trial (60%) was inserted into a series of trained step trials (30%) by shining the light cue at 60% of MSL.

**Figure 1:** Stepping Test. MSL: maximal step length (1.06 m)

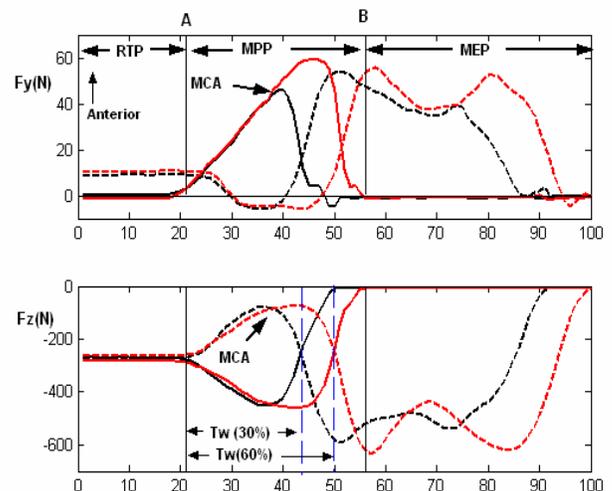

Force plates were used to measure kinetic data during stepping tests (Figure 1). Movement analyses were divided into three phases of forward stepping: Reaction time phase (RTP)-defined as time period from onset of light-cue stimulus to onset of step initiation. Motor preparatory phase (MPP)-defined as time period from onset of step initiation to toe-off of swing foot, and motor execution phase (MEP)- defined as time period from toe-off of swing foot to toe-off of stance leg.

### RESULTS AND DISCUSSION

The results from a single subject showed there is no observed delay in reaction time at 60% of MSL (253 and 254ms at 30% and 60% of MSL, respectively). This finding indicated the subject has approached the motor tasks the same way as previously trained tasks via a feedforward control mechanism, which means the motor program has been processed prior stimulus. The evidence of identical motor programming is indicated by generation of similar slope of anterior/posterior (A/P) force in the early stage of MPP, and later modified the ongoing motor program, which has been shown in this study as the timing of departure in slopes at 30 and 60%, defined as onset of MCA (Figure 2). The finding in this study showed the

onset of MCA occurred at 40% of a step cycle (500ms after onset of stimulus). The capability of developing MCA is very important for humans to overcome unexpected environmental challenges and achieve an optimal motor control. On the other hand, a delay of MCA would result in poor motor execution in the later phase.

In addition, MCA also was demonstrated by relatively higher peak force (60 vs. 47 N) and impulse in the A/P direction (14523 vs. 8218 N\*ms) at 60% compared to 30% of MSL (figure 2) in swing leg. A longer period for weight transfer (Tw) was observed at 60% of MSL (369 vs. 290 ms). During MEP, the stance leg in the late phase of MEP showed relatively higher second peak A/P force at 60% compared to 30% of MSL (53 vs. 39 N). Increasing Tw in MPP indicated further generation of propulsion force for the swing leg. Occurrence of a second Peak A/P force in stance leg at 60% of MSL indicated MCA existed in stance leg. In summary, occurrence of MCA coexisting in swing and stance legs is governed by highly coordinated motor programs.

**Figure 2:** Ground reaction forces in A/P direction ( $F_y$ ) and in vertical direction ( $F_z$ ) for 30% (black lines) and 60% (red lines) of MSL (upper and lower figures, respectively). Time is normalized by 100%. Solid lines represent force measures of the swing leg. Dash lines represent force measures of the stance leg. The time point at 0 represents onset of the stimulus (light cue) and time point at 100 represents toe-off of stance leg. A: onset of stepping; B: toe-off of swing leg.

### CONCLUSIONS

This study demonstrated the feasibility of measuring the onset and characteristics of MCA in a complex, lower-extremity motor task, and provided insight into understanding underlying control mechanisms of human locomotion.

## Artificial Neural Network Prediction of Center of Pressure Using Trunk Acceleration Inputs During Perturbed Human Bipedal Stance

### INTRODUCTION

This study investigates the feasibility of artificial neural network (ANN) prediction of changes in center of pressure (COP) during perturbed human bipedal stance using current and past COP and trunk acceleration inputs. The COP – COM (center of mass) variable has been shown to be correlated to COM acceleration during quiet standing [1]. We hypothesize that accelerations of a point on the trunk (estimate of COM) can be implemented by an ANN to predict COP. We seek to employ this ANN in a dynamic, feed-forward manner for controlling standing posture using functional neuromuscular stimulation (FNS) following spinal cord injury (SCI). Due to the delay in peak muscle force production after initial stimulation, we will apply a control loop that acts predictively by minimizing the difference between a desired COP and a future COP determined by the ANN.

### METHODS

Two able-bodied male subjects (25-27 yrs) have participated thus far. Each subject wore two belts, one around the waist and one around the chest (figure 1). Both belts were fastened to four non-elastic cotton-cloth ropes. Each rope was aligned in either the anterior-posterior (A-P) or medial-lateral (M-L) directions relative to the subject. Ropes were used to manually apply perturbations to the subject standing on an instrumented force-plate that actively measured COP. The subject wore a retroreflective sternum marker whose 3-D position was tracked using a VICON<sup>®</sup> camera system. The position data were double-differentiated off-line using a derivative-filter [2] to obtain trunk accelerations. Trials consisted of perturbing the subject, initially in erect stance, in different combinations of rope-pulls. Perturbations were moderate such that significant COP deviations were incurred yet the subject could make postural corrections to maintain bipedal stance without stepping.

Data from the aforementioned trials were used for training and testing an ANN for COP prediction at several future time increments (100, 150, 200, 250, 300 msec) on the order of neuromuscular delay. A three-layer, time-delayed feed-forward network [3] for back-propagation training was created. The inputs into the network were current and past values of three orthogonal acceleration components (x, y, z) and two horizontal-plane COP components (A-P, M-L). The outputs were changes in the two COP components at the previously specified future time-instants.

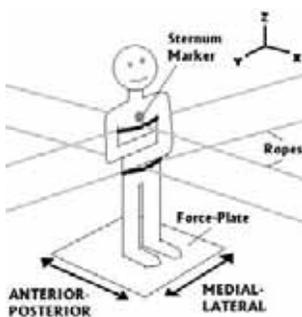

Figure 1. Experimental Set-up (not to scale)

### RESULTS AND DISCUSSION

After ANN training, correlation coefficients ( $R^2$ ) between true COP change and ANN-predicted output for test data were calculated as a measure of their respective fit. Results from a test sample having both A-P and M-L perturbations are shown in figure 2. Substantial correlation ( $> 0.7$ ) exists for both the A-P and M-L components.

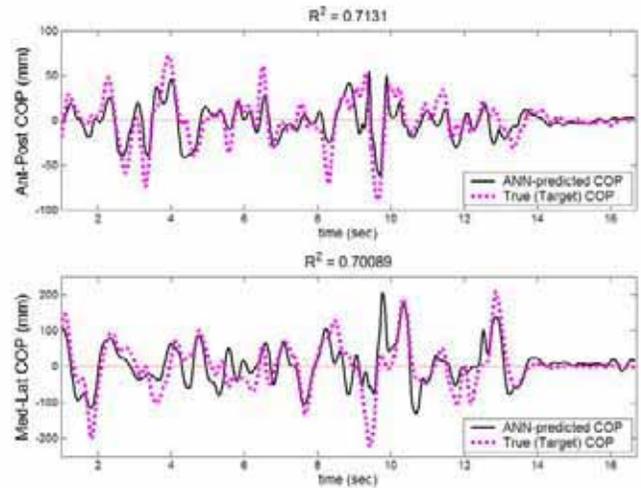

Figure 2. ANN prediction (200 msec in future) of changes in Ant-Post (top) and Med-Lat (bottom) COP for 1000-point (60 Hz sampling rate  $\rightarrow$  16.7 sec) test sample.

Improved correlation is expected with additional inputs (more markers, additional past values) and a more dynamic neural network structure that includes recurrent connections. Future investigations will implement accelerometer outputs rather than numeric differentiation of VICON position data. Accelerometer readings are likely not as accurate as the numerically-derived values currently used. However, it is expected that the accelerometer will be more sensitive to larger deviations in posture relative to steady-state swaying, making correlations during a perturbation trial higher. While feasibility has been demonstrated, the required accuracy of the ANN predictor can only be assessed when integrated in the full FNS control system. This will be done first in simulation prior to experimental evaluation.

### INTRODUCTION

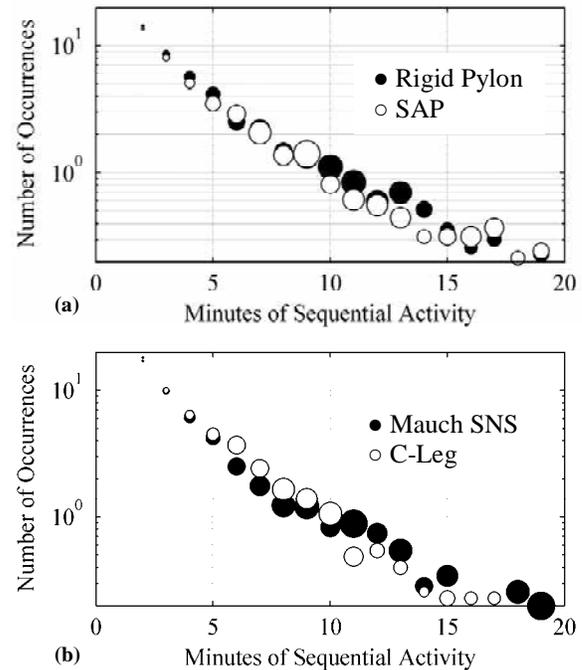

Prosthetic prescription is widely believed to have a strong influence on lower limb amputee activity levels. Optimum prescription should equate to maximum performance. Field measurements of activity is one method to assess performance on a functional level, yet few investigators have used this metric to explore how amputees actually use their prostheses in the community [1] and how prosthetic prescription might influence activity [2]. The purpose of this study is to discover if variation in prosthetic prescription can affect the activity levels of lower limb amputees. The secondary purpose was to discover the characteristics of their activity; specifically, how long are their bouts of activity, how frequently do they occur, and how many steps do they average during each bout.

### METHODS

Ten *transtibial* and five *transfemoral* amputees gave informed consent to participate in this Institutional Review Board-approved protocol. Activity levels were measured using a pager-sized instrument (StepWatch2; Cyma) attached to the distal end of the prosthetic pylon. The number of steps taken was collected for 1 week using a 1 minute sample and record interval. The prosthetic components of all subjects were held constant throughout the study except for the intervention of interest. The *transtibial* amputees (5 traumatic, 4 dysvascular, 1 infection; age  $52 \pm 6$  years; Ht.  $178 \pm 6$  cm; Wt.  $91 \pm 18$  kg), all long term prosthetic users, were provided with a SAP (Mercury™ Telescopic Torsion Pylon; Blatchford) and rigid pylon in random order. The activity of each subject was recorded following 3 weeks of acclimation. The *transfemoral* amputees (5 traumatic; age  $48 \pm 14$  years; Ht.  $171 \pm 4$  cm; Wt.  $76 \pm 10$  kg), all previous long term Mauch SNS (Ossur) users, were provided with a C-Leg (Otto Bock) and a Mauch SNS in random order. The activity of each subject was recorded following 3 months of acclimation.

### RESULTS AND DISCUSSION

The activity levels of neither *transtibial* nor *transfemoral* amputees were affected by their prosthetic prescription. Among *transtibial* amputees, no difference in activity level was observed across pylons (Rigid:  $3191 \pm 2230$  steps/day, SAP:  $3192 \pm 2207$  steps/day,  $p > .99$ ). Among *transfemoral* amputees, no difference in activity level was observed across knees (Mauch SNS:  $2675 \pm 976$  steps/day, C-Leg:  $2657 \pm 737$  steps/day,  $p > .96$ ). A study of *transtibial* amputees ( $n=13$ ) did find a difference across liners: subjects were more active while wearing a closed-cell low-density polyethylene liner (4135 steps/day) than a silicone liner (2262 steps/day) [2]. Considering that activity levels can vary widely between individuals [3], a large sample population might be necessary to adequately determine a functional activity level ceiling for lower limb amputees. However, if appropriate controls are placed on age and amputation etiology [1], a small sample

**Figure 1:** Bouts of daily activity (averaged over 1 week) for (a) *transtibial* amputees wearing rigid pylon or SAP and (b) *transfemoral* amputees wearing Mauch SNS or C-Leg. Circle diameter is proportional to number of steps per minute (1mm=20 steps/minute).

population might suffice to distinguish differences due to prosthetic prescription in within-subject experiments.

No differences were distinguishable in the characteristics of their daily activities averaged over a 1 week period (see Figure 1). When amputees walked for at least 5 minutes in a row, they averaged ~50 steps/minute. However, rarely were amputees active for more than 10 minutes at a time. Most of their activities (number of occurrences) consisted of short bouts of 3 minutes or less and during these short bouts they averaged ~14 steps/minute. Subjects in this study did not achieve the recommended minimum of 30 minutes moderate-intensity activity on most days of the week to promote health, psychological well-being, and a health body weight [4].

**INTRODUCTION**

Anterior cruciate ligament injuries occur 2-8x more often in females than males [1,2]. Over 70% of these injuries occur in a non-contact situation including cutting, pivoting and landing from a jump [3]. Several factors have been implicated in this predisposition including biomechanics [4]. The purpose of this study was to detect differences in kinetics and kinematics during cutting maneuvers that may contribute to this gender predisposition.

**METHODS**

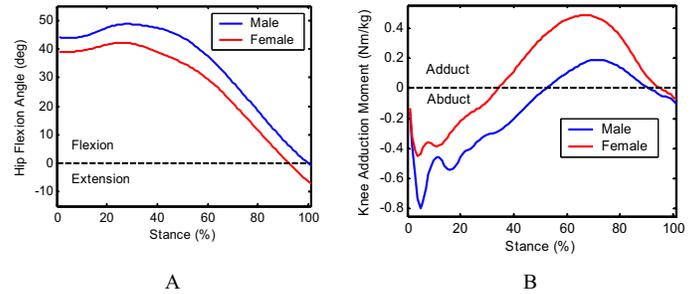

21 elite male and 21 elite female soccer players between the ages of 14-18 years underwent a complete 3D kinematic, kinetic and electromyographic (EMG) analysis of the lower limb during unanticipated running and cutting maneuvers. Hip, knee and ankle angles, forces and moments were collected during the stance phase of each maneuver. Subjects were instructed to run down the walkway of the lab at 3.5 ± 0.2 m/s. Just prior to their right foot landing on the force plate, a light system randomly directed the individuals to either 1) cut to the left (side-cut), 2) continue running straight or 3) cut to the right (cross-cut) until 5 successful trials were obtained for each direction. All cutting maneuvers were made at a 45-60° angle. The kinematic and kinetic waveforms for the entire stance phase of each task were analyzed using principal component analysis [5].

**RESULTS AND DISCUSSION**

There was no significant difference between males and females in age, body mass index (BMI), years of soccer experience or speed of the cutting maneuvers (Table 1). All players were injury free at the time of testing; however, many reported lower limb injuries previously in their soccer careers (M=62%, F=86%).

For the cross-cut and side-cut conditions principal component analysis revealed females exhibit a significantly smaller magnitude of hip flexion than males throughout stance (p=.01) (Figure 1A). In the cross-cut maneuver females also exhibited

a significantly larger magnitude knee adduction moment than their male counterparts (p=.03) (Figure 1B).

**Figure 1:** A) Females exhibit less hip flexion than males during cross-cuts & side-cuts (p=.01). B) Females exhibit a greater knee adduction moment than males during cross-cuts (p=.03).

**CONCLUSIONS**

The cross-cut was the most successful maneuver for identifying gender related differences in this elite soccer population. Females generated less hip flexion and a larger knee adduction moment than their male counterparts. These biomechanical differences may place the female ACL at greater risk for injury. Knowledge of these differences will aid in developing prevention programs to reduce non-contact ACL injuries in females.

## DIFFERENCES IN MUSCLE FUNCTION BETWEEN WALKING AND RUNNING AT THE PREFERRED WALK-RUN TRANSITION SPEED

Kotaro Sasaki and Richard R. Neptune

Department of Mechanical Engineering, University of Texas, Austin, TX, USA

Email: [rneptune@mail.utexas.edu](mailto:rneptune@mail.utexas.edu)

### INTRODUCTION

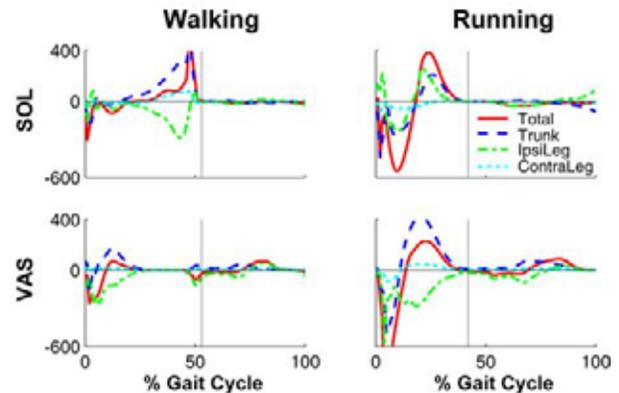

Walking and running are the two most common forms of human gait. Understanding differences in muscle function between the two gait modes would further our understanding of the neuromotor control principles that govern human locomotion. Recent modeling and simulation studies have identified individual muscle contributions to the body mechanical energetics during normal walking [1]. However, it is unclear whether these contributions are preserved when the gait mode switches from walking to running. Therefore, the objective of this study was to use forward dynamical simulations of walking and running at the same speed and assess whether individual muscles contribute to the same body segment mechanical energetics during the two gait modes.

### METHODS

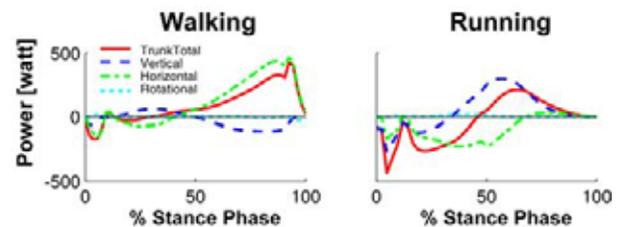

Forward dynamical simulations of walking and running at the preferred walk-to-run transition speed (~2 m/s) were generated using dynamic optimization such that the simulations reproduced the averaged experimental kinematic and ground reaction force data collected from 10 healthy subjects. A 2D musculoskeletal model with nine degrees-of-freedom (trunk anterior-posterior tilt, horizontal and vertical translation, hip, knee and ankle flexion-extension for both legs) consisting of a trunk and two legs (femur, tibia, patella and foot for each leg) and seventeen individual muscle actuators per leg was developed using SIMM [2]. The muscles included the gluteus maximus, anterior and posterior gluteus medius, adductor magnus, iliacus, psoas, biceps femoris long head, medial hamstrings, biceps femoris short head, vastii, rectus femoris, tibialis anterior, soleus and medial and lateral gastrocnemius. Thirty visco-elastic elements were attached to each foot segment to model the foot-ground contact [e.g. 1]. Individual muscle excitation patterns were derived from EMG data collected from the same subjects. Parameter optimization using a simulated annealing algorithm was used to fine-tune the onset, duration and magnitude of the EMG patterns to produce well-coordinated movements. A state-space segment power analysis was performed to quantify how individual muscles contribute to the body segment energetics [3].

### RESULTS AND DISCUSSION

The primary difference in how individual muscles distribute body segment mechanical power between walking and running was observed in the soleus (SOL). In walking, SOL absorbed ipsilateral leg power and transferred much of that power to the trunk from mid to late stance, then in late stance simultaneously generated power directly to the trunk (Fig. 1: SOL, Walking, 25-50% gait cycle). In running, SOL absorbed power from both the leg and trunk in the beginning of stance and then generated power to both the leg and trunk in mid stance (Fig. 1: SOL, Running, 0-30% gait cycle). In addition,

**Figure 1:** Distribution of total musculotendon power (*Total*) to the trunk (*Trunk*), ipsilateral leg (*IpsiLeg*) and contralateral leg (*ContraLeg*) during walking and running over the gait cycle. The vertical lines indicate toe-off. SOL: soleus; VAS: vasti. Units are in watts.

**Figure 2:** Trunk mechanical power generated by the soleus (SOL) during stance in walking and running. *Total*: total power; *Vertical*: vertical kinetic and potential power; *Horizontal*: horizontal kinetic power; *Rotational*: rotational power.

the power generated to the trunk by SOL exhibited different patterns between gait modes (Fig. 2). In walking, SOL provided positive horizontal and negative vertical power in late stance, which indicated that SOL acted to accelerate the trunk forward and decelerate the downward motion of the trunk. In running, near mid-stance SOL absorbed power from the trunk in the horizontal direction (i.e., decelerated its forward motion) while providing positive power in the vertical direction for body support. All other muscle contributions to body segment power were similar between walking and running, although the magnitudes and durations often differed between the two modes (e.g. Fig. 1: VAS).

## MUSCLE CONTRIBUTIONS TO THE FLIGHT PHASE IN RUNNING

Kotaro Sasaki and Richard R. Neptune

Department of Mechanical Engineering, University of Texas, Austin, TX, USA

Email: [rneptune@mail.utexas.edu](mailto:rneptune@mail.utexas.edu)

### INTRODUCTION

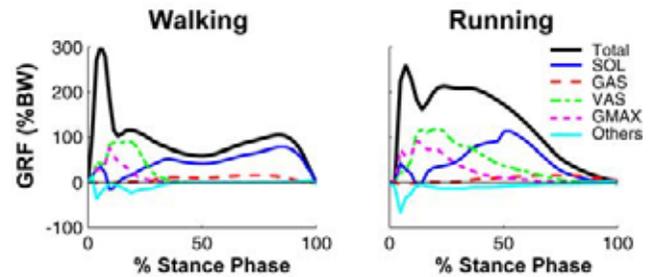

One of the most distinctive differences between walking and running is the existence of a flight phase in running rather than the double support phase that occurs in walking. This fundamental difference in gait mechanics indicates the need for muscles to generate greater vertical acceleration of the body's center of mass (COM) in running. Previous modeling studies of normal walking have shown that the uniarticular hip and knee extensors, and the ankle plantar flexors are the primary contributors to vertical acceleration of the COM from early to mid stance, and from mid to late stance, respectively [1, 2]. However, little is known about how individual muscles work in synergy to accelerate the COM upward to produce the flight phase in running. Therefore, the objective of this study was to identify which muscles contribute to the acceleration of the COM vertically and how these contributions differ between walking and running at the same speed.

### METHODS

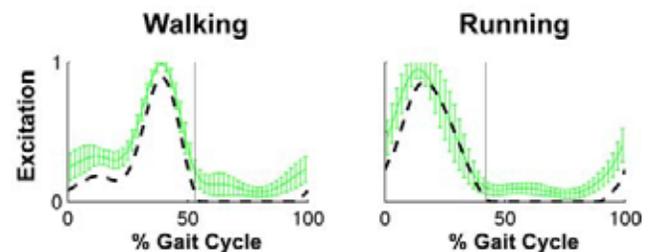

Individual muscle contributions to the vertical acceleration of the COM were obtained by quantifying each muscle's contribution to the vertical ground reaction force (GRF) using forward dynamical simulations of walking and running. A 2D musculoskeletal model with nine degrees-of-freedom (trunk anterior-posterior tilt, trunk horizontal and vertical translation, hip, knee and ankle flexion-extension for both legs) consisting of a trunk and two legs (femur, tibia, patella and foot per leg) and seventeen Hill-type muscle actuators per leg was developed using SIMM [3]. The muscles included in the model were the gluteus maximus, anterior and posterior gluteus medius, adductor magnus, iliacus, psoas, biceps femoris long head, medial hamstrings, biceps femoris short head, vastii, rectus femoris, tibialis anterior, soleus and medial and lateral gastrocnemius. The equations of motion were derived using SD/FAST (PTC, Needham, MA). Visco-elastic elements were attached to each foot segment to model the foot-ground contact [2]. Muscle excitation patterns were derived from measured group-averaged EMG patterns. A simulated annealing optimization algorithm was used to fine-tune the onset, duration and magnitude of the EMG patterns such that the simulations emulated group averaged experimental kinematic and GRF data collected from 10 young healthy subjects during walking and running at the preferred walk-to-run transition speed (~2 m/s). The contributions of each muscle to the vertical GRF were then quantified using a GRF decomposition [1, 2].

### RESULTS AND DISCUSSION

The primary contributors to vertical GRF were the soleus (SOL), vasti (VAS) and gluteus maximus (GMAX) in both walking and running (Fig. 1). In walking, VAS and GMAX contributions occurred primarily in early stance phase (~0-30% stance phase), and then SOL contributed from mid to late stance (~30-100% stance phase, see also [1, 2]). In running,

**Figure 1:** Individual muscle contributions to vertical GRF. Total: the total GRF including muscular and non-muscular components, Others: hamstrings, gluteus medius, tibialis anterior, rectus femoris, biceps femoris short head and iliacus-psoas combined.

**Figure 2:** SOL excitation patterns for the walking and running simulations (dashed line) and group average EMG linear envelopes (solid line, average  $\pm$  S.D.) at the preferred transition speed from heel-strike to heel-strike of the ipsilateral leg. The EMG data were normalized to the maximum value observed over the gait cycle. The vertical lines indicate toe-off.

the magnitude of the VAS and GMAX contribution increased and extended into mid stance (~0-60% stance), while the SOL contribution shifted earlier in the stance phase (~0-70% stance), which corresponded with a shift in SOL muscle activity (Fig. 2, [4]). These results indicate that the flight phase in running is produced by increased and prolonged VAS and GMAX and phase-advanced SOL contributions to the vertical GRF which provides the necessary vertical acceleration of the COM.

## IMPACT OF FLEXIBILITY ON MUSCULAR PERFORMANCE OF THE KNEE

Gustavo Nunes Tasca Ferreira, Luci Fuscaldi Teixeira-Salmela, Cristiano Q Guimarães, Geraldo Fabiano de Souza Moraes  
 Department of Physical Therapy/Universidade Federal de Minas Gerais – Brasil; e-mail: [jhsalmela@hotmail.com](mailto:jhsalmela@hotmail.com)

### INTRODUCTION

Despite the popularity of stretching programs for sport rehabilitation, little it is known about the relationships between gains in flexibility and changes in muscular performance. This aim of this study was to investigate the impact of static stretching on flexibility of the hamstrings and muscular performance of knee flexor and extensor muscles.

### METHODS

Thirty subjects (19 women and 11 men; aged:  $22.8 \pm 4.9$  years) with shortened hamstrings (60 legs), operationally defined as the loss of knee extension greater than  $30^\circ$ , took part in the study. Measures of flexibility were obtained with a goniometer and the amount of applied force was controlled by a manual dynamometer. Muscular performance measures on the isokinetic dynamometer at  $60^\circ$  and  $300^\circ/s$  were obtained before and immediately after the intervention. The intervention program consisted of 30 sessions of static stretching, performed bilaterally five times a week for six weeks. Measures of flexibility were reassessed six weeks after the cessation of the intervention (follow-up). Descriptive statistics and tests for normality (Shapiro-Wilk) were calculated for all outcome measures. The impact of the intervention was investigated using parametric and non-parametric analyses, depending on data distribution ( $\alpha < 0.05$ ).

### RESULTS AND DISCUSSION

As presented in Table 1, after the intervention, there were significant gains in measures of flexibility ( $p=0.000$ ) and muscular performance for the following parameters: angle of peak torque for hamstrings at  $60^\circ/s$  and  $300^\circ/s$  ( $p < 0.0001$  and  $0.018$ ); for work normalized by body weight at  $60^\circ/s$  and  $300^\circ/s$  for knee flexors ( $p=0.012$  and  $0.005$ ); for knee extensors ( $p < 0.0001$ ). Of the 10 subjects who comprised the follow-up group, repeated measures ANOVA revealed that gains in flexibility obtained with the intervention, were maintained ( $p=0.183$ ).

The observed gains of flexibility corroborated previous findings [1,2]. Considering evidence of stretching-induced sarcomerogenesis [2,3], it is possible to infer that after the intervention, the number of sarcomers in series in the hamstrings increased, and thus, improved their capacity to

vary length, which may explain changes of angle of peak torque in the direction of knee extension.

It is possible to speculate that the hamstrings became more capable of moving the leg over a larger angular distance during the same time interval. Increases in the number of sarcomers in series represent a larger capacity of the muscle-tendon unit to vary its length in a certain time interval [4], which can be translated by increases of angular velocity. Therefore, the slope of the curve is increased until the segment reaches the isokinetic programmed speed, generating a larger area below the curve, and thus increasing the generated work.

The observed increases in work generated by knee extensors after the intervention can be related to smaller passive resistance imposed by the knee flexors [2,3], once the range of motion used during tests was the same.

The retention of gains in flexibility can be explained by the fact that the stretching exercises were performed bilaterally and may have allowed the subjects to incorporate these gains in their daily lives, thus, attenuating the detraining effects.

### CONCLUSIONS

These findings indicated that the intervention resulted in gains in measures of flexibility and muscular performance and suggest that these gains had a positive impact on various parameters of muscular performance.

### INTRODUCTION

Acute hamstring strains are one of the most frequent injuries in sports involving sprinting [1,2]. Radiological analyses have shown that a large majority of hamstring injuries occur in the lateral hamstrings (BF-biceps femoris), while the medial hamstrings (ST-semitendinous, SM-semimembranous) are less frequently involved [3,4]. However, there is currently limited scientific data to understand injury mechanisms during sprinting and differences in injury rates between muscles.

The objective of this study was to characterize medial and lateral hamstring kinematics across sprinting speeds. We hypothesized that the BF would be subjected to greater stretch than the ST or SM. Our secondary hypothesis was that increasing sprinting speed would both increase and delay the occurrence of peak hamstring stretch within the gait cycle.

### METHODS

Fourteen athletes (6 female, 8 male, 16-31 yr old) participated in this study. Subjects had no previous hamstring injuries within one year prior to being tested. Whole body kinematics were recorded at 200 Hz while each subject sprinted on a high-speed treadmill at 80, 85, 90, 95, and 100% of his/her maximum sprinting speed. Hamstring kinematics were estimated using a 3-D, 29 degree-of-freedom model that included geometric descriptions of the BF, ST and SM muscles (Fig. 1). Model predictions of hip extension and knee flexion moment arms for the individual hamstring muscles were consistent with published data. [5,6].

Figure 1: Musculoskeletal model shown with markers and in posture of peak hamstring muscle stretch

The model was scaled to individual subjects. An optimization-based inverse kinematics routine was employed to compute joint angles from marker kinematics. At each time step, muscle-tendon lengths were determined by computing the distance from origin to insertion and accounting for wrapping about structures at the knee. Muscle stretch was defined as the lengthening of the muscle-tendon unit relative to the length in an upright posture. Repeated measures ANOVA were used to test for the significance ( $p < 0.01$ ) of the effects of speed and muscle on peak stretch and the time at which peak stretch occurred within the gait cycle (GC).

### RESULTS AND DISCUSSION

Average maximum sprinting speed was 9.4 m/s for the males and 8.1 m/s for the females. Peak muscle-tendon stretch occurred at ~90% GC (Fig. 2a). The BF was stretched an average of 9.5% beyond the nominal upright length, which was significantly more than the peak stretch of the SM (7.4%) and ST (8.1%). However, there was no significant variation in peak hamstring stretch with speed (Fig. 2b). There was a

slight delay (~2% of the GC) in the occurrence of peak hamstring stretch at the maximum sprinting speed.

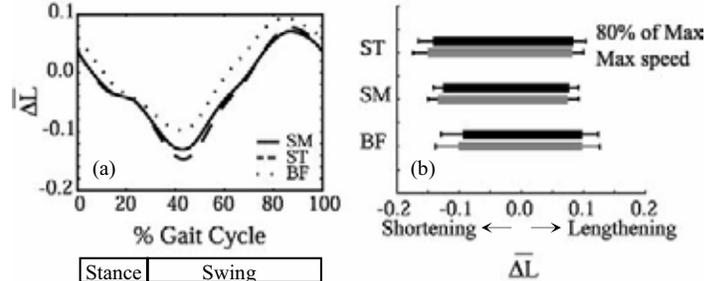

Figure 2: a) Peak hamstring muscle-tendon stretch ( $\Delta L$ ) occurs during late swing prior to foot strike. b) Overall excursions of the hamstrings over a sprinting gait cycle ranged from 19 to 23%, but did not vary with sprinting speed over the range (80-100% max) considered.

The differences in peak stretch between the medial and lateral hamstrings found in this study are primarily a result of differences in knee flexion moment arms between muscles. The ST and BF have similar hip extension moment arms [5], and thus each undergo similar stretch due to hip flexion. However, because the BF has a smaller knee flexion moment arm than the ST and SM muscles, knee flexion during late swing (Fig. 1) reduces the BF length less than the medial hamstrings. The net effect is that the BF experiences greater overall stretch, relative to the upright length, than ST or SM

### SUMMARY

Animal models of muscle-tendon injuries have shown that mechanical strain is a strong indicator of injury potential [7]. Therefore, the muscle-tendon stretch measures reported in this study provide insights into hamstring injury potential during sprinting. Our data support the idea that the potential for a lengthening strain injury to the hamstrings is greatest during the late swing phase of sprinting, when the muscles are maximally stretched and active [8]. Furthermore, we conclude that the higher injury rates for the BF may in part arise from differences in knee flexion moment arms between the hamstring muscles.

## SCAPULAR MUSCLE RECRUITMENT AND ISOKINETIC FORCE PRODUCTION IN INDIVIDUALS WITH IMPINGEMENT SYNDROME

Geraldo F. S. Moraes, Luci F. Teixeira-Salmela, Christina D.C.M. Faria, Gustavo N.T. Ferreira  
 Department of Physical Therapy/ Universidade Federal de Minas Gerais, Brazil e-mail: [geraldmoraes@terra.com.br](mailto:geraldmoraes@terra.com.br)

### INTRODUCTION

Dynamic neuromuscular imbalance of scapulohumeral rhythm has been related to the onset of the impingement syndrome and other related pathologies [1-2].

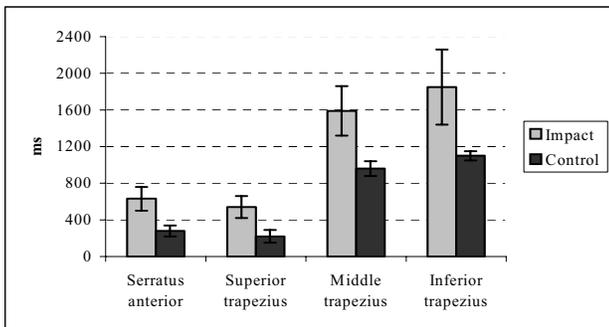

The aim of this study was to investigate muscular imbalance of the rotator cuff and scapular muscle recruitment in 10 individuals with impingement syndrome graded I and II compared to 10 asymptomatic subjects.

### METHODS

Recruitment patterns and latencies were determined by the electromyographic activity of the scapular stabilizer muscles (trapezius and serratus anterior) during shoulder elevation in the scapular plane. Isokinetic measures of muscular performance were determined by the antagonist/agonist work ratios of the medial (MR) and lateral rotators (LR) obtained with the dynamometer Biodex at speeds of 60 and 180°/s in the supine position. Descriptive statistics and tests for normality (Shapiro-Wilk) were performed for all outcome variables. ANOVA (2x2) was used to investigate side and group differences, as well as interactions, with a significance level of  $\alpha < 0.05$ .

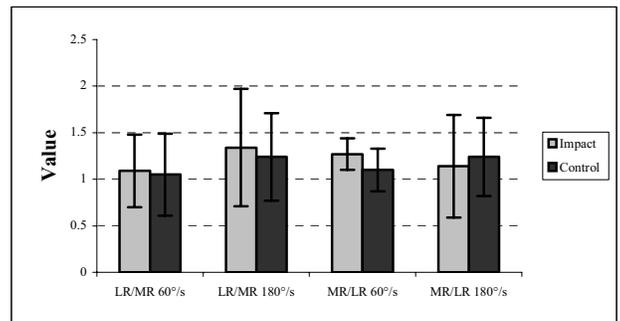

### RESULTS AND DISCUSSION

No group or side differences were found for the recruitment patterns. Supporting previous studies, the activation sequence involved first, the superior trapezius, followed by serratus anterior, middle, and inferior trapezius [1-2]. However, as illustrated in Figure 1, subjects on the impact group showed significantly higher latencies for all scapular muscles ( $F = 27.18 - 50.13$ ;  $p < 0.001$ ). In addition, a group-by-side interaction was found, indicating that the differences were significant only for the affected side ( $F = 18.75 - 37.39$ ;  $p < 0.001$ ).

**Figure 1:** Means (± SD) of latencies (ms) for the impingement (affected side) and control groups

No significant group or side differences were found for the muscular performance measures (Figure 2), which are opposite to the findings reported by Leroux et al. [3], in which the measurements were taken in the seated position. Ng and Lam [4] also reported significant differences for the antagonist/agonist work ratios of athletes obtained in the supine position.

**Figure 2:** Means (± SD) of isokinetic ratios for both groups

### CONCLUSIONS

Individuals with impingement syndrome presented significant delays for the recruitment of scapular muscles, indicating alterations of dynamic neuromuscular balance. Therefore, assessment of performance of the scapular stabilizer muscles appears to be more important for the detection of functional deficits in individuals with impingement syndrome, to better guide therapeutic interventions.

Isokinetic performance of shoulder rotators was not affected by the presence of impingement. Subject positioning during the isokinetic assessment may have provided a mechanical advantage for the rotator muscle actions and explain the lack of significant differences between groups for the muscle performance measures. These findings suggest that when performing shoulder isokinetic assessment, subject positioning should be controlled.

**THE THRESHOLD OF BALANCE RECOVERY IS NOT AFFECTED BY THE TYPE OF POSTURAL PERTURBATION**

Kodjo E Moglo and Cécile Smeesters

Research Center on Aging, Sherbrooke Geriatric University Institute, Sherbrooke, QC, Canada

Department of Mechanical Engineering, Université de Sherbrooke, Sherbrooke, QC, Canada

email: [Cecile.Smeesters@USherbrooke.ca](mailto:Cecile.Smeesters@USherbrooke.ca)

web: [www.cdrv.ca](http://www.cdrv.ca)

**INTRODUCTION**

Only recently have studies focused on postural perturbations at the threshold of balance recovery, i.e., perturbations large enough that balance recovery is not always possible and a fall can occur. The knowledge at the threshold of balance recovery is thus very limited. In particular, the effect of initial velocity on the threshold of balance recovery has not been quantified, despite experimental [1-2] and theoretical [3-5] qualitative evidence of its importance. This study quantified the effect of initial velocity on the threshold of balance recovery and developed a method to compare experiments with different initial velocities, regardless of the postural perturbation.

**METHODS**

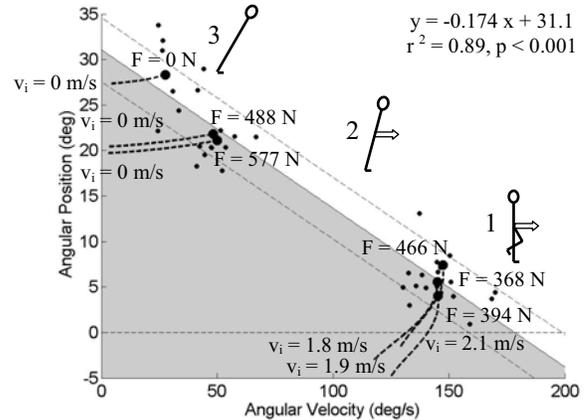

Three male and three female healthy younger adults participated ( $24.5 \pm 4.2$  yrs,  $1.72 \pm 0.05$  m,  $67 \pm 8.1$  kg). The maximum forward pull force that they could sustain and still recover balance using a single step was determined for three different walking velocities with no initial lean. The maximum forward lean angle that they could be released from and still recover balance using a single step was also determined for three different forward pull forces with no initial velocity. The forces and angles were sequentially increased and the postural perturbations were randomly ordered. Walking speeds, pull forces, angular positions and velocities, reaction, weight transfer and step times, and step lengths and velocities were measured using load cells and a motion measurement system. One-way ANOVAs with repeated measures were used to determine the effect of the type of postural perturbation.

**RESULTS AND DISCUSSION**

The experiments showed that (Figure 1 and Table 1):

- The maximum pull force younger adults could sustain decreased as initial walking velocity increased.
- The maximum lean angle younger adults could be released from decreased as initial pull force, which in effect adds initial velocity, increased.
- At the thresholds of balance recovery (maximum pull and leans trials), the type of perturbation did not affect weight transfer times, step times, step lengths and step velocities but did affect reaction times although only by 12 ms.
- The equivalent disturbance angular position and velocity points at the thresholds of balance recovery formed a

disturbance threshold line separating falls from recoveries, regardless of the postural perturbation.

**Figure 1:** The equivalent disturbance angular positions and velocities, i.e., the angular positions and velocities from the vertical of the line connecting the stance ankle and the center of mass at the time of joint torque activation.

**CONCLUSIONS**

Initial velocity, produced by walking or added by pulling, has a detrimental effect on the threshold of balance recovery. However, results from experiments with no initial velocity do predict results of experiments with initial velocity. In other words, the threshold of balance recovery is not affected by the type of postural perturbation. Experiments are currently underway to confirm these results in older adults.

## Dynamic Calibration of an Extended-Range Electromagnetic Flock of Birds Motion Tracking System

David W. Wagner and Matthew P. Reed  
University of Michigan - Ann Arbor,  
email: [dwwagner@umich.edu](mailto:dwwagner@umich.edu), web: [www.HUMOSIM.org](http://www.HUMOSIM.org)

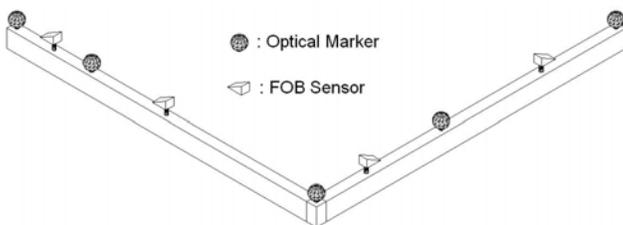

### INTRODUCTION

Electromagnetic (EM) motion tracking systems are a popular alternative to optical motion tracking systems. EM systems provide both position and orientation data from each sensor and can be used in environments with line-of-sight obstructions that would limit the use of camera-based systems. However, the presence of metal in the environment distorts the electromagnetic field and can cause significant errors [1,4]. Calibration procedures have been developed to improve accuracy by characterizing the distortion [2,3,4]. Previous efforts have used specialized fixtures with carefully controlled geometry to generate the reference data for calibration.

A new calibration technique is proposed that uses an optical motion tracking system as the source of reference data. The electromagnetic sensors are attached to a hand-held calibration wand that is also marked with optical targets. The wand is moved throughout the capture volume while data are gathered from both systems. Translation and rotation offsets are calculated for volume elements (voxels) of the capture space and subsequently applied to data from the electromagnetic system using an interpolating kernel.

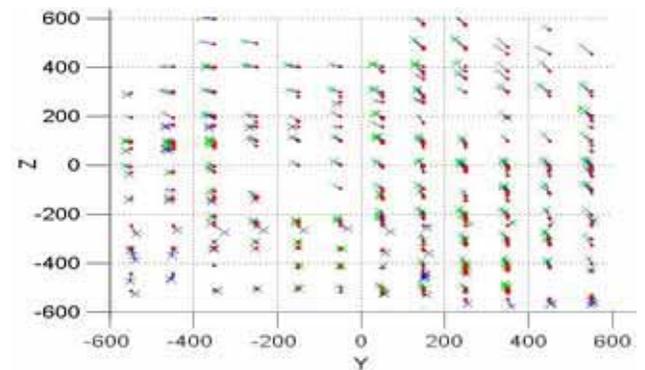

### METHODS

An Ascension Technology 'Flock of Birds' (FOB) electromagnetic tracking system with an extended range transmitter (ERT) was calibrated. Four sensors reporting both position and orientation were sampled at 50 Hz. Optical data were obtained using a Qualisys ProReflex MCU240 6-camera tracking system at 50 Hz. Five reflective markers, 25 mm in diameter, were placed on the wand, as shown in Figure 1. The configuration of the wand allowed the orientation of the FOB sensors to be calculated from the optical data.

**Figure 1.** Calibration wand, showing optical markers and electromagnetic sensors.

The FOB system was calibrated throughout a 3.6 x 4.8 x 2.0 m volume adjacent to the FOB transmitter. Data were gathered simultaneously from the two systems as the wand was moved slowly through the capture volume. Data were collected for 3 to 5 minutes for the main calibration dataset. The optical data were examined to verify that the capture volume was adequately spanned. Holes in the calibration dataset were filled with shorter 1-2 minute trials.

**Figure 2:** Positional offsets for all voxels in subset of the measurement volume.

Locally weighted linear regression was used to interpolate the scalar positional offsets for the FOB output position using a method similar to that reported by Day et al 2000 [2]. A Gaussian kernel centered at the FOB output position was used to determine weighting factors for the local regression. Orientation offsets were decomposed into Euler angles and handled in a similar fashion.

### RESULTS AND DISCUSSION

Three-dimensional translational offsets are shown for a subset of the capture volume (Figure 1). Voxel size is 50mm<sup>3</sup>. Circular dots indicate the reported FOB position and the connected cross is the associated global position. In practice, voxel size can be varied depending on the observed local field distortion, or the data can be used directly in the local interpolating functions, rather than aggregated into voxels. The accuracy with which the EM data match the optical data can be controlled in part by adjusting the density of the data gathered. Visual and quantitative tools provide feedback during the calibration process of the accuracy of the fit, allowing additional data to be gathered where needed.

Most previous approaches to EM system calibration have used specially constructed fixtures to move the EM sensors throughout the capture volume. The method reported here is faster and can easily be used around obstacles or with a changing environment. One group has reported using an optical system to obtain reference data [4], but only to improve the accuracy of measurements from a fixed-position calibration grid. Although the current approach is only practical when an optical system is available, it provides a relatively fast and accurate way of ensuring that data gathered from the two systems can be accurately merged for analysis.

## EFFECTS OF JUMP TYPE ON GROUND REACTION FORCES DURING LANDING IN CHILDREN

Bradley A. Black, Christine M. Snow, and Michael J. Pavol  
 Dept. of Exercise and Sport Science, Oregon State University, Corvallis, OR, U.S.A.  
 email: [mike.pavol@oregonstate.edu](mailto:mike.pavol@oregonstate.edu)

### INTRODUCTION

Bone loss associated with osteoporosis increases the risk of fracture in older adults. However, osteoporosis might be delayed and the incidence of fractures among older adults reduced by increasing peak bone mass during growth. In particular, pre-adolescence appears to be more responsive to interventions for increasing bone mass than adulthood. Known stimuli for increasing bone mass are large forces applied at high loading rates, such as those during landing from a jump. Indeed, a 7-month program of drop landings from a 61cm height enhanced gains in bone mass in children [1]. In this study, we determined whether other types of jumping activities in children produced ground reaction forces similar to those of the previously-reported drop landings.

### METHODS

22 healthy children (11 girls; mean  $\pm$  SD age:  $8.2 \pm 0.6$  years) provided informed consent to participate in this study. After a warm-up, each participant performed 5 trials each of 13 types of jumping activities. One type was a drop from a 61cm-high box. The other 12 types were performed from the ground and comprised all possible combinations of three factors: direction (vertical, forward, lateral), feet used (1-footed hops, 2-footed jumps), and continuity (single, continuous). All hops were on the dominant foot. In continuous trials, participants performed 2 identical hops/jumps (in opposite directions for the lateral trials) without coming to rest in between. Vertical hops/jumps were as high as possible. Forward and lateral hops/jumps were over marked distances of 80 and 55% of body height, respectively. Lateral hops/jumps were toward the dominant foot. The ground reaction forces acting on the dominant foot during the first landing of each trial were measured at 1080Hz using a force plate. The activity order was counterbalanced across participants. Practice was provided for each activity.

The peak force and peak rate of force increase (determined over a moving window of 4.6ms) on the dominant foot during the first landing of each trial were normalized to body weight and pooled across the 5 trials for each activity. Three-factor repeated-measures ANOVA identified loading differences across direction, feet used, and continuity. Paired *t*-tests with a Bonferroni correction compared the loading for each activity to that of the drop landings. An  $\alpha$  of 0.05 was used.

### RESULTS AND DISCUSSION

The peak forces during landing were greater for hops than for jumps, were greater for single than for continuous hops/jumps (except in the lateral direction), and were greater for forward hops than for vertical or lateral hops (Table 1). Peak forces during the drop landings exceeded those during all other jumping activities except the single, 1-footed, forward hops.

Similarly, the peak loading rates during landing were greater for single than for continuous hops/jumps (except in the lateral direction) and typically greater for forward than for vertical or lateral hops/jumps (Table 1). Peak loading rates for hops were greater than for jumps only in the lateral direction. Peak loading rates during the drop landings exceeded those during all other jumping activities.

The results make sense. Two-footed jumps allow sharing of the impact forces between the limbs at landing, reducing the peak loading. Continuous forward hops/jumps do not require forward momentum to be arrested upon landing, while continuous vertical hops/jumps likely include a large countermovement after landing, reducing the loading. Forward hops/jumps likely involved greater momentum at landing, hence greater forces and/or loading rates, than did vertical or lateral hops/jumps due to the greater horizontal velocity associated with the greater horizontal distance traveled. Yet, in no hop or jump from the ground did the participants generate energy equivalent to the potential energy at take-off of the drop jump, resulting in smaller impact forces and/or loading rates for these other activities.

### CONCLUSIONS

Compared to a variety of other jumps from the ground, single, 1-footed, forward hops produced the largest peak impact loadings in our sample of children. These hops were the only jumping activity from ground level that may produce as great an osteogenic stimulus as drop landings from a 61cm height.

**ANTICIPATION OF SLIPPERY FLOORS: MUSCLE ONSETS AND CO-CONTRACTION OF THE STANCE LEG**

April J. Chambers and Rakié Cham

Human Movement and Balance Laboratory, Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, USA  
 email: [ajcst49@pitt.edu](mailto:ajcst49@pitt.edu), web: [www.engr.pitt.edu/hmbl](http://www.engr.pitt.edu/hmbl)

**INTRODUCTION**

Falls are a major cause of injury, death and disability in the elderly [4,6,8]. In relatively healthy older adults, falls are often precipitated by base of support (BOS) perturbations such as slips and trips [1,5,6]. The use of proactive strategies has been revealed in gait studies using testing paradigms involving repeated exposure to a known perturbation [2,3]. The goal of this study, which has not been previously addressed, is to investigate the impact of anticipating real slippery floors on the muscle activity (onset and co-contractions) in the leading/left leg during gait on dry surfaces.

**METHODS**

Eleven young (20-33 yrs) and 9 older subjects (55-66 yrs), screened for neurological and orthopedic abnormalities, were instructed to walk at a self-selected pace across a vinyl tile walkway, while ground reaction forces and whole body motion were sampled at 1080 and 120 Hz, respectively. Also, EMGs were collected from the vastus lateralis (VL), medial hamstring (MH), tibialis anterior (TA), and medial gastrocnemius (MG) at 1080 Hz. Subjects were informed the first few trials would be dry, ‘baseline dry’ (BD). Without the subjects’ knowledge, a glycerol solution was applied at the left/leading foot-floor interface, generating an ‘unexpected slip. Subjects were then alerted that all remaining trials might be slippery, ‘alert dry’ (AD). Only the EMG data of the first 2 trials in the BD and AD conditions were analyzed here to minimize adaptation effects.

EMGs were rectified, low-pass filtered at 50 Hz using a zero-phase elliptical filter, and time normalized with respect to stance time (left foot) with 0% = Heel contact (HC) and 100% - Toe off (TO). The magnitude of the resulting EMG envelope was normalized within subject to the average peak value collected in the BD trials. Onsets were determined using a threshold of two standard deviations above baseline activity (with visual confirmation). A co-contraction index (CCI) was calculated based on the integrated (from -20% to HC and from HC to 20% into stance) ratio of the EMG activity of antagonist/agonist muscle pairs (TA/MG and VL/MH) using the equation proposed by Rudolph [7]. Within subject repeated measures ANOVAs were conducted on the onset, ankle and knee CCI using age (young/older), condition (BD/AD), and their interaction effect as independent variables. Significance level was set at 0.05

**RESULTS**

In general (exception is TA), muscle onsets were significantly affected by condition (Table 1). Specifically, the MG and MH were activated earlier in stance in the AD trials compared to the BD condition, finding that was evident in both age groups. Also, a significant age x condition interaction effect was seen in VL, with the older group delaying the activation of this muscle when anticipating slippery surfaces, while young subjects did not. Also, older subjects activated their MH earlier in stance with anticipation compared to young subjects.

Table 1: Mean Onset (standard error)

Onsets in % Stance	CONDITION			
	BD		AD	
	Older	Young	Older	Young
VL	-13.91 (1.02)	-14.27 (1.08)	-10.64 (2.02)	-15.84 (1.47)
MH	-14.26 (5.05)	-24.12 (1.15)	-19.10 (1.56)	-25.38 (.93)
TA	-9.62 (1.29)	-2.39 (3.09)	-9.03 (2.08)	-3.70 (3.14)
MG	20.39 (6.48)	23.18 (4.65)	8.04 (6.50)	3.22 (5.78)

Anticipation resulted in increased stiffness at the ankle and knee in both age groups (Figure 1). Additionally, significant age x condition interaction effects were seen at the knee as younger subjects increased stiffness in the AD trials compared to their BD levels more than older subjects, especially post HC. Interesting age-related differences in knee stiffening strategies exist between the pre- and post- HC phases as well.

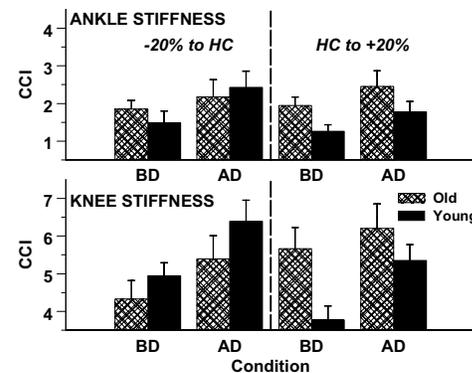

Figure 1: Ankle (top) and knee (bottom) CCI from -20% to HC (left) and from HC to 20% into stance (right) (standard error bars)

**DISCUSSION AND CONCLUSIONS**

In summary, anticipating slippery surfaces affects lower leg muscle activation onsets and ankle/knee stiffness. While young and older subjects adopted similar strategies at the ankle when anticipating slippery floors, there were age-related differences associated with the upper leg muscles. It is worth noting the most critical recovery responses to slips are generated at the knee and hip, not the ankle [9].

## COMPARISONS OF THE LOWER LIMB MECHANICS BETWEEN YOUNG AND OLDER ADULTS WHEN CROSSING OBSTACLES WITHOUT VISUAL GUIDE

Hao-Ling Chen and Tung-Wu Lu

Institute of Biomedical Engineering, National Taiwan University, Taiwan, [twlu@ntu.edu.tw](mailto:twlu@ntu.edu.tw)

### INTRODUCTION

Since tripping over obstacles during locomotion has been reported as one of the most frequent causes of falls in the elderly [1], research on the kinematics and kinetics of the lower extremities during this functional activity has received much attention [2-4]. The majority of previous studies in young adults during obstacle-crossing have been limited to presenting the kinematics of the leading swing limb and the kinetics of the trailing stance limb. It is noted that one has no visual cue when the trailing limb is crossing the obstacle, increasing the chance of tripping. Thus, a complete knowledge of the mechanics of obstacle crossing should include that of the limbs when the trailing limb is crossing, Fig. 1.

The kinematics of the crossing trailing limb has been reported for young adults [4] but the kinetics of the leading stance limb has not. Moreover, since aging may affect the performance of locomotion and obstacle negotiation, age effects on the mechanics of the leading stance limb and the trailing swing limb require detailed investigation. The purpose of the present study was thus to investigate the kinematics of the trailing swing limb and the kinetics of the leading stance limb when crossing obstacles of different heights in the healthy old people and to compare the results with those of the healthy young people.

### METHODS

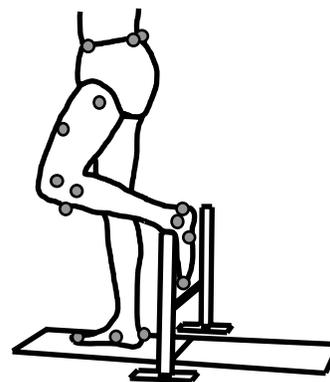

Fifteen young adults (age:  $23 \pm 3$  years, height:  $176.1 \pm 6.3$  cm, mass:  $68 \pm 8.6$  kg) and fifteen older adults (age:  $72 \pm 6$  years, height:  $160 \pm 5.7$  cm, mass:  $58 \pm 10.4$  kg) participated in the present study with informed consents. They all had normal corrected vision and were free of neuromusculoskeletal pathology. In a gait lab, each subject walked at self-selected pace and crossed obstacles of three different heights (10, 20 and 30% of leg length). Twenty-eight markers were used to track the motion of both limbs. Kinematic and kinetic data were measured with a 7-camera motion analysis system (Vicon512, Oxford Metrics, U.K.) and two force plates (AMTI, Advanced Mechanical Technology, U.S.A.) placed on each side of the obstacle. Height effects on temporal-distance gait parameters and joint angles of the trailing swing limbs as well as peak and crossing moments of the leading stance limbs were tested using RMANOVA for each age group ( $\alpha = 0.05$ ). Independent t-test was used for between-group comparisons.

### RESULTS AND DISCUSSION

The trailing clearance distances were not affected by height and age in both groups ( $p > 0.05$ ), in agreement with the literature [5-6]. Smaller leading heel-obstacle distances were found in the older group for all heights ( $p < 0.05$ ), suggesting that the older subjects may have higher risk of stumbling when the leading limb was crossing.

When the trailing toe was above the obstacle, the older group adopted bigger trailing hip flexion angles as well as bigger hip extensor, hip abductor and knee abductor crossing moments of the leading limb for all heights. Similar results were also found in the leading peak moments. Bigger joint crossing moments and more flexed positions of the stance limb may help to maintain a better stability. Bigger peak moments indicate that higher muscular demand was needed in the older group. In order to achieve the same trailing toe clearance as the young group, the older adults adopted bigger trailing hip crossing flexion angles.

The results of the study suggest that different temporal-distance, kinematic and kinetic strategies were used by the two age groups. The older group, with age-related muscle weakness, degradation of balance control and coordination, adopted a more conservative strategy possibly due to safety requirements.

**Figure 1:** Schematic diagram showing a subject's trailing limb crossing a height-adjustable obstacle while the leading limb is the stance limb.

## MECHANOMYOGRAPHY AND FORCE RELATIONSHIP DURING CONCENTRIC AND ECCENTRIC CONTRACTIONS OF THE VASTUS LATERALIS IN THE SPRIINTERS

<sup>1</sup>Chien-Hua Peng, <sup>1</sup>Yu Liu, <sup>1</sup>Shu-Mei Peng, <sup>1</sup>Jia-Yean, Chen, <sup>1</sup>Yi-Fang Lee  
<sup>1</sup>Chinese Culture University, Department of Kinesiology  
email: [jessiepeng@sparqnet.net](mailto:jessiepeng@sparqnet.net)

### INTRODUCTION

It has been investigated the mechanomyographic (MMG) signal may respond linear [1] or non-linear [3] relationship with force development. Different relationship depends on contraction types, force levels, angular velocities and the muscles studied [1, 3]. Studies suggested that the MMG properties may also differentiate muscle fiber types [5]. The purpose of this study was to investigate the MMG and EMG (electromyographic) amplitude responses of vastus lateralis to different force levels during concentric and eccentric contractions in the sprinters.

### METHODS

**Subjects.** Six male sprinters ( $26.1 \pm 1.6$  yrs) were recruited for this study.

**Experimental procedures.** Subjects were in seated position with belt over the hip and chair of leg extension machine, then randomly performed 30%, 50%, 70% and 85% MVC leg extension each 5 tests with starting knee angle  $90^\circ$  and extending to  $180^\circ$  at the speed of 1.5s up and 1.5s down controlled by beat metronome (40bpm, 1beat up, 1 beat down). Each subject practiced the speed control 2 times on nonconsecutive days one week ahead.

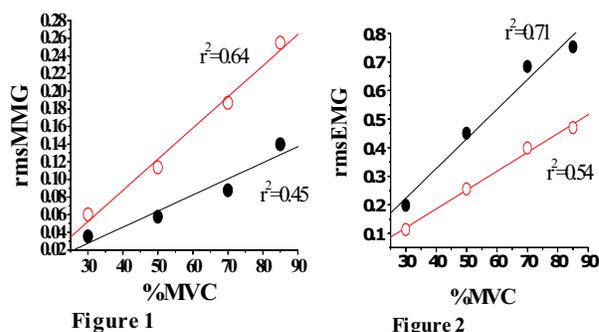

**Signal processing.** The MMG and EMG signals from vastus lateralis of nondominant leg were detected by biaxial accelerometer (acceleration range  $\pm 2g$ , Biovision), and surface electrodes (Biovision) respectively with both sample rate 1000Hz and bandpass filtering (2nd order Butterworth) 5-100Hz for MMG and 5-500Hz for EMG. The concentric and eccentric phases were separated by goniometer signal, and the middle 0.5s of each 1.5s recording was used to avoid initial burst [6]. The mean root mean square (time constant 100ms) of MMG (rmsMMG) and EMG (rmsEMG) for middle 3 of 5 tests were calculated.

**Statistical analysis.** The relationship between concentric and eccentric rmsMMG/rmsEMG with force and the difference between two phases of two signals were examined by linear regression model ( $y = a + bx$ , x: force, y: rmsMMG or rmsEMG) and two-way ANOVA respectively.

### RESULTS AND DISCUSSION

**MMG signal.** The rmsMMG showed positive linear relationship with increasing force level for both concentric ( $r^2 = 0.45$ , regression coefficient  $b=0.67$ ,  $P<.001$ ) and eccentric ( $r^2 = 0.64$ ,  $b=0.80$ ,  $P<.001$ ) contractions. The eccentric rmsMMG was greater than concentric rmsMMG for all levels of force ( $P<.05$ ).

**EMG signal.** The rmsEMG also showed linear relation with increasing force for concentric ( $r^2 = 0.71$ ,  $b=0.84$ ,  $P<.001$ ) and eccentric ( $r^2 = 0.54$ ,  $b=0.73$ ,  $P<.001$ ) contractions. Contrary to MMG, all levels of concentric rmsEMG were significantly greater than eccentric rmsEMG ( $P<.05$ ).

**Figure 1:** MMG-force relationship during concentric (●) and eccentric (○) contractions.

**Figure 2:** EMG-force relationship during concentric (●) and eccentric (○) contractions.

**Discussion.** The results of linear relationship of MMG/EMG amplitude and force during concentric and eccentric contractions conformed to previous study [1]. The lower EMG activity demonstrated decreased active motor units during eccentric phase [4]. The greater MMG activity during eccentric contraction of this study disagreed with the previous investigations of no difference [1] or lower activity [3] may result from faster speed of our experiment and fast-twitch fiber type subjects. Studies reported at higher velocities muscle sounds were from more superficially located fast-twitch fibers [2] and were less damped by surrounding tissues may result in greater MMG amplitude [7], and these may account for our study result.

### CONCLUSIONS

The MMG signal may detect the active motor units recruitment during isotonic concentric and eccentric contractions and also response the selectively activated fast-twitch fibers at faster velocity and with fast fiber type muscle during eccentric contraction.

## APPLICATION OF ARTIFICIAL NEURAL NETWORK TO PREDICT THE JOINT TORQUE OF LOWER LIMBS USING THE PARAMETERS OF GROUND REACTION FORCE DURING VERTICAL JUMP

<sup>1</sup> Yu Liu and <sup>2</sup>Shi-Ming Shih

<sup>1</sup>Chinese Culture University, Taipei, Taiwan; email: yliu@faculty.pccu.edu.tw;

<sup>2</sup>National College of Physical Education, Taoyuan, Taiwan

### INTRODUCTION

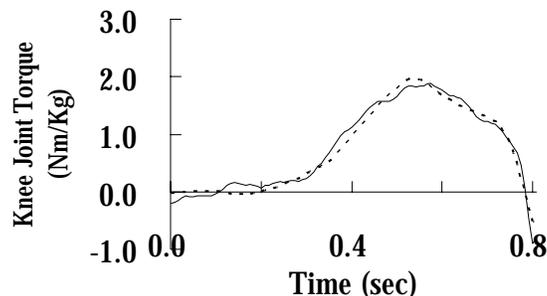

The measurement of ground reaction force (GRF) during vertical jump was often used to evaluate the athlete's muscular strength and power of lower limbs. However, the GRF could only specify the muscular power ability of lower limbs in whole and it couldn't reflect the muscle joint torque and neuromuscular control ability at each joint of lower limbs. To get the information of the joint torque, inverse dynamics calculation must be conducted by inputting the kinematic data and the data of GRF [1]. The purpose of this study was to develop an artificial neural network (ANN) model for predicting the joint torque at ankle, knee and hip by using the relevant parameters of GRF during vertical jump.

### METHODS

10 male sport students (age: 20.10 ± 0.91 yrs; height: 179.34 ± 4.25 cm; weight: 69.58 ± 3.91 kg) performed counter-movement-jump (CMJ) on a Kistler force platform (1200Hz). Meanwhile, the kinematic data of CMJ were recorded and digitized with a Peak Performance System at 120Hz. The GRF and kinematic data of support phase were than normalized as 100%. To calculate the joint torque at ankle, knee and hip, 2D inverse dynamics model was developed by inputting the GRF, kinematic data and Dempster's body segment parameters [1]. In this study we used a fully-connected, feed-forward network comprised of one input layer, one hidden layer and one output layer trained by back propagation using Gradient Steepest Descent Method [2]. The input parameters of this ANN model were time variables obtained by GRF measurement: time percentage, GRF, vertical displacement of center of mass (c.m.), speed of c.m. and power; the output parameters of the model were time data of joint torque at ankle, knee and hip. The data were scaled before input and rescaled after output. We used the software PCNeuron 4.1 to develop the ANN model and the root mean square (RMS) error of prediction to measure the network fitness..

### RESULTS AND DISCUSSION

One subject from the ten was chosen randomly as test sample for evaluating the network fitness. The data of rest nine subjects was used for modeling and training of the ANN. After trial-and-error optimization procedure, a "5-10-3 ANN model"

**Figure 1: The measured (solid line) and predicted (dotted line) joint torque at knee joint during CMJ.**

was found, in which there were 5 neurons in the input layer, 10 neurons (nodes) in the hidden layer and 3 neurons in the output layer.

The results of the test sample (Table 1) showed that, compare to the measured curves, the relative errors of the predicted peak joint torque at three joints were less than 4%. The RMS errors for all three joints were smaller than 0.04 revealing that the prediction errors of this model were well convergent. The predicted and the measured time curve of joint torque were also significantly correlated, the correlation coefficient were 0.967, 0.987 and 0.979 at ankle, knee and hip respectively. The figure 1 demonstrates that the predicted curve of joint torque at knee was fit well to the measured curve. Since the GRF could be simply measured in the sport science, the application of ANN using GRF is meaningful to study of joint torque without inverse dynamics during vertical jump.

### CONCLUSIONS

A back propagation ANN was developed by trial-and-error optimization technique to predict the lower limb's joint torque by using GRF during CMJ. We conclude that the ANN using GRF is feasible in the study of joint torque without kinematic measurement and inverse dynamics during vertical jump.

## SKI SKATING FORCE CHARACTERISTICS: COMPARISONS ACROSS SPEED

Gerald Smith, Bent Kvamme and Vidar Jakobsen  
Norwegian University for Sport and Physical Education; email: Gerald.Smith@nih.no

### INTRODUCTION

Two primary ski skating techniques, V1 and V2, have been typically thought of as uphill and flat terrain techniques, respectively. However it has become common for ski racers to push the V2 skate on steeper uphill. A recent physiological comparison of the techniques across a range of slopes found a cross-over point of relative effectiveness with similar costs on moderate uphill of about 4 to 5 degrees [1]. A 5° uphill slope was used for the measurements of the current experiment, allowing both techniques to be evaluated under similar physiological demands. Kinetic characteristics of ski skating have been measured in only a few situations [2], none involving V2 technique on uphill terrain and across a range of speeds. The objective of this experiment was therefore to determine how V1 and V2 kinetic characteristics change with skiing speed on moderate uphill terrain where racers commonly use both techniques.

### METHODS

Instrumented roller skis and poles were used to measure reaction forces during V1 and V2 skating on a large treadmill with a 5° uphill slope. A small electronic device was carried which telemetered the force data to a computer for synchronous recording along with 3-D position data. Markers on skis and poles were tracked using a Qualisys ProReflex system at 240 Hz. Using ski and pole positioning to orient the resultant reaction forces in the lab coordinate system, force components were calculated. From the force data, cycle characteristics, impulse, peak and average force (over a cycle) were determined.

Eight elite-level male skiers participated in two data collection sessions which were randomly assigned to a technique (V1 or V2 skating). After a warmup, ski speed was systematically increased from moderate to faster than race-pace relative to

each skier's capability. Three speeds within this range were analyzed. At each speed, 15 seconds of force and position data were recorded from which six cycles were analyzed. Mean values across the six cycles were used to represent a skier's characteristics at that speed.

### RESULTS AND DISCUSSION

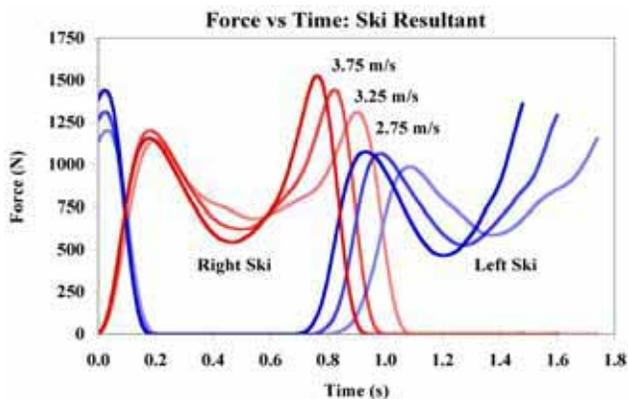

Cycle characteristics changed systematically for both skating techniques with both cycle length and frequency increasing with speed ( $P < 0.001$ ). Thus, control of skating speed on uphill terrain follows a different pattern than on the flat where frequency dominates [3]. Ski angle with respect to forward direction affects the proportion of reaction force which is propulsive. While ski angles were different for V1 and V2 techniques (about 19° vs. 15°) these changed little with speed. Peak forces (Figure 1) of both skis and poles increased with speed ( $P < 0.02$ ) while average forces over a cycle were nearly constant. Average propulsive force summed across skis and poles did not change with speed (Figure 2). The proportion of propulsive force from poling was about 50-55% for V1 and 70-75% for V2 skating with each decreasing slightly with increased speed ( $P < 0.03$ ).

### CONCLUSIONS

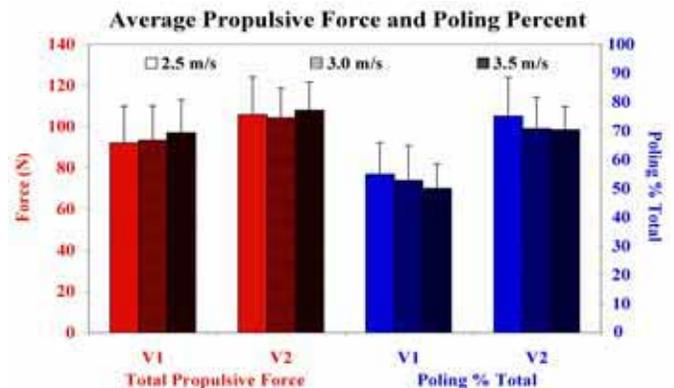

Treadmill ski skating forces change systematically in magnitude and timing as speed increases. However propulsive force component remains relatively constant with increasing speed as the resistive forces opposing motion (gravity and ski drag) do not change with speed.

### INTRODUCTION

Hemoperfusion is a therapy for the drug intoxicated patients using the activated charcoal column. Although studies on the charcoal adsorption in the industrial field are active, in medical applications, quantitative prescription is not available. More quantitative standard on the hemoperfusion prescription is required. In this study, hemodynamic analysis on the hemoperfusion was quantitatively performed with a mathematical model of the paraquat adsorption was represented.

### METHODS

#### HEMODYNAMIC MODEL

The paraquat adsorption in the charcoal column was simulated by solving the chemical reaction equation and mass balance equation simultaneously. The chemical reaction of adsorption was defined as the finite-rate reaction and stoichiometric coefficient and rate exponent were obtained from animal experiment. Langmuir model was used to fit the animal experiment data and calculate the parameters required to predict the adsorption kinetics

Blood flow rate of 120 mL/min was given as an inlet boundary condition and venous pressure of 10mmHg condition was set for the far enough from the column outlet. Darcy's law was used to model the porous media of the activated carbon and experimentally determined the porosity and flow resistance in the porous media.

To estimate the paraquat adsorption, the amount of paraquat absorbed and the time required for the adsorbent to take up half as much paraquat as it will at equilibrium. Mass flux distribution was also calculated by dividing the charcoal column into three parts from central region to peripheral region.

A commercial computer-aided design software package, GAMBIT 2.0 (Fluent, Inc.), was used to generate the two dimensional axisymmetric geometry and computational surface mesh of the charcoal column (Figure). A commercial CFD code, FLUENT6 (Flunet, Inc.) was used to discretize and solve the mass and momentum equations governing fluid flow through the porous media

#### ANIMAL EXPERIMENT

For Six dogs (Body Weight = 30 kg), 50 cc diluted paraquat solution was injected in intravenous injection. The paraquat level an hour after injection was 61.8 mg/L. Hemoperfusions were started one hour after injection for four hours and blood was sampled at 30, 60,120, 180, 240 min from arterial line. Blood flow rate was maintained at 120 mL/min and pumped with peristaltic roller pump (Gambro AK95). The Adsorption Charcoal Column used was ASRORBA 300C (Gambro). The paraquat concentration analysis of the blood samples were entrusted to Inha University Hospital.

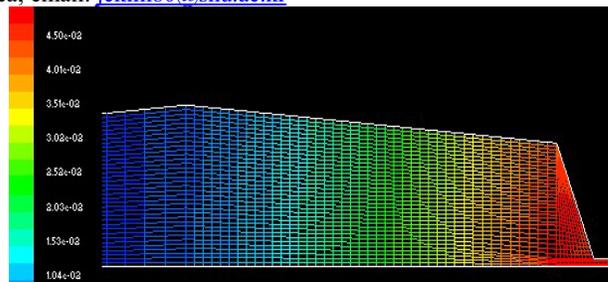

Figure: Paraquat concentration distribution in the charcoal column.

### RESULTS AND DISCUSSION

The peristaltic roller pump generated sine wave like mass flow with pressure drop about 15 – 20 mmHg. The charcoal column surface mesh was dissected in radial direction into three parts to assess the flow distribution. As shown in Figure, the concentration of the toxin is higher in the central region than that of peripheral region. This phenomenon is due to the mass flux inequality per unit volume. The mass flux ratio calculated per unit charcoal volume in each dissected part was 1: 1.7: 5.3 implying that 65% more influx was passed through the central region of the column and might lead to decrease in adsorption efficiency. At the interface of the porous media and blood inlet, secondary flow was observed, which possibly results in the risk of thrombosis formation in clinical application and this is an important factor in the life of charcoal column. The amount of paraquat absorbed during the hemoperfusion was 2.976g and the time required for the adsorbent to take up half as much paraquat as it will at equilibrium was 16.5 min implying the strong electrostatic interaction between negatively charged surface and paraquat cation.

### CONCLUSIONS

This simulation may be helpful to determine the quantitative prescription of hemoperfusion dose for the drug intoxicated patients. And more optimized flow pattern and geometry of the charcoal column are required to maximize the paraquat adsorption efficiency in the activated carbon.

### INTRODUCTION

The anterior cruciate ligament (ACL) is one of the most commonly injured ligaments in the knee. Its injury would lead to the degradation of stability and/or mobility of the joint. To regain stability and restore function after ACL injury, surgical reconstruction is frequently considered and a proper rehabilitation program is crucial for the recovery of the function. The accelerated rehabilitation program, which emphasizes early full knee extension and weight bearing as well as closed kinetic chain (CKC) exercises, has been proven to have good results after a long-term follow-up [1]. Being one of the most frequently used CKC exercises and a frequent activity of daily living, studies on the three-dimensional dynamics of stair locomotion in ACL-injured patients were limited. Previous studies of stair activities in ACL patients focused on the mechanical changes at the knee joint [2,3]. However, stair locomotion is achieved through a complicated mechanical interaction among the lower limb joints in three dimensions. The present study aimed to provide a more complete account of the possible biomechanical changes among the lower limb joints.

### METHODS

Ten ACLR subjects (28.3±8.5 years) and ten normal controls (21.4±1.7 years) were recruited in this study. Each subject performed stair ascent and descent on a three-step stair in a gait laboratory. A seven-camera motion analysis system (VICON 370, Oxford Metrics, U.K.) was used to measure the movement trajectories of each segment of the lower extremity. The ground reaction forces (GRF) were measured with a force platform (AMTI, Mass., U.S.A.), which served as the second step of the three-step stairs. Peak joint angles, peak joint moments and angular impulses of the lower limb joints in three dimensions during the stance phase of the stair activities were calculated and compared between groups using t-test and between affected and unaffected limbs using paired t-test. A significance level of 0.05 was used.

### RESULTS AND DISCUSSION

Compared to the normal knees, significantly smaller peak moments and angular impulses of the extensors and internal rotators at the affected knees were found during both stair activities while larger peak moments and angular impulses of the adductors and peak abduction angles were needed at the unaffected knees. Larger hip extensor impulses and smaller hip external rotation angles and smaller peak ankle plantarflexor moments at the affected limb during stair ascent were found (Figure 1). During stair descent, larger hip internal rotation angles, and smaller peak hip abductor moments and ankle plantarflexor moments in the affected limb

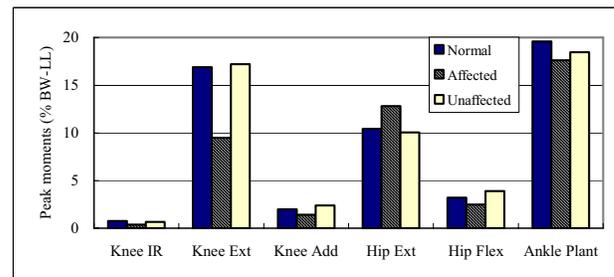

Figure 1: Peak joint moments during stair ascent.

were found while larger hip flexor impulses in the unaffected limb were required.

These results suggest that the ACLR knees had significant reduction in the mechanical loadings in the sagittal and transverse planes during both stair activities, possibly due to the need to protect the ACL graft as well as the deficit of the quadriceps strength, which may persist even at 24 months after reconstruction [4]. The compensations to these changes occurred mainly in the coronal components of the unaffected knees and at the hip joints, with different strategies for stair ascent and descent. The increased hip extensor impulses were used to compensate the reduced knee extensor impulses in the affected limb during stair ascent. During stair descent, the increased hip flexor impulses in the unaffected limb helped controlling the movements of the trunk.

### CONCLUSIONS

Significant mechanical changes in the sagittal and transverse components at the ACLR knees were found during both stair activities and the compensations occurred mainly in the coronal components of the unaffected knees and also at both hip joints with different strategies for stair ascent and descent.

### INTRODUCTION

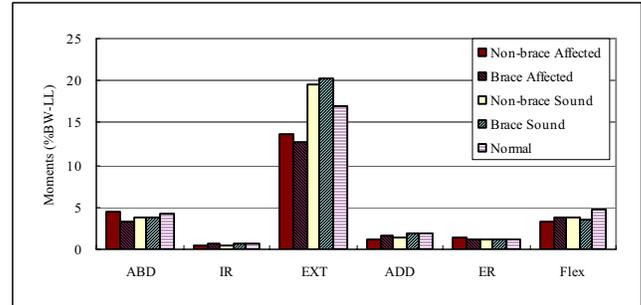

Anterior cruciate ligament (ACL) provides passive stability of the knee and involves in the guidance of the joint motion. Injury of the ACL would lead to the degradation of stability and/or mobility of the joint. Functional knee braces have been suggested to provide necessary stability for ACL injured individuals and to be a factor causing the change of the kinetics of the lower limb during gait [1]. But, knee braces only resulted in minor kinematic changes in the ACL deficient (ACLD) knees during single leg hops [2]. The efficacy of knee braces may be different for different activities. The efficacy of braces on ACLD subjects during stair locomotion, one of the most common daily activities, has not been reported. The purpose of this study was to examine the immediate effects of functional knee bracing on the mechanics of the lower limb joints in ACLD individuals during stair locomotion.

### METHODS

Ten ACLD subjects (26.1±7.3 years) were asked to perform stair ascent and descent in a gait laboratory first without and then with knee braces (DonJoy Goldpoint, Smith & Nephew DonJoy Inc.). The kinematic data were measured with a seven-camera motion analysis system (VICON 370, Oxford Metrics, U.K.) and the kinetic data with a force platform (AMTI, Mass., U.S.A.) that served as the second step of a three-step stairs. Joint angles, moments and angular impulses were calculated during the stance phase of the stair activities from the measured kinematic and kinetic data with a 3-D lower limb model. Peak joint angles, joint moments and angular impulses at the hip, knee and ankle joints in three dimensions were calculated and compared between bracing conditions and between affected and unaffected knees using paired *t*-test. Data from ten normal controls without bracing were also obtained.

### RESULTS AND DISCUSSION

The affected knees adopted quite similar movement patterns to the normal ones (Figure 1) while significant alterations at the affected hip and in the unaffected limb were noticed during stair activities. Bracing did not affect the biomechanics of the

**Figure 1:** Peak joint moments at the knee during stair ascent.

lower limb during stair locomotion except for minor changes in the flexion angle and flexor impulse at the affected hip and in the internal rotation angle and external rotator moment at the unaffected knee during stair ascent, Table 1. The adaptations of the locomotor system to ACL deficiency were evident although there had no significant mechanical changes at the affected knees. The bracing did not result in any significant alteration of the mechanics of the affected knees. These results suggest that the mechanical condition at the ACLD knees remained relatively unchanged mainly because of the adaptations at the other joints instead of knee bracing.

### CONCLUSIONS

The influence of knee bracing on the lower limb mechanics was not significant in ACLD subjects during stair locomotion. Bracing may not be used as a device to improve the performance of stair locomotion in these subjects.

## DETERMINING SUBJECT SPECIFIC TORQUE-VELOCITY RELATIONSHIPS WITH THE INCLUSION OF HIGH VELOCITY TORQUE DATA

Matthew Pain, Chris Mills and David Jessop  
 School of Sport and Exercise Sciences,  
 Loughborough University, LE113T, UK email: [M.T.G.Pain@lboro.ac.uk](mailto:M.T.G.Pain@lboro.ac.uk)

### INTRODUCTION

Modelling of the muscle force-velocity relationship normally utilizes a Hill type function in the concentric phase and a rapid increase to a plateau region in the eccentric phase. Muscle experiments in humans show depression in eccentric and low velocity concentric torque production [1], they have also been limited to joint angular velocities of less than  $\pm 400$  °s<sup>-1</sup>. The introduction of a ‘differential activation’ function [2] explains a possible mechanism for the force suppression observations. However without high concentric velocity torque data the bounds chosen for maximal velocity of contraction can have an important influence on the final fit of the curve to the experimental data.

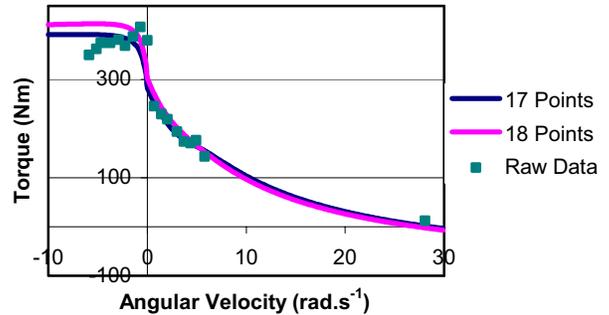

The aim of this paper is to examine the variation of a Hill type 4 parameter function, and a 7 parameter function, including differential activation, when maximal velocity torque data are included.

### METHODS

Measurements were taken on an elite martial artist, height 1.78 m, weight 90 kg, the protocols were approved by Loughborough University Ethical Advisory Committee.

Isovelocity torque data in concentric-eccentric cycles were collected in 50 °s<sup>-1</sup> intervals up to a crank angular velocity of 450 °s<sup>-1</sup> for flexion and extension of the knee and hip. Corrections for weight and differences between crank and joint angle were calculated. Peak isovelocity torques were determined for 17 angular velocities. High speed video (500 Hz) was used along with subject specific anthropometrics to determine joint torques during unloaded maximal flexion and extension of single joints. Joint torque near maximal velocity was used to provide an 18<sup>th</sup> torque-velocity value.

The Direct Optimization routine [3] was used to calculate the 4 and 7 parameter values that gave the best fit to the 17 data points. The upper bound for maximal angular velocity was set sufficiently high that it was not reached. The error between the 18<sup>th</sup> data point and that predicted by the two functions was calculated. The parameters were then re-optimized including 18 data points and its effect examined.

**Figure 1:** Torque profiles for knee extension using a 7 parameter function

### RESULTS AND DISCUSSION

As expected the 7 parameter function produced better fits to the dynamometer data than the 4 parameter function. The average RMS error for the 7 parameter fits was 24 % and for the 4 parameter fits 45 %. The 7 parameter function using 17 data points was better at predicting torque at higher angular velocities, 13 % error, than the 4 parameter function, 38 % error (Table 1). Optimizing for the 18 point dataset improved the 4 parameter error at high velocity to 8.9 % and the 7 parameter to 6.5 %. The 7 parameter function appears more robust at extrapolating to higher velocities when only dynamometer data are available.

### CONCLUSIONS

The 7 parameter function gives a better fit to the data than the 4 parameter function. It also extrapolates more accurately to predict high velocity data. The 7 parameter function is less sensitive to the maximum voluntary contraction bounds. The use of a 7 parameter function with dynamometer data should be used rather than a 4 parameter function even if eccentric data are not required.

## MODELING THE GYMNAST-MAT INTERACTION DURING VAULT LANDINGS

Chris Mills, Matthew Pain and Fred Yeadon  
 School of Sport and Exercise Sciences,  
 Loughborough University, LE113T, UK. email: [M.T.G.Pain@lboro.ac.uk](mailto:M.T.G.Pain@lboro.ac.uk)

### INTRODUCTION

Landings are an essential element in gymnastics and are a time when injuries may occur. Most injuries to gymnasts affect the lower extremity [1]. The landing surface and the landing control strategy adopted by the gymnast contribute to the dissipation of forces at landing.

The aim was to design a model of the landing surface and gymnast's body in order to obtain reasonable estimates of the landing forces experienced by the gymnast. Modeling the gymnast-mat interaction may help to reduce the forces experienced by the gymnast at landing and improve performance.

### METHODS

A subject-specific 6 link wobbling mass model of a gymnast was developed using Visual Nastran4D. Torque-angle-angular velocity functions for the model's joint torque generators were derived from isokinetic dynamometer measurements of the gymnast. A landing mat model based on independent mat testing [2] was also developed in Visual Nastran 4D. These two model were used to simulate the gymnast landing.

Landings from four vaults were recorded: a backward somersault, a forward somersault, a handspring vault and a tsukahara vault. Sixteen Vicon cameras (250Hz), a Phantom (v5) high-speed camera (1000Hz), a Kistler force plate (1000Hz) and a Biovision surface EMG system (250Hz) were used to collect data.

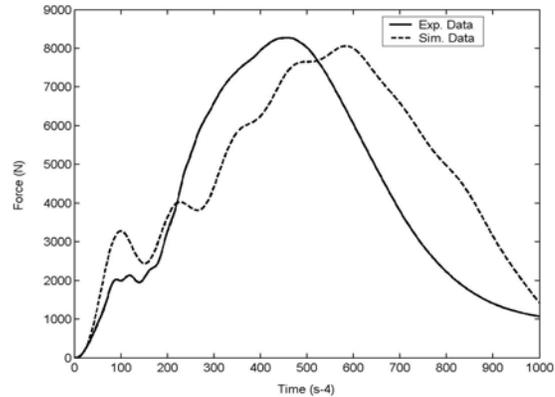

Simulation inputs for model evaluation were the body orientation, centre of mass velocity, joint angles and angular velocities of the gymnast during landing. Torque activation histories were optimized using a Simplex algorithm to minimize the difference between simulated and experimental ground reaction forces, joint angle and body orientation time histories.

### RESULTS AND DISCUSSION

The landing mat model matched the experimental material tests to within 1.4 % of the peak force and had an RMS difference of 1014.2 N. The majority of the RMS error arose from the latter half of the simulation. In the experiment the mat could lift from the force plate during the rebound phase

**Table 1:** Evaluation of the mat-gymnast model against the actual performance.

Gymnastic Skill	RMS (all joints)	RMS (body orientation)	RMS (Vert GRF)	RMS (Hor GRF)	Peak (VGRF)
Front Somersault	8 %	4 %	21 %	15 %	3 %
Back Somersault	15 %	1 %	15 %	36 %	23 %
Handspring	11 %	1 %	25 %	31 %	33 %
Tsukahara	35 %	8 %	20 %	21 %	2 %

**Figure 1:** A comparison of the vertical ground reaction forces for the gymnast-mat model and equivalent experimental data during the landing of a front somersault.

which could not occur in the simulation. The simulation of the gymnast only included a small part of the rebound phase.

The model of the gymnast and mat matched the actual performances with overall scores between 12 % and 21 %. The best match was obtained for the forward somersault skill (Table 1). This produced a difference between simulated and actual vertical peak force of 3 % with an RMS of 21 % (Figure 1). The computational run time limited the number of simulations and the complexity of the optimization routine. Manual variations in activation time histories produced better ground reaction force fits but slightly worse scores overall.

### CONCLUSIONS

The gymnast-mat model was able to reproduce the key elements of the landing dynamics. Optimization of the mat parameters and / or the torque activation patterns may provide an insight into equipment modifications or landing strategy changes that may reduce injuries in gymnastics.

## HIP AND KNEE JOINT MOMENT ANALYSIS DURING OBSTACLE CROSSING IN PATIENTS WITH UNILATERAL TOTAL KNEE REPLACEMENT

<sup>1</sup>Chen-Yu Lo, <sup>2</sup>Saiwei Yang and <sup>3</sup>Horn-Chaung Hsu

<sup>1</sup>School of Physical Therapy, China Medical University, Taichung, TAIWAN.

### INTRODUCTION

Total knee replacement (TKR) may be the best choice for improvement of the quality of life as the severity of knee osteoarthritis is progressing. Many clinical studies have examined the differences in kinematics during locomotion, such as level walking and stair climbing, and their results have been controversial [1,2]. Stepping over obstacles is a non-stereotyped, functional task which the elderly may encounter on their activities of daily living. For performing the task safely, the person will need good postural control, providing by good lower limb strength and coordination, and proper joint proprioception. Reduced proprioceptive sensory feedback, muscle strength or balance may disturb balance control. Such a mechanism may allow acceleration of degenerative joint conditions, and may account for the increased prevalence of falls seen in elderly subjects. According to Saari et al [1], hip extension tended to decrease, and decreased hip extension moment was noted in TKR patients during stair climbing. The purpose of this study was to investigate the kinetics of lower limb in patients with unilateral TKR during obstacle crossing, the more physical demanded daily activity and the relationship between moment and muscle strength.

### METHODS

Ten subjects with average age of 68 years old receiving primary unilateral TKR participated in this study. The posterior cruciate ligament was retained in knees with 5° or less varus/valgus alignment. Motion analysis was done between half and one year after surgery. Eleven healthy, age-matched elderly were recruited to the control group. Each subject was instructed to walk on level and to cross obstacle. Seven digital cameras (Vicon, Oxford Metrics, U.K.) synchronized with 2 force plates (AMTI, U.S.A.) were connected to the motion system to provide 3D kinetic and kinematic data during obstacle crossing. The height of obstacle was 20 cm, chosen for the relevance to daily activities, equal to the height of non-standard curb or doorstep. The average peak values of hip and knee joint moments during stance phase were measured. Moments were normalized by dividing body mass and leg length to reduce intersubject variability. Isokinetic concentric strength of hip flexor and extensor and isometric strength of knee flexor and extensor were collected at the same session.

Nonparametric tests were used as the distribution material was skewed. For kinetic data, Kruskal-Wallis one-way analysis of variance by ranks was used for group difference (operated side, non-operated side and control group). Spearman correlation coefficients were introduced to evaluate association between joint moment and isokinetic concentric muscle strength. Statistical differences were defined as significant at the  $\alpha = 0.05$  level.

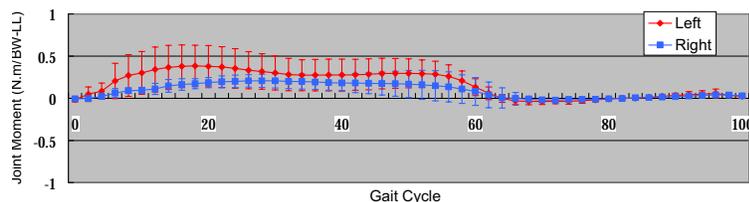

Figure 1: The knee adduction moment of right TKR (subject 8)

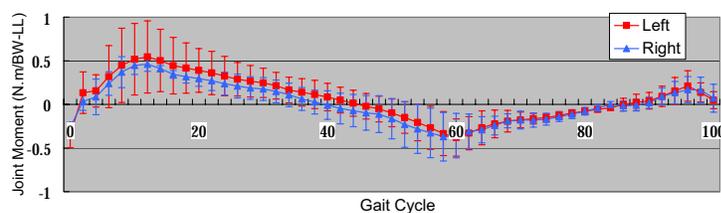

Figure 2: The hip adduction moment of right TKR (subject 8)

### RESULTS AND DISCUSSION

The first peak adduction moment of knee joint at the non-operated leg was higher than the contralateral side of the TKR group (Fig. 1). The difference between the non-operated leg and control group was not significant. The peak hip extension moment of non-operated extremities was higher than the operated side (Fig. 2). The hip joint moment was correlated with isokinetic hip extensor strength significantly.

Decreased hip extension moment may reflect a need to stabilize the lower leg in the beginning of stance. Higher knee adduction moment has been suggested as an indicator of static varus knee alignment [2]. Obstacle crossing could be sensitive to frontal plane movement of hip joint.

### CONCLUSIONS

Objective gait analysis assists for evaluation of the functional recovery and musculoskeletal deficiency after TKR. Hip adduction moment of the limb may be an indicator of medial knee compartment loading. Decreased hip extensor may influence the stability of knee joint. For patients with TKR, rehabilitation after surgery should focus not only on the gain of range of motion but also on of the strength training of knee joint as well as hip joint.

## ANTICIPATION MECHANISM AND INFLUENCE OF FATIGUE IN MEDIOLATERAL STABILOGRAM

<sup>1</sup>Roger G. T. de Mello, <sup>2</sup>Liliam F. de Oliveira and <sup>1</sup>Jurandir Nadal

<sup>1</sup>UFRJ/Biomedical Engineering Program, COPPE, Rio de Janeiro, Brazil,

<sup>2</sup>UFRJ/Biomechanics Laboratory, EEFD, Rio de Janeiro, Brazil; email: roger@peb.ufrj.br

### INTRODUCTION

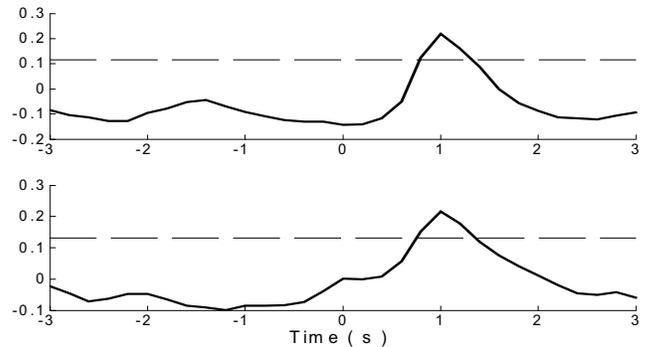

An important feature of the Central Nervous System (CNS) is its capability to foresee future movements of the body [1]. This control does not act by feedback and is named anticipation. Several investigators have focused anticipation by studying the synergism between anti-gravitational muscles and the ones responsible for limbs movements [2]. Others report that anticipation can be affected by fatigue [3]. This study aims to detect the anticipation mechanism and the latency between the gastrocnemius muscle myoelectric signal and the mediolateral (x) stabilogram during static posture and test the fatigue influence.

### METHODS

The instrumentation consisted of a vertical force platform and an electromyographic system, synchronized to register the stabilometric and myoelectric signals (EMG), with sampling frequencies of 50 and 1 kHz, respectively. Superficial silver/silver chloride electrodes (Ag/AgCl) were fixed on the lateral head of the gastrocnemius muscle. A group of 23 individuals (15 males and 8 females) were tested after free consent. The age was  $23.2 \pm 3.6$  years (mean  $\pm$  standard deviation), body mass  $70.6 \pm 10.9$  kg and height  $169.9 \pm 7.0$  cm. The individual stood on the force platform, with the feet together and the arms relaxed, for 120 s. Then he was asked to perform a maximum plantar flexion and maintain this position as much as he can support until muscle failure. During this time the right hand was gently placed on a stem on the platform side to avoid body unbalance. After muscle failure, the individual returned to the initial position for more 120 s data acquisition. The EMG RMS (RMS-EMG) values were calculated after mean removal at windows of 200 ms and stabilometric signals were subsampled to 5 Hz. The normalized cross correlation function (NCCF) was estimated for both pre- and post-fatigue data sets. The maximum correlation value and the corresponding lag were extracted from the NCCF of each individual. This lag was considered as estimation of the latency between signals. To test the presence of latencies as well as the differences between pre- and post-fatigue conditions, Students' t-test was applied ( $\alpha = 0.05$ ). Monte-Carlo simulation was applied to determine the critical value of the cross correlation function ( $\alpha = 0.01$ ).

### RESULTS AND DISCUSSION

The mean latency of the body displacement was significantly different from zero, either before ( $p < 0.001$ ) and after fatigue ( $p < 0.0015$ ). The fatigue caused an increase to the ensemble mean latency between RMS-EMG and mediolateral stabilogram, equal to  $0.82 \pm 0.91$  s before and  $0.90 \pm 1.17$  s after fatigue, however this increase was not significant

**Figure 1:** NCCF between RMS-EMG and x stabilogram (subject FA12), before (upper) and after (lower) fatigue (-- critical value by Monte Carlo simulation,  $\alpha = 0.01$ ).

( $p = 0.80$ ) (Figure 1). Only three individuals presented no significant correlation between RMS-EMG and the body sways. The mean maximum correlation decreased significantly later the fatigue of the  $0.39 \pm 0.23$  for  $0.28 \pm 0.16$  ( $p < 0.05$ ), decreasing ankle strategy for mediolateral control.

The cross correlation function permits the anticipation mechanism to become evident, in accordance to prior study [4]. These authors found a delay of the CP oscillations in relation to the rectified EMG signal, at magnitudes between 240 and 270 ms. This values differ from the ones in the present study, that are between 400 and 1.400 ms, agreeing with prior result for anterior-posterior stabilogram [3].

The results strengthen the hypothesis that an anticipatory control mechanism plays an important role on the body oscillation regulation. The plantar flexors fatigue decreases the ankle strategy control of the mediolateral sway and do not causes an increase to the time delay between the EMG signals of these muscles and the effective mediolateral sway of the center of pressure.

## MIGRATION OF MEDIAL-PIVOT AND POSTERIOR STABILIZED IMPLANTS

<sup>1</sup> Elise Laende, <sup>1</sup>Kevin Deluzio, <sup>2</sup>Allan Hennigar, <sup>2</sup>Chad Munro, <sup>2</sup>Stephen Arany, <sup>2</sup>Michael Dunbar

### INTRODUCTION

The fixation of the tibial component of a total knee replacement is critical to long-term function of the joint and is indicative of the success of the implant design and surgical technique. The pattern of implant migration, as measured by radiostereometric analysis (RSA), in the first two post-operative years has been shown to be predictive of the long-term fixation of the implant [1]. The purpose of this study was to compare the migration of the new ADVANCE® Medial-Pivot knee to the existing ADVANCE® Posterior Stabilized implant (Wright Medical Technology, Inc., Arlington, TN). There is evidence that in normal knees the lateral condyle pivots about the medial condyle in flexion and extension; the Medial-Pivot implant is designed to replicate this function [2].

### METHODS

Radiostereometric analysis (RSA) is an accurate radiographic technique for measuring relative motion between an implant and bone [3]. Tantalum beads inserted in the tibia and implant polyethylene component during surgery are highly visible in bi-planar x-rays taken during follow-up exams. Using a calibration box, the 3D co-ordinates of the beads define the positions and orientations of the implant and bone. Comparing the relative positions of the implant and bone in successive exams identifies movement of the implant with respect to the bone. The migration of the implant can be represented as the maximum total point motion (MTPM) of the prosthetic bead that moved the most, indicating the magnitude of migration without direction [1]. Commercial software (RSA-CMS, MEDIS, Leiden, The Netherlands) was used to determine the bead 3D co-ordinates from the stereo x-rays.

Sixty-six patients (48 female) with osteoarthritis were randomized to receive either a Medial-Pivot (MP) or Posterior Stabilized (PS) implant. Surgeries were performed by three surgeons following a standard protocol of PCL resection, patellar resurfacing, and RSA bead placement. Stereo x-rays were taken within 4 days post-operatively and at 6 and 12 months. General health and disease-specific health questionnaires, including WOMAC and KSS, were administered to all patients pre-operatively and at 6, and 12 months post-operatively.

### RESULTS AND DISCUSSION

The subject characteristics and did not significantly differ between groups (Table 1).

**Table 1.** Subject characteristics. Mean ± SD.

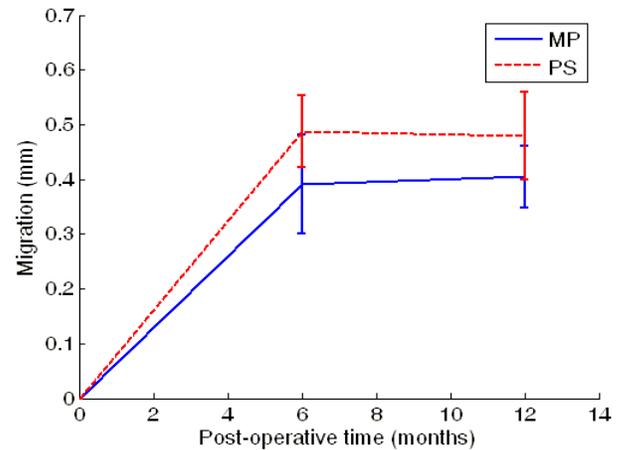

Subject Characteristic	MP (n=32)	PS (n=24)	p value
Age (years)	65.4 ± 7.4	65.9 ± 8.2	0.813
Weight (kg)	88.7 ± 17.4	86.4 ± 15.8	0.622
Height (cm)	163.8 ± 10.1	165.3 ± 7.3	0.535
BMI	33.0 ± 5.9	31.9 ± 5.5	0.453

The results of the health outcome questionnaires differed significantly between groups only for the KSS knee scores (Table 2).

**Table 2.** Health outcome questionnaire results. All scores out of 100, 100 being ideal. Mean ± SD.

Questionnaire	MP (n=28)	PS (n=22)	between group p-value
<b>Womac</b>			
pre-op	43.9 ± 20.4	41.7 ± 13.1	0.105
6 months post-op	76.4 ± 15.9	91.3 ± 6.0	
12 months post-op	78.7 ± 18.1	87.4 ± 9.4	
<b>KSS Knee Score</b>			
pre-op	38.7 ± 21.1	50.9 ± 21.7	0.005
6 months post-op	68.0 ± 25.4	71.9 ± 18.8	
12 months post-op	64.5 ± 21.8	72.4 ± 21.8	
<b>KSS Function Score</b>			
pre-op	43.8 ± 25.0	50.7 ± 15.0	0.293
6 months post-op	65.5 ± 14.8	74.3 ± 14.7	
12 months post-op	69.4 ± 24.2	71.0 ± 22.7	

The migration of the MP and PS groups were not different at the time points measured (Figure 1). The consistent level of migration at 6 and 12 months indicates favourable tibial component fixation and long-term success.

**Figure 1.** Maximum Total Point Motion (MTPM) of MP and PS implants at 6 and 12 months post-op for analyzed RSA cases to date (nMP=8, nPS=14). Mean and standard error of the mean shown. Between group p-value = 0.482.

### CONCLUSIONS

The similar migration pattern for the Medial Pivot implant to the accepted functional Posterior Stabilized implant supports the use of this implant in total knee arthroplasties. Long-term monitoring will continue to confirm the results to date.

### 3D UPPER BODY ACCELERATION MAGNITUDE FOR SELF-SELECTED AND FAST WALKING SPEEDS IN YOUNG AND OLDER ABLE-BODIED ADULTS

Vassilios G. Vardaxis, PhD

Division of Physical Therapy, Human Performance Laboratory, Des Moines University  
 Des Moines, Iowa; email: [vassilios.vardaxis@dmu.edu](mailto:vassilios.vardaxis@dmu.edu)

#### INTRODUCTION

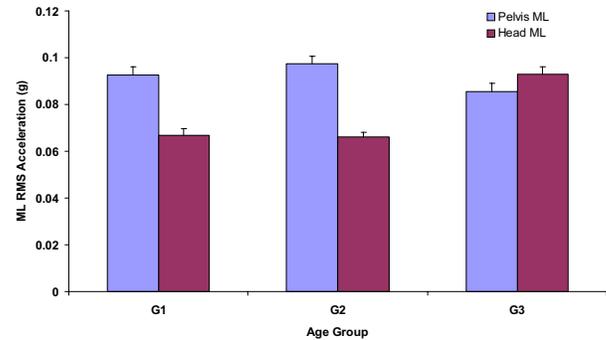

Changes in the aging neuromuscular system contribute to the decline of the functional capacity of the elderly with serious implications with respect to increased frequency of falls [1]. Quantification of the trunk/head kinematics (passenger of the locomotion system) during gait for different age groups, under various conditions may help identify potential degenerations in the control of the head [2]. A significant body of research exists examining trunk motion during gait, however, most of it includes a small number of subjects and a limited number of it includes head kinematics in 3D [2,3]. The purpose of this study was to assess whether any age or speed-related differences exist in the acceleration magnitude of the head and pelvis during self-selected normal and fast walking speeds.

#### METHODS

A total of 162 healthy adults/elderly participated in the present study. These subjects were classified in three age groups (G1, N=54, 24.4±5.8 yr; G2, N=60, 49.7±5.4 yr; G3, N=48, 70.4±5.7 yr). Subjects were asked to walk with a steady velocity of progression across a 10 m walkway at self-selected normal and fast walking speed, while 5 gait trials were collected at each speed using a 6-camera VICON system. A full-body marker set was used (31 markers) for gait analysis. The 3D location of the center of the pelvis and center of the head were determined. Velocity of progression, cadence, and stride length were determined. The instantaneous acceleration patterns for the pelvis and head in 3D (laboratory coordinate system) were derived using finite differences. The magnitude of the 3D accelerations: antero-posterior (AP), medio-lateral (ML), and vertical (VER) for pelvis and head were calculated using the root mean square (RMS) of the waveform patterns over the gait cycle. Univariate two-way repeated measures ANOVA was used to test for differences between age-groups (between effect) and between walking speeds (within effect).

#### RESULTS AND DISCUSSION

The older group walked with slower velocity of progression than the 2 younger groups for both speed conditions (Table 1). The average increase in velocity between speed conditions was 18.3% (normal, 1.32 m/s; fast, 1.56 m/s). There were no group differences in percent velocity of progression increase.

**Figure 1:** Mean (±SE) of pelvis and head acceleration magnitude (RMS) in the ML direction for all three groups.

The acceleration magnitude in all directions increased with speed, as expected. Between groups differences in acceleration magnitude were found for the pelvis in the AP direction ( $p < .001$ ) and for the head in the ML direction ( $p < .001$ ). There were no group differences in the VER direction. The elderly group walked slower than the younger groups and for both speed conditions exhibited greater head acceleration magnitude in the ML direction. Interestingly, the magnitude of the ML acceleration for the head in the older group was significantly higher than the ML acceleration magnitude of their pelvis ( $p < .05$ ) for both speed conditions (Figure 1). This data suggests that, while accelerometric 3D analysis is a promising tool in accessing dynamic balance for older adults, the dual reference point (pelvis, head) techniques can provide further insights in the control of the head motion for vestibular and visual field stability.

#### CONCLUSIONS

The musculoskeletal structures of the trunk in the elderly are unable to filter locomotion perturbations in the ML direction. The younger subjects use their trunk effectively to adjust the disturbances introduced by the locomotion to the pelvis.

## MUSCULOSKELETAL MODELING OF AN EMG-BASED NEUROPROSTHESIS FOR ARM FUNCTION

Robert F Kirsch (robert.kirsch@case.edu), Juan Gabriel Hincapié, Dimitra Blana, and Edward Chadwick  
 Department of Biomedical Engineering, Case Western Reserve University (<http://bme.case.edu/>)  
 Cleveland VA Functional Electrical Stimulation Center (<http://feswww.fes.case.edu/>)

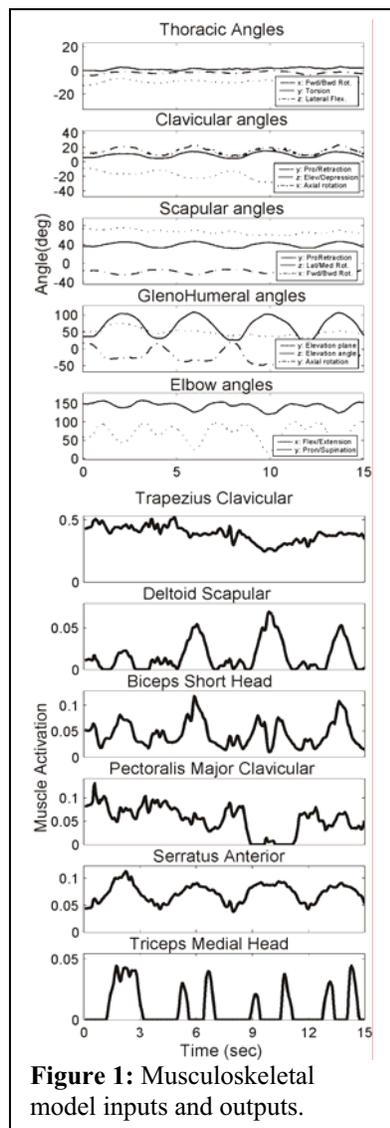

### INTRODUCTION

Individuals with C5/C6 Spinal Cord Injury (SCI) lose control over a number of upper extremity muscles. Specifically the hand muscles are paralyzed, there is partial loss of wrist and elbow extension, and several shoulder functions are lost, including horizontal flexion and adduction. Functional Electrical Stimulation (FES) can be used to stimulate paralyzed muscles to restore function to these individuals. The goal of this project is to determine an appropriate set of muscles to stimulate and the pattern of muscle stimulation that, when combined with retained voluntary function, would provide improved arm function. The proposed approach will eventually extract movement intention from the EMG activity of muscles that are under voluntary control and uses this information to specify the stimulation levels of needed for the paralyzed muscles.

### METHODS

Experiments were performed to measure the kinematics of a set of arm movements that reflect a wide range of daily activities. These kinematics were used as the input to a musculoskeletal model [1] in the performance of inverse dynamic simulations. These simulations generated a set of muscle activations that would produce each of the movements while minimizing the sum of squared muscle stresses. Figure 1 shows a set of arm kinematics [2] in the upper panels and the activations of several key muscles predicted by the inverse simulations (lower panels).

We then trained a time-delayed artificial neural network (TDANN) that took several of the muscle activation patterns as inputs and another set of muscle activation patterns as outputs. Specifically, we used

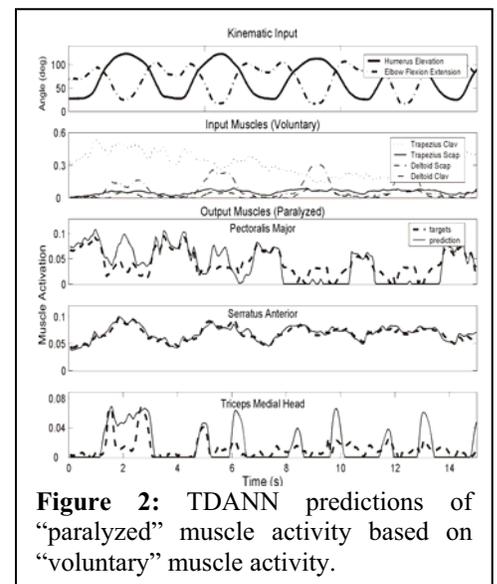

**Figure 1:** Musculoskeletal model inputs and outputs.

muscles that would be expected to have voluntary function (clavicular trapezius, scapular trapezius, clavicular deltoid, and scapular deltoid) in individuals with C5/C6 SCI as the inputs and muscles that would be expected to be paralyzed (pectoralis major, serratus anterior, medial triceps) as outputs. This TDANN was designed to predict *needed stimulation* of paralyzed muscles based on the *natural activity* of muscles with voluntary control.

### RESULTS AND DISCUSSION

Figure 2 shows an example of the ability of the TDANN to predict appropriate muscle activity. The upper panel shows the relevant arm kinematics. The next lower panel shows the “voluntary” activity of 4 muscles used as TDANN inputs. The lower 3 panels show the desired muscle activations (dotted lines) and those predicted by the TDANN (solid lines). Overall, the TDANN predictions were quite good across a wide range of different movements.

**Figure 2:** TDANN predictions of “paralyzed” muscle activity based on “voluntary” muscle activity.

### CONCLUSIONS

The TDANN approach to predicting needed muscle activation for “paralyzed” muscles from the activation of several “voluntary “ muscles has been shown to be accurate for dynamic movement conditions. This result indicates that an arm neuroprosthesis with EMG-based FES of key elbow and shoulder muscles should be feasible.

## CONTROL OF STABILITY DURING SLOPE LATERAL WALKING

<sup>1</sup>Chien-Ju Lin, <sup>1,2</sup>Lin-Hwa Wang, <sup>3</sup>Yi-Wen Chang and <sup>1</sup>Fong-Chin Su

<sup>1</sup>Institute of Biomedical Engineering and <sup>2</sup>Department of Physical Education, National Cheng Kung University, Tainan, Taiwan, <sup>3</sup>Department of Exercise and Health Science, National Taiwan College of Physical Education, Taichung, Taiwan; email: [fcsu@mail.ncku.edu.tw](mailto:fcsu@mail.ncku.edu.tw)

### INTRODUCTION

Nowadays, the workers' occupational safety is highly emphasized for all the developing countries. Tubular steel scaffolding, which is regulated not to be narrower than 30 centimeters is commonly used in Taiwan as construction false work and finishing structure of high headroom buildings. In this condition, the workers need to walk laterally on a narrow slope while lateral walking is not a usual gait pattern in our daily life. Center of pressure (COP) is the point where the ground reaction force is collectively exerted at the surface [1], and it has been widely used to analyze the control of stability [2,3]. Very little research concerns gait pattern in lateral walking and slope walking. Kawamura, et al. determined step length, width, time factors and deviation in the COP during upslope and down slope walking, and found that walking speed, deviation in COP and the ratio of stance phase to stance phase were different between level and slope walking [2]. Leroux, et al. investigated postural adaptation to walking on inclined surface. They concluded that it was necessary to modify trunk and pelvis alignment during slope walking [4]. The purpose of this study was to investigate the COP trajectory in level and slope lateral walking. Hopefully the results will provide useful information on improving laborers' working safety.

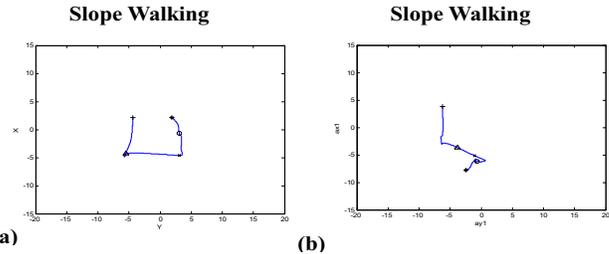

### METHODS

Five normal subjects (three males and two females, ages: 25±4.8 years, height: 166.9±7.2 cm and weight: 62.0±11.6 kg) participated in this study.

Two Kistler force plates (Kistler Instrument Corporation, NY, USA) were used in this experiment to collect the data of ground reaction force for further computation of COP. Foot switches (Motion Lab System, LA, USA) were synchronized with the force plates to identify gait phases during walking. The entire lateral walking cycle can be divided into two double support phases and two single support phases (right and left). The first double support phase started with the leading foot contact, and ended with the trailing foot off. The second started with the contact of trailing foot and ended with the leading foot clearing off from the floor. Slope inclinations were set at 5 degree. The subjects were instructed to walk with right leg leading from the bottom of the slope to the top at self-selected speed.

### RESULTS AND DISCUSSION

According to the COP trajectories (Figure 1), we found these subjects performed two kinds of gait patterns. Four subjects performed toe contact with their leading foot while only one subject performed heel contact. Those who walked with toe contact had a U-shaped COP trajectory. The COP moved backwards after contact and then turned left before trailing foot contact. At this moment, COP moved laterally until the leading foot off. After that, COP kept moving to the left and turned

**Figure 1:** (a) U-shaped COP and (b) S-shaped COP (\*: right foot contact; o: left foot off; x: left foot contact; Δ: right foot off; +: 2<sup>nd</sup> right foot contact)

forwards when the leading foot was performing hip abduction for next stride. However, the S-shaped trajectory indicated that the subject performed heel contact thus the COP moved forwards after contact.

Besides, the mean single-to-double support ratio (single support phase/double support phase) for level lateral walking and slope lateral was 0.31±0.04 and 0.24±0.03, respectively. The single support phase had a trend to be shorter during slope walking because walking on the slope was more unstable. Furthermore, the maximum velocity of the shift of COP during each phase is shown in Table 1. The result showed that during second double support phase the maximal velocity of COP shift during slope lateral walking was significantly larger than that during level lateral walking.

**Table 1:** Maximal sway velocity during four phases (unit: m/s)

	1 <sup>st</sup> Double Phase	Right Single Phase	2 <sup>nd</sup> Double Phase	Left Single Phase
<b>Level</b>	1.02±0.50	0.65±0.28	0.97±0.18	0.71±0.10
<b>Slope</b>	1.10±0.67	0.74±0.19	0.95±0.18	0.83±0.14*

\* p<0.05

### CONCLUSIONS

The most obvious difference in maximal COP shift velocity happened in the second double support phase. It is unstable for human to walk laterally on a slope. Therefore, the muscle activation and joint adaptation of lower extremities will be important to control the movement.

### INTRODUCTION

In this study, **Estrogen**, the most common hormone replacement therapy (HRT) agent, was used as single and combined with **Raloxifen**, a SERM type **osteoporosis** drug. Despite their high clinical uses, they have not been tried before, in combination. They act as agonist of each other in uterus and mammary glands. Therefore, it was expected to prevent HRT side effects by using the combinations while enhancing the healing of osteoporotic bone. As a third agent, **Vitamin K2** was chosen to be applied alone or in combination with Raloxifen. Although the recent studies mentioned the effects of Vit K2 on bone, its rebuilding and repair effect was not completely established. Hence, Vit K2-Raloxifen combination was applied and compared with the other groups as a new treatment. To understand the single and combined effects of these three agents, mechanical properties of bone was studied with both **strain gage** and **bending** theory methods on **ovariectomized** rat model. Also, histological evaluations of bone and uterine tissues were carried out together with blood analysis.

### METHODS

Rats (56) were divided into 7 groups as Estrogen (E), Raloxifen (R), Vit K2 (K), Estrogen and Raloxifen (E+R), Vit K2 and Raloxifen (R+K), Ovariectomized controls (C), and Sham operated group (S). All drug groups were ovariectomized before the treatments. Drug treatments were started three months after the surgery, and continued for 12 weeks. Estrogen and Vit K2 were applied by subcutaneous injection, while Raloxifen was administered orally. Uterus and right tibia were taken for histological analysis. Left tibia and both femora were wrapped in saline soaked gauze sponge and stored at -20°C until DEXA measurements and biomechanical testing.

### RESULTS AND DISCUSSION

All the treatments have resulted in numerically higher values for mechanical properties of femora and even significantly better values for tibia when compared to untreated controls (Table 1). The combined therapies performed better than the individual administrations and both of the controls. The modulus of elasticity was calculated from the strain gage data and compared with that obtained from the beam deflection formula. Computed moduli were consistent with literature. [1-3] However, there was a significant difference (about 13 times) between the values obtained from the two approaches. Similar difference was also observed and explained in another study for healthy rat tibia [2].

**Table 1:** Comparison of mechanical properties for tibia

TIBIA	ULTIMATE STRENGTH (MPA)	MODULUS OF ELASTICITY (GPA)	ENERGY ABSORBED (NMM)
C	100.11*	3.26	46.08
S	176.71	5.53	51.13
E+R	202.22	5.87	73.59 *
E	174.95	4.28	63.63
R	187.96	4.44	65.59
K	170.09	5.12	59.58
R+K	189.94	5.30	57.77

\* Statistically different from other groups

Biochemical analysis of blood showed an increase in bone formation (ALP activity) compared to controls. The highest ALP activity among all was observed in R group. Quantitatively, E+R had the maximum BMD values for proximal and distal of femur and tibia. As a general trend, treatment groups had better BMD values than the ovariectomized controls. Histologically, enlargement in uterus, and degeneration in connective tissue were highly observed in E group. However, such changes were less in combined groups and in the groups not involving estrogen. This implied that the adverse effects of estrogen on uterus could be reduced by using R.aloxifen.

### CONCLUSIONS

Antiresorptive agents are effective in osteoporosis prevention and treatment, but their combination was found to be much better mechanically, histologically and densitometrically than their separate usage. Strain gage data was thought to be more informative than the deflection data while determining the mechanical properties of rat femur under three point bending. Vit K2 was found to be an important factor in increasing the strength of bone especially at high stresses.

## EFFECTS OF TRUNK AND HIP STIMULATION DURING BIMANUAL REACHING AFTER SCI

<sup>1</sup> Stephanie J. Nogan, <sup>1,2</sup> Ronald J. Triolo, <sup>1</sup> Jonathan L. Sakai

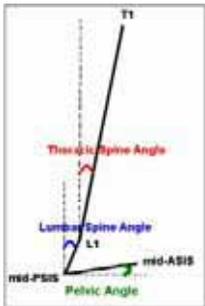

<sup>1</sup> Motion Study Laboratory, Cleveland FES Center, Louis Stokes Cleveland VA Medical Center, Cleveland, Ohio, USA

### INTRODUCTION

Functional electrical stimulation (FES) can be used to restore a variety of functional tasks in individuals paralyzed by spinal cord injuries (SCI). Individuals with low cervical or thoracic level spinal cord injuries (SCI) do not have control of all of the postural muscles of the trunk and hip, and therefore have difficulty during uni- or bimanual reaching tasks and often must rely on using one arm to hold onto the wheelchair for balance. Since mechanical stabilization of the trunk improves reach after SCI [1, 2], activation of the trunk and hip extensor muscles via FES should also positively impact spine and pelvic angles (**Figure 1**) and increase absolute sagittal reach length (**Figure 2**) during bimanual reaching.

**Figure 1:** Definitions of thoracic spine, lumbar spine, and pelvic angles.

**Figure 2:** Definition of absolute sagittal reach length.

### METHODS

Three recipients of a CWRU/VA implanted neuroprosthesis for exercise, standing, and transfers participated in this study [3]. Subject 1 (S1) had a T6 motor complete (ASIA A) SCI, and Subjects 2 (S2) and 3 (S3) had sensory incomplete (ASIA B) injuries at C7 and T5, respectively. All three had been using their neuroprosthesis for at least 3.5 years.

Stimulation patterns were created to activate the erector spinae, semimembranosus, and gluteus maximus for trunk stability during seated reaching. Six Vicon 370E optical markers were placed on the left and right acromion, wrist, and lateral femoral epicondyle, and T1 while seven Polhemus Fastrak radio frequency markers were placed on the left and right ASIS and PSIS, L1, and L3, since the wheelchair would obscure those markers from view.

After calibration and static postural data were collected, bimanual reaching trials were performed with no stimulation, trunk stimulation alone, and simultaneous activation of trunk and hip extensors. For the trials involving stimulation, the subject first turned on the appropriate stimulation pattern and became accustomed to the new posture (**Figure 3**). The subject reached to one of three target heights, held a box of one of three weights at the target for three seconds (**Figure 4**), and then returned the box to his/her lap.

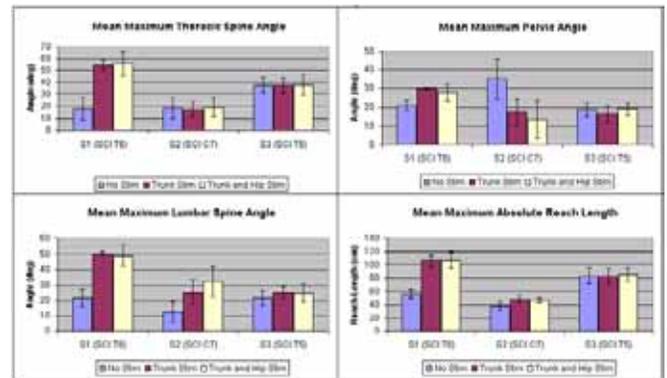

**Figure 3:** Subject finds a new posture for sitting when the stimulation is on.

**Figure 4:** Subject reaches towards the high target with stimulation on.

### RESULTS AND DISCUSSION

Thoracic spine, lumbar spine, and pelvic angles did not change significantly during the trials without stimulation as maintaining balance during bimanual reaching was very difficult without the use of trunk and hip muscles. The angles and absolute reach length generally improved with FES (**Figure 5**) since balance was achieved by the activation of the hip and back muscles.

**Figure 5:** Mean spine and pelvic angles, along with absolute reach length, for each of the 3 subjects for each of the 3 stimulation conditions.

### CONCLUSIONS

Trunk stimulation allowed neuroprosthesis users to reach further and carry heavier loads with more stability than without FES. Stimulation positively impacts posture and can augment reaching function after SCI. Inter-subject differences from this small study demonstrate the need for further investigation on how to optimize stimulation of the trunk and hips during bimanual tasks. The interactions between target height and weight carried, as well as the relative magnitudes of trunk and hip activation, remain to be determined.

## Is Lower Limb Joint Proprioception Systemic?

<sup>1</sup> Giselle Cross, <sup>1</sup>Patrick A. Costigan and <sup>1</sup>Scott K. Lynn

<sup>1</sup>School Of Physical and Health Education, Queen's University, Kingston, ON, Canada

Email: 3PAC13@post.queensu.ca

### INTRODUCTION

Proprioception, or joint position sense, provides feedback to the central nervous system that assists in appropriate muscle coordination during joint motion. Poorly controlled joint motion may lead to abnormal joint forces which are thought to be a risk factor for osteoarthritis (OA) in certain joints such as the knee. Proprioception decreases with age [1] and is further decreased in persons with knee OA [2] but we do not know if poor proprioception is a cause or effect of the disease [3]. It is also not known if proprioception is systemic across all joints.

If proprioception is systemic, then young and elderly persons will have different proprioceptive scores at all joints but the ratio of one joint to another will be similar regardless of age. If this were the case, we might be able to resolve the cause-effect relationship between proprioception and OA. The purpose of this study was to compare the ratio of ankle to knee proprioception between young and elderly group.

### METHODS

Ankle and knee proprioception were tested on 15 young ( $24 \pm 4$  years) and 14 elderly subjects ( $70 \pm 4$  years). Active to active angle reproduction (AR) was tested twice at each of 30, 45 and 60 degrees of knee flexion. The error between experimenter positioning and subject repositioning was averaged across all trials. Threshold of movement detection (TD) tests were performed at a knee angle of 45 degrees with an angular speed of 0.3 deg/sec. The subject signaled when they detected their leg moving and could correctly indicate the movement direction. The range of motion (ROM) before signaling was averaged across 5 flexion and 5 extension trials. Repeatability of both tests was assessed on 10 subjects over two separate days. The ankle TD score was divided by the knee TD score to determine the ankle:knee ratio. An AR ankle:knee ratio was also calculated. For all tests the subjects were blindfolded and listening to music to reduce information received from other sources. T-tests were used to determine differences between groups on all variables.

### RESULTS AND DISCUSSION

Repeatability testing showed that the AR test was not consistent ( $ICC < 0.6$ ) and consequently there were no differences on the ankle and knee AR scores or the AR ankle:knee ratio between the young and elderly (Table 1). The

TD test was repeatable ( $ICC > 0.8$ ) and the elderly had an increased ROM before movement was detected (Table 1) at both the ankle and the knee. There were no differences between the groups on the TD ankle:knee ratio variable.

The AR tests at the knee and ankle used protocols similar to those in the literature and also used different equipment at each joint, suggesting that the lack of repeatability was not due to equipment or the joint. Agreeing with the literature, the TD scores showed that proprioception acuity decreased at both the ankle and knee with increased age [1]. The TD ankle:knee ratio was not different between the age groups suggesting that the decline in proprioception is similar at both joint. This lends support to the notion that at least some forms of proprioception may be systemic.

This information may shed some light on the spectrum of results collected from persons with knee OA. We expect the proprioceptive test scores from OA knees to be worse than those from aged-matched controls. Since the ankle is seldom affected by OA, if subjects with knee OA also have poor ankle proprioception, we can assume that poor proprioception preceded the disease. If the ankle score is normal, then we can assume that the poor knee score resulted from the disease process.

### CONCLUSIONS

Active to active angle reproduction was not reliable at either the ankle or the knee. Both the ankle and knee threshold of movement detection scores were worse for the elderly but the ratio between the ankle and knee was not different between the age groups. These results suggest that some aspects of proprioception may be systemic.

## T2 VALUES OF PATELLAR CARTILAGE IN PATIENTS WITH OSTEOARTHRITIS

<sup>1</sup>Matthew F. Koff, <sup>2</sup>Kimberly K. Amrami, <sup>1</sup>Kenton R. Kaufman

<sup>1</sup>Biomechanics/Motion Analysis Laboratory, Department of Orthopedic Surgery, Mayo Clinic, Rochester MN

<sup>2</sup>Department of Radiology, Mayo Clinic, Rochester MN; email: [kaufman.kenton@mayo.edu](mailto:kaufman.kenton@mayo.edu)

### INTRODUCTION

Osteoarthritis (OA) is a debilitating disease which affects articular joints throughout the human body. Recently, the calculation of T<sub>2</sub> values for articular cartilage obtained from MRI has been developed to aid the diagnosis of OA [1]. T<sub>2</sub> values of cartilage are sensitive to the disruption of collagen fibers and changes in water content of cartilage seen during the onset of OA. Limited studies have been performed *in vivo* across varying degrees of OA (e.g. [2]). Relating T<sub>2</sub> values of cartilage to standard clinical staging methods of OA would be beneficial for determining the clinical applicability of this new technique. Therefore, the purpose of this study was to quantify differences of T<sub>2</sub> values of patellar cartilage across different stages of OA as defined by radiological examination.

### METHODS

Following IRB approval with obtained consent, 39 subjects (56 ± 11 y.o., 12 M, 27 F) were enrolled in the study. Standing lateral radiographs centered on the patella were obtained for each subject. Radiographs were graded for patello-femoral OA based on the Kellgren and Lawrence (KL) scale from 0 (no OA) to 4 (end-stage OA). Following the radiological exam, MR images of each subject's patellae were obtained. Examinations were performed with a clinical 1.5 T MRI system (Signa Excite 11.0, GE Healthcare, Waukesha, WI). A series of axial T<sub>2</sub>-weighted single spin-echo images were acquired along the length of the patella: TR = 1000ms, TE = 8,17,26,34,43,51,60,68,77 ms, 256x256 image matrix, slice thickness = 2mm, slice spacing = 4mm. After image acquisition, patellar cartilage was manually segmented on each image. T<sub>2</sub> values of patellar cartilage were calculated on a pixel-by-pixel basis using a custom written linearized least-squares program. Data from the first echo image was discarded in calculating T<sub>2</sub> values [3]. Pixels with T<sub>2</sub> values greater than 200 ms were considered outliers and were excluded from statistical analysis [4]. An average T<sub>2</sub> value generated from all analyzed pixels of each patella was used for statistical analysis. A one-way ANOVA was performed to determine any differences of patellar cartilage T<sub>2</sub> values across the KL stages of OA. Statistical significance was set at p<0.05.

### RESULTS AND DISCUSSION

A representative T<sub>2</sub> map of patellar cartilage is shown in Figure 1. Average calculated T<sub>2</sub> values of patellar cartilage across the KL stages of OA is shown in Table 1. The calculated T<sub>2</sub> values are similar to those in previous studies [1]. The T<sub>2</sub> values of patellar cartilage were approximately 63 ms for KL stages 0, 1, 2 and 3 with an increase to 74 ms for KL stage 4 OA. The statistical analysis found no significant differences among T<sub>2</sub> values across the KL stages of OA. The lack of differences of T<sub>2</sub> values across OA stages may be due to several factors. First, the KL staging of a joint assigns

an OA stage based on the overall radiographic appearance of a joint. Therefore, the KL staging is more likely to detect advanced stages of OA rather than the initial onset of the disease. If there is a rapid change of T<sub>2</sub> values during the onset of OA and not at later stages, then we would not expect to find differences using a KL protocol for staging OA. Second, the effects of volume averaging and chemical shift near the cartilage-subchondral bone interface may have artificially increased the calculated T<sub>2</sub> values. Finally, we had a limited number of patellae for KL stage 4 OA (n=2). An increase in the sample number may have resulted in T<sub>2</sub> differences among the OA groupings.

### CONCLUSIONS

T<sub>2</sub> mapping of patellar cartilage may provide a non-invasive method for accurate staging of OA within the knee. Additional studies evaluating different methods of grading OA may highlight the benefits and sensitivity of T<sub>2</sub> mapping in a clinical setting.

## ACUTE MUSCLE ADAPTATIONS TO A RESISTANCE EXERCISE

<sup>1</sup>Yusheng Yang, <sup>1</sup>Eliana Chaves, <sup>2</sup>Jean L. McCrory

<sup>1</sup>Human Engineering Research Laboratories, University of Pittsburgh

<sup>2</sup>Neuromuscular Research Laboratories, University of Pittsburgh

email: yuy7@pitt.edu, web: www.herlpitt.org

### INTRODUCTION

The neural factor (NF) and hypertrophic factor (HF) are the two major mechanisms related to improvements in neuromuscular efficiency [1]. Progressive resistance training results in neural and muscle hypertrophic adaptations that are primarily responsible for improved efficiency. Initial gains are related to the NF, which involves the interaction of facilitatory and inhibitory phenomena at various levels of the nervous system. Subsequent increases are attributed to the HF [2,3]. However, the timing of the neural adaptations is not yet documented. The purpose of this study is to examine neural adaptations resulting from a single-session of resistance exercise training. We hypothesized that the neural adaptations will be observed following a single session of resistance exercise training.

### METHODS

**Subjects:** Twenty-six healthy subjects (14 M, 12F) provided informed consent prior to participation in this study. Their age, height and mass were  $28.9 \pm 5.8$  yrs,  $1.8 \pm 0.1$  m and;  $68.3 \pm 11.6$  kg, respectively.

**Experimental protocol:** Surface electromyographic (EMG) activity of biceps brachii and triceps brachii on the dominant arm were recorded (2000 Hz, gain 1000, bandpass filter 15-500 Hz, CMRR 130 dB) during an elbow flexion task with resistances of 0 lbs and 3 lbs (pre-training). Subjects were then asked to perform the same task with 10 lbs resistance as a heavy resistance training exercise. Subsequently, EMG data were again obtained during the same task with resistance of 3 lbs and 0 lbs (post-training), respectively. Each lifting task was repeated five times within a 15 second period. The pace of movement was controlled by an audible cue of 60 bpm. The start and end of each repetition was determined with an electrogoniometer placed at the elbow.

**Data analysis:** Median frequency (MF) and integrated EMG (iEMG) were calculated for the concentric (CON) and eccentric (ECC) phases of each repetition. Data of middle three repetitions of each task were averaged for statistical analysis. A two-factor ANOVA [load (0 lbs, 3 lbs)  $\times$  training (Pre, Post)] with repeated measures was employed to test for significant changes in iEMG and MF. Separate analyses were performed for the CON and ECC data for each muscle. An alpha level of 0.05 was used for all tests of significance.

### RESULTS AND DISCUSSION

Following a single session of resistance exercise, significant reductions of biceps MF ( $p < 0.05$ ) and iEMG ( $p < 0.05$ ) during the CON action were noted (Table 1). Similar trends were noted in the ECC triceps MF ( $p = 0.17$ ) and iEMG ( $p = 0.08$ ). No changes were noted during the ECC action of the biceps. This CON neuromuscular efficiency gain of the biceps may be explained by the NF. Neural adaptations involve prime-mover motor unit activation and synchronous coactivation of the antagonist [4]. Given a hierarchical slow-twitch to fast-twitch motor unit recruitment pattern, decreased biceps CON iEMG in the post-training condition may indicate that less fast-twitch motor units were necessary to effectively accomplish the same task. The lower median frequency of stimulation may also be indicative of less fast-twitch motor unit involvement. The fact that no significant decreased changes of the iEMG or MF were found for the biceps during ECC action may reflect that there is less potential for neural adaptations with ECC than CON contraction. In the ECC action of the biceps, gravity could be considered the agonist while the biceps was the antagonist. It is not known how long these neural adaptations will persist or if there will be any carryover in the next training session. Also, a future study with isokinetic dynamometer at both directions may be needed to discriminate the dominance of neural adaptations in either CON or ECC muscle action.

### CONCLUSIONS

Our research indicates increased neuromuscular efficiency following a single session of resistance training can be observed in the agonist muscle during CON activation. This improved efficiency is attributed to neural activation rather than to muscle hypertrophy. This information must be considered when interpreting data of subjects who have performed multiple trials in various conditions in the laboratory. Our results may provide alternative training for athletes to improve their performance within a short period of time.

### INTRODUCTION

Although great number of researches has done to pointing the role of Peak Force (PF) and Rate of Force Development (RFD) in jumping, sprinting and other dynamic sports activity, their role in drop jump performance was not investigated. Young et al [4] investigated relationships between the strength qualities of the leg extensor muscles and performance in vertical jumps performed from a standing position (double leg takeoff) and a run-up (single leg takeoff). They were reported that speed strength tests correlated significantly with both jump types, but maximum strength did not. A few experiments determine the best dropping height and find the best method for drop jump with small angular displacement of the knee from 0.3m [5]. Stone et al [3] investigated relationships between power output in countermovement jump and squat jump at different load conditions, among stronger and weaker subjects. They were reported that stronger subjects have had greater power output at greater load conditions and concluded that maximal strength development is primary factor in jumping ability enhancement [2]. In the presence of different reports, to distinguish the influence of maximal strength and speed-strength in jumping abilities, role of leg extensor's peak force (PF), rate of force development (RFD), rate of force development normalized with peak force (RFD/PF) and time interval from generating 30% to 70% of peak force (T30-70%) in counter drop jump (CDJ) and bounce drop jump (BDJ) performance were tested [1]. RFD/PF and T30-70% represented rate at which force were produced independently of peak force.

### METHODS

Forty six male students of physical education, 23±1.9 years of age, 180.8±5.8 cm of height and 77.8±6.7 kg of weight, took part in a study. Isometric PF, (isometric) RFD, RFD/PF and T30-70% for hip and knee extensors, as well as foot plantar flexors, were measured with a strain-gauge dynamometer (Hottinger Baldwin Messtechnik, Germany; 0-5000N; 50Hz). Better of two attempts for every measured muscle groups were analyzed. Subjects also performed two CDJ and BDJ from height of 0.2, 0.3, 0.4, 0.5, 0.6 and 0.7 m. Jumps data: counter-bounce drop jump height and time (CDJH, BDJH, CDJT, and BDJT) presented in (Table 1). Count-bounce drop jump power output (CDJP BDJP), were collected using Ergo-Jump contact mat - Bosco's test system.

Better CDJ and BDJ from every height were analyzed. Dynamometry data were compared with CDJH and BDJP, using Pearson's product – moment correlation.

### RESULTS AND DISCUSSION

With dynamometry data, PF for all muscles groups correlated significantly with RFD ( $p < 0.001$ ). Correlations between RFD/PF and T30-70% were the strongest ( $p < 0.001$ ), we found significantly correlation also, between CDJH and BDJP ( $p < 0.001$ ). PF and RFD of measured muscles groups, correlated significantly with CDJH and BDJP, but RFD/PF and T30-70%, did not. Since RFD depend upon amount of produced force (i.e. peak force) and rate at which force were produced, it is not known whether the peak force produced by muscles or rate at which they were generated force, had greater influence on RFD. For the hip extensors, correlations with RFD were stronger in CDJ from lower heights, only. Bounce drop jump power output (BDJP) showed stronger correlations with RFD of knee extensors in jumps from lower heights. Factor analysis showed that peak force factors for all measured leg extensor muscles, have had greater overall influence on drop jump performance, even if their influence on RFD variability were lower. It was concluded that peak force factors have a greater role in CDJ and BDJ performance, regardless of stronger correlations between BDJP and RFD of knee extensors, as well as between CDJH and RFD of knee and hip extensors in some jumps.

### CONCLUSIONS

From a practical approach, to improve impact jumping ability, depending upon stretch shortening cycle, these results suggests that improving a maximum strength, rather than speed strength, should be a primary component of training programs.

## VOLUMETRIC MEASUREMENT OF THE SUBACROMIAL SPACE AT THE SHOULDER

<sup>1</sup>Paula M Ludewig, <sup>2</sup>Edward Gonda, and <sup>3</sup>Fred A Wentorf

<sup>1</sup>Program in Physical Therapy, <sup>2</sup>Biomedical Engineering, and <sup>3</sup>Department of Orthopaedics

### INTRODUCTION

Shoulder pain is a common and debilitating condition. One theorized mechanism for the development of shoulder pain and associated rotator cuff tendonitis is compression of the soft tissues within the subacromial space of the shoulder as the arm is elevated. However, current methods of subacromial space measurement are limited. The purpose of this study was to develop and validate a volumetric description of the subacromial space at the shoulder, and describe changes in this space during passive humeral scapular plane abduction.

### METHODS

The subacromial volume was defined as an extension of the supraspinatus outlet area described by Zuckerman et al.<sup>1</sup> Shoulder anatomical landmarks for 3 cadaveric specimens and an anatomical shoulder model were digitized in 3-D from CT scans (1mm contiguous helical slices) of the scapula and humerus with the arm in a neutral position (at side). Sets of 3 specific anatomical landmarks were used to define planes representing superior, medial, lateral, anterior and posterior borders of the subacromial space (Figure 1). Sequential triangular volumes were defined within the space and summed to define the overall volume (Vo). This volume is then further subdivided into anterior (Va), middle (Vm), and posterior (Vp) subvolumes representative of specific anatomic subcomponents of the subacromial space.

A portion of the humeral head crosses the plane defining the lateral border of the Vo, and the volume of this intersecting portion of the humerus is determined (Vi). Finally, Vo-Vi = the remaining space available to accommodate the rotator cuff soft tissues (Vr). Reductions in this remaining volume may increase impingement risk. Motion data is also collected for each specimen using 3-D electromagnetic motion sensors rigidly fixed to the bony segments via intercortical pins. Registration blocks which can be defined in the sensor frames by surface digitizing and are visible in the CT are used to build reference frames linking the motion data to the CT anatomical data.<sup>2</sup> The Vi and Vr can then be calculated in multiple arm positions using matrix transformations from the sensor data to rotate the anatomical data. Motion and CT data from 1 cadaver were used to describe these changing volumes

**Figure 1.** Superior/medial view of the subacromial volume superimposed on the scapula.

at neutral, 40°, 60°, 90°, and 120° of humeral scapular plane abduction relative to the thorax. For validation, the anatomical model was rigidly fixed in 2 positions, anatomical neutral and with the humerus abducted ~ 90° relative to the scapula. Sensor orientation data and CT scans were collected in both positions. Volume measures calculated from the rotated anatomical data (experimental method) were compared to calculations based on the CT scan in the second position (criterion reference).

### RESULTS AND DISCUSSION

The available subacromial volumes prior to considering humeral intersection are represented in Table 1. The Vr progressively decreased as humeral elevation increased with the smallest value at the 90° arm position, consistent with the clinically described position of shoulder impingement. The Vr then increased slightly in the 120° arm position (Table 2). The Vr calculated from the experimental method was 20.43 ml and the criterion reference value 20.45 ml, representing a 0.1% error. These volumetric measures may provide additional insight into mechanisms of development and rehabilitation for shoulder impingement syndrome.

**SPEED RELATED CHANGES IN LOWER LIMB JOINT CONTRIBUTIONS TO MECHANICAL ENERGY DURING GAIT OF STROKE SUBJECTS**

Luci Fuscaldi Teixeira-Salmela, Marie-Hélène Milot, Sylvie Nadeau, Denis Gravel, France Pottie

CRIR, Site IRM, École de Réadaptation, Université de Montréal, Canada, E-mail: [jhsalmela@hotmail.com](mailto:jhsalmela@hotmail.com)

**INTRODUCTION**

Estimations of the relative contributions for each joint to the total energy involved in gait at different speeds may be central to precisely understanding the nature, extent, and degree of compensation across joints in subjects with locomotor disorders to provide more efficient rehabilitation.

The purpose of this study was to determine the relative contributions of the ankle, knee, and hip joint muscles to the total energy generated and absorbed during gait at natural and maximal speeds with stroke subjects.

**METHODS**

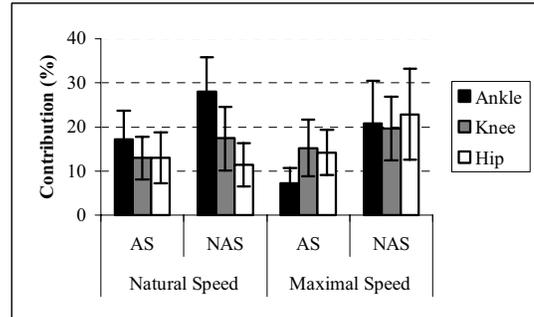

Fifteen subjects (five women and 10 men), mean age (58.3 ± 13.8 years), walked with their low-heeled shoes (five wore ankle-foot orthoses) without ambulatory aids. They were asked to walk at their natural speed and then, as fast as possible along a 9-meter walkway. Data were obtained with a 3-D Optotrak system and AMTI force platforms. An inverse dynamic approach was used to yield kinetic variables. Work generated and absorbed during gait by flexors and extensors for all joints were summed and the relative contributions to total positive and negative work for both speeds were calculated for each joint. Three within-factor repeated measures ANOVA, followed by contrasts, were used for laterality, joint, and speed effects.

**RESULTS AND DISCUSSION**

Mean (±1 SD) values for the natural and maximal speeds of 0.70 (± 0.30) m/s and 1.28 (± 0.37) m/s, were similar to those previously reported [1].

**Side effects:** For the generation contributions, significant differences between sides for both speeds were found only for the ankle and hip joints. For absorption, differences were significant for the ankle and knee (Table 1).

The relative contributions of the affected (AS) /non-affected (NAS) sides to the total energy generated at natural speed were 40/60%. Corresponding values for absorbed work were 41/59%. At maximal speed, the respective values were 38/62% and 36/64%, demonstrating, as opposed to healthy subjects [2], the asymmetric nature of hemiparetic gait [1].

**Figure 1:** Relative contributions (%) of ankle, knee, and hip to total energy (generation + absorption) across speeds

**Joint effects:** For AS, contributions at the ankle were different from the other joints at both speeds, whereas for the NAS, all differences across joints were significant only for natural speed.

**Speed effects:** Supporting previous findings with healthy subjects [2], contributions at the knee and hip increased at maximal speed, while those at the ankle substantially decreased (Figure 1). Increases in generation were higher at the hip, whereas those in absorption were higher at the knee.

**CONCLUSIONS**

These findings demonstrated the interplay between limbs and joints associated with increases in walking speed. The asymmetry of hemiparetic gait indicates greatest contributions of the NAS side at both speeds. This model easily identifies segments that compensate for others with different task demands. The next step is to apply this model to determine effects of lower limb strengthening programs on these relative contributions for stroke victims.

## SIT-TO-STAND PERFORMANCE WITH YOUNG AND ELDERLY SUBJECTS

Carolina Mitre Chaves, Fátima Goulart, Marcia Chagas-Vallone, Patricia Brito, Luci F. Teixeira-Salmela  
Department of Physical Therapy, Federal University of Minas Gerais, Brazil; E-mail: [carolinamchaves@uol.com.br](mailto:carolinamchaves@uol.com.br)

### INTRODUCTION

Sit-to-stand is an often performed functional task in daily life and an important requirement for other functional movements. Among the elderly, the difficulty to stand is common and has been considered as a risk factor for institutionalization and falls [1,2,3].

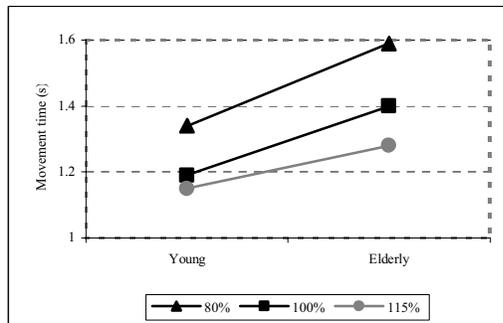

The aim of this study was to evaluate the sit-to-stand task with gender-matched healthy young and elderly individuals at three distinct seat height conditions.

### METHODS

Fourteen young (28.14± 5.91 yrs.) and 14 elderly individuals (68.71± 2.49 yrs.) were included. The sit-to-stand task was investigated using an accelerometer, electromyography (EMG), and force platforms. Investigated variables included: reaction times, movement times, latencies, and EMG activity of the tibialis anterior, erector spinal, hamstrings, and soleus muscles, as well as the body elevation index. Conditions were determined according to subjects' knee height, with the seat adjusted to 80, 100, and 115% of knee height. Three within-factor repeated measure ANOVA (2X2X3) was used to investigate age, gender, and seat height effects

### RESULTS AND DISCUSSION

Reaction time did not differ between conditions, however, both reaction and movement times were greater for the elderly (Figure 1) and the latencies were slower for all muscles ( $p<0.01$ ), except for the tibialis anterior. The elderly increased their movement times when the seat was lowered and decreased it when it was elevated ( $p<0.01$ ). This demonstrated that regardless of gender, increases in seat height affected functional performance for elderly individuals. Significant interactions between age and gender for the young subjects were found, indicating that men were faster than women.

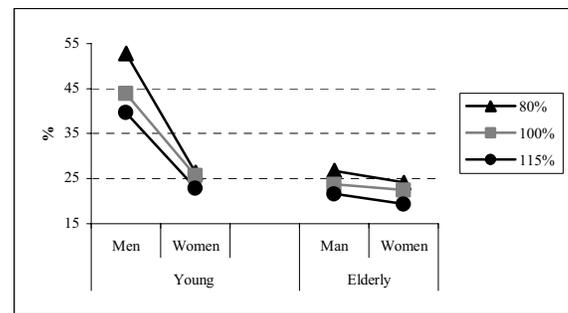

**Figure 1:** Effect of seat heights on movement time (s)  
When the seat was lowered (80% condition), there was observed greater EMG activity for the tibialis anterior and quadriceps muscles ( $p<0.01$ ), but no differences between the

other conditions. In addition, the tibialis anterior was recruited earlier in the 80% condition ( $p<0.05$ ), demonstrating its function as a preparatory muscle for the sit-to-stand task [3].

When the seat was elevated, decreases in EMG activity were found for all muscles, with the quadriceps being the main generator in the sit-to-stand task. Large variability was observed for the erector spinal muscles, probably indicating different individual strategies [3]. Hamstring activity was not influenced by seat heights

The body elevation index was determined by the amount vertical force generated, when standing from a chair. Differences in the body elevation index were found between groups and were gender-related, indicating that for young subjects, men showed a higher index (Figure 2).

**Figure 2:** Body elevation index (% body weight) for the young and elderly groups across conditions

### CONCLUSIONS

The present findings showed that increases in seat height were associated with decreases in movement time for the elderly and for EMG activation of the tibialis anterior and quadriceps for both young and elderly subjects. When the seat was lowered, movement time and EMG muscle activity increased for both groups. Based upon these findings, these strategies may be adopted by rehabilitation professionals to train the sit-to-stand task, especially with elderly subjects

## RESONANT FREQUENCY SHIFTS IN OSTEOTOMISED GOAT TIBIAE

JE Brouwers, PAJ de Leeuw, GJ Streekstra, L Blankevoort  
 Orthotrauma Research Center Amsterdam,  
 Academic Medical Center, University of Amsterdam, the Netherlands.  
[guido@brouwersweb.com](mailto:guido@brouwersweb.com)

### INTRODUCTION

Diagnosing a bone fracture without the availability of X-rays is sometimes difficult. Osteophony is the assessment of bone integrity by analyzing its vibrations and is a non-invasive technique that could eventually assist general practitioners in correctly diagnosing fractures [1]. In case of a hip fracture, percussing the patella and auscultating the symphysis pubica results in a different sound, as compared to the healthy contra lateral side [2]. The pitch of the sound represents the resonant frequency. Nevertheless, listening with a stethoscope provides subjective results. By recording and analyzing the signals, the results become objective. Bone can be easily excited on prominences without much soft tissue coverage. The skin covering this prominence could influence the resonant frequency [3].

The goal of this study is to assess the influence of skin covering the point of excitation and to assess the influence of a standardised osteotomy on the resonant frequency of bone.

### METHODS

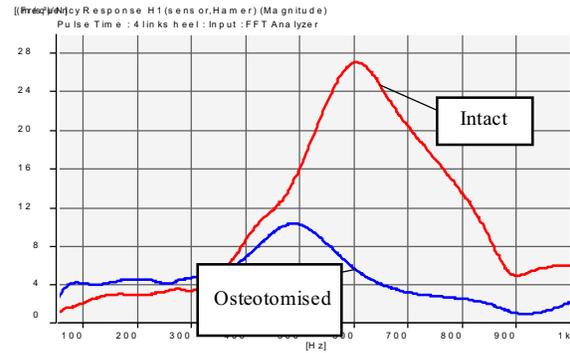

For the experiments, 16 goat tibiae (8 fresh cadavers) are used. The medial malleolus is percussed with a hammer, instrumented with a force transducer. The response is measured with an acceleration sensor screwed into the tuberositas tibiae. After a measurement with skin covering the malleolus, the skin is removed and the experiment is repeated by percussing the bare malleolus. Subsequently, halfway between the malleolus and the tuberositas, a stepwise osteotomy is made (1/3, 2/3 and completely through). An osteophonogram is made by analyzing the transfer function between both signals, using a 2 channel data acquisition and analysis system (Pulse, Bruel & Kjaer, Denmark) coupled to a notebook PC (Figure 1). In the osteophonogram the resonant frequency is detected by the software.

### RESULTS

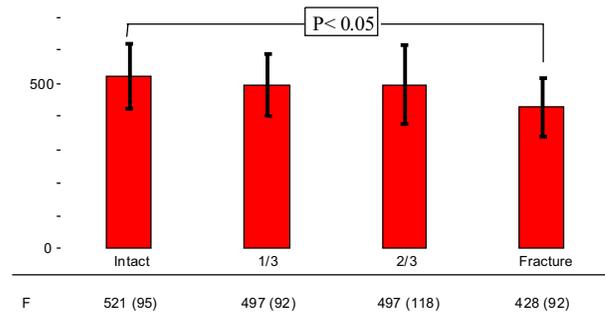

There is no statistically significant difference between the resonant frequency of a goat tibia with or without skin covering the medial malleolus (paired T-test), the Pearson correlation coefficient is 0.992 ( $p < 0.05$ ).

Also, no significant difference is found between intact bone and a 1/3-osteotomy or between intact and a 2/3-osteotomy (Figure 2).

There is a significant decrease in the mean resonant frequency between an intact and a fully osteotomised goat tibia (521 vs. 428 Hz; Anova and Bonferonni post hoc analysis:  $p < 0.05$ ).

**Figure 1:** Typical example of an osteophonogram with the resonant frequency shift between an intact (red curve) and a completely osteotomised goat tibia.

**Figure 2:** Average resonant frequency in Hz (with standard deviation) of the intact and the osteotomised (1/3, 2/3 and 3/3= fracture) goat tibiae.

### CONCLUSIONS

Soft tissue covering bone prominences at the point of excitation does not influence the resonant frequency.

The resonant frequency of a fully osteotomised goat tibia is significantly decreased as compared to the intact tibia.

Osteophony seems to be a promising non-invasive method to detect bone fractures.

## STIFFNESS MEASUREMENT OF THE GLENOHUMERAL JOINT

Edward Chadwick, Robert Kirsch and John Chae

Case Western Reserve University and The Cleveland FES Center

### INTRODUCTION

Stroke is the leading cause of activity limitation among older adults in the United States. More than 700,000 strokes occur each year [1], with a prevalence of approximately 4 million (AHA, 1997). A common complication of stroke is hemiplegic shoulder pain with reported prevalence ranging between 34% and 84% [3][2].

Shoulder pain following stroke has been associated with subluxation in the gleno-humeral (GH) joint, but this is disputed and the aetiology is poorly understood. It is hypothesised that dynamic stability is a better predictor of pain than subluxation, which is a simple measure of joint instability.

The objectives of this research are to identify the mechanical and neuromuscular changes in the hemiplegic shoulder following stroke and their relationship to the development of pain, and to investigate possible mechanisms underlying that pain. Mechanical characteristics of the gleno-humeral joint will be determined using a system identification technique, modelling the shoulder as a second-order system.

### METHODS

Displacement perturbations in the range 0-6Hz, 0-2cm, were applied to the arm during a constant force task, using a mechanical manipulator, while measuring end-point forces using a force transducer. The subject was firmly attached to the manipulator by means of a cast from the mid humerus level to the wrist, with the elbow in 90°.

System Identification techniques were used to quantify dynamic stiffness of the shoulder, with humeral end-point motion as input and end-point force as output for the system.

$$\begin{bmatrix} F_x(f) \\ F_y(f) \end{bmatrix} = \begin{bmatrix} H_{xx}(f) & H_{xy}(f) \\ H_{yx}(f) & H_{yy}(f) \end{bmatrix} \begin{bmatrix} X_x(f) \\ Y_y(f) \end{bmatrix} \quad (1)$$

### RESULTS AND DISCUSSION

Figure 1 shows stiffness curves for the three principal directions (leading diagonal) as well as the interaction between directions (off-diagonal). The curves for  $K_{xx}$  (top left) and  $K_{zz}$  (bottom right) have the typical tick-mark shape of a second-order system, but the curve for  $K_{yy}$  (centre) is all over the shop.

Partial and multiple coherence values for the identifications were found to be very good in the principal directions.

## SMALLER SWAY DURING QUIET STANCE ATTRIBUTES TO EFFECTIVE USE OF BODY VELOCITY

<sup>1,3</sup> Kei Masani, <sup>2</sup> Albert H. Vette, <sup>3</sup> Masaki Abe, <sup>3</sup> Kimitaka Nakazawa and <sup>2</sup> Milos R. Popovic

<sup>3</sup>Research Institute NRC; email: masani@idaten.c.u-tokyo.ac.jp

### INTRODUCTION

The nature of the control mechanism responsible for ensuring stability during quiet standing has attracted the attention of many researchers, since larger sway is supposed to relate to falling, which is a serious problem in elderly. However, the mechanism that determines the sway size remains unclear.

Using cross-correlation analysis, we found that the modulation of calf muscle activity matches body sway during quiet standing, and that the muscle activity precedes body sway with about 200ms [1]. It was also demonstrated that the central nervous system attributes a significant role to the body velocity information in order to generate the preceding motor command [1, 2].

In the present study, we tested the hypothesis that a more effective utilization of the body velocity information leads to an improved stabilization of the body.

### METHODS

Experimental study: 24 young (Mean age 27yrs; Male 11, Female 13) and 22 elderly (66yrs; M 11, F 11) healthy subjects were asked to stand quietly for 90 sec and five trials. The body sway and electromyogram (EMG) in the right soleus muscle were measured. Due to the space limitation, we do not compare distinct age group characteristics in this abstract.

Simulation study: We provided an explanation for the experimental results by means of a numerical simulation. Human quiet stance was simulated using an inverted pendulum model regulated by a proportional and derivative (PD) controller. The parameter sets of the simulation, such as proportional gain (Kp), derivative gain (Kd) and closed-loop time delay, were selected with the goal of generating a realistic cross-correlation function (CCF) between the motor command and body sway as demonstrated in [2].

Analysis: The correlation coefficient (CC) and time shift (TS) were determined using the peak of CCF between body sway and EMG (Experimental study) or motor command (Simulation study). Sway size was evaluated as the standard deviation of body sway.

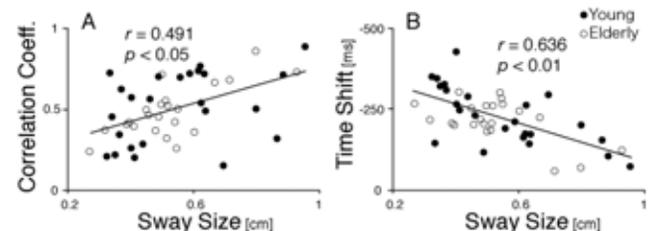

### RESULTS AND DISCUSSION

Figure 1 shows the results of the experimental study. The results indicate that for a person, who sways less, CC is smaller (A) and TS longer (B). For both age groups, this tendency is more distinct in male than in female subjects (not shown in this abstract).

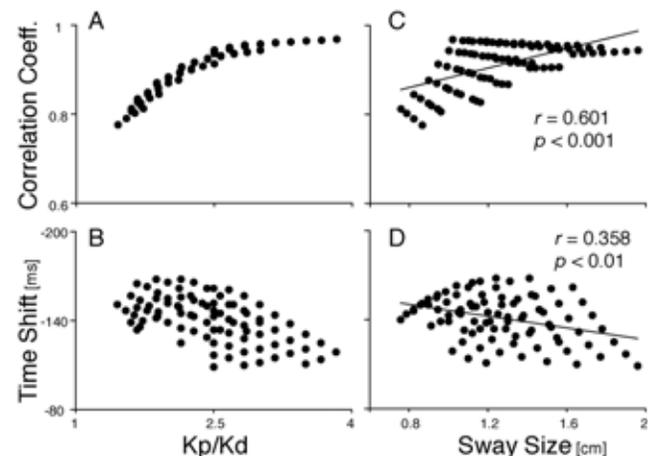

The experimental results inspired us to consider the contribution of the velocity information in the central nervous system. We reported in [1] that a larger Kd generates a faster

fluctuation of the motor command. Therefore, the CC between body sway and motor command is expected to be smaller when the body is controlled by means of a larger Kd gain. The relation is shown in Figure 2A. Also, a controller with a larger Kd gain is capable of producing a longer TS, since the phase of the derivative time series leads the position time series [2], as shown in Figure 2B. Additionally, since a larger Kd is more capable of compensating the noise torque, the ratio of Kp/Kd correlates with the sway size ( $r=0.316, p<0.01$ ). As a result, a smaller sway size relates to a smaller CC and longer TS for the simulation as well (Figure 2C, D).

Comparing the results in the experimental and simulation studies, we conclude that the person who shows the smaller body sway utilizes the larger body velocity information.

**Figure 1:** Results of the experimental study. Sway size vs. CC (A) and TS (B) of the CCF between EMG and body sway. Note that the positive CC indicates that the larger EMG correlates with the forward body position, that the negative TS indicates that the EMG precedes the body sway, and that the vertical axis of B is reversed.

**Figure 2:** Result of the simulation study. The ratio of Kp/Kd vs. CC (A) and TS (B) of the CCF between motor command and body sway. Sway size vs. CC (C) and vs. TS (D). Plots are from 89 simulations. See notes in Fig. 1.

## CHANGES IN MECHANICAL CHARACTERISTICS OF THE PLANTARFLEXOR MUSCLES IN INDIVIDUALS WITH DIABETES MELLITUS

<sup>1</sup> Smita Rao, <sup>1</sup> Jason Wilken, <sup>2</sup> Charles Saltzman and <sup>1</sup> H John Yack  
<sup>1</sup> Graduate Program in Physical Therapy and Rehabilitation Science,  
<sup>2</sup> Orthopedics and Rehabilitation; email: [smita-rao@uiowa.edu](mailto:smita-rao@uiowa.edu)

### INTRODUCTION

Foot ulcers are estimated to develop in 15% of all individuals with DM<sup>1</sup> and have been linked to repetitive mechanical stress. Loss of ankle range of motion (ROM) and increased stiffness are two factors that have been implicated as potential contributors to plantar loading<sup>2</sup>.

Attempts to document changes in passive ankle ROM and stiffness in individuals with DM have uncovered mixed results<sup>3,4</sup>. Differences in criteria for determining passive end ROM and for quantifying stiffness, as well as variations in the extent of pathology in subjects with DM, may account for ostensible differences in ankle ROM and stiffness. During gait: attempts to document plantar loading have not controlled for the confounding effect of walking velocity, which has been shown to influence plantar loading<sup>5</sup>. The biomechanical relationships between passive and dynamic gait measures of ankle ROM and stiffness, and plantar loading are not well understood. The **purpose** of our study was to examine the association between passive ankle ROM and stiffness measured at rest and during gait, in individuals with DM and neuropathy, and to use this information to help understand how ankle ROM and stiffness may influence plantar loading.

### METHODS

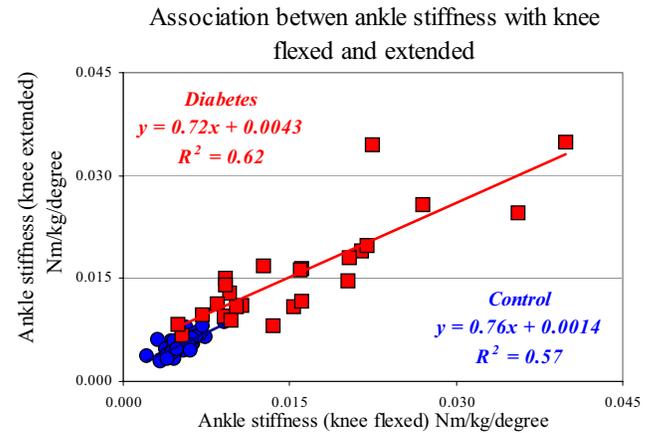

Twenty-five subjects with DM, neuropathy and no ulcer and 80 age and gender matched non-diabetic controls participated in clinical ankle ROM and stiffness testing. Ten subjects from each group were tested during gait. In subjects with DM, type and duration of DM, most recent HbA1c levels and presence of neuropathy (using Semmes-Weinstein monofilaments) was documented.

**Passive Testing:** Passive ankle ROM was quantified as angular displacement between the tibial crest and the plantar aspect of the foot, measured with a custom built device, while applying torques of 15, 20 and 25 Nm. Passive ankle stiffness was calculated as the slope of the curves over 15-25 Nm intervals. **During gait:** Plantar pressures were recorded at 60 Hz using in-shoe insoles (Novel Inc, MN), ankle ROM was measured using kinematic data collected using infrared markers (Northern Digital Inc, Waterloo, Canada) placed on the foot, leg and thigh segments, kinetic data was collected using a force-plate embedded in the walkway (Kistler Inc., NY) as subjects walked at 0.89 m/s. Data was processed to yield sagittal plane ankle kinematics and kinetics and ankle stiffness was calculated during second rocker.

### RESULTS AND DISCUSSION

**Passive:** Subjects with DM showed higher ankle stiffness (0.016 vs. 0.005 Nm/kg<sup>0</sup>,  $p < 0.001$ ) and less peak dorsiflexion (13.5 vs. 21.5°,  $p < 0.001$ ) than age and gender matched control subjects during clinical testing. **Gait:** The groups did not show differences in stiffness (0.068 vs. 0.076 Nm/kg<sup>0</sup>,  $p = 0.97$ ) or peak dorsiflexion (9.8 vs. 11.7°,  $p = 0.93$ ) utilized during gait.

**Passive:** Ankle stiffness with the knee extended was significantly associated with ankle stiffness with the knee

**Figure 1:** Graph depicting association between passive ankle stiffness with the knee flexed and extended in subjects with diabetes (red squares) and non-diabetic controls (blue circles)

flexed in subjects with DM, as well as in non-diabetic individuals (Figure 1). In subjects with DM, HbA1c levels and duration of DM showed fair association with ankle stiffness in the knee extended position ( $r^2 = 0.48$  and  $0.24$  respectively,  $p < 0.01$ ). **Gait:** In subjects with DM: peak plantar pressure showed a positive association with ankle stiffness during gait ( $r^2 = 0.51$ ,  $p = 0.02$ ) and stride length ( $r^2 = 0.49$ ,  $p = 0.03$ ). In control subjects: peak pressure was positively associated with stride length ( $r^2 = 0.42$ ,  $p = 0.02$ ) but not with ankle stiffness during gait ( $r^2 = 0.06$ ,  $p = 0.68$ ).

### CONCLUSIONS

The unique findings of our study revealed that while subjects with DM had restricted passive ankle ROM and increased stiffness compared to control subjects, these measures did not represent ankle motion or stiffness utilized during gait. Peak passive stiffness was about 18 and 23% of ankle stiffness during gait, in control and DM groups respectively, suggesting that individuals with DM may utilize higher contribution from passive stiffness to ankle stiffness during second rocker in gait.

In spite of differences in ankle ROM and passive stiffness, subjects with DM demonstrated ankle stiffness and plantar pressures, similar to control subjects, while walking at identical speed, 0.89 m/s. This may represent an effective strategy adopted by subjects with DM to modulate plantar loading using kinematic pattern.

### INTRODUCTION

Immobilisation affects mechanical properties of muscle [1, 2]. Animal experiments showed that passive mechanical properties of muscle belly, which play an important role in movement, changed with immobilisation [1]. However, these results might not be directly applicable to humans in vivo because of the differences in species. Moreover, the influence of immobilisation differs muscle to muscle [2]. Recently, the passive mechanical properties of the human gastrocnemius (GAS) muscle belly in vivo can be measured using ultrasonography [3].

The aim of this study was to investigate the effect of 20 days bed rest (BR) on passive mechanical properties of the human GAS muscle belly in vivo.

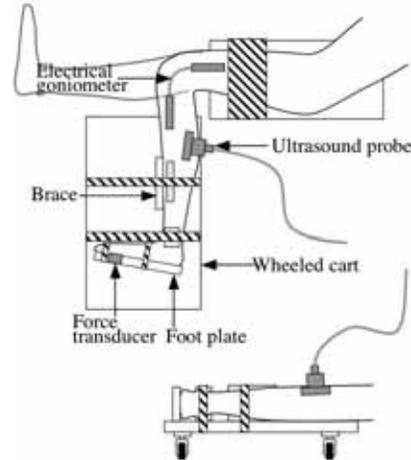

### METHODS

Subjects were four healthy males ( $20 \pm 0$  yr). Each subject provided written informed consent. Subjects remained at a continuous  $6^\circ$  head-down tilt throughout a 20-days BR period. Five days before the start of the BR period and a day after the end of the BR period, passive mechanical properties and muscle thickness of the GAS muscle belly were measured. This study was approved by the ethical review board of NASDA and the Faculty of Medicine, the University of Tokyo.

Each subject lay on his right side with the right hip joint flexed and held constant within the range of  $30^\circ$  to  $50^\circ$ . Transverse ultrasound images of the medial head of the GAS were taken during passive slow knee extension from  $65^\circ$  to  $5^\circ$  with a constant ankle joint angle of  $10^\circ$  dorsiflexion. The change in passive ankle joint moment ( $M_p$ ), which is produced only by the GAS length change, was also measured.

Baseline of the  $M_p$  was defined as the plantarflexion moment in the knee joint angle range of  $55^\circ$  to  $60^\circ$ , in which the moment was almost constant for all subjects. The first point to rise above the 99 % confidence interval of the baseline of the plantarflexion moment for  $5^\circ$  while extending the knee joint was set as the onset of the  $M_p$  produced by the GAS, and the knee joint angle at this onset was defined as the slack knee joint angle for the GAS ( $\theta_s$ ). The slack length of the GAS muscle fascicles (Lfs) was defined as the length of the GAS muscle fascicles (Lf) at  $\theta_s$ . The relationship between Lf and  $M_p$  in the knee joint angle range from  $5^\circ$  to  $\theta_s^\circ$  was fitted with a linear regression equation using a least squares method.

Muscle thickness of the GAS (Tm) was measured from left leg at 70% of the lower leg length proximal to the lateral malleolus using a B-mode ultrasonography.

**Figure 1:** Top and side view of the experimental setup used for the measurement of the passive ankle joint moment during passive slow knee extension.

### RESULTS AND DISCUSSION

Tm slightly decreased from  $60 \pm 2$  mm to  $59 \pm 2$  mm with BR.  $\theta_s$  decreased from  $42^\circ \pm 6^\circ$  to  $28^\circ \pm 12^\circ$ , but Lfs was almost constant (the pre-BR Lfs was  $42 \pm 4$  mm and the post-BR Lfs was  $44 \pm 5$  mm). Thus, BR had little effect on Lfs, which was in agreement with the previous result [1]. The slack length of the human GAS tendinous tissues in vivo might be lengthened with BR, although the tendinous tissues of rabbit soleus muscle in vitro were shortened with immobilisation [1]. The slope of the relationship between Lf and  $M_p$  in the knee joint angle range from  $5^\circ$  to  $\theta_s^\circ$  decreased from  $0.085 \pm 0.027$  Nm/mm to  $0.071 \pm 0.042$  Nm/mm with BR. Thus, BR decreased the passive stiffness of the human GAS muscle belly in vivo, although the stiffness of rabbit soleus muscle fascicles in vitro was unchanged with immobilisation [1].

### CONCLUSIONS

Twenty days of bed rest had little effect on the slack length of gastrocnemius muscle belly, but decreased its passive stiffness.

## HOW MUCH DO THE HIP ABDUCTORS CONTRIBUTE TO THE GAIT STABILITY FOR AMPUTEE WITH A PROSTHESIS?

Tae Soo Bae, Jae Youn Lee, Song Hak Im, S.K. Kim, M.S. Mun  
 Korea Orthopedics and Rehabilitation Engineering Center, email: [bmebae@iris.korec.re.kr](mailto:bmebae@iris.korec.re.kr), web: [www.korec.re.kr](http://www.korec.re.kr)

### INTRODUCTION

The appropriate abduction torque by hip abductor muscle is essential to the balance and stability control of frontal plane stability of pelvis during walking. Without adequate abduction torque on the stance limb, above-knee amputees tend to lean trunk toward the amputated side during single-limb support in the frontal plane. The aim of the present study was to analyze the role of hip abductors which control the gait stability at walking speeds using 3-D musculoskeletal dynamic models for amputees by the inverse dynamic analysis.

### METHODS

Ten transfemoral amputees with lower-limb prosthesis and ten healthy subjects were involved and gait analysis was performed by motion analyzer. Subjects were instructed to walk at three speeds at which they felt fast, most comfortable, and slow. Using SIMM, we made the musculoskeletal model for stump using anthropometric data which were obtained from computed tomography and MRI. After consultation with clinicians and references, the insertion points of muscles related to hip motion were redefined. Four primary abductors-the gluteus medius (GMed), the gluteus minimus (GMin), tensor fasciae Latae(TFL) and two secondary abductors-the piriformis (PF) and the satorius (SAT) were considered in this study. Next, we made the 4-bar linkage prosthetic model scaled to the stump model. (Figure 1) The dynamic equation of motion for amputee and normal subject was derived using SD/FAST and an inverse dynamics simulation was produced by Dynamics Pipeline. We adapted the muscle parameters of normal subjects to those of amputees through the sensitivity analysis referred to the comparative results from isokinetic and isometric test using dynamometer (Biodex) and also to the help of clinicians.

### RESULTS AND DISCUSSION

During single-limb support period in the frontal plane, the pelvic obliquity of right legs of normal was 3~8 degrees greater than those of amputated leg of amputees which showed the negative sign of obliquity for amputees meaning that they tend to lean trunk toward amputated leg.

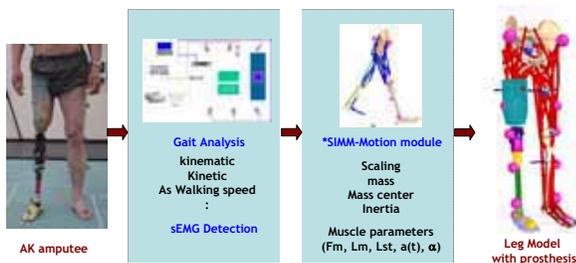

Figure 1 The configuration of experiment and simulation

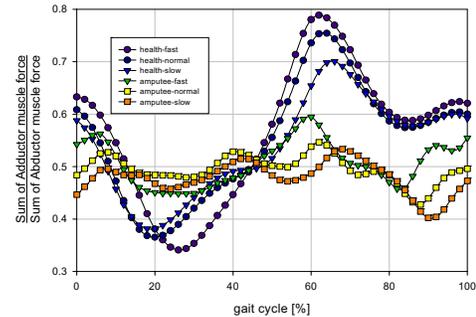

Figure 2: Comparison of the ratio of the sum of adductor muscle force with that of abductor muscle force

The muscle force of GMin is 11% (about 80N) and that of GMed is 20% (about 100N) over bodyweight(BW) less than those of the normal. The force of TFL and SAT is not different in pattern and scale. But that of PF is 39% of BW (about 390N) less than normal. The sum of adductor and abductor muscle force was less than that of normal at swing phase and at stance phase respectively. In view of the ratio of the sum of adductor muscle force to that of abductor muscle force, the weakened abductor during stance phase and the weakened adductor during swing phase were observed in contrast to normal subjects. And as walking speed increases, the force of abductor and adductor is vertically increased and decreased for normal gait. But for amputee gait they are shifted back as walking speed increases. (Figure 2)

### CONCLUSIONS

From musculoskeletal model for normal and amputee gait as walking speed increased, weaken abductor results in excessive adduction in the frontal plane and then inadequate valgus torque was generated. The PF, GMin and GMed in order were significantly weak ( $p < 0.05$ ). The abductor and adductor forces are vertically increased and decreased for normal gait but shift-back for amputee gait as the walking speed increase. By dynamic modeling of musculoskeletal motion during gait, it was found that the magnitude or pattern of muscle forces and moments was different between amputees and normal subjects in three dimensional planes.

**INTRODUCTION**

There has not been enough biomechanical research done about how motions occur in a series and about task-oriented motions. In particular, biomechanical characteristics of the sit-to-walk component of the Timed Up and Go Test have not been accounted for [1], although this series of motions is observed most frequently in daily living. Additionally, there is not enough intervention done to improve the sit-to-walk sequence. We often see people with physical disorders stand up and initiate gait unstably, and we often treat patients who have a history of falls and fractures from attempting to stand up and initiate gait.

The purpose of this study was to clarify the normal characteristics of this series of motions for healthy elderly people.

**METHODS**

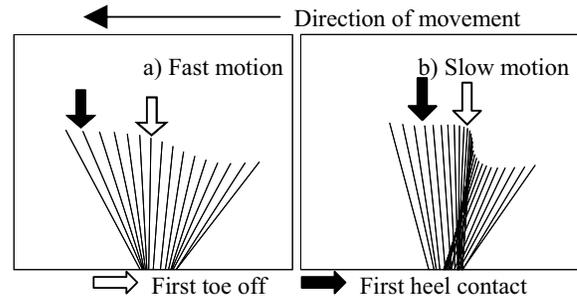

At first, as a pilot study we researched the patterns of the sit-to-walk for healthy elderly people [2]. We asked 18 healthy elderly people to stand up and walk as fast as possible, and we found that there are two patterns for this series of motions. One pattern involved small movements of the lower extremities, which is advantageous for fast motion. The other included large movements of the lower extremities, which are advantageous for stability, in spite of slower motion.

We defined these two motion patterns as the fast motion and the slow motion. In the present study, we analyzed the biomechanical characteristics of these two motions, while constraining the speed of the motions. The characteristics of 8 healthy elderly people (69.8±3.9 years old) were obtained.

Kinematic data was obtained by VICON 512 3D motion capture system (Oxford Metrix Ltd.). Kinetic data was obtained using two Kistler force plates. Ground reaction force (GRF) data was represented as  $F_x$ , right-left (left is plus),  $F_y$ , anterior-posterior (anterior is plus), and  $F_z$ , vertical (upper is plus).

**Table 1:** Difference between fast and slow motion

		fast	slow
<b>GRF</b>	$F_x$ [N]	64.7±12.8	61.6±11.9
	$F_y$ [N]	163.2±27.4	115.7±33.3
	$F_z$ [N]	592.1±70.3	605.2±75.5
<b>COM - CFP inclination</b>			
	First toe off [deg]	89.4±4.5	83.2±4.3
	First heel contact [deg]	105.5±5.9	93.8±5.7

**Figure 1:** Movement of COM and CFP at y-z plane from starting movement of the head to first heel contact

**RESULTS AND DISCUSSION**

The maximal value of GRF is indicated in Table 1. Only the component of  $F_y$  was significantly different between the fast and the slow motions ( $p < .001$ ). Inclination of the center of the body mass (COM) to the center of the foot pressure (CFP) at the first toe off and the first heel contact was larger in the fast motion than in the slow motion (more than 90 deg; forward inclination, less than 90 deg; backward inclination) ( $p < .001$ ) (Table 1). During the fast motion, the OFP barely moved at stand up, and then gradually moved forward. During the slow motion, the CFP moved forward at stand up, then moved backward and the first toe off was achieved (Table 1).

In the first swing of the sit-to-walk series, the maximal values of the vertical and lateral GRF of the stance leg were not different for both fast and slow motions. But the forward GRF was significantly larger in the fast motion. GRF means acceleration of COM. So only forward acceleration was larger in the fast motion. In the fast motion, the CFP moved forward gradually and constrained the forward movement of the COM, because the COM moved faster. In the slow motion, the CFP moved forward at stand up in order to constrain the COM movement. COM movement was slower in the slow motion, so the CFP moved backward in order to induce a forward COM movement. We believe that the forward GRF shows a force couple on the sole of foot, and the COM-CFP movement shows a reverse pendular model.

We did not analyze the motions that subjects actually carried out in daily living. This point is a limit of this study. But we think it is important to analyze sit-to-walk as a series of motions.

### INTRODUCTION

With the development of functional neuroimaging in recent years, several studies have been reported upon cortical reorganization induced by intervention in stroke patients [1,2]. The repetitive bilateral exercises improved functional motor performance of the affected upper extremity of hemiparetic patients [3].

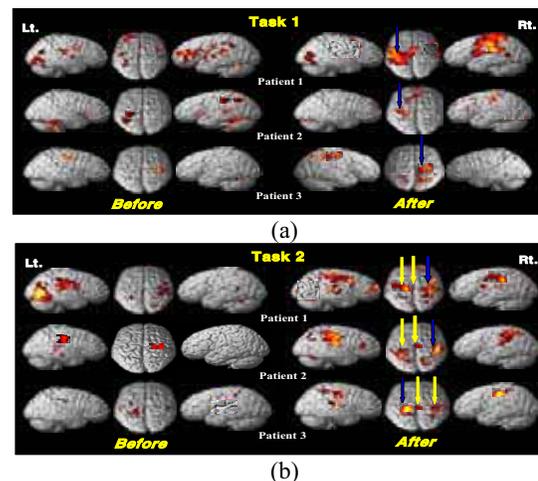

The purpose of this study was to demonstrate the effect of repetitive symmetric arm training, which was designed to improve upper limb function, on functional recovery and upon cortical activation changes in chronic hemiparetic patients using functional magnetic resonance image (fMRI).

### METHODS

A symmetrical upper limb motion trainer was made of M.C. Nylon suitable for MR environments and designed the affected side can be passively controlled with the same movement according to the active motion of the unaffected side. Totally six subjects participated in this study. As a control group, three of them were right-handed healthy male subjects (age: 34±5 years). In three patients (age: 43.3±6 years), two patients were left hemiparesis and the other was right hemiparesis. All patients received the training at 1hr/day, 5 days/ week during 6 weeks. Fugl-Meyer scores (FMS) were obtained every two weeks during the 6-week training. Before and after the 6-week training program, the blood oxygen level dependent (BOLD) fMRI measurements employing the echo planar imaging (EPI) technique (TR/TE/α=1900/40/90°, FOV=240mm, matrix size= 64×64 and slice thickness=5mm), were performed using a 3T MR scanner (GE Medical System, Milwaukee, USA) with a head coil. A T2-weighted anatomical volumetric images (FSE, TR/TE/α= 4500/104/90°, FOV=240 mm, matrix size=256×256 and slice thickness=5mm) were obtained. During fMRI experiments, two motor tasks were assigned to each subject: Task 1 was an only active wrist extension/flexion on the unaffected and Task 2 was the passive wrist extension/flexion of affected hand by an active wrist movement of unaffected side using the nonferritic device. Significance of the activation between the rest and the task was threshold at  $p<0.001$ .

### RESULTS AND DISCUSSION

In all three patients, FMS of the affected hands improved significantly after the 6-week training program ( $p<0.05$ ). In Task 1, the only dominant wrist movement, in control group, activations in the primary contralateral sensori-motor cortex (SMC) were observed. In Task 2, on the other hand, the passive wrist movement of the non-dominant hand driven by

**Figure 1:** Cortical activations before and after training during Task 1(a) and Task 2(b) ( $p<0.001$ ), increasingly activated (blue arrow) and newly activated (yellow arrow) areas compared before the training.

the active wrist movement of the dominant hand, activations in the primary bilateral SMC, supplementary area (SMA) and premotor area (PMA) were observed. In fMRI results in Task 1, a cortical activation in the contralateral (affected) side was observed after the training (Figure 1 (a)). However, Task 2 showed that the contralateral PMA of the unaffected wrist and the bilateral SMA were newly activated and activations in contralateral SMC increased in Patients 1 and 3. However, cortical activations in contralateral SMC of unaffected wrist, bilateral PMA and bilateral SMC were newly activated in Patient 2 (Figure 1 (b)).

### CONCLUSIONS

In three patients with chronic hemiparesis after brain injury, specific repetitive symmetric upper limb training appears to improve FMS and induce cortical reorganization. This association supports that developed arm trainer improves arm function by inducing reorganization of motor cortex networks.

## EFFECTS OF TAPING MATERIALS ON ISOKINETIC PERFORMANCE AT THE ANKLE MUSCLES

<sup>1</sup> Yang Hua Lin and <sup>1</sup> Chung Hung Wu

<sup>1</sup>Graduate Institute of Rehabilitation Science, Chang Gung University, Taoyuan, Taiwan; email: [linyh@mail.cgu.edu.tw](mailto:linyh@mail.cgu.edu.tw)

### INTRODUCTION

Athletic taping has been one of the most popular methods to support the weakened joint. Although there have been the positive effectiveness of ankle taping on the range of ankle motion there are few reports about the effect of taping materials on the joint performance such as muscle activity. The purpose of this study was to examine effects of different taping materials on isokinetic performance of the ankle muscles. The null hypotheses was proposed as taping could not affect significantly neither the isokinetic performance of the underlying muscles nor those in accordance with different taping materials.

### METHODS

Forty-five young healthy adults (mean age=24.7 ± 3.4 yr) without any history of ankle sprain within past six months were volunteered to participate in this study and randomized into three groups as a non-elastic taping group (n=15) with athletic white tape, an elastic taping group (n=15) with kinesio tape and a control group (n=15). Tapings was done along the tibial anterior and the peroneal group according to the principles provided by Illustrated Kinesio-Taping [1]

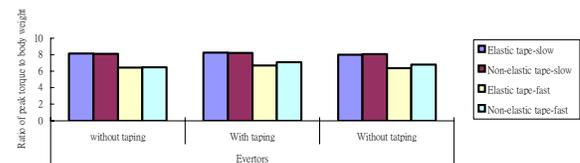

CYBEX NORM™ system was used to measure isokinetic performance of ankle muscles with concentric dorsiflexion-plantarflexion and eversion-inversion movements of the ankle, which were interpreted as ratio of peak torque to body-weight values ratio for reciprocal concentric contraction at angular velocity of 60°/sec and 120°/sec. There were three conditions to be tested as (1) untaped condition, (2) taped condition, and (3) untaped condition for the two groups with using two different tape materials

Each subject did three repetitions of contraction at each condition with assigned slow and fast speeds. The data were examined with ANOVA to determine the statistical significance of the factors of conditions and groups.

### RESULTS AND DISCUSSION

Types of taping material did not show the significant difference in isokinetic peak torque of ankle muscles except ankle invertors with non-elastic taping compared with that in the control group without any taping (Table 1.). The isokinetic peak muscle torque significantly affected by the testing speed as previous studies but did not show a combined effect by the taping materials used.

Regardless the taping materials were used, the isokinetic peak torque of ankle evertors at slow speed and fast speed showed significantly better performance under taped condition than those showed under untaped condition (Figure 1.), which occurred in the ankle invertors at fast speed as well.

**Figure 1.** Isokinetic peak torque of ankle evertor under taped vs untaped condition

### CONCLUSIONS

In this study, taping materials did not demonstrated significant effects on the isokinetic peak torque of ankle muscles. When the ankle was taped the ankle evertors showed significantly increased isokinetic peak torque, which was compared with those under untapped conditions before and after.

## PATELLA ALTA IS ASSOCIATED WITH PATELLOFEMORAL MALALIGNMENT AND REDUCED CONTACT AREA

Samuel R. Ward, Michael R. Terk, and Christopher M. Powers

Musculoskeletal Biomechanics Research Laboratory, Department of Biokinesiology and Physical Therapy  
University of Southern California, Los Angeles, CA email: sward@ucsd.edu

### INTRODUCTION

Patella alta or “high riding patella” is a condition that is thought to predispose individuals to patellofemoral joint dysfunction. The purpose of this study was to compare patellofemoral alignment and contact area in persons with patella alta to subjects with normal patellar position and determined the association between the vertical position of the patella, patellofemoral malalignment, and contact area.

### METHODS

Twelve patients with patella alta and thirteen subjects with normal patellar position participated. The presence of patella alta was determined using the Insall-Salvati index as measured on sagittal magnetic resonance images of the knee [1]. Mediolateral patellar displacement, tilt, and patellofemoral joint contact area were quantified from axial MR images of the patellofemoral joint obtained with the quadriceps contracted and the knee at 0°, 20°, 40°, and 60° of flexion.

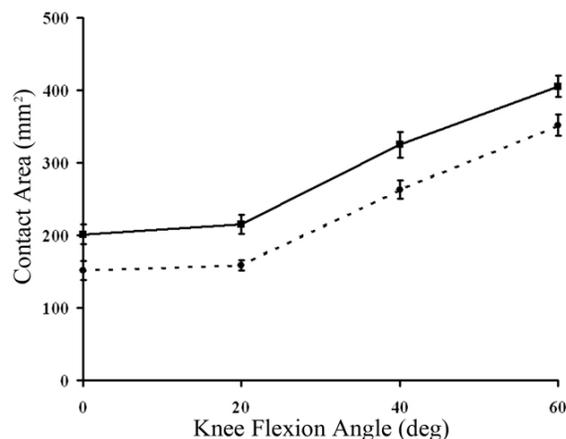

Statistical comparisons between groups were made as a function of joint angle using two-way ANOVAs with repeated measures. *Post-hoc* Tukey tests were used to identify between group differences at each knee flexion angle when significant interactions were present. Values are reported as mean  $\pm$  SE unless otherwise noted.

### RESULTS AND DISCUSSION

Lateral patellar displacement was greater in subjects with patella alta compared to subjects with normal patellar position at 0° of knee flexion ( $85.4\% \pm 3.6\%$  versus  $71.3\% \pm 3.0\%$  of patellar width lateral to midline,  $p < 0.007$ ). However, group differences were not observed between 20° and 60° of knee flexion. Lateral patellar tilt was also greater in subjects with patella alta compared to subjects with normal patellar position ( $21.6^\circ \pm 1.9^\circ$  versus  $15.5^\circ \pm 1.8^\circ$ ,  $p = 0.028$ ). Again, group differences were not observed between 20° and 60°. Subjects with patella alta had systematically less patellofemoral joint contact area compared to subjects with normal patellar position. On average, these individuals had 19% less contact area in the range of knee flexion angles tested ( $231.2 \pm 9.1 \text{ mm}^2$  vs.  $286.7 \pm 8.8 \text{ mm}^2$ ,  $p < 0.001$ ; Figure 1). However, a maximum difference of 26% was observed at 20° of knee flexion ( $158.5 \pm 10.6 \text{ mm}^2$  vs.  $214.9 \pm 10.2 \text{ mm}^2$ ).

The vertical position of the patella was positively associated with lateral patellar displacement ( $r^2 = 0.365$ ,  $p < 0.020$ ) and lateral patellar tilt ( $r^2 = 0.274$ ,  $p = 0.002$ ) at 0° of knee flexion. At knee flexion angles between 20° and 60° these associations were no longer significant. The vertical position of the patella

was negatively correlated with patellofemoral joint contact area at all knee flexion angles tested ( $r^2 = 0.404 - 0.196$ ,  $p < 0.05$ ) with greater degrees of patella alta being associated with less contact area.

**Figure 1.** Total patellofemoral joint contact area was measured as a function of knee flexion angle in control subjects (solid line) and patients with patella alta (dotted line). There was a significant reduction in contact area in the patients with patella alta across all knee flexion angles tested.

### CONCLUSIONS

Our data confirm the clinical assumption that patients with patella alta have greater degrees of patellofemoral joint malalignment compared to persons with normal patellar position. The reduced contact area observed in this population supports previous investigations that have found persons with patella alta demonstrate elevated patellofemoral joint stress (force per unit area) during functional tasks [2]. The association between patellar position and patellar malalignment was strongest at full knee extension, which suggests that this is a position of instability in this patient population.

## SCALING OF HUMAN LOWER EXTREMITY MUSCLE ARCHITECTURE TO SKELETAL DIMENSIONS

Samuel R. Ward, Laura H. Smallwood and Richard L. Lieber

Department of Orthopaedic Surgery, University of California and VA Medical Center, San Diego, CA; email: rlieber@ucsd.edu

### INTRODUCTION

Modeling is widely used by investigators to understand neuromusculoskeletal disorders. Architectural properties of the muscles in these models are based on estimates from a relatively small sample of cadaveric specimens [1,2]. Given that the skeletal dimensions of modeled individuals will almost certainly vary from the skeletal dimensions of the cadaveric specimens, architecture must be scaled to match the skeletal dimensions of the modeled subjects. However, these assumptions have never been tested in humans. Therefore, the purpose of this study was to define the scaling functions of human architecture to measured skeletal dimensions.

### METHODS

Eight formaldehyde-fixed cadavers were prepared by skinning and isolating the quadriceps and hamstring muscles. The mass of each muscle was measured after dissection and isolation from adjacent muscles. Fiber lengths and pennation angles were measured from three to five predetermined locations within each muscle using digital calipers and a goniometer. Sarcomere lengths for each muscle fiber bundle were determined by laser diffraction using the zeroth to first order diffraction angles as previously described [3]. To account for variations in muscle fiber length that occur during fixation, fiber bundle lengths were normalized by scaling measured sarcomere length to a standard sarcomere length for human muscle of 2.7  $\mu\text{m}$  [4]. Using these normalized muscle fiber lengths, PCSA was calculated using the following equation [5]:

$$\text{PCSA (cm}^2\text{)} = \frac{\text{Mass (g)} \cdot \cos \theta}{\rho \text{ (g/cm}^3\text{)} \cdot L_f \text{ (cm)}}$$

where  $\rho$  represents muscle density (1.112  $\text{g/cm}^3$ ) [6] and  $\theta$  represents surface pennation angle.

Femur length (cm; distance from the greater trochanter to the lateral epicondyle) and body mass (kg) were measured as potential scaling factors for fiber length and PCSA, respectively. Since body mass was only available for five cadaveric specimens, statistics scaling PCSA based on mass

was restricted to these samples. Simple linear regression was used to determine the slope and strength of the association between architectural measurements and skeletal dimensions.

### RESULTS AND DISCUSSION

Muscle fiber length scaled poorly with femur length. In fact, only fiber length of the short head of biceps femoris scaled with femur length. In contrast, PCSA scaled well with body mass (Table 1). Although rectus femoris, vastus medialis and semitendinosus did not have statistically significant model fits, the PCSA of these two quadriceps muscles had good model fits and were close to achieving significance (*p-values* 0.05-0.06).

### CONCLUSIONS

Although more data are needed to fully elucidate these scaling relationships, these data represent a more robust sample than previous studies estimating architectural values [1,2]. However, based on these data, it appears that PCSA scales well with body mass but muscle fiber length does not scale, in general to femur length.

## ROTATOR CUFF MUSCLE ARCHITECTURE: IMPLICATIONS FOR GLENOHUMERAL JOINT STABILITY

Samuel R. Ward<sup>1</sup>, Laura H. Smallwood<sup>1</sup>, Jan Fridén<sup>2</sup>, and Richard L. Lieber<sup>1</sup>

<sup>1</sup>Department of Orthopaedic Surgery, University of California and VA Medical Center, San Diego, CA; email: rlieber@ucsd.edu

<sup>2</sup>Department of Hand Surgery, University of Göteborg and Sahlgrenska University Hospital, Göteborg, Sweden

### INTRODUCTION

Muscle architecture provides insight into the excursion and force generating ability of muscles. Previous studies comparing the architecture of the shoulder rotator cuff muscles failed to normalize muscle fiber lengths to sarcomere length and, consequently, the position of shoulder fixation influenced previous fiber length and physiological cross-sectional area (PCSA) estimates. The purpose of this investigation was to determine the architecture of the four rotator cuff muscles using fiber lengths normalized to sarcomere length.

### METHODS

Ten fresh-frozen shoulders were prepared by skinning, Formalin fixing, and rinsing in 1X PBS. The mass of each muscle was measured after sharp dissection from bony attachments. Fiber lengths and pennation angles were measured from three to five predetermined locations within each muscle using digital calipers and a goniometer. Sarcomere lengths for each muscle fiber bundle were determined by laser diffraction using the zeroth to first order diffraction angles as previously described [1]. To account for variations in muscle fiber length that may occur during fixation, fiber bundle lengths were normalized by scaling measured sarcomere length to a standard sarcomere length for human muscle of 2.7  $\mu\text{m}$  [2]. Using these normalized muscle fiber lengths, PCSA was calculated using the following equation [3]:

$$\text{PCSA (cm}^2\text{)} = \frac{\text{Mass (g)} \cdot \cos \theta}{\rho \text{ (g/cm}^3\text{)} \cdot L_f \text{ (cm)}}$$

where  $\rho$  represents muscle density (1.112 g/cm<sup>3</sup>) [4] and  $\theta$  represents surface pennation angle.

One-way repeated measures ANOVAs and *post-hoc* T-tests with Bonferroni corrections were used for between muscle comparisons. Values are reported as mean  $\pm$  SE unless otherwise noted.

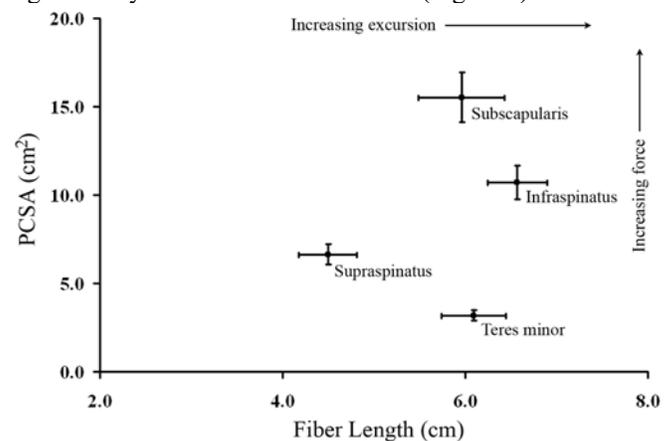

### RESULTS AND DISCUSSION

Masses were significantly different among all muscles. Subscapularis was the heaviest (101.8 g  $\pm$  11.5 g), followed by infraspinatus (78.0 g  $\pm$  7.5 g), supraspinatus (34.0 g  $\pm$  4.3 g) and teres minor (21.2 g  $\pm$  2.0 g) muscles.

Fiber lengths were significantly shorter in the supraspinatus muscle (4.50 cm  $\pm$  0.32 cm) compared to the infraspinatus (6.57 cm  $\pm$  0.33 cm), teres minor (6.10 cm  $\pm$  0.35 cm) and subscapularis (6.00 cm  $\pm$  0.47 cm) muscles (Figure 1). This is interesting in light of the fact that the supraspinatus and infraspinatus sarcomere lengths (3.23  $\mu\text{m}$   $\pm$  0.05  $\mu\text{m}$  and 3.18  $\mu\text{m}$   $\pm$  0.06  $\mu\text{m}$ ) were significantly longer than the teres minor

(2.80  $\mu\text{m}$   $\pm$  0.07  $\mu\text{m}$ ) or subscapularis (2.52  $\mu\text{m}$   $\pm$  0.09  $\mu\text{m}$ ) muscles. This implies that, at approximately neutral shoulder positions, the intrinsic length of the fibers is relatively long in these muscles. Secondly, it demonstrates that architectural studies that do not normalize muscle fiber lengths to sarcomere length significantly overestimate fiber lengths in supraspinatus and infraspinatus muscles.

The PCSA of supraspinatus (6.6 cm<sup>2</sup>  $\pm$  0.6 cm<sup>2</sup>), infraspinatus (10.7 cm<sup>2</sup>  $\pm$  1.0 cm<sup>2</sup>), teres minor (3.2 cm<sup>2</sup>  $\pm$  0.3 cm<sup>2</sup>) and subscapularis (15.5 cm<sup>2</sup>  $\pm$  1.4 cm<sup>2</sup>) muscles were all significantly different from each other (Figure 1).

**Figure 1.** Scatter plot of normalized muscle fiber length versus PCSA. Supraspinatus muscle had significantly shorter muscle fiber lengths than the other three rotator cuff muscles and all muscles had significantly different PCSAs.

### CONCLUSIONS

Based on architecture, subscapularis would produce the largest forces, while infraspinatus would operate over the widest range of shoulder positions. Surprisingly, supraspinatus has the shortest muscle fibers, indicating that its function as a glenohumeral stabilizer is limited to a relatively narrow range.

## THE EFFECT OF LOAD SCALING ON THE COORDINATION AND PERFORMANCE OF COUNTERMOVEMENT JUMPS

<sup>1</sup> Sarah E. Kruger, <sup>1</sup> Eric L. Dugan, <sup>1</sup> Philip B. Newell, and <sup>2</sup> Tim L.A. Doyle

<sup>1</sup> School of Physical Education, Sport, and Exercise Science, Ball State University, Muncie, IN 47306, USA

email: [sekruger@bsu.edu](mailto:sekruger@bsu.edu) web: [www.bsu.edu/biomechanics/](http://www.bsu.edu/biomechanics/)

### INTRODUCTION

In recent years, numerous studies have been conducted using dynamic systems theory (DST) as a means to examine kinematics and stability in human movement patterns. While the performance aspects of the countermovement jump have been studied heavily [1,2], the effect of load scaling on the coordination of the jump squat movement is currently unknown. It is likely that the changes in jump squat performance are mirrored by changes in jump squat coordination. Therefore, the purpose of this project was to assess the coordination and performance of the jump squat movement for multiple loading conditions using the principles of DST.

### METHODS

This study involved seventeen male participants ranging in age from 18 to 30 years (mean age  $21.1 \pm 2.6$  years). The mean body mass was  $94.5 \pm 18.2$  kg while the mean body height was  $1.78 \pm 0.06$  m. All participants were free of lower body injury at the time of data collection. Each participant was required to undergo an initial familiarization session which was utilized to determine the participants' three repetition maximum (3 RM) for the squat movement. That 3 RM value was then used to predict the one repetition maximum (1 RM) which was necessary to establish the amount of weight required for each loading condition during the jump squat testing session. For that actual testing session, two jump squats were performed for each loading condition, 0-60% of each participants' 1 RM incremented by 10% for each trial. Two-dimensional video capture was used to assess kinematics and a force platform in combination with a linear position transducer was used to determine power.

### RESULTS AND DISCUSSION

Regardless of the participants' strength background, the power output values decreased as the applied load was increased from 0-60%. No difference was found in the power values achieved during the lower loading percentages of 0-20%, which is significant because all but two participants reached their peak power by 20% of their 1 RM value. This finding

indicates that peak power is produced with little to no applied load. The mean power values for all participants can be observed in Table 1.

However as the power outputs were decreasing, the mean absolute relative phase (MARP) values for the shank-thigh and thigh-trunk relationships were increasing. This increase in MARP signifies that a more out-of-phase relationship was occurring between segments and two segments working in greater opposition indicates that a change in coordination is taking place. The MARP values calculated from 0-30% were found to be statistically similar and can be identified as the more highly coordinated jump squat trials. The values achieved above 30% of 1 RM, confirm that as the applied load was increased that the participants' were shown to deviate from their normal jump squat movement pattern. The mean MARP values can also be found in Table 1.

### CONCLUSIONS

More highly coordinated movement patterns and greater power output values were found to occur at lower percentages of load (0-30%). The lack of change observed from 0-30%, indicates that the participants were efficient in carrying out the jump squat movement at those percentages and that the movement pattern observed was the preferred pattern of motion. Since the results established for the unloaded condition were consistent with those found up to and including 30%, it can be concluded that jump squat performance was stable throughout that range of 1 RM percentages. On the whole, these results indicate that optimal jump squat performance is achieved at lower loading percentages and also suggest the existence of a relationship between power output and coordination.

## Kinematic Analysis of Kolman acrobatics in the High Bar Exercise

<sup>1</sup>Min-Chung Shen and Chien-Lu Tsai

National Taiwan Normal University, Taiwan

<sup>1</sup>Corresponding author; email: fast1123@mail.taipeilink.net

### INTRODUCTION

The high bar exercise is one of the six events in men's artistic gymnastics. Kolman, which is an element with super E difficulty, is categorized into the flight-acrobatic element group in the high bar exercise (Figure 1) [1]. The well execution of the flight-acrobatics which is difficult to perform is critical for getting a high score in a competition.

In this study, we used Kwon 3D analysis software to analyze the kinematical parameters of the images of Kolman acrobatics performed by an outstanding Taiwanese gymnast. The present results could provide some critical information to gymnasts to safely and perfectly perform Kolman.

### METHODS

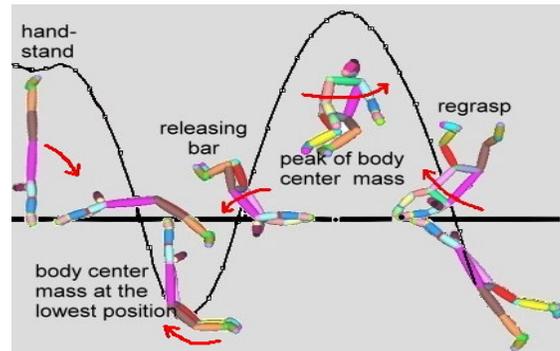

We used two high speed cameras (Redlake) with 125Hz recording frequency and 1/625 sec shutter speed were used to synchronously record the 3D images of the Kolman acrobatics. Digitalization of the recorded images and analysis of the kinematical parameters of the gymnast's body segments were carried out by Kwon3D 3.1 Performance System [2]. The values of the parameters were analyzed with the Mann-Whitney test to reveal the kinematical characteristics of Kolman and the important factors which determine the successful execution of this acrobatics.

### RESULTS AND DISCUSSION

In the period of gymnast swinging down from handstand, no parameter had significantly different values in the successful and failed Kolman. When the center-of-mass (COM) of gymnast's body arrived at the lowest position, the projected position of the COM in the failed Kolman was significantly farther away the projected position of the bar on the X-axis in the coordinate ( $0.24 \pm 0.02$  m,  $P=0.034$ ), comparing to that in the successful Kolman ( $0.17 \pm 0.05$  m). The value of the horizontal acceleration of the COM in the failed Kolman ( $-2.68 \pm 0.77 \text{m/s}^2$ ) was significantly smaller than that in the successful Kolman ( $1.19 \pm 1.56 \text{m/s}^2$ ) ( $P=0.034$ ). The results indicated that the gymnast may plucked the bar too early and then had an excessive component of force along the horizontal direction of body movement while he failed to perform Kolman (Table 1).

**Table 1:** Two kinematical parameters of the center-of-mass of gymnast's body when the center-of-mass arrived at the lowest position.

Kolman	Parameters	
	Projected position on the X-axis (m)	Horizontal acceleration ( $\text{m/s}^2$ )
Successful	$0.17 \pm 0.05$	$1.19 \pm 1.56$
Failed	$0.24 \pm 0.02$	$-2.68 \pm 0.77$
P value	0.034	0.034

**Figure 1:** The schematic process of completing Kolman. The change of the position of the gymnast's body center mass was illustrated by the curve.

The gymnast plucked the bar twice at different time points before released from the bar. The first pluck occurred when the gymnast's COM arrived at the lowest position; the second one occurred after the COM passed the lowest position. After the second pluck, the value of the horizontal acceleration of the COM in the failed Kolman ( $36.03 \pm 2.05 \text{m/s}^2$ ) was significantly higher than that in the successful one ( $30.42 \pm 2.28 \text{m/s}^2$ ) ( $P=0.034$ ). That probably caused an excessive force to overfly the bar and then led to a drawback in regrasping the bar.

### CONCLUSIONS

The timing to pluck the bar and the horizontal component of the bar-plucking force are likely to be the important tipping points to affect the performance of the gymnast who carries out the Kolman. We suggested that gymnasts and coaches should pay attention to the timing and the skills with which to pluck the bar for getting an adequate force to complete the whole acrobatics successfully.

### INTRODUCTION

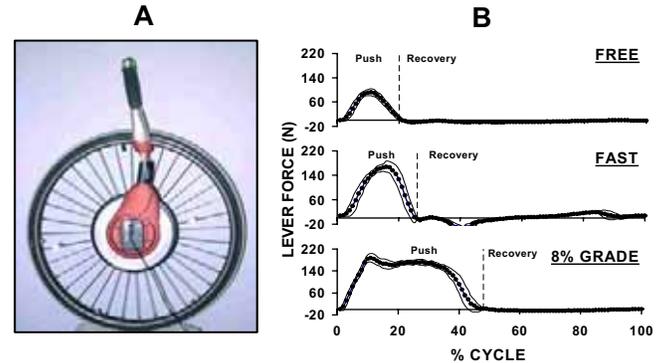

Lever-propelled wheelchairs (WC) have been described as more efficient and less physically demanding than pushrim-propelled WC [1]. Propelling with a lever mechanism is thought to provide a more effective transfer of power by placing the arms in a more natural segmental position and orientation [2]. In particular, those with limited energy resources or those with upper extremity pain/weakness may benefit from this alternative mode of manual WC ambulation. While demand on the upper extremities during standard WC propulsion has been documented [3,4], investigation of the upper extremity forces and moments magnitude and direction is required to better understand demands during ambulation with lever-propelled WC. The objective of this work was to determine the joint forces and moments during lever propulsion using a kinematic and kinetic model and an instrumented lever.

### METHODS

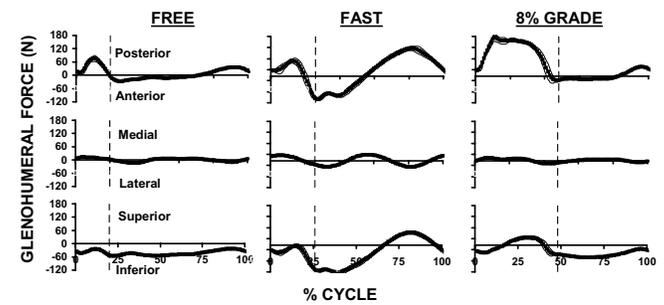

A set of prototype levers (Wijit®, SuperQuad) were custom fabricated and the right lever was instrumented with foil strain gauges (Micro Measurements) mounted below the handles (Figure 1A). Reflective markers were placed at the lever shaft and on the right upper extremity and trunk to define the three-dimensional motion of the lever, hand, forearm, upper arm, and trunk segments. Subjects propelled a lever-mounted Quickie GPV® WC positioned on a stationary custom WC ergometer [3]. Data were recorded at a self-selected free and fast propulsion speed (level ground simulation) and at a simulated 8% grade. Wheel torque (2500Hz, A/D Data Translation) and three-dimensional motion of the right upper extremity and lever was recorded (50Hz, Vicon®) during each 10-sec propulsion trial. Reaction force normal to the lever was determined from wheel torque and lever length. Upper extremity joint kinematics was determined from the recorded motion data using a Euler/Cardan rotation sequence. A 4-segment 3D upper extremity inverse dynamics model of the right upper extremity was implemented (Visual3D) to calculate the joint forces and moments during lever propulsion. Onset of reaction force was used to determine the push and recovery phase timing of each propulsion cycle (%CYCLE).

### RESULTS AND DISCUSSION

Mean hand reaction force (Figure 1B) and glenohumeral net joint forces (Figure 2) are shown for a 41 year old subject with T12 complete paraplegia (ASIA-A) for 17 years while propelling at free, fast, and graded propulsion. Vertical dashed lines represent the mean transition from the push to recovery phase. Peak lever forces occurred in the middle of push phase in free, the end of push phase in fast, and the beginning of push phase in graded propulsion. Peak posterior joint force was seen during the push phase in the free and graded

**Figure 1:** A) Instrumented Wijit® lever design. B) Lever reaction force during propulsion

**Figure 2:** Glenohumeral net joint forces during lever propulsion.

propulsion while peak force was seen during the recovery phase of fast propulsion. Medial/lateral forces were minimal. Inferior joint forces were seen in the push phase of free and fast while superior forces were seen in the push phase of graded and the recovery phase of fast, indicating the increased effects of inertial loads at high velocities and cadence. The relative difference between posterior and upward joint forces reflected a shift in upper extremity demands from vertical to horizontal direction compared to previously reported push phase forces with a standard pushrim WC [3,4]. Within-subject comparison of the upper extremities demands during lever and standard WC propulsion will be studied. The joint kinetic model allows us to investigate these demands during lever WC propulsion.

### INTRODUCTION

A biological body includes various electrolytes. Some studies tried to analyze the structure of organs with measurement of local electric impedance [1, 2]. To avoid the change of structure by movement of ions with a direct current, an alternating current is applied to measure electric impedance of electrolyte solutions. High impedance of a micro-electrode disturbs to distinguish signal of local impedance at specimen from that of the other part of the electric circuit. In the present study, a new methodology to measure local mechanical property has been proposed, and measurement system has been designed with a micro-vibrating electrode. The effect of viscosity on local impedance of the biological gel was evaluated with the proposed system.

### METHODS

The impedance between two electrodes soaked in an electrolyte solution varies with the distance between them. When the distance oscillates sinusoidally with a mechanically vibrating electrode, the impedance oscillates, too. The oscillation corresponds to the variation of impedance of the local space, where the electrode is vibrating. The variation was analyzed with spectrum and the amplitude at the corresponding frequency was measured. The electrode was made of a glass micro-capillary filled with a potassium chloride aqueous solution (3 mol/L). A platinum wire was inserted in the center of the capillary to decrease impedance of the electrode. The diameter of the tip of the capillary is 0.01 mm. One of the electrodes was vibrated with a piezoelectric actuator. The measurement system consists of an oscillator, an amplifier, a spectrum analyzer, a phase-contrast optical microscope, a charge-coupled device camera, and a monitor (Fig. 1).

The manufactured system was applied to measure electrolytes: the sodium chloride aqueous solution, the potassium chloride aqueous solution, a quail egg, and human blood. Variation was made in the viscosity of the solution with dextran. The viscosity was measured with a cone and plate viscometer. The measurement has been performed at 25 degrees centigrade.

### RESULTS AND DISCUSSION

The experimental data show that impedance increases with the decrease in the concentration of sodium chloride in the solution from 9.0 to 0.1 percent, and with the increase in the amplitude of vibration of the electrode to 0.023 mm. The results also show that impedance depends on the variation of electrolytes and that the ratio of impedance between the potassium chloride (0.1 percent) and sodium chloride (0.1

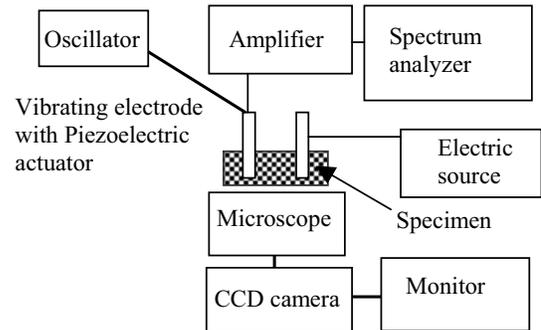

Figure 1: Measurement system.

percent) is 1.15, which can be approximated to 1.21 calculated from electric conductivity of chronological scientific tables. The experiment with a quail egg shows that the impedance is independently measured of that of the surroundings, when the electrode stuck into the yolk is vibrating: while the impedance varies with the concentration of electrolyte in the surroundings, when the electrode is not vibrating.

The signal was also picked up as a function of viscosity, when the electrode was vibrated in the sodium chloride aqueous solution including dextran. The impedance increases with viscosity at higher frequency (>100 Hz), and with frequency at higher viscosity (>0.01 Pa s).

The result with human blood shows that impedance of the blood varies with coagulation process.

### CONCLUSIONS

The experimental data show that the designed system is effective to detect the effect of viscosity on local impedance of biological gel.

## EMG BASED TRIGGERING AND MODULATION OF STIMULATION PATTERNS FOR FES-ASSISTED AMBULATION – A CONCEPTUAL STUDY

<sup>1</sup>Anirban Dutta, <sup>2</sup>Rudi Kobetic and <sup>1,2</sup>Ronald Triolo, PhD

<sup>1</sup>Departments of Biomedical Engineering and Orthopaedics, Case Western Reserve University,

<sup>2</sup>Motion Studies Laboratory, Louis Stokes VA Medical Center; email: [adutta@case.edu](mailto:adutta@case.edu)

### INTRODUCTION

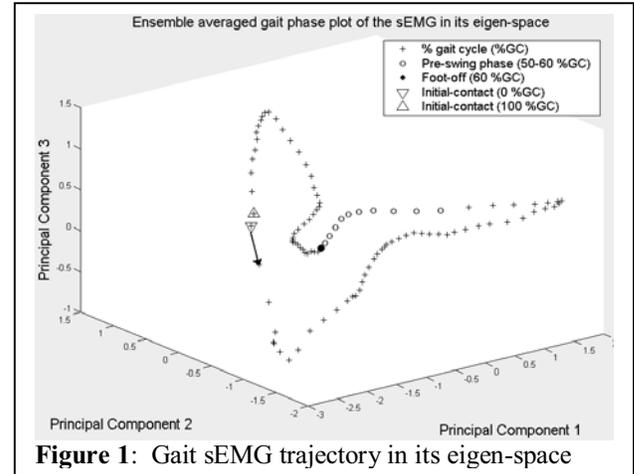

The surface electromyogram (sEMG) from the rectus-femoris is a good indicator of the gait-speed in able-bodied subjects [1], and may be used to temporally scale functional electrical stimulation (FES) patterns to change the speed of assisted gait [2]. The purpose of this study was to investigate the potential of utilizing the sEMG as both a proportional and discrete control source for FES-assisted ambulation after incomplete spinal cord injury (ISCI). The ability to modulate volitional sEMG was measured in two subjects with ISCI and four able-bodied volunteers to determine its suitability as a proportional command input for FES to paralyzed synergists. The muscle activations during over-ground walking of the able-bodied subjects were further analyzed to determine whether the sEMG can provide a consistent trigger that could replace of the mechanical switches currently employed during FES-assisted ambulation.

### METHODS

Two subjects with incomplete spinal cord injury (age 22 and 36 yrs, C7 ASIA C and T4 ASIA D respectively) and four able-bodied volunteers (ages 25 to 54 years) participated in the study. Subjects were positioned on a Biodex System3 dynamometer (Biodex Medical Systems, USA) with the knee fixed isometrically at 30 degrees of flexion while surface recording electrodes were positioned over the rectus-femoris. The sEMG was pre-amplified by a CED 1902 preamplifier (Cambridge Electronic Design, England) and low-pass (1000 Hz) filtered before sampling at 2200 Hz by AT-MIO-64F-5 data-acquisition card (National Instruments, USA). The rectified sEMG was normalized by the average value during maximum voluntary contraction (MVC) before modulating the vertical position of a tracking signal displayed to the subjects on a computer monitor. Subjects were instructed to track a rectified 0.01 Hz sinusoidal target signal of amplitude 0.7. A set of five, 100-second trials were taken for each subject and the results were ensemble averaged. Mean square tracking error (MSE) between the target and sEMG modulated pursuit signals were computed separately for the ascending and descending phases of each trial. Able-bodied subjects then participated in walking trials in which linear envelopes of the sEMGs were derived bilaterally from the tibialis, quadriceps, hamstrings, triceps surae and gluteal groups with the VICON motion analysis system (Oxford Metrics Ltd., Oxford, UK). Principal component analysis was performed to reduce the order of the data [3]. Analysis was then performed in the eigen-space of the sEMGs for pattern identification.

### RESULTS AND DISCUSSION

The MSE for the ISCI subjects were 6.72 % MVC during phases of increasing muscle activity, and 9.69 % MVC for the relaxation phases. The MSE for the able-bodied subjects were

6.39 and 5.59% MVC for the increasing and relaxation phases, respectively.

The first four principal components (PC) of the sEMG during able-bodied gait accounted for about 98% of the variance (%VAF) in the data. **Figure 1** shows the sEMG in its eigen-space defined by the first three PCs (90.67 %VAF). The data-points representing the pre-swing phase of the gait cycle were clustered together in a pattern and may be appropriate for use as a gait event detector. The presence of such a pattern of volitional muscle activations remains to be confirmed in a set of partially paralyzed muscles in individuals with ISCI.

### CONCLUSIONS

ISCI subjects performed as well as the able-bodied subjects during increasing muscle activity, while their performance degraded during relaxation of the muscle, implying that the sEMG may potentially be a proportional control source. Furthermore, a consistent pattern of muscle activation exists during the pre-swing phase in the able-bodied subjects. If such a pattern of volitional muscle activation exists during the switch activated FES assisted gait in ISCI subjects, then it might be used to replace the manual mechanical triggers and better integrate and coordinate stimulation with their intact voluntary function. This is the topic of current investigation.

## GRAVITY-INDUCED TORSION AND VERTEBRAL ROTATION IN IDIOPATHIC SCOLIOSIS

<sup>1</sup> Clayton Adam, <sup>1</sup>Mark Pearcy and <sup>2</sup>Geoff Askin  
<sup>1</sup>Queensland University of Technology, Brisbane, Australia  
<sup>2</sup>Mater Children's Hospital, Brisbane, Australia

### INTRODUCTION

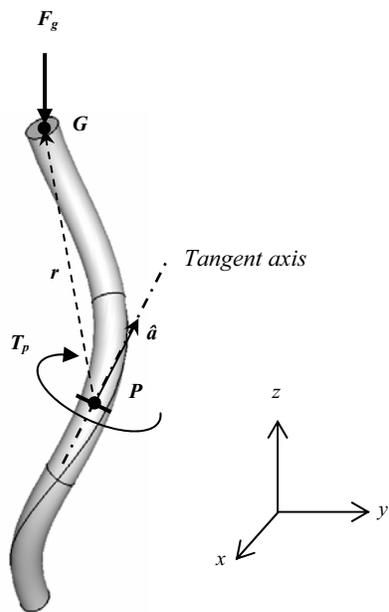

Vertebral rotation is an important aspect of spinal deformity in scoliosis, associated with ribcage deformity (rib hump). Although both lateral curvature and axial rotation appear to increase together in progressive scoliosis, the mechanisms driving vertebral rotation are not clearly established and it is not known whether lateral curvature precedes rotation, or vice versa. This study investigates the hypothesis that intravertebral (within the bone) rotation in idiopathic scoliosis is caused by growth in the presence of gravity-induced torsions, the twisting moments generated by gravitational forces acting on the scoliotic spine.

### METHODS

The twisting moment  $T_p$  acting at an arbitrary point  $P$  on a three-dimensional spinal curve is given by

$$T_p = M_p \hat{a},$$

where  $M_p = r \times F$  is the total moment due to gravity force  $F$  acting at (vector) distance  $r$ , and  $\hat{a}$  is the tangent to the spinal curve at  $P$  (Figure 1).

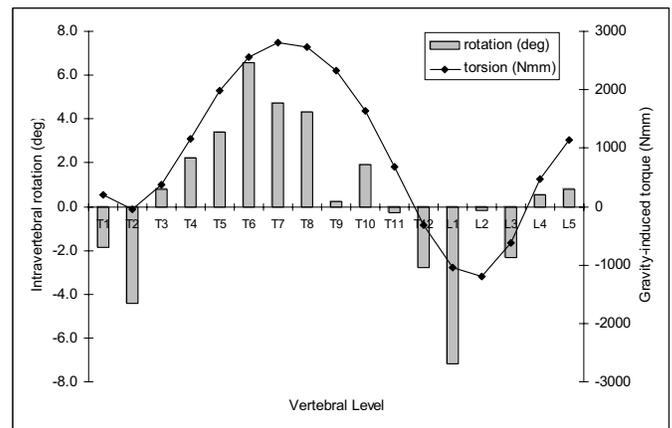

**Figure 1:** Torque  $T_p$  about a 3D curved column due to gravity loading  $F_g$

Standing radiographs for five idiopathic scoliosis patients were used to define three-dimensional curves representing the approximate axes of rotation of each spine, running along the anterior edge of the neural canal from T1 to S1. The equilibrium equations above were then solved to calculate gravity-induced torsions exerted by head and torso weight about the spinal axes for each patient. Intravertebral rotations

were measured for the same patients using Aaro & Dahlborn's technique [1] with reformatted computed tomography images in the plane of superior and inferior endplates of each vertebra. The gravity-induced torsion curves were compared with intravertebral rotation measurements to see whether gravity-induced torsion is a likely contributor to intravertebral rotation.

### RESULTS AND DISCUSSION

Gravity-induced torques as high as 4 Nm act on the spines of idiopathic scoliosis patients due to static body weight in the standing position. Maximum intravertebral rotations (for a single vertebra) were approximately  $7^\circ$ . There appears to be general agreement between the measured intravertebral rotations and profiles of gravity-induced torsion along the length of the spine (Figure 2). Rotation measurements confirm the finding of previous authors [2] that maximum intravertebral rotations occur at the ends of a scoliotic curve (with little relative rotation at the apex), and this finding is consistent with the gravity-induced torsion profiles calculated.

**Figure 2:** Comparison of gravity-induced torsion and measured intravertebral rotation for a single patient

### CONCLUSIONS

Gravity-induced torsion is a potential cause of vertebral rotation in idiopathic scoliosis. Since the spine must be curved in three-dimensions (out of plane) to produce such torques, vertebral rotation would be expected to occur subsequent to an initial lateral deviation, suggesting that coronal curvature precedes axial rotation.

## COMPUTER SIMULATION OF MOTORCYCLE-CAR ACCIDENT

Cheng-Yu Wu, Saiwei Yang,  
Institute of Biomedical Engineering, National Yang Ming University, Taiwan  
email: [swyang@ym.edu.tw](mailto:swyang@ym.edu.tw), web: <http://rehab.ym.edu.tw>

### INTRODUCTION

Motorcycle is a highly mobile transportation vehicle, due to least or no add-on protective device for the motorcyclist the accident is to result in severe spinal injury or fetal death. Head, knee and leg are reported over 45% of injury rate [1]. The accident reconstruction presentation is necessary to inspect the rationale and mechanism of accident occurring and responsibility due, For the purpose of injury mechanism and protection devices development computer simulation has been used extensively [2, 3, 4, 5].

The purpose of this study was to construct a light weight motorcycle-automobile accident computer simulation to understand the impact locations and forces on the body segments for the accident presentation and protective device development.

### METHODS

A motorcycle weighted 100Kgs and a car weighted 1200Kgs were modeled using ADAMS 11.0 (MSC software Co., USA). The motorcyclist was simulated as Hybrid III50% and constructed using LifeMod (Biomechanics Research Inc, USA). In addition, **Standard Pendulum-Hybrid III** impact experiment was used to validate computer construction of the dummy. Four common collision types were studied namely head-on, 90 degrees lateral impact, 45 degrees side-swipe, and bumper-rear-end collision.

### RESULTS AND DISCUSSION

The pendulum-dummy simulation showed well correspondence in acceleration-time slope. In the head-on collision simulation the motorcycle had speed of 35 Km/hr and car was 55 Km/hr at the time of collision. The head was hit on the windshield first with impact force of 7586N and then the head hit the ground first in prone position with force of 15,874 N (at time of 0.85 second)(Fig. 1). For the 90 degree side collision, the motorcycle speed was 34 Km/hr and car was 35 Km/hr, the motorcyclist had the arm and head hit on the front hood with impact force of 6976N and then had the shoulder hit on the ground in supine position first then turned to side wall( Fig. 2). The impact on the scapular was 10,033N (at 0.75 second). For the 45 degree-side collision, the speed of motorcycle and car was 35 and 55 Km/hr, respectively. The head hit on the engine hood first (at 0.93 second) and then fell across the hood with head on the ground (650N, 1.19 second) in prone position. For the bumper to rear end collision, the speed of motorcycle and car was 22 and 62 Km/hr, respectively. The buttocks were hit on the hood first with impact force of 9507N, then thrust anteriorly to the ground with butt hit first (Fig. 3). The force on the butt was 11320N and 9391N on the head at the time of impact to the ground.

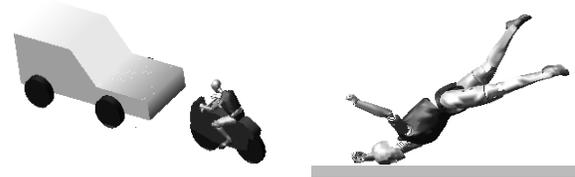

Fig. 1 : Head-on collision

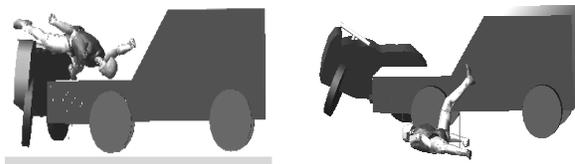

Fig. 2 : 90 degrees side impact

Fig. 3: Bumper to rear end collision

### CONCLUSIONS

The simulations showed the head was the most injured part, especial impacted to the ground after crashed by a car in any direction. 90 degree side collision resulted in shoulder severe injury when impacted to the ground. The bumper to rear end collision created a large momentum and resulted in sacrum-back trunk severe injury.

This simulation demonstrates a useful means for the motorcyclist garment development.

**The difference of net muscle torque of lower extremity by using different body segment parameter in gymnast**

<sup>1</sup> Wei-Hua Ho <sup>2</sup>Ching-Wen Hu <sup>1</sup> Tzyy-Yuang Shiang, <sup>3</sup>Chan-Chin Lee  
<sup>1</sup>Taipei Physical Education College, Taiwan; email: afa@tpec.edu.tw  
<sup>2</sup>Nanshan High School, Taiwan <sup>3</sup>Tzu-Chi medical center, Taiwan

**INTRODUCTION**

Body segment parameter (BSP) is an important data of biomechanics research, due to the difference of races, age, sex, fitness level, sports event and other factors of subjects, which would lead to disparity between reality and research results. Consequently, the purpose of this study is to compare and discuss the difference caused by using different body segment parameters models and ground reaction force to calculate net muscle torque during gymnasts during vertical jump.

**METHODS**

Four Taiwanese elite (2 male and 2 Female) participated in this study. Kistler force platforms and Kodak high speed video camera (10K Hz) were used to obtain the ground reaction force and kinematics data during vertical jump, then inverse dynamics formula (Enoka,2000) and three BSP models were applied to calculate the net muscle torque of joint of lower extremity. Three BSP models included cadaver method (Dempster, 1955), gamma-ray method (Zasiorsky 1983), and young Taiwanese male from MRI method (Ho, 2002) , and the subject's individual BSP which also established by MRI method.

$$SEE = \sqrt{\frac{\sum (x' - x)^2}{n}} \dots\dots\dots (1)$$

Those subjects individual BSP was used as the standard to calculate Standard Estimate Error (SEE) value and compare the difference of ankle, knee and hip joint kinetic data among the BSP models (equation 1).

**RESULTS AND DISCUSSION**

Table 1 show that the male and female gymnast SEE value of ankle, knee and hip joint net muscle torque during vertical jump. The joint net muscle torque of lower extremity

determined from MRI method and gamma-ray method was similar. But, the joint net muscle torque determined from the cadaver method was obviously larger than other BSP models. Especially, the SEE of hip joint net muscle torque was 7.4902 and 6.4252 for both male subjects. In the past, the most often used approach to establish segment inertial properties was the data obtained from elderly male cadavers (e.g. Dempster, 1955 et al.). But the results of this study show that Dempster's cadaver model has the largest SEE value when determine the joint net muscle torque. Therefore, appropriate BSP model should be chosen when the subjects' individual BSP is not available.

**CONCLUSIONS**

It is very important to choose the appropriate BSP model when doing human subject study which can reduce the inaccuracy of results. Researches should consider the similarity between the subjects of study and the subjects of BSP model, such as sex, age, race, living style, diet, fitness level, and representative of samples.

## HOW DOES OBESITY AND GENDER AFFECT FOOT SHAPE AND STRUCTURE IN CHILDREN?

<sup>1</sup> Annaliese Dowling, <sup>1</sup> Julie Steele and <sup>2</sup> Louise Baur

<sup>1</sup> Dept of Biomedical Science, University of Wollongong, Wollongong, NSW Australia,

<sup>2</sup> Dept of Paediatrics and Child Health, The Children's Hospital, Westmead, NSW Australia; email amd02@uow.edu.au

### INTRODUCTION

Obesity is a prevalent disease of today's society which has many negative consequences which affect an individual's quality of life. One system of the human body which is affected by obesity is the musculoskeletal system as it must endure the added mass and adiposity on a daily basis. It has been suggested that pathologies of the lower extremity may be exacerbated in obese individuals as a consequence of increased mechanical loading of the lower limbs by their additional mass (1-3).

As the feet are the foundation for stance and dynamic tasks, it is postulated that the increased loading associated with obesity would place the feet at risk of pathology. Obese children have been found to display an increased plantar contact area compared to non-obese children (3-5). In addition the foot shape and dimensions of obese children's feet were found to be different from children of normal mass. However, this was found in a small sample of 10 obese children therefore it is unclear whether this relationship exists in a larger sample of obese children. These children displayed significantly larger foot shape dimensions for 17 out of the 26 measurements recorded. These children's feet were broader, taller and thicker in comparison to the non-obese children (7). Therefore the purpose of this study was to determine whether the foot shape and foot structure characteristics of obese children's feet could be replicated in a larger population of children and whether it was moderated by gender.

### METHODS

Forty-five obese (30 girls and 15 boys;  $9.2 \pm 1.4$  years; BMI  $24.98 \pm 2.6$  kg/m<sup>2</sup>) children in the 7 to 12 year age group were matched to 45 non-obese children ( $9.2 \pm 1.4$  years; BMI  $16.34 \pm 1.2$  kg/m<sup>2</sup>), for gender, age and height. Height and weight were measured to calculate body-mass index and classified according to international cut-off values. Right and left static footprints were obtained using a pedograph to calculate the Arch Index of each child's feet to characterise foot structure. Twenty-six foot shape variables (lengths, breadths and circumferences) for both the right and left feet were recorded to characterise foot shape (8). Paired *t*-tests revealed 10 significant differences between the right and left limbs of the 90 subjects. Therefore, a random foot was selected for each subject via a random number generation for each subject before further analyses in order to limit any bias in the data. Means and standard deviations were calculated for the total sample for Arch Index derived from the footprints and the foot shape values. After testing for normality and equal variance, two-way analyses of variances (ANOVA;  $p < 0.05$ ) were calculated using the random foot data to determine whether there were any main effects of age and/ or gender on the dependent variables.

### RESULTS AND DISCUSSION

The mean Arch Index values obtained for the obese and non-obese children were  $0.23 \pm 0.05$  and  $0.17 \pm 0.08$ , respectively. While standing the obese children generated significantly greater plantar contact area indicating flatter feet compared to their non-obese counterparts, plantar contact area however was not affected by gender. Similarly, obese children have significantly greater foot dimensions for 17 of the 26 variables ( $p \leq 0.05$ ). The non-obese children displayed greater mean values for only two ankle dimensions although this was not significant. However, gender did affect the shape of the foot in children regardless of body type. In general the foot shape parameters were greater for the boys compared to the girls. From these results, it is evident that obese children have significantly broader, higher, and thicker structural features in their feet compared to their non-obese counterparts. The results in this study encompass a larger population of children and similar trends are showing through this data set more clearly than Dowling & Steele's (2001) and have greater mean foot shape values in comparison which may reflect the increasing prevalence of obesity in children. However, no significant interactions between gender and obesity were found for the dependent variables.

### CONCLUSIONS

Gender did affect the foot shape and structure in children regardless of their body type. The mechanism behind the obese child's foot shape and structure is currently unknown therefore more research is warranted examining the bone density and bone stresses to determine definitely whether obesity is detrimentally affecting the musculoskeletal architecture of obese children.

### INTRODUCTION

The plantar pressure pattern has been used as the evaluation tools for foot disorders, the numerical values of peak pressure in heel and metatarsal areas are usually critical, however, these local maximum values are highly affected by the walking speed, measurement sensing hardware as well as software used. By using an in-shoe pressure measurement system, Kernozek found that the plantar peak force tended to increase with gait speed mainly in the heel region, and almost no changes in the forefoot regions [1]. Hsiang et al [2] used a force plate and found out the path of center of gravity changed in faster walking speed which also resulted in an adverse effect on the variability and the reliability of the gait pattern. White et al [3] also found that increasing the walking speed induced higher peak ground reaction forces in loading response of a gait cycle but the reaction forces decreased linearly in mid stance, and no profound change in push off phase. Zhu's study showed that as walking cadence increased, pressure-time integrals and foot-to-floor contact durations decreased, and peak plantar pressures increased [4].

The objective of this study was to find out the effect of walking cadences to the plantar pressure by an innovative pressure platform-type system with higher sampling rate.

### METHODS

Ten healthy young volunteers without any foot pain or disorders, five for each male and female gender with mean ages of  $22 \pm 3$  years old and body weight of  $61 \pm 13$  kgs were recruited. The subjects were asked to walk along a 10M pathway with barefoot in three speeds normal walking speed, and 30% higher and lower of normal one on the RS-Scan 1M Footscan high frequency platform system (Rsscan Int. Belgium). Ten successful foot-print data of each cadence were collected for further analysis in nine interesting region namely toe mask (T1) five metatarsal head masks (M1,M2,M3,M4,M5), and two heel masks (H1, H2).

### RESULTS AND DISCUSSION

The average self-path normal walking speed was  $98.23 \pm 4.53$  steps/min, 30% lower was  $72.46 \pm 4.22$  steps/min, and 30% higher was  $132.57 \pm 6.37$  steps/min. The maximum peak plantar pressure was  $17.02 \text{ N/cm}^2 (\pm 3.39)$ ,  $21.02 \text{ N/cm}^2 (\pm 3.65)$ , and  $21.79 \text{ N/cm}^2 (\pm 4.05)$  for lower, normal, and higher walking speed, respectively. These peak values were at the left medial heel region. The pressures were linearly increased as walking speed increased, except at the left forefoot region which showed highest at the speed of normal walking (Figure 1 and 2). The contact time at each marked region was decreased as the walking speed increased. The maximum contact times of all subjects were at the right 3<sup>rd</sup> metatarsal head. The impulses were

also decreased as the speed increased but the maximum values were at left 2<sup>nd</sup> metatarsal head for all subjects.

These results are similar to that of referred studies except the plantar pressure at the left forefoot regions. Inman reported that the flexion angle at the loading response reduced by 67% when walked at 60m/min and by 38% at 120 m/min in comparison with 90 m/min. This study showed similar result at the left foot during midstance to push off response. This may imply that, the dominant leg (left foot in this study) is used to control the walking speed path which may result in changing of ground reactions

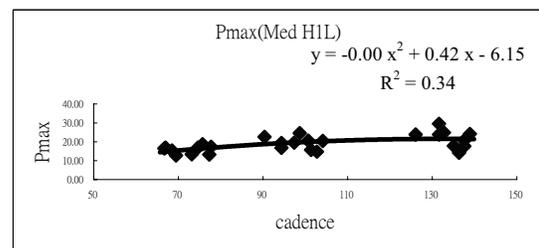

Fig. 1: The relationship of Peak pressure and cadence at left foot medial heel region

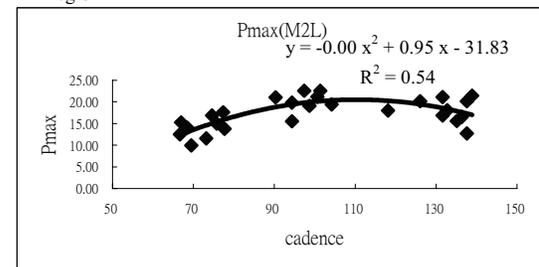

Fig. 2: The relationship of Peak pressure and cadence at left foot second metatarsal head

### CONCLUSIONS

The results showed that with second order linear regression the peak plantar pressure was basically increased as the walking speed increased except the left forefoot region which had its highest value at the normal speed. The contact time and impulse were decreased as the speed increased.

**IMMEDIATE EFFECTS OF AN INCLINED BOARD AS A TRAINING TOOL  
 FOR THE TAKEOFF MOTION OF THE LONG JUMP**

Hiroyuki Koyama,<sup>1</sup> Yuya Muraki,<sup>1</sup> and Michiyoshi Ae<sup>2</sup>

1. Doctoral Program of Health and Sport Sciences, 2. Institute of Health and Sport Sciences  
 University of Tsukuba, Japan, [koyama@lasbim.taiiku.tsukuba.ac.jp](mailto:koyama@lasbim.taiiku.tsukuba.ac.jp)

**INTRODUCTION**

Various methods have been used to learn and improve long jump techniques in training. Since simplifying practice conditions with the use of auxiliary tools is effective in improving techniques, jumpers frequently use auxiliary training methods. An inclined board from which a jumper takes off may be one of the most frequently used technical training tools. Although there have been some investigations on the characteristics of the takeoff motion from an inclined board, changes in the takeoff motion immediately after the use of an inclined board have not been investigated thoroughly. Therefore, the purpose of this study was to investigate immediate effects of the use of an inclined board on the takeoff motion of the long jump.

**METHODS**

Eight male long jumpers from the varsity athletic club were videotaped with two high-speed VTR cameras (250 Hz) set perpendicular to the runway. Four different kinds of jumps were performed: normal long jump, long jumps on upward inclined boards with different inclinations (2.5 and 5.0 deg), and jumps on a raised flat board (0 deg, but at height of 5 cm). To investigate immediate effects of the boards on the takeoff motion, pre and post trials were performed by subjects, using their normal technique, before and after the jumps from the boards. Two-dimensional coordinates of the body segments were reconstructed by using reference markers set on both sides of the runway. Linear and angular kinematics of joints and segments and the location of the center of gravity (CG) were calculated. To test differences between pre and post trials, dependent t-tests were used with a significance level set at 5%.

**RESULTS AND DISCUSSION**

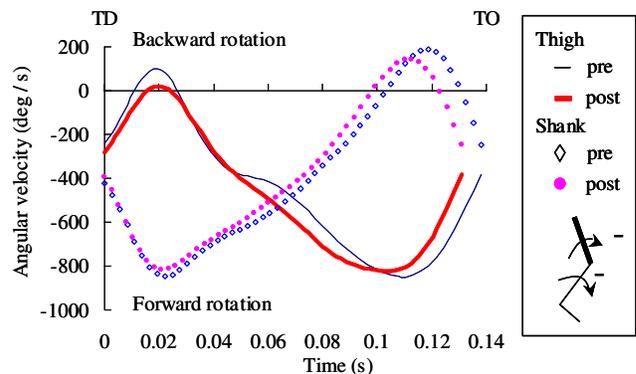

Jump distance for the post trial was significantly longer than that for the pre trial (post, 6.59 ± 0.29 m; pre, 6.48 ± 0.38 m; *p* < 0.05). Table 1 shows the CG velocity at touchdown (TD) and toe-off (TO)

**Table 1** Mean values of horizontal and vertical velocity (HV, VV) of the CG at the touchdown (TD) and toe-off (TO) of the takeoff, decreasing rate of the horizontal velocity during the takeoff phase, and ratio of the vertical velocity at toe-off to the reduction in the horizontal velocity during the takeoff phase (V-H ratio) for the pre and post trials

		Pre		Post		Difference (* <i>p</i> < 0.05)
		Mean	SD	Mean	SD	
TD	HV <sub>TD</sub> (m/s)	8.89	(0.35)	9.01	(0.31)	post > pre *
	VV <sub>TD</sub> (m/s)	-0.50	(0.17)	-0.61	(0.12)	ns
TO	HV <sub>TO</sub> (m/s)	7.42	(0.47)	7.69	(0.36)	post > pre *
	VV <sub>TO</sub> (m/s)	3.11	(0.16)	3.03	(0.14)	ns
	ANG <sub>TO</sub> (deg)	22.8	(1.4)	21.5	(1.2)	pre > post *
Decreasing rate of HV (%)		-16.6	(2.7)	-14.6	(2.0)	pre > post *
V-H ratio		2.17	(0.36)	2.34	(0.20)	ns

of the takeoff phase. There was no significant difference in the vertical velocity at the TD and TO between pre and post trials. The horizontal velocity at the TD and TO for the post trial was significantly greater than that for the pre trial, and the rate of decrease in the horizontal velocity during the takeoff phase for the post trial was significantly smaller than that for the pre trial. No significant difference between the pre and post trials was observed in the ratio of the vertical velocity at the TO to the reduction in the horizontal velocity during the takeoff phase. However, six of the eight subjects enhanced the ratio for the post trial (116.1 ± 10.3%) in comparison to that for the pre trial. These results indicate that the jumpers in the post trial were able to convert the horizontal velocity to the vertical velocity more effectively than in the pre trial, regardless of the higher approach velocity for the post trial.

Figure 1 shows the average thigh and shank angular velocities of the takeoff leg during the takeoff phase. Although there were no remarkable differences in patterns of the thigh and shank angular velocities during the takeoff phase, the forward rotation of the thigh just after the TD for the post trial was faster than that for the pre trial. Moreover, in the middle of the takeoff phase for the post trial, the thigh rotated faster than it did for the pre trial. An intersection of the thigh and shank angular velocities indicated the instant at which the takeoff leg knee flexed to its maximum. The intersection for the post trial appeared significantly earlier than that for the pre trial, resulting in less flexion of the takeoff leg knee for the post trial (post, 28.6 ± 4.1 deg; pre, 32.4 ± 2.8 deg; *p* < 0.05) and a larger knee joint angle at the maximum knee flexion for the post trial (post, 134.6 ± 4.9 deg; pre, 130.6 ± 6.5 deg; *p* < 0.05). The reduced knee flexion of the takeoff leg for the post trial was effective in exerting large extension torque because leg extension force abruptly decreased for a knee joint angle less than 130 degrees. These results reveal that inclined boards can induce immediate effective changes in the takeoff motion for the long jump, and that they would be an appropriate training tool for learning and improving the takeoff techniques of the long jump.

**Figure 1** Averaged patterns of angular velocities of the thigh and shank of the takeoff leg during the takeoff phase for the pre and post trials

## KINETIC ANALYSIS OF EACH HAND DURING GOLF SWING WITH USE OF AN INSTRUMENTED GOLF CLUB

Sekiya Koike, Hitoshi Shiraki, Norihisa Fujii and Michiyoshi Ae

University of Tsukuba, Ibaraki Pref., Japan  
Institute of Health and Sport Sciences, koike@taiiku.tsukuba.ac.jp

### INTRODUCTION

The roles of the upper extremities during golf swing are transfer of the energy generated by the lower extremities into a golf club and control the club head to place in a hitting point. Since the golf club is manipulated by both hands in swing motion, the upper extremities and the club make a closed multi-segment loop. Therefore it is impossible to determine the forces and moments acting on the club by each hand with only visual information of motion of the club. The purpose of this study was to investigate three dimensional kinetics of each hand using an instrumented golf club to measure forces and moments exerted on the grip handle of the club.

### METHODS

Figure 1 shows the structure of the instrumented grip handle. Eleven pairs of strain gages were attached on the outer diameter of an aluminium light weight rod. These strain gages were used to calculate: 1) The torsional moment acting on the grip axis between the hands; 2) The bending moments; and 3) The tensile and compressive axial forces. The output of the sensors was converted into the values of forces and moments by resolving the static equilibrium equations. Two spherical markers with negligible-mass shafts were attached on the club shaft for the purpose of measuring the orientation of the moving club. Two professional golf players volunteered to participate in this study as subjects. They swung three kind of clubs such as driver, number 5 Iron club and sand wedge. The positions of markers of the body segment endpoints and of the clubs were captured with VICON motion analysis system operating at 250Hz. A personal computer was used to store the strain gauge signals that were amplified through dynamic strain amplifiers. The sampling frequency of the force and moment data collection was 500Hz.

### RESULTS AND DISCUSSION

Figures 2 (a) and (b) show the forces exerted by each hand with respect to subject B during forward swing motion with the number 5 Iron club. These values are expressed in a swing club coordinate system  $\Sigma_{swc}$ , where the unit vectors of  $\Sigma_{swc}$  were defined as follows:  $z_{swc}$  is a normal unit vector of the swing plane,  $y_{swc}$  is a unit vector from club head to grip-end and  $x_{swc}$  is a unit vector perpendicular to these vectors. The horizontal axes of the figures denote normalized time from the beginning of forward swing motion (0%) to the impact (100%). The  $x_{swc}$ -axial force of the head side hand decreased slightly toward 30% time and increased gradually in the period of about 70% time, and then decreased rapidly toward the impact. The  $x_{swc}$ -axial forces of the hands showed inversion patterns approximately with respect to sign. The result indicates that the forces acted as couple force and did not accelerate the rotational motion along the swing plane just before impact. The  $y_{swc}$ -axial force of the head side hand kept constant value by 70% time and increased dramatically and reached the peak at approximately 90% time, and then it kept

the peak value toward the impact. On the other hand, the  $y_{swc}$ -axial force of the grip-end side hand showed a different pattern, increased gradually from 80% time to the impact. The resultant force increased gradually toward the impact due to increase in centrifugal force.

### CONCLUSIONS

To investigate kinetics of each hand during golf swing motion, an instrumented golf club with strain gauges was used to solve the closed multi-segment loop problem. From the results, the kinetic responses of the two players showed considerably different patterns with use of the clubs. The ability to quantify acting forces and moments of each hand during golf swing has the potential to (1) understand the mechanics of swing motion, (2) provide useful information for prediction of injury due to inappropriate swing.

### INTRODUCTION

Arm-hand function (AHF) is essential in activities of daily living. In patients suffering from cervical spinal cord injury (C-SCI) AHF is severely impaired. During rehabilitation they have to learn to use their residual capacities to (partially) compensate for the loss of function [1]. In some cases muscle transpositions are carried out to restore a specific arm or hand function. Many AHF test use a time score as a critical factor. However, such tests do not provide insight in either the quality of movements, nor in the mechanisms that govern compensation of function loss and the associated changes in muscle co-ordination that occur in C-SCI patients [2].

A 3D robotic arm (HapticMaster, FCS Control Systems BV, NL) has been developed with which movement-specific force may be exerted on a subject performing an upper extremity task, thus controlling the movement trajectory/position, velocity and acceleration of the arm (figure 1).

The aim of the present study is to investigate the potency of the HapticMaster (HM) in simulating activities of daily living (ADL) and to investigate the effects of specific changes in the applied force and resistance on muscle activation patterns during upper extremity task performance.

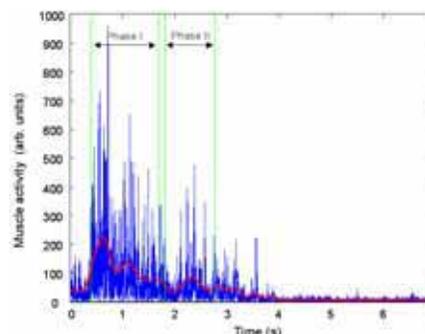

**Figure 1:** Experimental setup **Figure 2:** Cylinder grip

### METHODS

15 healthy volunteers, (m/f=6/9; mean age 24.6 yr, range 21-30 yr; mean height 1.76 m, range 1.50-2.00 m) participated. Subjects, while seated, performed 2 standardised ADL tasks, i.e. lifting a full soft drink can vertically over a distance of 30 cm (phase 1) and back (phase 2) using a cylinder grip (task A) (figure 2) and moving a small light weight object horizontally over a distance of 30 cm from left to right and back using a 3-point grip (task B). Task C and D were identical to A and B as to spatial displacement, but objects' masses were simulated by the HM. Each task was performed 8 times (trials).

Activity of 21 (focal and postural) muscles of the arm and trunk was recorded using surface EMG (sample rate: 1000 Hz; Sample time: 7s. Also object displacement was recorded using an IR-camera system (PRIMAS, Delft Motion Analysis, Delft, NL). Data were analysed off-line using MATLAB (The Math

Works Inc., Natick, Mass). EMG data were full wave rectified, low-pass filtered (2<sup>nd</sup> order Butterworth filter) and normalised to the movement cycle (figure 3). Within-subject signal reproducibility and between-subject signal similarity were assessed using intraclass correlation coefficients (ICC) across trials. Similarity between muscle activation patterns between task A/C and B/D was assessed by calculating correlation coefficients (R) for all muscles.

**Figure 3:** Example of EMG recording

### RESULTS AND DISCUSSION

Within-subject reproducibility, expressed as mean ICC, was higher than 0.80 in 77.4% of all cases. ICC values in task A and C were generally higher than in task B and D. ICC values associated with between-subject reproducibility were higher than 0.60 in 79.8% of all cases. Mean R-values were above 0.60 in 81.0% of cases for task A and C and in 95.2% of cases for task B and D.

### CONCLUSIONS

During the 'real world' ADL tasks and the HM simulated tasks similar muscle coalitions were activated. This finding corroborates the idea that the HM may be used to develop and adequately simulate upper extremity tasks conditions with which arm muscle function may be evaluated. This is especially important in those persons whose arm function is impaired and who receive rehabilitation treatment to improve their arm-hand function performance. Next to the evaluation aspects the HM may offer the opportunity to train arm performance in patients with sensorimotor deficits caused by impairments of the central nervous system.

## EFFECTS OF AFO-ASSISTED ANKLE ANGLE POSITION ON DYNAMIC KNEE STABILITY IN BRAIN INJURED AND SPINAL CORD INJURED PATIENTS

<sup>1)</sup> D. Beckers, <sup>1)</sup> A. Waelen, <sup>1,2)</sup> H.A.M. Seelen

<sup>1)</sup> Rehabilitation Foundation Limburg, Hoensbroek, The Netherlands

ham.seelen@irv.nl

### INTRODUCTION

In stroke patients and patients with an incomplete spinal cord injury (SCI) normal gait is affected. One of the problems is the lack of ankle control due to either paresis of the ankle dorsiflexors and/or spasticity of the calf muscles, causing either primary toe-strike or, in mild paresis, drop foot. Another phenomenon observed is (often extreme) knee hyperextension in the latter part of the stance phase, often aggravated by weakness of the quadriceps muscles. This knee hyperextension can be viewed as an attempt to stabilise the knee to facilitate push-off. However, next to the kinematic inefficiency, this hyperextension will, over time, cause severe damage to the joint at its ligaments. Whereas it has been shown that the use of an ankle foot orthosis (AFO) does not impair lower leg muscle function [1], the effect of AFO use on knee dynamics has not been investigated systematically. Aim of the present study was to assess the effect of AFO-assisted ankle angle position on knee motion and walking symmetry in patients with unilateral dropfoot or pes equinus due to stroke or incomplete SCI.

### METHODS

14 subjects (4 incomplete SCI and 10 stroke patients; m/f=8/6; mean age 48.5 (13.6)) participated. All subjects were able to walk unaided for at least 20 m. Gait was evaluated in three AFO conditions: no-AFO (NA), AFO with an ankle angle of 0° dorsiflexion (AA0), and AFO with an ankle angle of 10° dorsiflexion (AA10). Each patient used a custom-built AFO. A hinge at the ankle level facilitated the use of several (fixed) ankle angles (figure 1).

**Figure 1:** Ankle foot orthosis with variable ankle angle.

Gait timing parameters were recorded using bilateral insole pressure sensors (IDM, RIS GmbH, Berlin, Germany). Sample rate was 50 Hz. Sample time was 1 minute. Bilateral knee joint movement was recorded using 2 biaxial electrogoniometers (Penny & Giles, XM110, Biometrics,

Gwent, UK). Data were recorded at 100 Hz on a portable data logger (Porti-24/ASD, TMS Int., Enschede, NL) (see figure 2).

**Figure 2:** Equipment used.

Maximum knee extension and knee flexion ratio (FR) between affected and unaffected limb were calculated. Data were analysed off-line using Matlab software (The Math Works Inc., Natick, Mass). Statistical analyses included Friedman two-way analysis by ranks. Post-hoc multiple comparison was performed using Wilcoxon signed ranks tests.

### RESULTS AND DISCUSSION

Average maximum knee extension at the affected side was 4.8° larger in condition NA relative to condition AA10 ( $p < 0.01$ ), whereas differences between NA and AA0 (NA: 3.3° more knee extension) as well as between AA0 and AA10 (AA0: 1.7° more knee extension) failed to attain significance levels. As to walking symmetry, ankle angle manipulation did not lead to significant changes in either the FR between AFO conditions or in the stance phase duration between conditions.

### CONCLUSIONS

Changing the ankle angle of an AFO may be used in stroke patients and in incomplete SCI patients suffering from either dropfoot or pes equinus to reduce harmful knee hyperextension during gait. Optimal active knee control is present when the knee remains (slightly) flexed. In contrast, gait symmetry seems not to be influenced by manipulation of the AFO ankle angle in these patients. Although other AFO parameters may also influence knee hyperextension during gait, like stiffness of the AFO and heel height, a stiff AFO or a high heel may reduce or even prevent normal rocking of the foot during the stance phase, thus reducing walking ability. This trade-off between different AFO characteristics should always be kept in mind.

## A BIOMECHANICAL ANALYSIS OF SPIKE MOTION FOR DIFFERENT SKILL LEVELS OF MALE VOLLEYBALL PLAYERS

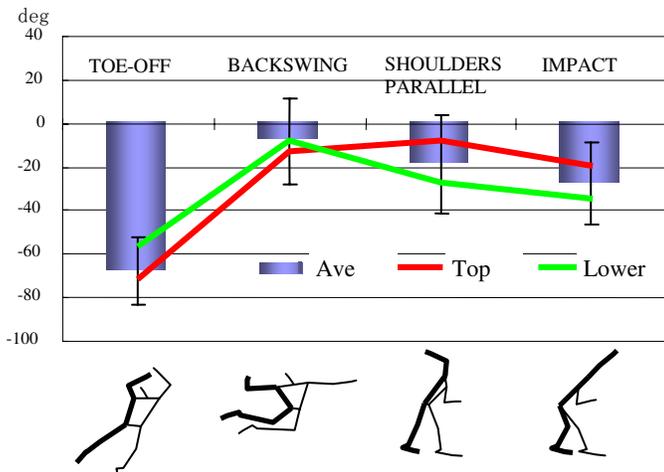

<sup>1</sup>Walter Quispe Marquez, <sup>1</sup>Masanao Masumura, <sup>2</sup>Michiyoshi Ae  
<sup>1</sup>Master Program of Health and Sport Sciences, <sup>2</sup>Institute of Health and Sport Sciences  
 University of Tsukuba, Japan

### PURPOSE

The purpose of this study was to three-dimensionally analyze the spike motion for world elite and Japanese university volleyball players, and identify differences in swing motion to obtain information for coaching spike techniques.

### METHODS

Eighteen male volleyball players ( $1.94 \pm 0.07$  m,  $85.7 \pm 8.67$  kg) participated in this study as subjects. Nine were national players from Canada, Serbia Montenegro, and Japan, and seven university players of Japan. Spike motions of Serbia Montenegro and Japanese players were recorded during two official games of the World League (2002, Osaka) with two high-speed VTR cameras (250 Hz, 1/1000 sec). Canadian players and Japanese university players' spike motions were captured with Vicon Motion System 612 (eight cameras, 120 Hz) using 39 reflexive markers. 3D data from VTR were reconstructed using a DLT method. Data smoothing was done with a Butterworth digital filter and the Wells and Winter method at optimum cutoff frequency of 5~12Hz. The trial in which the fastest right hand velocity at impact was obtained for each subject was used for further analysis. The subjects were grouped by the right hand velocity as a criterion. The five fastest and the five slowest players were referred to as the top and lower groups, respectively. Upper arm joint angle and joint angular velocity were primary variables for comparison of spike motions. Right hand height and velocity at the impact, trunk kinematics and relative velocity between segment end points were also computed. The data were normalized from the toe-off to the impact as 100% and averaged every 1%. Right hand velocity at the impact was related to the other variables by Pearson's correlation coefficient with  $P < 0.05$ . Differences between the two groups were tested with t-test at  $p < 0.05$ .

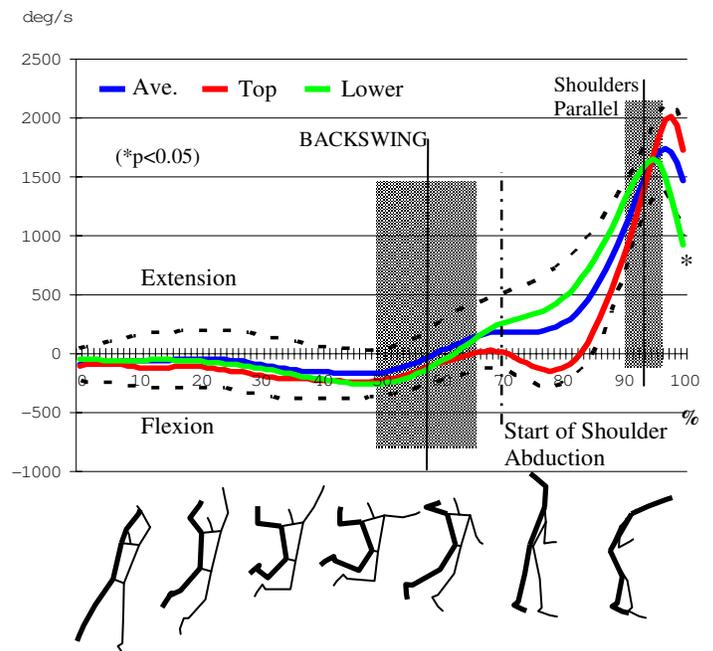

**Figure 1:** Right shoulder horizontal adduction/abduction angle.

### RESULTS AND DISCUSSION

Right hand velocity at the impact was significantly related to the shoulder abduction and horizontal adduction angles at the toe-off.

Figure 1 shows the right shoulder horizontal add/abd angle at the events of spike motion for the average, top and lower groups. During the backswing phase following toe-off, the top group elevated the upper arm. However, the lower group abducted the right shoulder considerably smaller than the top group. Figure 1 indicated that the lower group started the horizontal abduction earlier and greater than the top group. Moreover, the horizontal adduction at the impact was greater in the lower group than that of the top group. The right shoulder was accelerated through the forward rotation of the trunk, and then, the upper arm horizontal adduction was retarded in the top group in the forward swing, whereas the lower group precociously adducted the shoulder mentioned above.

Figure 2 shows the change in angular velocity of the right elbow joint after the toe-off. Although there was no difference in the pattern of the elbow angular velocity before the start of rapid shoulder abduction (indicated by a vertical dotted line in figure 2), after the start, the elbow angular velocity for the top group became negative, and then increased rapidly toward the impact. This indicated that the lower group continued extending the elbow after the start of shoulder abduction while the top group could use stretch-shortening cycle to increase the elbow extension velocity.

**Figure 2:** Right elbow angular velocity from toe-off to impact moment. Ave=average

## EFFECTS OF GAIT TRAINING WITH TREADMILL AND SUSPENSION IN CHILDREN WITH SPASTIC CEREBRAL PALSY

<sup>2</sup>Department of Rehabilitation Medicine, Chi-Mei Medical Center,

<sup>3</sup>Institute of Biomedical Engineering, College of Engineering, National Cheng Kung University, Tainan, Taiwan  
email: rjc47@mail.ncku.edu.tw

### INTRODUCTION

Independent ambulation is a big concern for the family of the children with cerebral palsy (CP). How to improve the children's ambulatory ability is considered the primary focus of most therapeutic interventions. The purpose of the study was to examine the effect of a 12-week gait training with treadmill and suspension on the gross motor function measure and gait performance in children with spastic CP.

### METHODS

Eight children with spastic CP met the inclusion criteria and participated in the study. Children were pair matched based on their functional category with Gross Motor Function Classification System and then randomly divided between two groups AB and BA. Children in the AB group first received regular therapeutic exercises except gait training for 12 weeks then received treadmill and suspension gait training for another 12 weeks. The sequence of treatment program was reversed for children in the BA group.

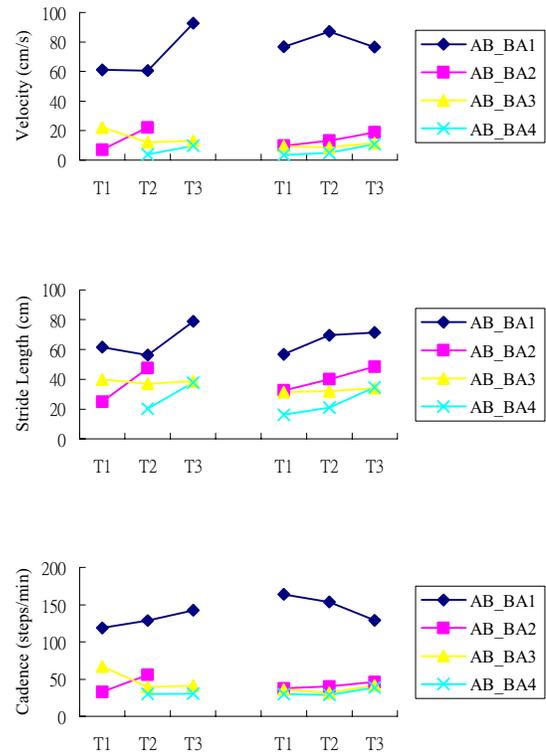

A commercial treadmill (Trackmaster TM210AC) capable of slow speeds with a minimum speed of 0.1 m/s and able to increase its speed with an increment of 0.1 m/s was used for gait training in this study. Suspension was achieved with LiteGait (LiteGait, Scottsdale, AZ). A harness was provided to subjects for weight suspension and safety during gait training. One therapist sat behind the child and corrected for foot placement during gait training. The regular therapeutic exercises were based on traditional pediatric exercises. The treatment duration of treadmill gait training or therapeutic exercises was 2-3 times a week and 30 minutes a time.

Gaitrite electronic walkway system (GAITrite, CIR. Systems Inc. Clifton, NJ 07012) was used to measure the gait temporal-spatial characteristics of the subjects in the study. Other than temporal-distance parameters of gait, muscle tone, selective motor control, gross motor function measure were assessed and measured three times: before treatment (baseline), after the first phase of treatment and after the whole session of treatment.

### RESULTS AND DISCUSSION

The gait performance of each subject at three measurement times is presented at Figure 1. The results showed that gait velocity, and stride length improved after gait training with treadmill and suspension. No change of cadence was noted. As the gross motor function measure was concerned, the treadmill gait training effect was significant on the sub-scores of standing, walking and the total score. The effect on sitting sub-score was only marginal ( $p = 0.0587$ ).

Our results are consistent with previous preliminary studies or

**Figure 1:** Gait performance of each subject at three measurement times

case reports of nonambulatory patients [1-3], showing that the task-oriented gait training is a promising treatment program.

### CONCLUSIONS

Children with spastic CP benefit from gait training with treadmill and suspension with partial weight support in stride length, gait velocity and certain gross motor functions. It is suggested that gait training with treadmill and suspension with partial weight support is a promising treatment for children with spastic CP.

**EFFECT OF A DUAL TASK ON WALKING PERFORMANCE IN PRESCHOOL CHILDREN**

Rong-Ju Cherng, Ling-Yin Liang and Yang-Ting Young

Department of Physical Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan  
 email: rjc47@mail.ncku.edu.tw

**INTRODUCTION**

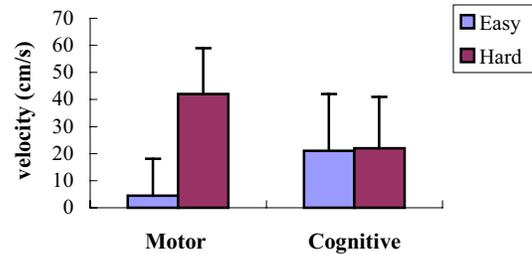

In many situations, children at preschool need to perform motor or cognitive tasks concurrently while walking. For example, they may be talking, carrying a lunch tray, listening to the teacher’s instructions, etc. when they walk. Therefore it is important to understand the potential effect of concurrent tasks on walking. The purpose of the study was to examine the influence of a concurrent motor or cognitive task on walking performance in typically developing preschool children.

**METHODS**

Fifty-five typically developing 4- to 5- year-old (M = 60.1 months, SD = 6.9) preschool children, 28 boys and 27 girls participated in the study. Each child performed 3 trials for each of the following 5 test conditions: free walking (single task), walking while carrying an empty tray (concurrent motor task – easy), walking while carrying a tray with 7 marbles inside the tray (concurrent motor task – hard), walking while performing a forward digit rehearsal task (concurrent cognitive task – easy), walking while performing a backward digit rehearsal task (concurrent cognitive task – hard). The sequence of the conditions was randomly determined for each child. The digit rehearsal task was adjusted individually according to each child’s digit span assessed before the experiment. Several measures of walking performance were collected, three of which were reported here: velocity (cm/s), stride length (cm), and cadence (steps/min). Repeated measures one-way ANOVA was used to analyze the differences of walking performance among single task: free walking, and dual motor task, and dual cognitive tasks. Two-way ANOVA (2 task x 2 level) was used to further analyze the dual-task cost interaction between type and difficulty level of secondary tasks. A level of 0.05 was used for statistical significance.

**RESULTS AND DISCUSSION**

Table 1 presents the walking performance under single and dual task conditions. There were significant difference of walking performance (velocity, stride length and cadence) between free walking and motor dual or cognitive dual tasks. However, there was no significant difference of walking performance between motor dual or cognitive dual condition. Figure 1 presents the dual-task cost of gait velocity between motor and cognitive dual tasks. The results showed a

**Figure 1:** Dual task interference cost of gait velocity

significant level effect ( $p < 0.001$ ) and the interaction effect of the type and level of the secondary tasks ( $p < 0.001$ ). However, there was no significant difference of the type effect (n.s.)

The reaction time of easy and hard cognitive task at single task test condition was significantly different with 1.16 s and 1.43 s respectively ( $F = 23.929, p < 0.000$ ). However, the reaction time of easy or hard cognitive task was not significantly different between at single task and at dual task. (1.16 s vs. 1.23 s;  $F = 2.666, p = 0.105$  and 1.43 s vs. 1.69 s;  $F = 3.121, p = 0.080$  respectively).

Combining the results of reaction time and the walking performance, we proposed that the reason of no difference of gait velocity between easy and hard cognitive task is that the interference of the cognitive task on gait velocity may be a fixed amount, not affected by its difficult level. Carrying a tray (motor dual task) needs visual monitoring, which may share a common visual motor control of gait. Carrying a tray with marbles in it needs more load of visual motor control than carrying an empty tray. Therefore, the interference effect was bigger with hard level than easy level of the task. Future studies are needed to investigate which phases or events of gait cycle are affected by the dual motor or dual cognitive tasks.

**CONCLUSIONS**

Children of 4- to 5-year-old have difficulty maintaining walking performance by decreasing their walking efficiency (decreasing speed, stride length and cadence) while concurrently performing other motor or cognitive task.

**Table 1:** Walking performance under single and dual task conditions

	Single Task Free Walking	Dual Task-Motor Task			Dual Task-Cognitive Task

## SHORTENING VELOCITY OF HUMAN PLANTAR FLEXORS IN VIVO AND ITS RELATION TO CONTRACTION INTENSITY AND KNEE ANGLE

Kazushige Sasaki and Naokata Ishii  
Department of Life Sciences, University of Tokyo  
email: [cc47710@mail.ecc.u-tokyo.ac.jp](mailto:cc47710@mail.ecc.u-tokyo.ac.jp)

### INTRODUCTION

To measure the intrinsic shortening velocity of human muscles in vivo, we have recently developed a technique, the principle of which is based on the 'slack test' developed by Edman [1] for single muscle fibers. Using this technique, the unloaded shortening velocity ( $V_0$ ) of contractile component can be determined without an effect of the recoil of series elastic component (SEC).

The purpose of this study is to measure  $V_0$  of human plantar flexors at varied levels of contraction intensity. In consideration of the biarticular structures of medial and lateral gastrocnemius muscles, we also examined if a change in knee angle affects  $V_0$ .

### METHODS

Eight male subjects participated in the present study. Each subject performed voluntary contractions on a custom-designed ankle dynamometer, with which high angular velocities (up to 20 rad s<sup>-1</sup>) can be attained. During the testing session, the subject's right foot was attached firmly to the footplate by using inelastic straps.

Isometric plantar flexion force was measured during maximum voluntary contraction (MVC) at an ankle angle of approximately 10-15° dorsiflexion. Then, while the subject performed an isometric contraction with a given force level (10%, 50%, and 80% of MVC), the footplate was released and rotated at a high speed (quick-release movement). The distance of release ( $\Delta L$ ) ranged between 35° and 50°, which is above the SEC strain of plantar flexors during MVC estimated in the previous studies [2,3].

Since a considerable ankle rotation occurs even during an isometric plantar flexion [4],  $\Delta L$  was corrected for the ankle rotation during an isometric contraction preceding the release by using an electrical goniometer. In addition, the force signals were corrected for passive force and inertia by using a transfer function. After correction, the time between the onset of release and the beginning of force redevelopment ( $\Delta t$ ) was determined (Figure 1). Relations between  $\Delta t$  and  $\Delta L$  for varied release distances were fitted with a linear regression, the slope of which provided  $V_0$  of plantar flexors.

All the subjects completed two testing sessions with the knee extended or flexed, which were taken on separate days. In the flexed knee position, the knee was flexed 120°, at which the biarticular gastrocnemius muscles can transmit negligible contractile forces to the calcaneus, as suggested previously [5]. Even in the extended knee position, the knee was slightly flexed (within 20°) to prevent pain or discomfort due to immoderate stretch of the gastrocnemius muscles.

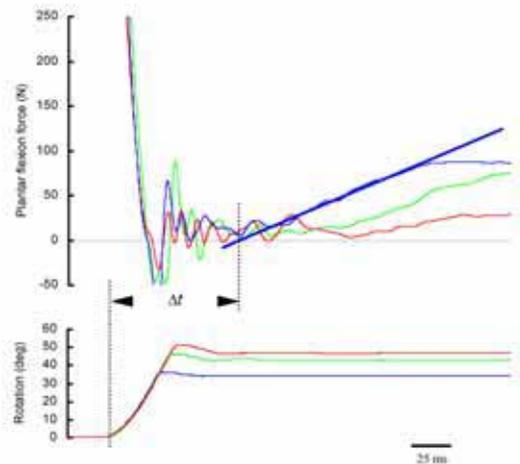

Figure 1: Superimposed force and angle recordings from three quick releases with different release distances.

### RESULTS AND DISCUSSION

Representative results from one subject (Figure 2) showed that  $V_0$  increased with contraction intensity in the extended knee position, suggesting progressive recruitment of faster motor units. In the flexed knee position, however, such a tendency was not observed. This may be due to the ineffectiveness of the gastrocnemius, which has a higher percentage of fast-twitch fibers and longer fascicles, to produce and transmit muscle forces.

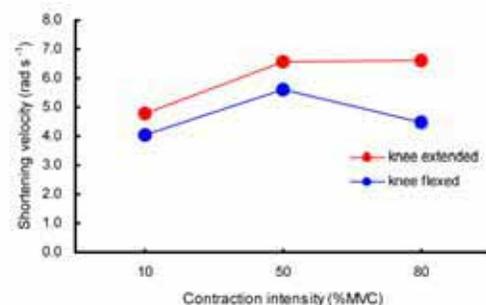

Figure 2: Representative relations between contraction intensity and  $V_0$ .

## THE INFLUENCE OF DIFFERENT MECHANICAL STIMULI AND GROWTH ON THE MECHANICAL PROPERTIES OF THE ACHILLES TENDON IN THE FEMALE RAT

Kirsten Legerlotz, Gert-Peter Brüggemann and Anja Niehoff  
 Institute for Biomechanics and Orthopedics, German Sport University of Cologne, Cologne, Germany  
 e-mail: Legerlotz@dshs-koeln.de

### INTRODUCTION

Even though tendon injuries rank among the most frequently occurring sport injuries [1], the adaptation of the tendon to exercise is not well investigated. It is known that different kinds of physical activity create different mechanical stimuli on biological materials leading to different adaptation effects. This has been shown for example for bone tissue [2] but had not yet been investigated for the tendon. Therefore, the aim of this study is to analyze the effect of running exercise, which creates single impacts with short rest periods between the impacts (~2.4 Hz)[3] in contrast to vibration strength training, that creates close following impacts; and growth on the mechanical and morphological properties of the rat Achilles tendon.

### METHODS

Forty-two female Sprague Dawley rats of 11 weeks age ( $233 \pm 20$ g) were divided into four groups: a basis control group (BC, n=10) that was killed at the beginning of the study; a non-active age matched control group (AMC, n=10); a voluntary wheel running group (RT, n=10) that was single housed and had free access to a running wheel; and a vibration strength training group (VST, n=12). The VST group trained voluntarily in a rat squat machine, where the rats had to lift a weight to reach a special food. When the weight was lifted a vibration plate (25 Hz) under the rat's feet was activated. Three rats of the VST group had to be excluded from the study, because they did not use the squat machine frequently enough. After a 12 week training period the rats were killed by decapitation and the Achilles tendon was dissected. The left Achilles tendons were at first cyclically tested with 30 cycles up to 10 N. With the last cycle the hysteresis and creep (in % of the original length) were determined. Afterwards the tendons were tested until failure to determine the ultimate load, ultimate load per body mass, stiffness and deformation. The right Achilles tendons were embedded in paraffin and will be sectioned and stained to determine the cross sectional area.

The significance of difference between the groups was determined by an one-way ANOVA. All statistical tests were evaluated using  $\alpha < 0.05$ .

### RESULTS AND DISCUSSION

The average running distance of the rats in the RT group was  $9.6 \pm 2.9$ km/day. The animals of the VST group lifted the weight (250 - 450g at the end of the study) for  $161 \pm 112$ s/day. At the end of the study the AMC group ( $327 \pm 31$ g) was significantly heavier than RT group ( $283 \pm 25$ g,  $p = 0.010$ ). There was no significant difference between the VST group ( $305 \pm 36$ g) and the other two groups concerning the body mass. Regarding the mechanical properties of the Achilles tendon, no significant differences could be found between the groups (Table 1). But if the ultimate load is adjusted according to body mass, the BC group revealed significantly ( $p \leq 0.001$ ) higher values than the AMC and the VST group. Thus, neither vibration strength training nor growth cause an increase in the ultimate load of the tendon but rather the ultimate load per body mass decreases. Running training seems to compensate an age related decrease of the ultimate load per body mass. These results indicate that the kind of mechanical stimulus has an influence on the mechanical properties of the Achilles tendon but that the tendon is predominantly influenced by growth effects in younger adult rats. These results are in line with the hypothesis of Smith et al. [4] who formulated that once an optimised tendon is formed during skeletal maturity no more distinct adaptation will occur.

**INTRODUCTION**

Postero-anterior mobilization involves the application of vertical forces on the human spine when the subjects lying prone. It is commonly used clinically for changing the spinal stiffness and symptoms of back pain patients. Previous research modeled posteroanterior mobilization as three-point bending of the lumbar spine, which was considered to be a beam supported at the pelvis and the thoracic cage [1]. But geometric effect of the spine on the segmental stiffness of the spine was still not be considered. The aim of this study was to measure the curvature change of the lumbar spine to PA mobilization of different lumbar spinal segments.

**METHODS**

Seventeen normal subjects (mean age = 30.71 ± 5.82, mean height = 1.71 ± 0.05m, mean weight = 65.53 ± 8.12 kg) agreed to participate in this study. Subject was requested to lie on the unpadded plinth with the face down. Posteroanterior mobilization force was applied to the spinous process of each level of lumbar spine by an experienced physiotherapist.

The spine was modeled as a beam support at thoracic cage and pelvic (Figure 1). Force applied to the spine was continuously monitored and captured by the use of a non-conductive force plate (4060-NC Bertec Corporation, Columbus, OH 43229, USA), which was mounted underneath the unpadded plinth. An electromagnetic tracking system (Fastrak, Polhemus Navigation, Colchester, VT) was used to measure the change in curvature of the spine. Two electromagnetic sensors were used to measure the local curvature change of the spine (e.g. Mobilizing L3, measure angle between L1 and L5 level). The bending stiffness (EI) of the spine was derived from the bending force and the local change in curvature of the spine by moment area method (Equation 1).

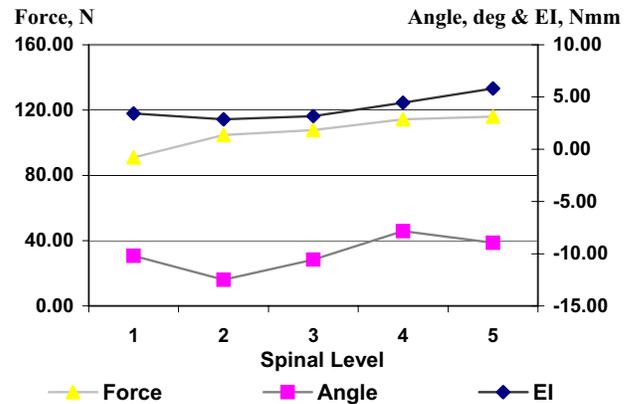

**Figure 1:** A beam model representing deflection of spine under posteroanterior mobilization.

$$EI = \frac{\int_b^a M dx}{\theta_{ab}} \quad \text{(Equation 1)}$$

**RESULTS AND DISCUSSION**

Figure 2 shows the result of mobilizing different lumbar level. The mean frequency of mobilization for all five lumbar levels was 1.64 ± 0.13 Hz. Higher force was applied to the spine when mobilizing L4 & L5 level, and more resulting spinal curvature change was found on these levels than the remaining levels. However, these levels were found to be stiffer than the remaining levels.

**Figure 2:** The average center of oscillation of the mobilizing force, change in spinal curvature (angle between L1 and L5) and stiffness (EI).

**CONCLUSIONS**

The influence of spinal level and geometry on bending stiffness should be considered when clinical changes in spinal stiffness were evaluated.

## VOLUNTARY STRENGTH TRAINING AND RUNNING EXERCISE INDUCE SITE-SPECIFIC BONE ADAPTATION IN ADULT FEMALE RATS

Anja Niehoff, Kirsten Legerlotz and Gert-Peter Brüggemann  
 Institute for Biomechanics and Orthopedics, German Sport University of Cologne, Cologne, Germany  
 email: [Niehoff@dshs-koeln.de](mailto:Niehoff@dshs-koeln.de)

### INTRODUCTION

Previous studies have confirmed that physical activity has a positive effect on morphological and mechanical properties of bones [1,2]. Nevertheless, one has to consider that different types of exercise affect specific bone adaptation [3,4]. The loading pattern of the mechanical stimulus, including strain rate, loading cycle frequency, strain direction and distribution, peak strain magnitude and number of cycles is of critical importance. Thereby, a high-frequency low-risk mechanical loading pattern turned out to be strongly osteogenic [5]. In addition, it was found that a low-frequency loading regime is osteogenic with a rest period between each loading cycle [6]. The purpose of the study was to analyze the effect of vibration strength training with a high frequency of 25 Hz in compared to running exercise with a low frequency of ca. 2 Hz [7] and rest between the loading cycles on bone mechanical and morphological properties in the adult female rat.

### METHODS

Forty-two 11 weeks old ( $233 \pm 20$ g) female Sprague-Dawley rats were randomly assigned to a basic control group (BC;  $n=10$ ), a voluntary wheel running group (RUN;  $n=10$ ), a vibration strength training group (VST;  $n=12$ ) and a non-active age-matched control group (AMC;  $n=10$ ). The RUN group had free access to a running wheel. The VST group trained voluntarily in a rat squat machine, where the rats had to lift a weight to reach special food. When the weight was lifted a vibration plate (25 Hz) under the feet was activated. The time of lifting the weight was monitored. After 12 weeks of exercise the rats were killed by decapitation and the right femur and tibia were dissected. Peripheral quantitative computed tomography (pQCT) was performed by transverse image sets of multiple slices at 7%, 7% + 5mm from the proximal tibial plateau and at 50% the total tibial length. Femora were scanned at 5, 5.5 and 6 mm from the distal plateau and at 50% of the total bone length. To determine the mechanical properties the bones were loaded until failure by a 3-point bending test using a material testing machine (Z2.5/TN1S, Zwick, Germany). The support distance

was 15 mm for tibia and 16 mm for femur. The broadness of support points was 2 mm for tibia and 4 mm for femur. The crosshead speed during testing was 10 mm/min. The cross-sectional moment of inertia was calculated from the pQCT measurements at 50% of the total length of the bone. The significance of difference between groups was determined by one-way ANOVA ( $\alpha < 0.05$ ).

### RESULTS AND DISCUSSION

Three rats of the VST group had to be excluded from the study, because they did not use the squat machine on a regular basis. The average running distance of the RT group was  $9.6 \pm 2.9$ km/day. The VST group lifted the weight (mass: 250-450g) for  $161 \pm 112$ s/day. At the end of the study animals of the AMC group ( $327 \pm 31$ g) were significantly heavier than those of the RT group ( $283 \pm 25$ g,  $p=0.010$ ). The mechanical properties of tibia and femur in the different groups are summarized in table 1.

**Tibia:** The cancellous BMD was significantly ( $p=0.001$ ) higher in the RUN group compared to the BC group. There were no significant effects of vibration strength training on the analyzed pQCT parameters. The BC group had always significantly ( $p<0.05$ ) lower values in contrast to the AMC, RUN and VST group.

**Femur:** On the diaphyseal site the RUN group had a significantly lower cortical area ( $p=0.003$ ), cortical ( $p=0.003$ ) and total ( $p=0.011$ ) BMC compared to the AMC group.

### CONCLUSIONS

Mechanical stimulation by exercise with different frequency regimes affects site-dependent bone adaptation.

## Kinetic Gait Analysis of Powered Gait Orthosis using Fuzzy logic Controller

SungJae Kang, Jei Cheong Ryu, Gyo Suk Kim, Seung Mun  
Korea Orthopedic & Rehabilitation Engineering Center(KOREC)  
Email: kangsj@iris.korec.re.kr, web: www.korec.re.kr

### INTRODUCTION

At KOREC, a prototype of a powered gait orthosis has been developed to reduce the energy consumption and the muscle fatigue. Each hip joint of the PGO is flexed by an air muscle operated by pressurized air enabling the patient to walk. The air muscle behaves like a human muscle and connects one side of the torso section to the upper part of the same side of the brace. The role of artificial muscle is to assist hip flexion during swing phase. Therefore, the patient can walk with less energy expenditure by using a PGO than using an RGO. The PGO a modification of an RGO[1] incorporating two pneumatic muscle actuators(PMA), a compressed air system, pressure and joint angle sensors. In the present study, PGO which controlled by fuzzy algorithm for hip flexion and analyzed for SCI patients who used the developed PGO with the three-dimensional motion analysis system.

### METHODS

The concept of the PGO driving system is to couple the right and left sides of the orthosis by specially designed hip joints and pelvic section. The driving system of powered gait orthosis(PGO) consists of the orthosis, sensor, control system. An supply system is composed of an air compressor, 2-way solenoid valve(MAC, USA), accumulator, pressure sensor. Role of this system provide air muscle with the compressed air at hip joint constantly(Fig. 1). PGO which controlled by fuzzy algorithm for hip flexion.

Two subjects(39±2.8 years) who were two adult normal male and one paraplegic male participated in this study. Subjects were recruited from the laboratory staffs and patient of the hospital. Their heights and weights ranged from 170±1.7 cm, 60.5±7.5kg, respectively.

Subjects were performed the gait analysis five times per one month after gait training on PGO during about three months.

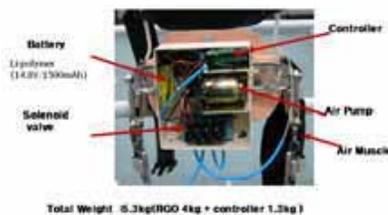

Figure 1: PGO system

### RESULTS AND DISCUSSION

This figure 2 shows the sagittal plane internal joint moment during a single gait cycle. As a results, the maximum hip flexion angles PGO's gait was 57° during swing phase and maximum hip flexion moment was 0.86Nm/kg. Maximum knee flexion/extension moments were about 0.89Nm/kg and 0.68Nm/kg. Maximum ankle dorsiflexion moments is 1.08Nm/kg. PGO's moment curve was similar to normal gait. The ratio of the duration of the swing phase of fuzzy controlled PGO gait shows 40.4% as an approximation to the normal gait.

Figure 2: Hip, Knee, Ankle moment

### CONCLUSIONS

We are proposed fuzzy controlled PGO's system using air muscle of hip joints for SCI patients. This PGO controlled by fuzzy controller looks like a excellent device comparative of others. Because the ratio of the duration of the swing phase of fuzzy controlled PGO was similar to the characteristic curve of normal gait. it directly became the causes to increase the gait speed of PGO.

**EFFECT OF BILATERAL ASYMMETRY OF LOWER MUSCLE FORCES  
 ON VERTICAL JUMPING HEIGHT: A SIMULATION STUDY**

<sup>1,2</sup> Shinsuke Yoshioka, <sup>2</sup>Akinori Nagano and <sup>1</sup>Senshi Fukashiro

<sup>1</sup> Department of Life Sciences (Sports Sciences), University of Tokyo, Japan; email: [syoshioka@riken.jp](mailto:syoshioka@riken.jp)

<sup>2</sup> Computational Biomechanics Unit, RIKEN, Japan

**INTRODUCTION**

Properties and function of each bilateral component of the human body are basically symmetrical. Thus, when human movements such as jumping and walking are investigated, a bilateral symmetry is assumed. However, in reality, they are not precisely symmetrical. Additionally, little is known about the effects of bilateral asymmetry of musculoskeletal properties on various human movements. It is hard to address this question using experimental protocols because of the difficulty in controlling the asymmetry of the human body.

The purpose of this study was to investigate the effects of bilateral asymmetry of lower muscle forces on the biomechanics of a vertical jumping motion using computer simulation.

**METHODS**

A model of 3D human body musculoskeletal system was developed using DADS-3D (LMS International). Segment inertial parameter and muscle parameter values were derived from [1] and [2], respectively. A dynamic activation mechanism to represent the transfer lag between the neural input signal and the musculotendon force development [3] was implemented. In addition, Hill-type muscle F-V-L relations, elements to limit the joint range of motion, and ground reaction force [4] were implemented. Fifteen muscles for each leg were implemented. Properties of each muscle were bilaterally symmetrical and derived from [5] and [6].

Two types of models were developed. One model had the same construction and properties as above mentioned (Model-Bal). Another model had basically the same construction and properties as above mentioned, except for the muscle force

(Model-Imbal). All muscle forces in the right leg of Model-Imbal were 5% greater than those of Model-Bal, while All muscle forces in the left leg of Model-Imbal were 5% smaller than those of Model-Bal.

Mathematical representations of the skeletal, muscle and activation dynamics were programmed in FORTRAN, then compiled with DADS-3D. Muscle activation profiles were searched using Bremermann's [7] numerical optimization method (Figure 1). The objective function was vertical jumping height.

**RESULTS AND DISCUSSION**

Jump movements were generated with the models above mentioned (Figure 2, 3). The jump movement of Model-Imbal was similar to that of Model-Bal. The jumping heights of Model-Bal and Model-Imbal were almost the same. However, actions of a few muscles such as m.gluteus medius were different between Model-Bal and Model-Imbal. It was revealed that the actions of those muscles are important for the coordination of jumping in Model-Imbal.

### INTRODUCTION

Composite bones are synthetic bones made of a hard glass-fibre reinforced epoxy shell (representing cortical bone) with a foam centre (representing trabecular bone). They are useful tools for experimental studies on orthopaedic implants as they have little variability between them, are more convenient to handle and store than cadaveric bones, and are cheaper and easier to source. Finite element (FE) models of composite bone can be used to evaluate new and modified designs of joint prostheses and fixation devices. Although FE models of the composite femur have been created and validated [1,2], no validated FE models of the composite tibia yet exist.

The aim of this study is to create an FE model of the composite tibia (Mod. 3101 Pacific Research Laboratories, WA, USA) and validate it against experimental results. As an initial step, the FE model was validated against the results obtained by Cristofolini and Viceconti [3], who measured deflections in the bone due to simple loading conditions.

### METHODS

CT (HiSpeed CT/i, GE Medical Systems, USA) images of a composite tibia taken at 2 mm intervals in the transverse plane were segmented, and 3D models of the outer surface geometry of the bone and the geometry of the surface between the epoxy shell and the foam were created (sliceOmatic, TomoVision, Virtual Magic Inc., Montreal, Canada). These two surface geometries are now available at the BEL Repository, <http://www.tecno.ior.it/VRLAB/>. The surface geometries were used to create a 10-node tetrahedral solid mesh of the tibia (MSC.Patran, 2004 r2, MSC.Software Corporation, USA). Five different meshes consisting of 64349 to 110363 nodes were created; convergence of the results was checked. The reinforced material and the foam were both assumed to be isotropic with Poisson's ratios of 0.3 and with Young's moduli of 14200 MPa and 69 MPa, respectively [3].

In the reported experimental study [3], the bending stiffnesses of eight composite tibiae were estimated by bending them in the latero-medial and antero-posterior planes. A four-point bending jig was used for load application (up to 500 N), while an extensometer was used to measure the mid-diaphysial deflection. The average results of five tests done on each bone, as well as the overall average, were presented. The experiments were simulated on the FE model (MSC.Marc, MSC. Software Corporation, USA) and model deflection and stiffness results compared to experiment.

In the reported experimental study [3], the torsional stiffness of the eight composite tibiae were estimated by applying a 5 Nm moment to the proximal end and measuring the angle of twist. The average torsional stiffness for each specimen, as well as the total average, was presented. To simulate the experiments on the FE model, two forces, parallel to each other and to the transverse plane, were applied to the proximal tibia. The surface nodes in the distal 30 mm of the tibia were fixed.

Model displacements were used to calculate the angle of twist and torsional stiffness and compared to experimental results.

### RESULTS AND DISCUSSION

For anterior-posterior bending, the FE analysis gave a deflection of 0.266 mm and a bending stiffness of 1880 N/mm. This stiffness is within 1% of the average experimental value and is well within the reported range of values [1]. For latero-medial bending, the FE analysis gave a deflection of 0.553 mm and a bending stiffness of 904 N/mm. This stiffness is within 4% of the average measured value and within the range reported [1].

For torsion, the FE analysis gave an angle of rotation of the proximal tibia with respect to the distal tibia of 0.762° and a torsional stiffness of 6.56 Nm/degree. This stiffness is just over 20% higher than the measured average and outside the maximum measured value as well [1]. While the reasons for this large discrepancy are not clearly understood, it is possible that simplified boundary conditions in the FE model which ignored the two end mounting pots in the experiment may have led to slight, yet unwanted, deflections in the model. The assumption that the material properties of the composite bone were isotropic may also have contributed to the error.

It is of interest to note that only the bending stiffness and torsional stiffness were compared between the experimental results and the FE model, as this was the only information reported on the experimented tibiae. The surface strains generated due to these types of loading were not measured in the reported study. Therefore, while the model can be used reasonably accurately in cases where deformations are concerned, it may not yield accurate results if stresses or strains are analysed. Further experiments using more comprehensive loading conditions have been done on a strain gauged composite tibia. These results are now being compared against FE results. Additional attention is being dedicated to the proximal epiphysis.

### CONCLUSIONS

This study has used the only reported experimental data on the second generation composite tibia (Mod. 3101 Pacific Research Laboratories, WA, USA) to validate an FE model of the same. The FE model can be used to evaluate conditions where bending predominates and should generate accurate results. However, for loading situations where torsion is predominant, less accurate results may be generated.

## Fusion of biomechanics data for patient monitoring in pediatric skeletal oncology

<sup>1</sup>Fulvia Taddei, <sup>2</sup>Marco Manfrini, <sup>3</sup>Alberto Leardini, <sup>3</sup>Maria Grazia Benedetti and <sup>1</sup>Marco Viceconti

<sup>1</sup>Laboratorio di Tecnologia Medica, <sup>2</sup>Dipartimento di Oncologia Muscolo-scheletrica, <sup>3</sup>Laboratorio di Analisi del Movimento Istituti Ortopedici Rizzoli, Bologna, Italy; email: [tecno@tecno.ior.it](mailto:tecno@tecno.ior.it); web: [www.tecno.ior.it](http://www.tecno.ior.it)

### INTRODUCTION

The term *data fusion* indicates the methods and the technologies that allow the synergistic combination of disparate data into a new dataset, which potentially contains more information than the sum of the original data. We applied data fusion to combine medical imaging, movement analysis, muscolo-skeletal modeling, and finite element analysis data, into a coherent representation of local skeletal loading during certain motor tasks. This approach has been used to estimate the risk of fracture under fully unprotected walking in pediatric patients, which underwent a major skeletal reconstruction due to the presence of a bone sarcoma.

### METHODS

At each periodic control the patient is examined with a CT scan of the reconstructed and of the contro-lateral regions. In the first post-operative control, we also perform a complete MRI examination of the lower limbs.

Whenever possible, before the imaging session, the patient is instrumented with a redundant set of radio-opaque and reflective markers, firmly attached to the skin. This includes four markers per segment in addition to those used for a standard gait analysis [1]. The movement analysis session is accurately planned in advance among the surgeon, the physiatrist, and the bioengineers, in order to maximize the collected information, while minimizing the risk of spontaneous fractures. This required the development of a special protocol for children, which considers the need, in the early stages of the follow-up, of protected walking.

CT, MRI and all movement analysis data (kinematics, ground reaction forces, EMG) are imported into a data fusion application (Data Manager, B3C, Italy), which allows the complete spatial and temporal registration of all data, using the skin landmarks as fiducial points. Data are then processed to extract the skeletal geometry, the distribution of mineral density inside each bone, the joint centers, the line of action and the lever arm of all relevant muscles, etc. The software provides also a virtual palpation environment that allows the accurate definition of the joint reference systems following the ISB standardization, and let you compute all biomechanical quantities necessary to predict the muscle and the joint forces with static optimization. At the same time the bone data are processed to create a subject-specific finite element model. Loaded with muscle and joint forces, the model predicts the stresses and strains induced in the bone for each time frame of the recorded task [2]. Robust quality insurance protocols are used to monitor all instrumentations. All uncertainties are factored into a Montecarlo simulation that provides a full sensitivity analysis on the stress predictions [3]. The stress results are then imported back in the Data Manager and fused with the rest of the data. Using the advanced interactive

visualization features of the Data Manager, the stress results are reported to the medical professionals fused with the anatomical (imaging) and functional (gait analysis) data of the patient (Fig. 1). This dramatically improves the efficacy of doctor-engineer communication.

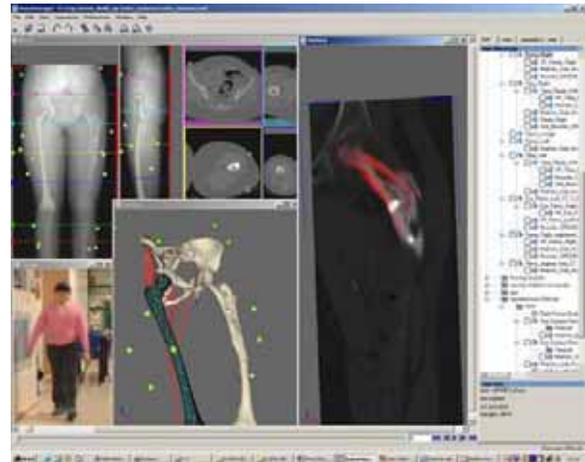

Fig. 1 The DataManager environment. In clockwise order, from top-centre: the CT dataset taken with the markers attached to the patient skin; the FEM results mapped onto the CT volume; the FEM model of the right femur within the muscle-skeletal model used to predict muscle forces; a movie of the walking task. On the right the tree structure used to organize the different data.

### RESULTS AND DISCUSSION

So far the method has been used with 4 patients; for 2 of them we already have more than 5 controls. The only warning raised with this procedure so far, was confirmed by sub-capital slippage complication during unprotected walking, occurred a few months later.

The method is becoming in our hospital the *de facto* standard for planning the rehabilitation protocol in these very difficult cases. This poses major problems, as the whole procedure currently requires a large amount of time to collect, process and analyze all these data. However, we are optimistic that improvements in the software algorithms can provide the level of automation that is necessary for large-scale clinical usage. In the meanwhile, preliminary attempts are being made to use this methodology also in the pre-operative planning phase.

## DOES STRAPPING THE ROWER TO THE SEAT ENHANCE ROWING PERFORMANCE?

A.J. "Knoek" van Soest, J. van Zeil and T. Guhr

Faculty of Human Movement Sciences and IFKB, Free University Amsterdam, the Netherlands

email: [k.vansoest@fbw.vu.nl](mailto:k.vansoest@fbw.vu.nl)

### INTRODUCTION

A well-known coordination problem in rowing is to prevent "shooting the slide"; rowers must prevent lifting themselves from the sliding seat, which may occur when pulling too hard on the oar handle. We have three indications that this constraint may limit performance. First, novice rowers are known to shoot the slide quite often. Second, the vertical seat reaction force in expert rowers approaches zero during the pull phase [1]. Third, a simulation study indicated that eliminating the no-slide-shooting constraint on coordination by "strapping the model to the sliding seat" may increase performance during the first stroke [2]. Thus, in this experimental study we address the question if rowing performance can be improved in well-trained rowers by strapping them to their sliding seat. As the mechanics of ergometer rowing have been shown to be comparable to on-water rowing, this question is addressed in the context of ergometer rowing.

### METHODS

Six well trained rowers participated in two ergometer rowing tasks, using an instrumented Concept IIC rowing ergometer. The first task, mimicking the start of a race, was to perform a series of two maximal strokes, starting from zero flywheel velocity. The second task, mimicking high-intensity steady state rowing, was to row 500 meters, where the first and last 150 meters (approximately 15 strokes each) were performed at maximal intensity. Both tasks were performed three times, both under normal conditions and while strapped to the sliding seat. Apart from a warming up period of 20 minutes, the participants had no training with the strap. The rowing ergometer was instrumented with 6-channel AMTI force transducers under the feet and under the sliding seat; a one-channel force transducer was mounted between the handle and the chain. An Optotrak system was used to measure kinematics. From these data, mechanical work and average mechanical power delivered by the rower to the ergometer during the stroke phase were calculated. Data were analyzed using paired Student's *t*-tests and ANOVA ( $p=0.05$ ).

### RESULTS AND DISCUSSION

Results for the first two strokes after the start are summarized in Table 1. The significant difference in  $\min(F_{\text{seat}_z})$ , the minimum of the vertical force under the seat, indicates that subjects used the strap. This resulted in a higher peak handle force, which in turn resulted in higher stroke work and higher average power output during the stroke. Together, these results indicate that in this task, removing the no-slide-shooting-constraint on coordination by strapping the rower to the sliding seat allows rowers to pull harder at the handle and thus to perform better.

Results for the the high-intensity steady state rowing task investigated were less clear. While  $\min(F_{\text{seat}_z})$  was significantly lower when strapped, and rowers thus appear to use the strap, this did not result in a significantly higher average power output in a group analysis (data not shown). However, ANOVA's on the individual subjects indicated that in 3 out of 6 subjects, average power output was significantly higher in the strapped condition, with relative differences between 2.0% and 3.7%.

One possible explanation of the results is that during high-intensity steady state rowing (as opposed to short-duration sprinting), physiological limitations on power output are such that the no-slide-shooting constraint is "inactive". This would imply that during steady state rowing, removing this constraint by strapping the rower to the sliding seat is ineffective. Another possibility, that will be addressed in a future study, is that subjects need to learn to exploit the strap during steady state rowing.

## EFFECT OF SINGLE PULSED ELECTROMAGNETIC FIELDS STIMULATION ON THE PROLIFERATION OF MESENCHYMAL STEM CELLS

Ming-Tzu Tsai, Walter H. Chang, Ru-Jyuan Hou, Dai-Wei Wu

Bone Tissue Engineering Research Center, Chung Yuan Christian University, TAIWAN, E-mail: [g9102504@cycu.edu.tw](mailto:g9102504@cycu.edu.tw)

### INTRODUCTION

Mesenchymal stem cells (MSCs), which have the capacity of self-renewal and multipotent potential of differentiation, is the promising tool for bone tissue engineering, such as bone repair and reconstruction [1]. However, the origin and number of MSCs are still the problems in clinics. Based on the few population of MSCs contained from adult bone marrows, the main objective of this research was to enhance the recruitment of MSCs in vitro by using physical stimuli, single pulsed electromagnetic fields (sPEMF) stimulation. The activity of MSCs was estimated by MTT assay as well as the histomorphological stain.

### MATERIAL AND METHOD

**Bone marrow MSCs primary culture.** MSCs were isolated from bone marrows of bilateral femora and tibiae acquired from 4-6-week-old male Wistar rats. Isolated MSCs were resuspended in  $\alpha$ -MEM containing 10% FBS [2].

**sPEMF system.** sPEMF was well-established in our lab for many years. The parameters of sPEMF were: single pulse, 7.5 Hz, 1.3, 2.4, and 3.2 Gauss of magnetic intensities. The stimulation period of sPEMF was two hours a day for 14 days.

**Experimental design.** Isolated bone marrow MSCs were cultured in 8-well chamber slides for two days, and then cells were exposed to sPEMF stimulation with specific parameters for 2 hr/day for 14 days. Conditioned medium and cells were collected and assayed at day 0, 3, 6, 9, 12, and 14.

**Proliferation and differentiation assay.** The proliferation and of MSCs was determined by MTT assay. The differentiation of osteoblasts and adipocytes from MSCs were evaluated by von Kossa stain and Oil Red stain.

### RESULT AND DISCUSSION

Fig. 1-2 showed von Kossa stain of osteoblasts and oil-red O stain of adipocytes differentiated from bone marrow MSCs. It indicated that bone marrow MSCs still had multipotent ability of differentiation after appropriate PEMF stimulation with specific parameters. Fig. 3-5 showed the proliferation of MSCs with three original MSCs densities with/without PEMF stimulation with different intensities. PEMF-50, PEMF-500, and PEMF-1000 maintained higher proliferation than their controls during 14-day period (Fig. 3). The effect of PEMF stimulation with 2.4 G and 3.2 G inhibited cell viability of MSCs, especially 3.2 G of magnetic intensity. The original cell densities of MSCs also had dose-dependent relationship with their growth rate with or without PEMF exposure.

### CONCLUSION

The purpose of this study was to estimate the ability of PEMF stimulation on MSCs proliferation in vitro. It indicated that physical stimuli might be a promising physical stimulus for MSCs expression in the future.

## INDUCED ACCELERATION CONTRIBUTIONS TO LOCOMOTION DYNAMICS ARE NOT PHYSICALLY WELL-DEFINED

George Chen

Honda Fundamental Research Laboratories, Mountain View, CA

Rehabilitation R&D Center, VA Palo Alto Health Care System, Palo Alto, CA

Mechanical Engineering Department, Stanford University, Stanford, CA; email: [chen@rrdmail.stanford.edu](mailto:chen@rrdmail.stanford.edu)

### INTRODUCTION

Induced segmental acceleration and power analysis has been advocated in the assessment of muscle and joint moment function during locomotion [1-4]. The analysis quantifies the contributions of individual forces and moments to the accelerations, reaction forces, and powers produced during a task [5]. The purpose of this study is to assess whether induced acceleration contributions to locomotion dynamics are physically well-defined or whether contributions depend very much on the formulation of the model. The assessment was made possible by the analyses of simple, theoretical locomotor task using different models.

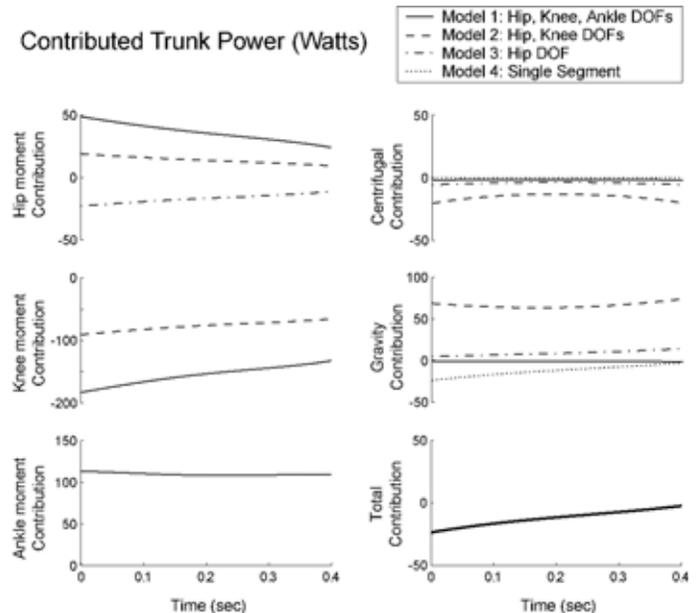

### METHODS

The theoretical locomotor task was based on a planar, rigid-body simulation created using dynamical-equations-of-motion generated by SD/FAST. The body consisted of four rigid segments – the trunk, and thigh, shank, and foot of the supporting leg. The contralateral leg was not included. Joint moments at the hip, knee, and ankle were prescribed to posturally support the configuration of the body as it rolled forward, in a pendular motion, over a pin joint connecting the tip of the foot to the ground.

Induced acceleration analyses [5] were performed, using four models, to determine the contributions of joint moments and centrifugal and gravity forces to the mechanical power of the trunk and leg. Model 1 represented all body degrees of freedom, and Models 2 through 4 represented progressively fewer degrees of freedom by locking the ankle, knee, and hip joints. Since these degrees of freedom were posturally supported and did not accelerate during the task, all four models completely described its simulated dynamics.

### RESULTS AND DISCUSSION

The trunk powers contributed by each moment or force differed (both in magnitude and direction) between models, even though the total contributions were identical for all models and equal to the simulated powers (Fig. 1). Since the joint moments did not generate nor absorb energy, the contributed leg powers (not shown) were equal in magnitude to the contributed trunk powers but opposite in sign. In Model 1, the knee moment directed much power away from the trunk (i.e., power contribution was negative), but its effect was mostly cancelled by the positive contributions from the hip and ankle moments. The total power contribution to the trunk was modest and negative. As degrees of freedom were progressively eliminated in Models 2 through 4, the power contributed by each joint moment changed and were reduced in magnitude, overall. However, the total contributions

**Figure 1:** Using models 1 through 4, trunk power contributed by each moment or force and total contribution by all moments and forces. Note: Total contribution was the same for all models.

remained the same. In Model 4, the effect of gravity, by itself, accounted for the total power contribution to the trunk.

### CONCLUSIONS

Even though all four models completely described the simulated dynamics of the theoretical locomotor task, the induced acceleration decomposition of mechanical powers differed between models. To conclude, induced acceleration contributions to the dynamics of a task are not physically well-defined. The application of the analysis in the assessment of muscle and joint moment function during locomotion should be critically reevaluated.

**In vivo determination of muscle architecture parameters by ultrasonography: applications to the brachialis muscle of normal subjects and persons after stroke**

<sup>1</sup>Le Li, <sup>1</sup> KaiYu Tong

<sup>1</sup>Jockey Club Rehabilitation Engineering Centre, The Hong Kong Polytechnic University, Hong Kong, China  
 Correspondence author email: rctong@polyu.edu.hk

**INTRODUCTION**

It is believed that muscle architectural parameters have effects on the muscle's force generating capacity. The pennation angle, fibre length and thickness of the muscle has been described mainly with the data obtained in preserved cadavers or specimen before. However, cadaver data are limited in their usefulness since muscle undergo shrinking during the fixing process.

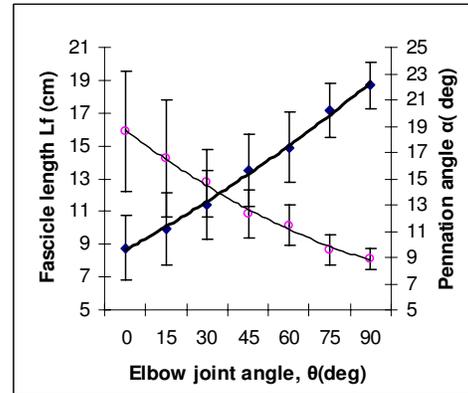

Ultrasonography can be used to measure the changes of muscle fibre length and pennation angle reliably and non-invasively. It has become possible to describe human muscle architecture in vivo by ultrasound. This study is aim to quantitatively describe the brachialis muscle architecture parameters in rest and muscle contraction condition for normal and subjects after stroke.

**METHODS**

Brachialis muscle's architecture parameters including pennation angle, muscle fibre length for six unimpaired subjects and six hemiparetic subjects after stroke were measured using ultrasound imaging technology at rest and different levels of muscle contraction. At rest, the measurements for normal subjects were done at elbow positions from 0°-90° flexion with increase of 10° and measurements for pathological subjects were done from 10°-80° since some of them could not extend their arms to full extension. In muscle contraction, the subjects were asked to perform 20%, 40%, 60%, 80% and 100% maximum voluntary contraction(MVC) isometrically at the fixed position of 90° elbow flexion(elbow fully extended called 0° flexion).

**RESULTS AND DISCUSSION**

Ultrasound measurement of muscle pennation angle and muscle fibre length were comparable with results from cadaver data in literatures. These parameters changed with elbow joint position and muscle contraction activity. The changes in muscle parameters were different between normal and pathological subjects. The finding was that fibre length of pathological subjects change less than normal subjects which may indicate the effects of spasticity.

**Figure 1:** Muscle pennation angle and fibre length change with elbow flexion angle in rest(data from normal subjects)

**CONCLUSIONS**

This preliminary study finds in vivo ultrasonography could measure muscle architecture parameters and the results are comparable with anatomical data from unimpaired cadavers. Pathological subjects' muscle architecture parameters are different from normal subjects by ultrasonography. The results can be used to study the muscle properties and give useful information for force and tension calculation in the neuromusculoskeletal modelling. Application of in vivo ultrasound study on musculotendon complex is to find the relationship between the force generating of the muscle and muscle's architecture parameters. Other aspect of the applications is to have the musculoskeletal model parameters on specific subject with difference in architecture.

## THE TRUNK TWIST ANGLE DURING BASEBALL BATTING AT THE DIFFERENT HITTING POINTS

<sup>1</sup>Takahito Tago, <sup>2</sup>Michiyoshi Ae and <sup>2</sup>Sekiya Koike

<sup>1</sup>Doctoral Program in Health and Sport Sciences, University of Tsukuba ; email: [tago@lasbim.taiiku.tsukuba.ac.jp](mailto:tago@lasbim.taiiku.tsukuba.ac.jp)

<sup>2</sup>Institute of Health and Sport Sciences, University of Tsukuba

### INTRODUCTION

Most of investigations on the baseball batting have focused on the batting motion for hitting a ball at the center of strike zone. However, since a pitcher in real baseball game tries not to throw the ball toward the center of strike zone, it is useful to identify how batters change the batting motion to hit the ball at various points in the strike zone. Although we can easily observe how the arms and legs are changed to carry the bat toward various hitting points, we have no information enough to teach an appropriate trunk motion to batters, which has been advocated to be important.

The purpose of this study was to investigate the change in twist angle between the shoulders and hips during baseball batting at the different hitting points.

### METHODS

Subjects were ten right-handed male skilled batters of a varsity baseball club. Informed consent was collected after the explanation of the experiment procedure. Nine hitting points were set in the strike zone according to the baseball rules: three heights (high, middle, low) based on the subject's height and three courses (inside, center, outside) based on the width of a home plate. The subjects were randomly assigned nine hitting points and hit at least five times at each hitting point. The ball was set on a batting-tee stand at the hitting points assigned. The trial in which fastest ball velocity and good feeling of subjects were obtained was chosen at each hitting point for analysis.

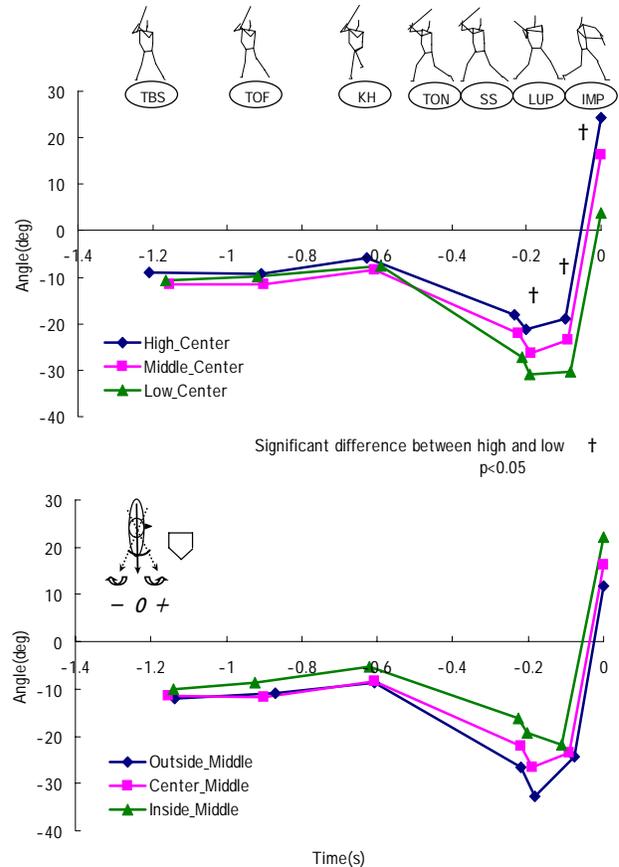

Kinematic data were collected by using Vicon 612 system with nine cameras operating at 120Hz. Batting motion was divided into six phases by seven instants of motion event: Take-back start (TBS), Toe-off (TOF), Knee high (KH), Toe-on (TON), Swing start (SS), Left upper arm parallel (LUP), and Impact (IMP).

A trunk twist angle was defined as the angle between a line connecting the hips and a line connecting the shoulders, which were projected on a horizontal plane. A positive angle of the trunk twist means that the shoulder rotation to the hitting direction, i.e. forward rotation, is larger than that of the hips.

A repeated two-way ANOVA was used to test differences in the angular kinematics among hitting points at a significant level of 0.05.

### RESULTS AND DISCUSSION

The upper figure of Figure 1 shows changes in trunk twist angle for hitting the ball at three heights (high, middle, low). The shoulder rotation to the opposite hitting direction, i.e. backward rotation, was significantly larger in the low ball hitting from SS to LUP than that of the high ball hitting, and the shoulder forward rotation significantly

**Figure 1.** The trunk twist angle in the High—Low and Outside—Inside ball hitting.

smaller in the low ball hitting at IMP than that of the high ball hitting. These differences in the shoulder rotation between the high and low ball hitting indicated that the different trunk motion and timing were used in swinging the bat for high and low ball hitting.

The lower figure shows changes in trunk twist angle for hitting the ball at three courses (outside, center, inside). The shoulder backward rotation was larger in the outside ball hitting from TON to LUP than that of the inside ball hitting, and the shoulder forward rotation tended to be smaller in the outside ball hitting at IMP than that of the inside ball hitting. However these differences were not significant.

These results suggest that when hitting a high ball a batter should rotate the shoulders backward in small range from SS to LUP and use the large forward rotation from LUP to IMP, and that in hitting a low ball a batter should use large backward rotation of the shoulders from TON to LUP and use the small forward rotation from LUP to IMP.

## STUDY OF THE INVERSE DYNAMICS OPTIMAL CONTROL TECHNIQUE IN CYCLING

### INTRODUCTION

In recent developments, the authors have shown the possibility of considerable decreases of computational time, if a hybrid technique optimal control technique is applied [1,2] to find muscle activation patterns in musculoskeletal systems. The so-called Inverse Dynamics Optimal Control (IDOC) method breaks the classical Forward Dynamics Optimal Control Problem (OCP) in two steps:

- a) Finding the joint torque curves through the Inverse Dynamics analysis of a real or simulated system;
- b) Formulate an OCP that minimizes a cost function comprising a muscle-activation related expression augmented with an error function part between the moments calculated by inverse dynamics and the actual moment generated by muscles. Only muscle dynamics is considered in the OCP dynamic constraints, removing Multi-Body System (MBS) differential equations of the OCP formulation. These equations greatly increase the numerical cost of the OCP, as discussed in [3] for posture.

In this paper, the IDOC method was applied to cycling. The low numerical cost associated with the IDOC method should contribute to improve clinical applicability of mathematical modeling and optimal control, in the prescription of custom rehabilitation programs.

### METHODS

Initially, a MBS of human pedaling was formulated. The crank, ankle, knee and hip torques in both sides were calculated for a subject performing a constant angular velocity cycling movement. The multi-body system is a 2-D, eight bars and three degrees of freedom linkage with two closed loops. Each bar represents crank, stationary bar, thigh, shank and ankle for right and left sides (Figure 1). The model dimensional and inertial parameters, as well as the measured pedal forces, were taken from [4,5].

The IDOC problem was formulated considering ten lower-limb muscles (*gluteus medius*, hamstrings, *biceps femoris* short head, *gluteus maximus*, ilipsoas, *rectus femoris*, *vasti*, *gastrocnemius*, *soleus*, *tibialis anterior*). A Hill-type muscle contraction dynamics was used. The dependence of the muscle moment arms with joint angles was taken from [6]. The OCP was formulated and solved in the framework of the Consistent Approximations Theory, using the RIOTS toolbox for Matlab [7].

### RESULTS AND DISCUSSION

The torque curves obtained by the MBS inverse dynamics analysis has shown a good agreement with data published by other authors [8]. In addition, the joint torque curves formed

by the sum of the individual muscle contributions, after the IDOC solution, were very similar to the inverse dynamics outputs. A series of numerical tests was carried out to find the most suited cost function that should lead to a reasonable matching between the calculated and EMG muscle activation patterns. This exploration is still in progress. However, feasible solutions were found for some muscles, compared to EMG and OCP data presented by [9]. Namely, *soleus*, *gastrocnemius*, hamstrings and *rectus femoris* has shown similar shapes. Other muscles, however, showed a good agreement with [9] in the maximum activation amplitudes, but with some phase distortion. Other classes of constraints, like endpoint equality and inequality constraints are currently being explored. The computational time used to perform the IDOC solution in one cycle of pedaling at 60 rpm was around 3-4 hours using a 450 MHz Pentium III processor. The results suggest that the method may a suitable alternative to low-cost optimal control analysis of cycling.

## LOAD-SPECIFIC RELATIONSHIPS BETWEEN MUSCULAR POWER AND BONE MINERAL DENSITY

<sup>1</sup>Brandi Row and <sup>2</sup>Peter Cavanagh

<sup>1</sup>The Centre for Studies in Aging, Sunnybrook and Women's College Health Sciences Centre, Toronto, Canada, <sup>2</sup>Cleveland Clinic Foundation, email: [Brandi.Row@sw.ca](mailto:Brandi.Row@sw.ca)

### INTRODUCTION

Lower extremity muscular strength (STR) influences bone mineral density (BMD) of the proximal femur (PF) and lumbar spine (LS) in older adults [1]. However, when body size is taken into account, STR is not independently associated with BMD of the PF in older adults [2]. In various lower extremity muscle groups, normalized STR and power (PWR) contributed to the best predictive models of BMD in older adults [3]. Further, PWR of lower extremity muscles contributed uniquely to BMD, even when taking sex, age, BMI, and STR into account [3]. The purpose of this study was to determine 1) which factors of PWR (force and velocity) are most predictive of BMD, and 2) at which loads relative to maximal STR is the relationship between PWR and BMD optimized in older adults.

### METHODS

Pre-intervention STR, PWR and BMD data were collected for 48 healthy older adults (28 females, 20 males; ages 65-82 yrs) who were accepted into an exercise intervention study previously described [4]. Subjects with osteoporosis, joint replacements and those already participating in resistance-training programs were excluded. Dual X-Ray Absorptiometry (DXA) scans (Hologic, Inc., Bedford, MA) were used to assess whole body lean body mass (LBM) and BMD at the PF and LS. Subjects performed STR tests (one-repetition maximum, 1RM) for Leg Press (LP), Hip Abduction (AB), Hip Adduction (AD) and Hip Flexion (HF) using resistance-training machines. PWR was determined for each exercise: the concentric motion was completed 'as fast as possible' at loads of 30, 50 and 70% of 1RM (except for LP, where 30% 1RM is too light to perform safely). PWR (force\*velocity during the PWR test), and STR (in kg and Watts, respectively) were normalized by dividing by the lean body mass of the total leg in kg. Regression analyses were conducted using statistical software (Minitab, State College, PA). The 'best subsets' feature was used in order to determine the combination of variables (lowest bias, highest adjusted R<sup>2</sup>) accounting for the most variance in BMD. Systematic variations of the regressions were conducted in order to determine the optimal relationship between the load (% 1RM) used during the PWR tests and BMD, and to determine which component of PWR (force or velocity, VEL) was the most influential for BMD.

### RESULTS AND DISCUSSION

While sex was the leading predictor of BMD (women < men), the VEL component of PWR was also an important predictor of PF BMD, while the normalized force component was not. For LS BMD, however, *both* VEL and force parameters were important predictors (Table 1). Regression models for Proximal Femur BMD were optimized with PWR tested at a load of 50% 1RM (Figure 1). Conversely, models for Lumbar Spine BMD were optimized at a load of 70% 1RM.

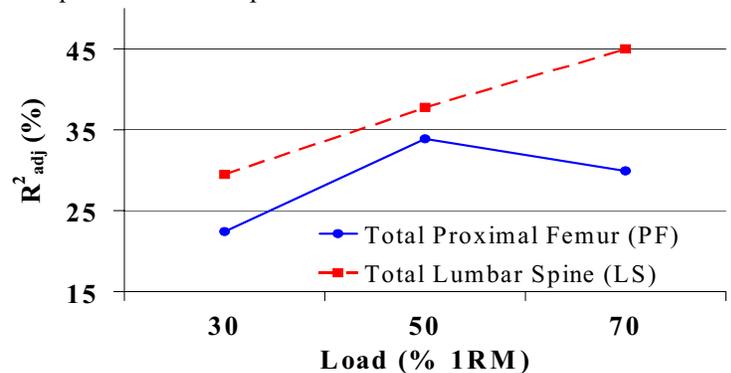

Figure 1: R<sup>2</sup><sub>adj</sub> for PF and LS BMD for models as in Table 1.

### CONCLUSIONS

This study revealed that PWR tests at moderate loads (50% 1RM) produced the best relationship between PWR parameters and PF BMD. A load of at least 70% 1RM was required to optimize this relationship with LS BMD. Given the predominance of VEL as a predictor of BMD, particularly for PF BMD, high velocity resistance training should be evaluated as a method for improving BMD in older adults. Further, investigations should focus on whether such load-specific relationships optimize training outcomes for PF and LS BMD.

### INTRODUCTION

Fatigue affects muscle activation and coordination during complex tasks such as walking, jumping, and landing [1,2,3]. Moreover, it is commonly believed, and there is some evidence to support, that injuries occur more often near the end of practices and competitions when athletes are fatigued [1]. However, few studies have examined the effects of fatigue on landing mechanics during stop and go tasks [e.g. 4,5]. The fatiguing protocols used in these exemplar studies targeted the musculature used specifically for jumping, which may not be representative of the cardiovascular and muscular fatigue that develops during a game or practice. The purpose of this study was to examine landing mechanics in male and female athletes performing stop and go landing tasks in fatigued states representative of game conditions.

### METHODS

Twenty healthy athletes (10 male, 10 female) participated in this study after giving their written informed consent. The testing session involved warm-up, pre-fatigue testing, a fatiguing protocol, and post-fatigue testing. The pre and post fatigue testing involved 4 different tasks: 1) 90 degree cut, 2) 45 degree cut, 3) forward step, and maximum vertical jump after landing from a 0.5 m high box.

The fatigue protocol consisted of a 10 minute progressive incline treadmill run followed by an "M-drill". The M-drill was a 3 by 3.5 m pattern of forward, backward, and side ways steps with vertical jumps. The pattern was repeated until 1) lap time slowed to 150% of their fastest time or 2) completion of 10 laps and inability to achieve maximum jump height.

During pre and post testing, GRFs were measured with two AMTI force plates. High speed digital video data were collected using two Photron cameras. The subjects performed 3 vertical jumps between each post trial to maintain their level of fatigue. The GRF data for the 90 degree cut and vertical jump tasks only are presented in this abstract. Data were analyzed with a three way repeated measures ANOVA at  $\alpha = 0.05$ .

### RESULTS AND DISCUSSION

The initial vertical impact GRF peak of the cutting leg was significantly greater in the post fatigue trials as compared to the pre fatigued trails (Figure 1). Additionally the time to the

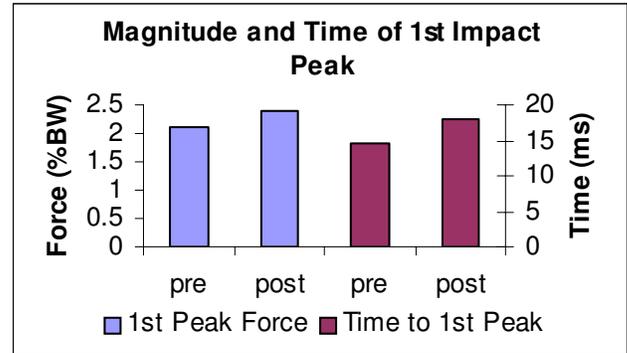

Figure 1: Impact peak & time to peak pre and post fatigue.

first vertical GRF peak was significantly longer in the post fatigue trials (Figure 1). A non significant decrease in impulse was also observed pre to post fatigue ( $p=0.056$ ; Table 1). There was no significant gender or task interaction.

The increased peak impact forces and times to peak impacts suggest altered landing strategies utilized by the subjects in the fatigued state. This is supportive of previous research using localized fatiguing protocols which suggests subjects respond to fatigue with varying combinations of increased bilateral variability and increased impact forces during the landing phase of stop and go tasks [4].

### CONCLUSIONS

Significant increases were found in vertical GRFs during the landing phase of stop and go tasks in pre and post fatigued conditions, along with significant difference in the timing of the GRF peaks. Alterations in landing mechanics observed in fatigued states, such as those that might be encountered in practice and game situations, may pre-dispose athletes to increased risks of injury. Further research in the relationship to fatigue and injury occurrence appears to be warranted.

**INTRODUCTION**

Fast and target orientated movement is common in daily life and in sports. Skeletal muscle fatigue is defined as the failure to maintain required or expected torques or the increasing efforts to maintain the same torque output level (2). Previous study has shown that torque of maximal voluntary contraction (MVC) declined and the contraction and relaxation prolonged after fatigue (1). It is possible that the ability of movement control after fatigue declines by fatigue, especially in fast movement. Co-contraction is one form of the controlling strategies defined as the simultaneous recruitment of two muscles. Since fatigue results in slowing of contractile speed and increase recruitment during submaximal isometric contractions (3), the error of movement, especially fast movement, should increase. It is not clear whether this increased movement error can be corrected by adjusting the control pattern of agonist- antagonist muscle pairs.

**METHODS**

10 volunteers with averaged age  $22.9 \pm 1.97$  participated. Subjects sat on a rigid chair with one foot fixed firmly on the platform of the torque measurement system (fig.1). The signal from the force transducer as well as a target line was displayed on a screen where subjects can clearly view. The electromyography (EMG) signals were recorded from soleus and tibia anterior muscle (fig.2).

**Fig1.** Torque measurement system

**Fig2.** Tibialis anterior and Soleus EMG electrode placement

The test was started with 5 MVC of dorsiflexion. Fatigue was defined as subjects' torque was hard to reach 50% MVC. 40% of the MVC was calculated to set the target line. Following the MVC test, the subject conducted 5 fast and 5 slow isometric dorsiflexions with peak torque just hitting the target line before and after TA fatigue. The systematic errors of torque generation and co-contraction ratio of EMG firing were calculated. Two-way repeated-measures of ANOVA was used to examine the effects of fatigue and speed on systematic error, co-contraction ratio. A significance level of  $p < 0.05$  was used.

**RESULTS AND DISCUSSION**

In this study, we observed the higher systematic errors and co-contraction ratio in the fast contractions (Table 1 & 2). We expected participants used co-contraction for improving the performance of force generation.

**Table1.** The mean and Std. of Systematic error in pre-test and post-test in the fatigue and control session.

	Systematic error (%)			
	Experimental group		Control group	
	fast	slow	fast	slow
Pre	11.69±4.80	4.55±2.16*	9.10±3.91	3.38±0.99*
Post	24.31±6.53 <sup>†</sup>	10.27±4.10* <sup>†</sup>	8.16±3.77	4.65±1.92*

**Table2.** The mean and Std. of co-contraction ratio of the TA and Sol in the pre-test and post-test in the fatigue and the control session.

	Co-contraction ration (%)			
	Experimental group		Control group	
	fast	slow	fast	slow
Pre	0.81±0.14	0.67±0.24*	0.76±0.19	0.67±0.28*
Post	0.82±0.10	0.80±0.20* <sup>†</sup>	0.80±0.15	0.58±0.34*

If the phasic activation associated with the accuracy control of the force, it is interesting to know if the pattern switched to reduce error after fatigue. According to the result (Table2), the co-contraction ratio was only increased in the slow contractions but was unvaried in the fast contractions. This increase of the co-contraction ratio was parallel to the change of systematic error (Table1). After fatigue, the magnitude of the systematic error increment was higher in the fast contractions than in slow contractions indicating the accuracy was adjusted in the slow contractions. It is possible that the change of co-contraction ratio in the slow contractions was for increasing the accuracy of movement.

**CONCLUSIONS**

Our results supported that the systematic of force generation increased after fatigue in both the fast and slow isometric contractions. The slow isometric contractions had smaller increment in the systematic error related to the change of the agonist-antagonist activation patterns.

## REDUCED FORCE CONTROL AND INCREASED CONTRALATERAL TRAPEZIUS CO-ACTIVATION AMONG SUBJECTS WITH WORK RELATED MUSCULOSKALETAL SYMPTOMS

Bente R. Jensen, Theis B. Hansen and Marianne Pilegaard  
Institute of Exercise and Sport Sciences, University of Copenhagen, Denmark.  
email: brjensen@ifi.ku.dk

### INTRODUCTION

Increased values of vibro-tactile sensory threshold indicating entrapment of peripheral nerves have been documented among computer users with severe upper extremity symptoms [1]. However, our knowledge regarding potential functional consequences is limited. The aim was to study fine motor control and upper extremity muscle activation in subjects with and without symptoms.

### METHODS

Three groups of female subjects participated. The +sPC group (44 yrs, n=15) had severe upper extremity symptoms and worked at the computer for 75 % of the working day. The -sPC group (43 yrs, n=11) had no symptoms and worked at the computer for 73 % of the working day. The control group (44 yrs, n=9) had no symptoms and worked at the computer for 2 h or less per day. Upper extremity fine motor control was measured in a submaximal handgrip force control task. The task (12 s) was to increase the handgrip force (right hand) as fast as possible to a level above a predetermined upper threshold force level (led feedback) and then decrease the force to below a predetermined lower threshold (led feedback) as fast as possible [2]. The force control task was performed at 3 submaximal absolute force levels, corresponding to 5, 10 and 20 %MVC (maximum voluntary contraction) for a healthy reference group. Each task was repeated 3 times. Task frequency (number of cycles per second), peak force and rate of force increase and decrease for the three groups were calculated. Surface EMG was recorded from mm. trapezius (left and right), right m. extensor carpi radialis, m. extensor digitorum, m. extensor carpi ulnaris and m. flexor carpi radialis during the task and related to maximum values. Average forearm muscle activity expressed as static, mean and peak activity was calculated. Finally, handgrip strength (highest 1-s value out of 3 trials) was measured.

### RESULTS AND DISCUSSION

Handgrip strength was 32.0(SE 1.6) kg, 33.1(1.4) kg, and 33.3(1.4) kg for the +sPC, -sPC, and the ctrl group, respectively. Thus, no group differences in muscle strength were found. Task frequency decreased with increasing upper force threshold level for all three groups. However, the frequency of the force control task (across all force levels) was lower for the +sPC group compared to the control group (Figure 1). This could be explained by a slower force increase and a slower force decrease in the +sPC group

compared to the control group, whereas no between group differences were found in the peak force during the force control task. Rate of force increase and rate of force decrease was highly correlated ( $r = 0.84$ ,  $p < 0.001$ ).

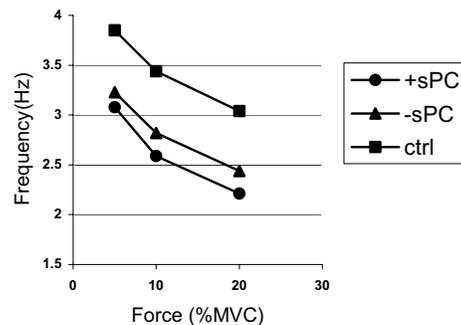

Figure 1: Task frequency during the force control task.

The +sPC group had minor but significantly lower static forearm muscle activity level at all three force levels, a lower mean activity level at the 20 %MVC task and a tendency to a lower mean activity level at the 5 %MVC task than the ctrl group. These differences may be explained by the lower frequency of the force control task in the +sPC group. The increase of the upper force threshold was mainly reflected in the peak activity levels while the static activity remained unchanged. In general, the activity of the mm. trapezius was significantly lower than in the forearm muscles during the force control tasks. The peak activity level of the left m. trapezius was higher in the +sPC and the -sPC groups at the two lowest force levels and higher in the -sPC at the highest force level compared to the ctrl group, while no group differences were found for the right m. trapezius.

### CONCLUSION

Impaired fine motor control and increased contralateral shoulder muscle activity were found in the symptomatic group despite of well-maintained muscle strength.

**INTRODUCTION**

For the global kinematics of the cervical spine, the upper cervical spine plays a considerable role for maintaining the head in the horizontal plane or for compensating coupling motion occurring at cervical lower segments. Presently, for a better understanding of human biomechanics, procedures using computerized human models have been implemented to analyze the structural mechanics of the human body in attempt to obtain accurate virtual models [1,2,3]. The aims of this study are to develop a standardized protocol for analyzing the *in-vitro* kinematics of the upper cervical spine, and to combine individual kinematics data with anatomical data for 3D bone modelling and simulation.

**METHODS**

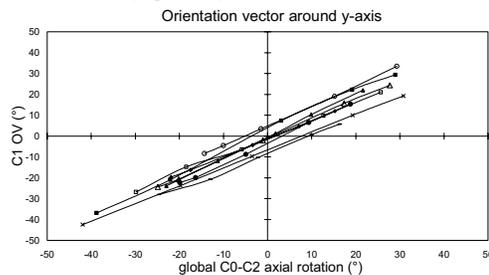

Specimens were sampled from donators and processed according to strict ethical regulations. Medical imaging was acquired by computed tomography (Siemens SOMATOM) in neutral position for nine specimens. Individual morphometric data were extracted for each osseous segment. 3D reconstruction was performed after object segmentation and identification using Amira® (Germany). For each specimen, the lower cervical segments and related soft tissues were removed as well as the mandible and anterior neck viscera. The upper cervical segments and their ligaments, suboccipital muscles and fascias were kept intact. Fiducial markers (Fidm) (aluminium balls: Ø 4mm) were placed on the atlas, axis and skull (figure 1). Using a 3-D digitizer (Faro® arm, model 08 Bronze, USA), each Fidm was identified in 5 successive specimen positions of each flexion-extension and axial rotation. For each bone, a local reference system was defined using anatomical landmarks according to the International Society of Biomechanics recommendations [4]. For each vertebral displacement, rotation and translation were computed according to anatomical axis (x,y,z). Helical axis orientation and location were also computed and implemented in kinematics models (figure 2).

**Figure 2:** Kinematics model and instantaneous helical axis (IHA) during axial rotation at C1-C2 level

**RESULTS**

The different steps of this protocol for combining morphological data and interpolation of kinematics data from discrete positions were carried out using a validated registration method<sup>2</sup>. Moreover, a reliability study performed for anatomical and metallic marker digitizing demonstrated good reproducibility of the 3D digitizing. For each specimen, different kinematics patterns were observed, although primary motion was similar (figure 3).

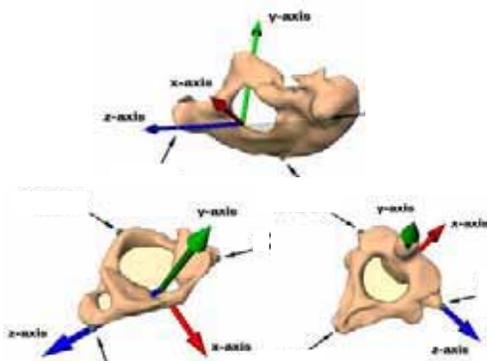

**Figure 3:** Axial rotation of C1 on C2 (orientation vector, OV) as a function of global C0-C2 movement for each specimen.

**DISCUSSION**

Considering the presence of surrounding tissues (muscle, fascia) our results are comparable to those found in the literature for the global range of movement as well as for motion patterns. Sampling of human morphological data and modelling represents a significant source of information in the understanding of the biomechanical processes. Such validated models are also needed in the field of advanced care and health knowledge. Moreover, combining *in vitro* and *in vivo* data analysis of the normal mechanical behaviours of the musculoskeletal system would provide the design of specific biomechanical models for understanding of pathogenic functional mechanisms of the upper cervical spine.

## DYNAMICAL DIFFERENCES BETWEEN NORMAL AND STEREOTYPICAL BODY ROCKING

<sup>1</sup> Karl Newell, <sup>1</sup> Lee Hong and <sup>2</sup> James Edfish

<sup>1</sup>The Pennsylvania State University,

<sup>2</sup>J. Iverson Riddle Developmental Center; email: [slh343@psu.edu](mailto:slh343@psu.edu)

### INTRODUCTION

Stereotypical body rocking has been noted as one of the most common repetitive behaviors exhibited by patients diagnosed with mental developmental disorders [1]. It has been argued that such behaviors should not be classed as being independent of the instrumental activities of daily living [2]. The aim of this experiment was to compare differences and similarities between the dynamics of sitting and body rocking in adults with profound mental retardation and healthy adult controls.

### METHODS

7 adults (aged between 31 and 45 years) diagnosed with severe or profound mental retardation (Vineland Adaptive Scales), residents of a state developmental center, were selected due to their regular engagement in body rocking stereotypies (MR group). These participants were not on any regimens of medications. 3 adult males and 3 adult females from the University community served as the controls, matched to be within 10% of the age, weight and height of the disordered patients. The Institutional Review Board of the Pennsylvania State University and the Western Carolina Center provided approval for the informed consent and experimental procedures involved.

A force platform (AMTI Model S6-4) placed beneath a wooden block (length 46.4 cm x width 50.8 cm x height 48 cm) served as the data collection device, while the participants were seated upon this block, which had no back, thus preventing the participants from leaning against it. The motion of the centre of pressure (CoP) of generated by the participants force outputs served as the dependent variable.

MR group participants were measured while exhibiting stereotypical body rocking behavior and during a protocol in which they were sitting still. Matched control participants were asked to simulate body rocking by oscillating at a preferred frequency and amplitude and were then asked to sit as still as possible. 3 trials lasting 10 s were recorded for each participant in the still and body rocking conditions.

### RESULTS AND DISCUSSION

For the controls, similar modal CoP oscillation frequencies were noted during both sitting still and voluntary rocking (Figure 1). However, the complexity of the CoP time series was higher during quiet sitting, marked by increased approximate entropy (values). The MR group however, demonstrated an opposite direction of change. While the modal frequency of CoP oscillations was lower during sitting still, no differences were noted between the complexity of the CoP time series during quiet sitting and body rocking.

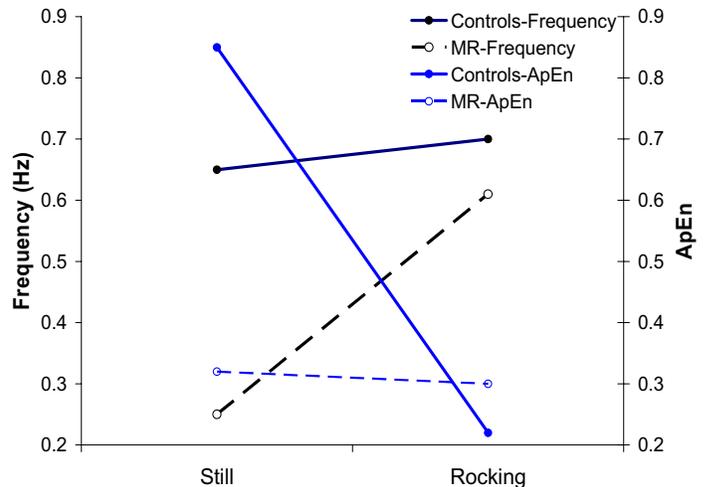

Figure 1. Mean ApEn and modal frequency values during both sitting still and body rocking in both the MR group and matched controls.

### CONCLUSIONS

The results are supportive of the idea that sitting and body rocking possess similar dynamics in healthy adults. Similarities in the dynamics of body rocking in controls and MR group suggest that both behaviors possess similar modes of organization, though with different scaling values. Greater dynamical stability afforded by body rocking as opposed to sitting still could be a contributing explanation for the regular occurrence of such stereotypical behaviors in MR patients.

#### INTRODUCTION

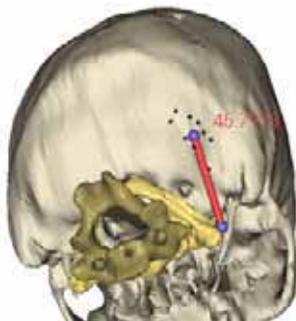

Upper cervical muscle biomechanics is poorly reported in the literature. However, these muscles seem to play an important role in head stabilization during cervical spine movement. The objectives of this study were to analyze the *in vitro* 3D moment arms of the suboccipital muscles during upper cervical spine movement and to implement these biomechanical muscle data in a musculoskeletal model.

#### METHODS

Kinematics data were sampled from digitizing technical markers (aluminum balls: diameter, 4mm) placed on the upper cervical segments (skull, C1 and C2) of 7 fresh specimens. Suboccipital muscles (rectus capitis posterior major (RCPm), rectus capitis posterior minor (RCPm), obliquus capitis superior (OCS), obliquus capitis inferior (OCI)) were kept intact to assure accurate digitizing of their insertions (Mmark) and fiber orientation in a maximal flexion position. Five successive positions for axial rotation (AR) and flexion-extension (FE) were processed. Axial rotation was achieved from maximal right rotation to maximal left rotation. All kinematics and muscle data were obtained using a 3-D digitizer (Faro® arm, model 08 Bronze, USA). Moreover, medical imaging of each specimen supplied morphometric data for 3D reconstruction (Amira®, Germany). According to a validated registration method [2], registration of kinematics and muscle data with morphometric data was processed using the DataManager software (<http://www.tecno.ior.it>). Muscle orientation was defined by the line of action, a straight line between attachment centroids (figures 1 and 2).

Then, for both movements, muscle lengths were computed for the five positions. Muscle moment arm was computed using a tendon excursion method previously described [4].

**Figure 1:** Surface muscle markers (●) after digitizing of the

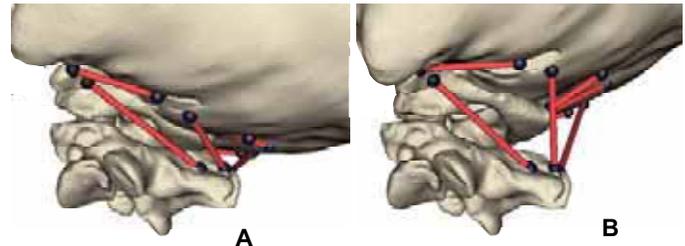

right occipital insertion of the OCS. Centroid of attachment site (●), muscle action line (—) and length (mm).

#### RESULTS AND DISCUSSION

Average moment arms (table 1) showed comparable value between right and left muscles for both movements. Absolute moment arms were similar for RCPm, OCS and OCI in AR and for RCPm, RCPm and OCS in FE. Moment

arm magnitude was close to zero for RCPm in AR and for OCI in FE. In general, moment arms were larger for AR except for RCPm. For AR, our results confirmed the antagonist role of OCS compared to RCPm and OCI.

**Figure 2:** Musculoskeletal model of one specimen in extension (A) and maximal flexion (B) of the C0-C2 complex. Muscles action line (—) and insertion (●).

	AR		FE	
	left muscle	right muscle	left muscle	right muscle
<b>RCPm</b>	1.9 (12.4)	-0.7	19.3 (7.1)	22.1 (5.3)
<b>RCPM</b>	-23.3 (5.0)	22.3 (5.8)	14.9 (3.6)	18.8 (5.0)
<b>OCS</b>	24.5 (6.5)	-22.8 (11.1)	17.2 (3.4)	17.5 (5.1)
<b>OCI</b>	-24.6 (2.1)	24.8 (3.0)	-2.2 (8)	-2.2 (6.6)

**Table 1:** Average suboccipital muscle moment arms (mm) and SD during AR and FE. Negative values represent antagonist action regarding the primary movement.

Our data were sampled using an accurate device that is commonly used in the literature. Kinematics data were computed using validated method for registration of different data sets. If some morphometric and biomechanical data are found in the literature, only few are available about suboccipital muscle length variations and moment arms. Our results are partially in agreement with previous studies [3]. Vasavada et al [3] have observed similar data in AR concerning the investigated muscles but differences are observed for flexion extension. These differences are most probably due to different methodological approaches. In this study kinematic and muscle data were obtained from the same specimens. This integration provides an interesting source for the analysis of musculoskeletal mechanic using an integrated computer graphic environment.

### INTRODUCTION

Standing balance and mobility has been essential to our daily lives and physical wellbeing, especially to the aged and/or people with physical disabilities [1]. Understanding its functions is important in improving safety in their daily lives, especially in decreasing fall risks and improving their physical wellbeing. The purpose of this study was to investigate the characteristics of anterior tilting movement and the difference in balance and mobility function in respect to the time of day, i.e. AM and PM by analyzing coordinates of the center of foot pressure (CFP) and the minimum jerk theory [2].

### METHODS

Fourteen older subjects (older group: 8 female, 6 male; age  $63.3 \pm 6.04$  years) and nine younger female subjects (younger group: age  $20.5 \pm 0.53$  years) were recruited for this study with informed consent. On the Kistler force platforms, the subjects were instructed to stand still barefoot for the first five seconds. When they hear a beep, they were to tilt their body forward as quickly as possible around the ankle joint keeping the heel on the force platforms and holding that position until the second beep. When the third beep is heard, they were instructed to go back to the previous erect position as quickly as possible. The subjects kept the anterior tilt position for about 15 second and the total time was 30 seconds per trial (Figure 1). The subjects had two trials in a single day. The subjects were evaluated three times in a single day i.e. AM (around 8:30) and PM (around 15:30), and were tested over five non-consecutive days in a span of two weeks. The subjects sat down for about a minute to rest between the tests. The signals from the force platforms were sampled at 30Hz using A/D converter and PC. Analyses were done using variables derived from x-y coordinates (x: medial-lateral; y: anterior-posterior) of CFP. Each CFP data was analyzed statistically, and the level of significance was set at  $P < 0.05$ .

**Figure 1:** Standing and tilting postures. A: standing still; B: anterior tilting; C: return to the previous position

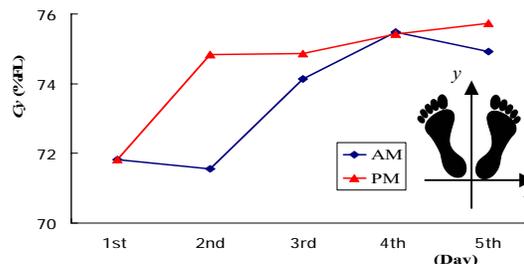

### RESULTS AND DISCUSSION

The mean anterior-posterior CFP coordinate ( $C_y$ ) for 5 seconds when the subject returned to the previous erect position was found to be significantly more posterior than for 5 seconds prior to the tilting position (paired t test,  $P < 0.05$ ). Similar results were also obtained from subjects. The subjects appear to lose

their sense of positioning when a relatively stressful posture is applied to their lower extremity muscles. This phenomenon was observed in both groups. Therefore, there is a possible risk of posterior fall, when a person tries to lift a relatively heavy object, which is in front of her/him.

The  $C_y$  of while maintaining the anterior tilting position was found to be significantly more anterior in PM than in AM (Figure 2, Repeated measures ANOVA;  $P < 0.05$ ). Conversely, this means that a person does not have better mobility in AM as in PM. The human foot is long and narrow and the distance between the ankle and toe is longer than that of between the ankle joint and the heel. In other words, a more anterior CFP is advantageous in controlling the standing position using the braking function of the triceps surae. Therefore, when treating patients and caring for older people, we need to keep in mind that there is a difference in the standing balance and mobility in respect to the time of day.

There were no significant difference in the jerk costs (JC) of x-y coordinates of CFP in respect to the time of day during the standing still and maintaining the anterior tilting positions as well as the phases of the anterior tilting and posterior returning motions in. This suggests that the task adopted in this study was linear movement, indicating that a significant difference in JC motion smoothness was not obtained between AM and PM.

**Figure 2:** Mean CFP y-coordinate  $C_y$ . Values are expressed in percentages to the foot length (FL) from the heel ( $P < 0.05$ ).

### CONCLUSIONS

Since there seems to be an illusion of postural control to some extent, we have to keep that in mind when we care for not only older adults but also healthy persons who require physical therapy. For a much better detailed understanding in the differences of postural control and mobility in time of day, additional evaluations, such as electromyography and three dimensional motion analysis, are needed.

### INTRODUCTION

There is substantial research on the effects of both ankle and knee braces on lower extremity kinetics and kinematics, when these braces are worn independently [1,2,3]. However, bracing of the knee and ankle simultaneously, for both prophylactic and rehabilitative purposes, is a common practice in athletics. While prophylactic bracing in athletes may be beneficial, some research has demonstrated potentially detrimental effects on lower extremity function. Of particular concern in this regard, are the effects that may be due to the combined use of ankle and knee braces. It has been speculated that the mobility limitations induced by multiple braces may create aberrant motion and forces at other joints that may result in injury. Therefore, the purpose of this investigation was to determine how ankle bracing alone, knee bracing alone, and ankle and knee bracing together affect lower extremity kinetics and kinematics during straight ahead jogging in healthy subjects.

### METHODS

Eighteen subjects with no history of lower limb pathologies within the two years prior to this study participated in the investigation. Each of the subjects performed a series of jogging trials with each of four brace conditions (no brace (NB), ankle brace (AB), knee brace (KB), ankle and knee brace (ABKB)). An Ankle Stabilizing Orthosis (Medical Specialties Inc.) and the functional knee brace (dj Orthopaedics, LLC.) were fitted to each subject according to manufacturers' guidelines. The subject rode a stationary bike, at a comfortable self selected pace for 5 minutes to provide a period of accommodation to the braces prior to the jogging trials. Each subject was then required to complete five to seven trials of straight ahead jogging for each of the randomized bracing conditions. Gait data was collected using a six camera, 3-D HIREs video system, a gait analysis software package and two force platforms. This data was analyzed for each of the subject's trials to determine the affects of the different brace conditions on the individual's gait pattern.

### RESULTS AND DISCUSSION

Average knee, ankle and hip joint angles for the NB, AB, KB and the ABKB groups were calculated and statistically compared at the point of peak knee moment (PKM). Figure 1 illustrates a statistically significant reduced knee joint angle at PKM in the KB and ABKB conditions compared to the NB condition. Results also revealed significantly reduced ankle joint plantarflexion ( $p = .046$ ) at PKM in the AB trials and a significantly reduced hip flexion angle ( $p = .034$ ) in the KB and ABKB trials.

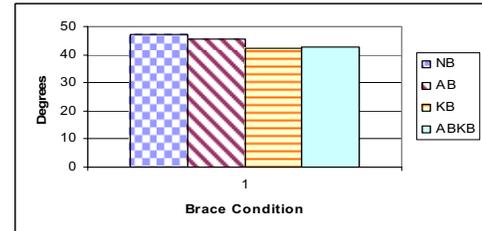

Figure 1: Left Knee Position at PKM.  $p = .007$

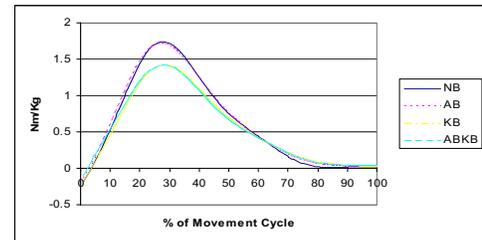

Figure 2: Left Knee Moments

Additionally, although not statistically significant, there were interesting trends in the joint moment data that illustrated a decreased knee extension moment in the KB and ABKB conditions (Figure 2). Additionally, there appeared to be a reduced ankle joint moment in the AB condition when compared to the other conditions. Finally, the ABKB condition appeared to evidence a slightly higher peak hip moment compared to the other conditions.

Previous studies have demonstrated a pattern of knee extensor torque adaptation during jogging, associated with FKB use, indicative of reduced stress on the ACL [1,2]. However no previous research has addressed the influence of simultaneous knee and ankle bracing on lower extremity function. It does appear from the current results that knee and ankle bracing may be protecting their respective joints, through a reduction in the moments. However these bracing conditions may be predisposing other areas of the body, specifically the hip and low back, to potential injury. With the rise in the use of prophylactic combined knee and ankle bracing in athletics, it is important for clinicians to be aware of these possible predisposing factors, even though the braces may be of some benefit in reducing injury.

## FINITE ELEMENT BONE MODEL INCORPORATING HETEROGENEITY AND ANISOTROPY FROM CT

C.M. Müller-Karger, C.A. Larrazabal  
 Departamento de Mecánica, Universidad Simón Bolívar, Caracas, Venezuela.  
 email: [cmuller@usb.ve](mailto:cmuller@usb.ve), <http://www.did.usb.ve/biomecanica>

### INTRODUCTION

This investigation seeks to achieve a heterogeneous and anisotropic characterization of bone in a simple form and with low computational cost. The ultimate purpose is to create a model and a platform to design and simulate medical devices. CT is used to develop a geometric reconstruction of the bone, and to assign the heterogeneous and symmetric mechanical properties to the elements of the model. The directions of symmetry of the material are determined based on prior knowledge that they are aligned with the principal stresses (Wolf Law). Bone material is considered to be orthotropic.

Several models based on CT consider the bone to be heterogeneous and isotropic. Only a few models take into account anisotropy, using either bone remodeling theories [1,2] or complex trabecular models [3].

### METHODS

A femur model was constructed using 197 images, spaced every mm at the epiphysis and every 4mm in the diaphysis. The images were 211x211 pixels, with a resolution of 0.7 mm/pixel, calibrated with a phantom.

Segmentation of the images produced a wire model that was imported to ANSYS. This FE software was programmed for the automatic construction of the solid model. Using 10 nodes tetrahedrons, various meshes were created for a convergence study. Plots of von Mises stresses, equivalent deformation and energy of deformation were evaluated for twenty points of all models. Then, a mesh of 43125 elements was chosen. The load condition used was the same as the one presented by Doblare and Garcia [2]. Assignment of mechanical heterogeneous properties was computed at every centroid of the elements using a program developed by the authors.

If the bone behaves as an object with orthotropic symmetry, it is necessary to determine nine non-zero elastic constants of the flexibility matrix: three Young modules  $E_1, E_2, E_3$ ; three shear modules  $G_{12}, G_{13}, G_{23}$ ; and six Poisson ratios  $\nu_{12}, \nu_{21}, \nu_{13}, \nu_{31}, \nu_{23}, \nu_{32}$ , of which only 3 are independent. Young modulus in the axial direction ( $E_3$ ) is related to density estimated from the CT using known equations. To obtain the remaining elastic constants, information of previous studies that have determined these properties by mechanical tests [4] was used. Resulting the following relations:

$$\begin{aligned} E_3 &= 1 & E_2 &= 0.67 * E_3 & E_1 &= 0.67 * E_3 \\ G_{32} &= 0.3 * E_3 & G_{13} &= 0.27 * E_3 & G_{12} &= 0.22 * E_3 \\ \nu_{21} &= 0.3 & \nu_{31} &= 0.95 * \nu_{21} & \nu_{32} &= 0.79 * \nu_{21} \end{aligned} \quad (1)$$

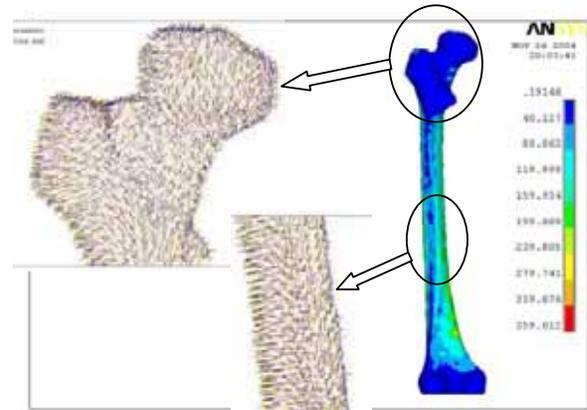

The FEM analysis provides the stress components of the three coordinated planes for each element. These are then used to solve the eigenvalue and eigenvector problem of the Stress

Matrix, in order to obtain the principal directions for every element of the model. The principal directions obtained for a heterogeneous and isotropic model are used as seed for an iterative process to find the actual direction of the mechanical properties. Convergence is verified for the three angles of every element.

To define local coordinate system in FEM programs the Euler angles ( $\alpha, \beta, \chi$ ) are required. These are obtained from the principal stresses vectors with a rotation matrix.

### RESULTS AND DISCUSSION

A comparison between isotropic and anisotropic models of the femur is performed. Results indicate that it is necessary to consider anisotropy to model bone tissue. Figure 1 shows results for a heterogeneous and anisotropic model.

**Figure 1:** Orientations of the coordinates systems are shown for the epiphysis and diaphysis. Plot of von Mises stress is for the whole model.

### CONCLUSIONS

We developed methodology to represent a bone model with a mechanical property and a material symmetry system for every model element. Numerical results indicate that even models with a relatively small number of elements leads to reliable results. The model reflects the highly heterogeneous and anisotropic characteristics of the bone, and operates at very low computational cost, using normal CT. The model is not intended as a substitute of microscopic bone models [3].

### INTRODUCTION

Pennate muscles have aponeuroses and external tendons, both of which have been regarded as elastic materials. However, limited information is available on the behavior of each of the two tissues of human muscles during contractions. Some attempts have been made to determine mechanical properties of these structures in vivo [1, 2], but the data have been obtained in a 'static action' of the muscle-tendon complex, not in a 'dynamic action' in which most human movements are performed. The purpose of this study was to investigate the differences between the behavior of the aponeurosis and external tendon of the medial gastrocnemius muscle (MG) in dynamic actions. We determined the length changes of the aponeurosis and external tendon of MG during concentric and eccentric actions of the ankle joint using ultrasonography.

### METHODS

Nine male subjects ( $23.5 \pm 1.4$  yr,  $171.5 \pm 6.6$  cm,  $64.1 \pm 6.1$  kg, mean  $\pm$  SD) performed concentric (CON) and eccentric (ECC) plantar flexion exercises preceded by an isometric action (Pre-iso) on an isokinetic dynamometer (CON-TREX, CMV AG, Switzerland) with pre-set velocity of 5°/s. The range of motion of the ankle was set from 100° to 60° (90° was the neutral anatomic position; positive values for dorsiflexion). Each of concentric and eccentric exercises was performed at three contraction intensities; maximal voluntary contraction (CONmax, ECCmax), and 30 and 60% of MVC (CON30%, CON60%, ECC30%, ECC60%). From Pre-iso to the end of joint motion, the subjects kept the pre-set level of contraction intensity through a visual feedback of the exerted torque. In addition, the subjects performed static ramp actions with the ankle positioned at 100° and 60°.

During the exercises, ankle joint angle and torque were measured, and simultaneously length changes of the aponeurosis and external tendon of MG were determined using two ultrasound apparatuses (SSD-5500, SSD-6500SV, Aloka, Japan) with electronic linear array probes of 10 MHz and 7.5 MHz wave frequency, respectively. The Achilles'

tendon force was calculated by dividing the torque by the moment arm of MG, estimated with a procedure described in a prior study [3].

### RESULTS AND DISCUSSION

In CON, the length of external tendon significantly shortened from the level of Pre-iso in all test conditions, with decreasing Achilles' tendon force. However, those change of aponeurosis was significant only in CONmax (Table 1). In ECC, the external tendon was elongated in all test conditions with increasing Achilles' tendon force, while aponeurosis was not elongated even in ECCmax (Table 1, Fig. 1). In static action at 60°, the lengths of both aponeurosis and external tendon increased across force level. However, the length of aponeurosis did not change in static action at 100°.

The present results indicate that, in concentric and eccentric actions, the behaviors of the tendon tissues of MG differ between aponeurosis and external tendon. From the findings obtained here, it may be assumed that the external tendon of MG plays a role of storing and releasing elastic energy. On the other hand, it is suggested that the aponeurosis of MG releases the pre-stored elastic energy in concentric actions, while it acts just for transmitting the muscle force in eccentric actions.

### CONCLUSIONS

The present study provides evidence that there is a difference between the length changes of aponeurosis and external tendon in dynamic actions. In addition, the present results indicated that the elastic behavior of aponeurosis differ depending on the types of exercises (concentric or eccentric).

### INTRODUCTION

Previous published descriptions of foot and ankle kinematics are incomplete because they are selective in their location of measurement devices on the foot. There is a particular dearth of information on navicular, cuboid, cuneiform and metatarsal kinematics. We aimed to describe the kinematics of the tibia, talus, calcaneus, navicular, cuboid, three cuneiforms, five metatarsals and proximal phalanx of the hallux during a cadaver based simulation of walking.

### METHODS

A dynamic cadaver model (walking simulator) was used to apply load to the tibia and leg tendons in a manner to move the specimen in a manner similar to walking. The walking simulator consists of a rigid metal frame supported by four wheels, which is pulled along a track by a motor and cable. Attached to the frame is a pneumatic cylinder which applies vertical load to the below knee cadaver specimen. Artificial muscle forces are applied through attachments to nine individual tendons (tibialis posterior, tibialis anterior, flexor hallucis longus, flexor digitorum longus, Achilles, peroneus brevis, peroneus longus, extensor digitorum longus and extensor hallucis longus) using eight motors (extensor hallucis and digitorum longus are tied together). The tibial loading, forward progression of the tibia and tendon force actuators are open loop controlled and adjusted manually. The duration of stance is approximately 2 seconds and ends prior to toe off, at about 80% of normal stance. Data were collected on 13 specimens (age 32 to 80). Clusters of 4 reflective markers were attached to each bone using 1.6mm K wires.

Eular angles were computed for 22 anatomical joints. To assess the repeatability of the walking simulation, the coefficient of multiple correlation (CMC) was calculated for the kinematic data and ground reaction forces.

### RESULTS AND DISCUSSION

The simulator produced repeatable simulations of gait for each foot. CMC for the major rearfoot joints (ankle, sub talar, talonavicular and calcaneo cuboid joints) were all > 0.6. Table 1 shows mean range of motion at each joint during the simulated stance phase (mean of 13 feet). The kinematic

pattern at the ankle and sub talar joints was in line with in vivo kinematic data [1]. We found greater frontal and transverse plane motion at the talonavicular joint (mean of 11.6° and 15.5° respectively) than at the calcaneocuboid joint (mean of 5.9°, 6.8° respectively). The concept of the 'mid tarsal' joint, at which the navicular and cuboid move as a single functional unit relative to the calcaneus and talus, is broadly supported by the data. Whilst there was relative motion between the navicular and cuboid, both joints dorsiflexed during the first 60% of the simulated stance phase, and plantarflexed thereafter. Both joints everted and abducted during the first 30% of the simulated stance phase, and inverted and adducted thereafter.

The motion between the cuneiforms and navicular, and the cuboid and cuneiforms was greater than we had anticipated. At the medial cuneiform/navicular joint there was on average 9.8°, 6.5° and 3.1° in the sagittal, frontal and transverse planes respectively. The motion between metatarsals 4 and 5 and the cuboid was consistently larger than the motion between the other metatarsals and their cuneiforms. Metatarsals 1-3 moved an average of just 4.7° and 5° in the sagittal and frontal planes relative to the cuneiforms, whereas metatarsals 4 and 5 moved 9.8° and 9° respectively in relation to the cuboid.

Our data demonstrate that all mid and forefoot joints have an important role in the overall kinematic function of the foot. For example, based on the mean data sagittal plane motion between the navicular and talus, navicular and medial cuneiform, and medial cuneiform and the first metatarsal, totaled 23.9° during the part of stance simulated. This is comparable to the motion at the ankle and sub talar joints. The motion between the cuneiforms and navicular (9.8°, 8.5° and 10.5° for the medial, central and lateral cuneiforms respectively in the sagittal plane) was comparable to, or in some cases exceeded, the motion between the talus and navicular (9.6°) and between the calcaneus and cuboid (6.9°).

### INTRODUCTION

In recent decades, ballroom dancing has become very popular around the world. With an increasing number of people putting on their dance shoes, ballroom dancing has, in fact, become more than just a predominant social activity. Many competitive ballroom dancers had sustained dance-induced injuries. The goal of this study was to investigate the injury incidence and footwear satisfaction in competitive ballroom dancing.

### METHODS

Personal interviews were conducted on 29 male competitive ballroom dancers in Singapore. The personal particulars of each subject were acquired in section I of the survey. This was to categorize subjects into different age groups, dancing experience, and level of expertise. Section II of the survey investigated the injury profile of each subject whereby the average number of injuries per year sustained was documented. In addition, each subject was asked to describe during which actions were injuries occurred. In section III, the level of satisfaction of dance footwear in use was recorded. Subjects rated dance shoes in terms of satisfaction on a scale of 1 (least satisfied) to 5 (most satisfied). Factors taken into account were traction, fit, impact absorption, support, height, comfort, and arch.

### RESULT AND DISCUSSION

#### Injury Incidence

The male Latin dancers generally had a higher injury profile as compared to the Standard dancers. The most common injuries in male Latin dancers occurred at the back ( $14.0 \pm 7.5$  injury/year), ankle ( $13.4 \pm 7.4$  injury/year), hip ( $11.8 \pm 8.2$  injury/year), and foot ( $10.7 \pm 5.4$  injury/year). The injuries at the back and hips were probably due to the vigorous upper body actions required in the Latin dances. The Samba and Cha Cha Cha especially required a lot of hip rotation and hip thrust. The Samba roll required extreme stretching and bending of the back in anti-clockwise directions. The basic Cha Cha Cha steps, on the other hand, had the dancer thrusting the hips to move forward, backward, or sideways. When acute actions were performed sharply at a fast tempo, the male Latin dancers were easily prone to injuries if no proper care was taken. Male dancers generally had the exaggerated jumping and landing actions in the routine for Paso Doble. When these actions were not executed properly, dancers could injure the foot. Furthermore, male dancers were sometimes required to support their partners, causing extra stress on the body.

Footwork was a very important factor in competitive ballroom dancing. Whether it is the sensual Rumba or the lively Jive, tremendous stress was placed on the dancers' feet. Furthermore, dancing in heels (1 ~ 1.5 inch) had aggravated this stress. Thus, proper warm-up must be performed before engaging in vigorous dance training.

The main locations of common injuries sustained by the male Standard dancers were found at the foot ( $5.1 \pm 3.2$  injury/year), ankle ( $4.8 \pm 3.1$  injury/year), shin ( $3.8 \pm 3.1$  injury/year), and wrist ( $3.5 \pm 3.1$  injury/year). Although the nature of the Standard dances differed greatly from the Latin dances, amount of stresses placed on the dancers' feet could also be very enormous. Adequate control in the foot and ankle was required to maintain the up-down motion in the Waltz, and the Slow Foxtrot. On the contrary, fast galloping and jumping actions were required in the Viennese Waltz, and the Quickstep. In the Standard dances, the couple covered huge distances on the dance floor with the male dancer taking the lead over his partner. The male dancer prompted the female dancer by means of the upper and lower extremity contact. For example, in the Standard ballroom dance Waltz, the male dancer would take the first step forward. And when his shin touched the partner's, she received the cue and subsequently took a step backwards. The constant rubbing and collision of the shin could have resulted in the occurrence of shin injuries.

#### Footwear Satisfaction

The subjects were generally satisfied with the dance footwear in use. The more significant variables include the fit ( $4.0 \pm 0.8$ ), impact absorption ( $3.6 \pm 1.0$ ), support ( $3.6 \pm 1.0$ ), and comfort ( $4.0 \pm 1.0$ ). One possible explanation for the high satisfaction rate of the fit may be that the front of the foot was completely covered by the footwear of male dancers. And the fit of footwear could also be adjusted with the tightening or loosening the shoelaces. For impact absorption of dance footwear, subjects had a more uniform pressure distribution on the feet due to the relatively high contact area with the surface of the dance floor. The arch of the dance shoes became steeper as the heel height increased. Since the heel heights of the dance shoes for male dancers were significantly lower than female's at 1 to 1.5 inch, the tendency for developing foot problems with the shoe arch was greatly reduced.

## PREDICTION OF LOWER LIMB SEGMENT KINEMATICS FROM FOOT ACCELERATIONS

Yannis Goulermas, David Howard, Lei Ren, Richard Jones, Chris Nester, Jiri Canderle

 Project: (Real-Prof) : IST 2001/38429, [c.j.nester@salford.ac.uk](mailto:c.j.nester@salford.ac.uk), [www.realprof.eu.com](http://www.realprof.eu.com)

### INTRODUCTION

Whilst gait analysis has proved useful for clinical applications its use is still limited by the cost of the facilities, the time and resource required for data collection and analysis, and the fact that the data is only a snapshot of how a patient walks under laboratory conditions. We do not know how representative gait assessment in a laboratory is of gait during daily lives. As a result of these limitations there are efforts to develop “wearable” gait laboratories that provide continuous and daily monitoring of gait. The basis of these systems is that a suitably small number of wearable sensors can be used to measure and represent human motion and activity. Through these systems 1000’s rather than 10’s of gait cycles from real world situations can be assessed and a truly representative quantification of patient gait (and other activities) acquired. Of the technical challenges in this development, the use of as few and simple motion sensors as possible and the extraction of the maximum amount of motion information as possible is paramount. This would lead to small, inexpensive, light weight and therefore acceptable wearable systems, and yet little or no compromise on data quality for gait researchers. The work described here uses acceleration data of the foot to predict sagittal plane foot, shank and thigh kinematics. For the “wearable gait laboratory” concept this emulates the use of accelerometers to measure foot acceleration, but the extraction from that of full lower limb sagittal plane kinematic data.

### METHODS

Kinematic data were collected on 8 subjects using the CAST marker system for the foot, shank, thigh and pelvis and 10 Vicon cameras. From the foot markers the acceleration of the foot in two directions were determined. Also, foot, shank and thigh angles in the sagittal plane are calculated. Several different regression techniques were used (eg: Linear regression, Multi Layer Perception, Polynomial, Functional Link and Radial Basis Neural Networks and k-Nearest Neighbours, Generalised Regression Networks), to predict the foot, shank, and thigh motion patterns from the foot acceleration data. Data from 5 gait cycles for each of the 8 subjects was used with a 4-fold Cross-Validation process. The 8 subjects are split to 4 groups of 2, and each time we use 3 groups for training of the regression tools and 1 for testing of the tools. The final errors are calculated from averaging the errors for the 4 runs of the training-testing stages. The errors measured were the used Cross-Correlation coefficient (CC), the Root Mean Square (RMS), the Maximum Absolute Deviation (MAD) and a Thresholded Absolute Deviation (TAD) that represents the percentage of angle error predictions exceeding a user-defined threshold set to 5°. Table 1 presents these errors for each of the six predicted signals. Figure 1 (top) displays single (1 out of the four) repetitions of Cross-Validation (where subjects 7 & 8 are used to test

algorithms and all other 1,...,6 are used for training). Figure 1 (bottom) presents the training (top graphs -6 subjects) Figure 3 displays testing of  $\theta_{rl}$  prediction ( $r$  = right leg,  $l$  = left leg,  $f$  = foot,  $s$  = shank,  $t$  = thigh..

## REACTION TO A LOSS OF BALANCE IN HEALTHY MENOPAUSAL-AGED AND YOUNG WOMEN

<sup>1</sup>Doug Wisner and Kurt DeGoede

Elizabethtown College, Department of Physics and Engineering, Elizabethtown, PA, degoedek@etown.edu

<sup>1</sup>presently enrolled in the Penn State College of Medicine, Hershey Medical Center, Hershey, PA, dmw294@psu.edu

### INTRODUCTION

Falls and fractures related to those falls are a significant problem in elderly adults [1]. Epidemiological studies have also shown that there is a greatly increased risk for distal forearm fracture in women that are not elderly, but experiencing menopause [2]. Osteoporosis cannot explain why other fracture sites do not show the same increase in fracture rate [3] or why these women are also falling much more frequently than their younger counterparts [4].

This is a pilot study designed to determine the reaction of menopausal-aged women, **M**, to a fall situation (balance disturbance) and compare that reaction to those of younger women, **Y**. It is hypothesized that the menopausal-aged women will have slower arm reaction time, RT, than the younger women in an actual balance disturbance and that the older women would have slower movements while attempting to regain their balance with their arms. **M**t previous work has focused on differences between young women and those over the age of 65 and only a few studies have looked at reactions to actual fall conditions or at upper extremity reactions to these conditions [5].

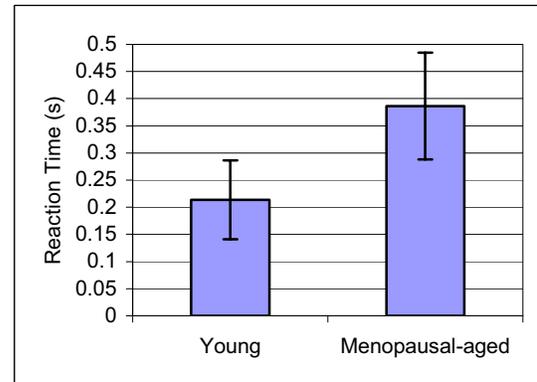

### METHODS

Three healthy young women and three healthy menopausal-aged women were recruited from the Elizabethtown College community. The young women had a mean age of  $20 \pm 1$  years and the menopausal-aged women had a mean age of  $50 \pm 1$  years. Subjects were screened by a written health evaluation, signed an informed consent form, and all procedures were approved by the institutional review board.

Subjects were asked to step onto a balance disturbance platform, with hands at their sides, wrists contacting switches placed at their hips. Each was fitted in a safety harness to prevent any fall to the ground and told to try to keep her feet in place at all times, but that she was free to move her hands. Subjects were asked to react as naturally as possible to any loss of balance that may happen during the study. The electronic switches captured timing data and arm movements were recorded by two Sony digital cameras and a SIMmotion capture system (SIMI Reality Motion Systems, Germany).

Twenty trials were conducted with the **Y** at multiple drop heights (up to 8.25 cm) to determine a minimum effective balance disturbance. With this determined, ten trials were conducted with the **M** at this height.

The hypothesis was tested in using a student t-test assuming unequal variance. Two-tailed t-values below .05 were considered significant. RT's that were more than 4 stdev from the mean of the other trials for that subject were discarded as outliers (3 instances).

**Figure 1:** Average reaction time for the two groups.

### RESULTS AND DISCUSSION

There was no relationship between trial number and RT in the **Y** and **M** and that there was no relationship between drop height and RT in the **Y** ( $r < 0.5$  for all subjects).

The **Y** and **M** responses at the minimum effective balance disturbance (5.7 cm drop) showed **Y** reacted with a mean RT of 21473 ms and **M** reacted with a mean RT of 38698 ms. A trend is noticeable, as shown in figure 1, but there is not a statistically significant difference with the limited number of subjects here ( $p = 0.08$ ). The **Y** reactions times were just faster than those reported in slips while walking (250 – 300 ms) [5]. The movements themselves were very similar between **Y** and **M**, table 1.

This data, though limited, suggests a potential decline in the ability to respond to a fall disturbance as early as at 50 years of age in women. However, surprisingly, the velocity and magnitude of the responses appears essentially unchanged.

	<b>Y</b>	<b>M</b>
<b>Movement amplitude (m)</b>	0.12 $\pm$ 0.07	0.17 $\pm$ 0.12
<b>Maximum velocity (m/s)</b>	1.3 $\pm$ 0.5	1.2 $\pm$ 0.7

## GAIT ADAPTATION: LEAD TOE CLEARANCE CONTINUALLY DECREASED OVER MULTIPLE EXPOSURES WITH AND WITHOUT ON-LINE VISUAL INFORMATION

Chris Rhea and Shirley Rietdyk  
Health and Kinesiology Department, Purdue University  
email: srietdyk@purdue.edu

### INTRODUCTION

Reduced vision of the lower limbs is a common occurrence in activities of daily living. Carrying a laundry basket up stairs reduces vision of both the lower limbs and the obstacle (stair). Patla [1] has shown that absence of vision of the lower limb relative to an obstacle changed the trajectory of the swing limb. Rietdyk et al. [2] found that similar visual interference did not change the trajectory of the swing limb when accommodating an elevated surface, and suggested that the lack of change may have resulted from increased exposure. The purpose of this research was to determine if increased exposure to an obstacle with visual interference and full vision modified toe clearance of the lead limb during gait.

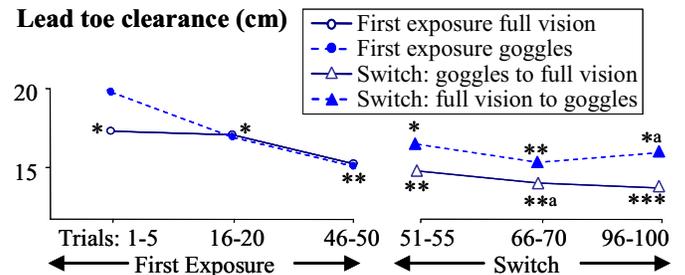

### METHODS

The lower limb kinematics of six subjects (23.8 yrs) were examined while stepping over a 10 cm obstacle. Subjects performed 50 blocked trials with full vision and 50 blocked trials with visual interference which were randomized so half of the subjects received full vision first. Goggles blocked the view of the lower limb and the obstacle two steps prior to stepping over it. Lead toe clearance was examined. A 2x2x3 (vision x order x trials (grouped as first, middle, and last five trials)) ANOVA was run.

### RESULTS AND DISCUSSION

Subjects tripped on 1% of the obstacle crossing trials, all trips occurred with the trail limb. A significant interaction was observed for lead toe clearance (vision x order x trials,  $p < 0.0001$ ). Post hoc analyses for the full vision trials revealed that toe clearance decreased 12.1% over the first 50 trials (solid line in figure 1). While the initial large margin (17.3 cm) reduced the risk of tripping with the lead limb, the proactive strategy would require an increase in energy consumption and also reduced stability [3]. Therefore, an ideal toe clearance should be high enough to prevent tripping, but low enough to maintain stability and reduce energy costs. With increased exposure, and without specific instructions or external feedback from the experimenters, the subjects reduced their toe clearance. This indicates that subjects were attending to 'internal' feedback to decrease the toe clearance during this dynamic task. Visual feedback, presumably from view of the knee in the periphery [1], would allow the subject to continually reduce the limb elevation.

Toe clearance was 19.9 cm for the first five trials with visual interference, an increase of 2.5 cm (14%) relative to the full vision condition, consistent with Patla [1]. Due to visual interference, feedback would not be received from the view of the knee in the periphery. Generally, spatial estimates with vision are considered to be less variable than other sensory modalities [4]. As only kinesthetic information could provide the feedback, limb elevation increased to compensate for variability. Subjects reduced toe clearance by 23.4% during

**Figure 1:** Lead toe clearance across 100 trials for full vision (open circles and triangles) and goggles (closed circles and triangles). Asterisks indicate significantly different responses, \*a indicates the response was not different from \* or \*\*, \*\*\* was not different from \*\* or \*\*\*.

the first 50 trials, the reduced toe clearance values were not different from the full vision group after 20 and 50 exposures.

Following 50 exposures with full vision, subjects who received visual interference for the first time showed an increase in toe clearance (dotted line in right half of Fig. 1), which did not decrease over 50 trials. However, the subjects who received visual interference first did not demonstrate a decrement in performance when vision was provided. These findings are consistent with the motor control literature where motor learning during aiming tasks has been shown to be specific to the sources of afferent information used to optimize performance during practice [5]. These findings are especially interesting as we did not specifically instruct subjects or provide feedback regarding toe clearance.

It is important to note that the toe clearances observed here were slightly higher than those observed in the literature [e.g. 1]. This between subject difference may affect the overall magnitude of the decrease, but we would still expect to see a decrease with repeated exposures. Further analyses will examine clearance of the trail limb and toe clearance variability during this task.

### CONCLUSIONS

During initial exposure, toe clearance decreased for both full vision and visual interference conditions, and after 20 trials the toe clearance was not different across the visual conditions. However, when subjects switched to another visual condition, those with initial visual feedback showed a decrement in performance, which was not observed when the initial trials were without visual feedback.

## HUMAN BILATERAL DEFICIT DURING DYNAMIC, MULTI-JOINT LEG PRESS MOVEMENT

Dean Hay, Vinicius Aguiar de Souza, Senshi Fukashiro  
 Department of Life Sciences, University of Tokyo, Japan  
 email: w\_dean\_c\_hay@hotmail.com

### INTRODUCTION

Bilateral Deficit (BLD) is used to describe the decrement of the maximum performance elicited by two limbs working simultaneously when compared to the sum of each limb working independently. Both impaired reaction time and decreased force production have been observed in humans during bilateral movements [1, 2]. However, other studies have demonstrated no bilateral deficit [3], or differences dependent upon the motor task and type of athlete [4].

The purpose of this study was to determine whether or not BLD was present during a dynamic movement (**horizontal leg press**) under conditions where the relative load was equal for single and two-legged jumps.

### METHODS

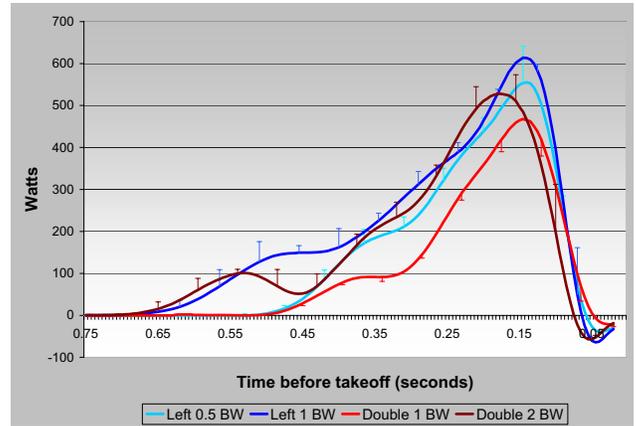

Five healthy male subjects (Age:  $27.8 \pm 3.5$  yrs; Weight:  $72.2 \pm 4.7$  kg; Height:  $1.76 \pm .03$  m; mean  $\pm$  SD) participated in this study with informed consent. Subjects were positioned in the supine position on a horizontal leg press machine and performed a randomized series of left, right, and double leg maximal jumps. Loads were adjusted for single leg (0.5x and 1x body weight - BW) and double leg (1x and 2x BW) jumps. Each condition was repeated 4 times for a total of 24 trials.

Kinematic (200 Hz) and reaction force (1000 Hz) data were recorded along with EMG (1000 Hz) from 6 muscles of the left leg (Sol, MGas, BFem, VMed, RFem, GMax). Joint torque, power, and work were calculated for the ankle, knee, and hip of the left leg (Armo, G-sport, Japan). EMG root mean square (RMS) was also determined. Single and double leg jumps were normalized then statistically analyzed using a repeated measures general linear model (5 subjects x 6 conditions x 4 trials).

The bilateral deficit index was calculated by the formula:

$$BI = 100 * (\text{single leg} - \text{double leg}) / \text{single leg}$$

A positive value denotes a bilateral deficit.

**Figure 1:** Average knee joint power for 4 conditions with standard deviation bars (one subject).

### RESULTS AND DISCUSSION

As there was no significant difference between left and right leg impulse, subsequent analyses were limited to left leg - double leg trials. Left leg jump impulse was significantly greater than double leg impulse (Left 0.5BW vs. Double 1BW; Left 1BW vs. Double 2BW, respectively). Sol, RFem, and VMed showed BLD, while MGas and GMax exhibited bilateral facilitation. Work for each joint exhibited significant BLD (Table 1).

### CONCLUSIONS

Bilateral deficit during a multi-joint leg press movement is negatively associated with load. Our data show that BLD is greater during explosive, rapid movement, suggesting general impaired fast-twitch motor unit recruitment. Implications of the results are discussed.

## THE MODIFICATION OF PEDALING SKILL WITH REAL-TIME REPRESENTATION OF PEDALING FORCE IN NON-CYCLISTS

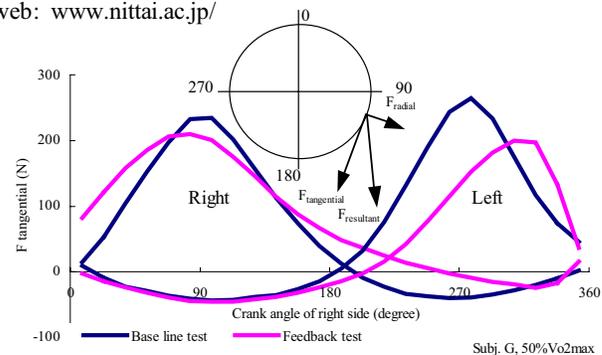

<sup>1</sup> Tetsunari Nishiyama and <sup>1</sup> Takayuki Sato  
<sup>1</sup> Human Performance Laboratory, Nippon Sport Science University  
 ; email: nishiyama@nittai.ac.jp, web: www.nittai.ac.jp/

### INTRODUCTION

By the real-time representation of the force on the pedal during bicycling, even non-cyclists can quickly modify the pedal force. The effect of such feedback instruction will vary in individuals. We examined the effect of modification on the pedaling mechanics induced by the real-time representation of the force-pattern applied to the pedals during bicycling in non-cyclists. Also the modified force pattern was examined in relation to the energy consumption.

### METHODS

Seven males (23-31yrs) participated in a maximal  $\text{Vo}_2$  test, baseline test, and feedback test. In the baseline test, the subjects were asked to pedal naturally without any feedback instruction using a racing type ergometer. Both feet were fixed to the pedals. They pedaled the load of 30, 50 and 70%  $\text{Vo}_2\text{max}$ , at a cadence of 70 rpm. The pedaling forces of tangential ( $F_{\text{tan}}$ ) and radial ( $F_{\text{radial}}$ ) directions to the crank arm were measured in the left and right pedals using a strain-gauge method. The resultant force ( $F_{\text{result}}$ ) was determined from  $F_{\text{tan}}$  and  $F_{\text{radial}}$ . The crank angle was measured by a potentiometer and defined 0 degree at the top position. Each pedal force was averaged on thirty revolutions of the crank. The  $\text{Vo}_2$  was averaged on the last 30 seconds of each 5 minute load. The delta mechanical efficiency was calculated from oxygen consumption and mechanical work in each load. After two to five days of the baseline test, the feedback test was conducted with visual and oral instructions. The visual instructions show the subjects the PC monitor displaying  $F_{\text{result}}$  and  $F_{\text{tan}}$  on the clock diagram every 30 degree of crank cycle. The subjects were given an explanation of the mechanisms of  $F_{\text{tan}}$  and  $F_{\text{result}}$ . After at least 5 minutes practice periods, the subjects were asked to try the following movement, “ $F_{\text{result}}$  turn to the direction of  $F_{\text{tan}}$  in 90-180 and 180-360 degree of crank cycle on the both pedals”. The representation of the clock diagram on the both sides continued during the bicycling while oral

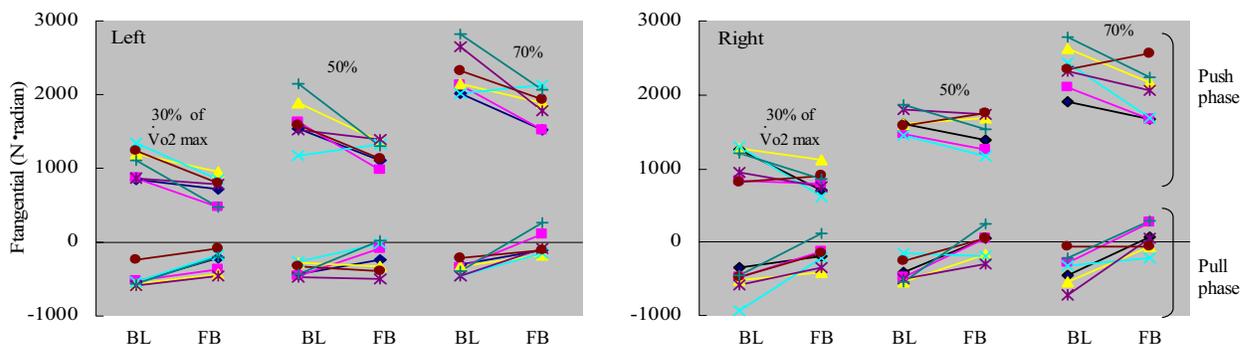

**Figure 1:** Averaged tangential force in thirty cycles.

instruction was sometimes given.

### RESULTS AND DISCUSSION

In the modification of the pedaling mechanics with the feedback intervene, the  $F_{\text{tan}}$  decreased in the push phase (0-180 degree of crank angle) and increased in the pull phase (180-360 degree) (Fig. 1, 2). Generally, as shown in Fig. 2, the modified right  $F_{\text{tan}}$  in the pull phase showed large increase, which was the predominant side in all subjects, in comparison with the left one, and the left  $F_{\text{tan}}$  of the push phase showed large decrease than the right one.

In the load of 30% $\text{Vo}_2\text{max}$ , the increase of the right  $F_{\text{tan}}$  in the pull phase was correlated to the increase of  $\text{Vo}_2$  in the modified pedaling. Such the modification of pedaling force was not always reflected effectively for the oxygen consumption. Thus, the excessive modification of the pedaling force made the mechanical efficiency decrease. However, the changes of the pedaling mechanics, such in pull or push phase and the left or right leg, was varied in the subjects. It was confirmed that the feedback effect of the pedaling skill should be evaluated in the relationship between the individual difference of the pedaling modification and energy consumption.

## EFFECT OF INCREASED MECHANICAL STIMULI ON FOOT MUSCLES FUNCTIONAL CAPACITY

Gert-Peter Brüggemann, Wolfgang Potthast, Björn Braunstein and Anja Niehoff  
 Institute for Biomechanics and Orthopaedics,  
 German Sport University Cologne; email: [brueggemann@dshs-koeln.de](mailto:brueggemann@dshs-koeln.de)

### INTRODUCTION

As biological structures receive mechanical stimuli they are getting stronger. If muscles, tendons and bones are not in use they will decrease strength and their functional capacity. The biological structures of the foot can be trained by barefoot walking or workout through the speculated higher loading. No scientific evidence for a causal relationship between increased foot loading and functional improvement of foot structures could be found in the literature. The foot arch and the foot functional capacity is strongly related to the strength of the flexor muscles of the metatarsophalangeal joints (MPJ): M. flexor hallucis longus (FHL) and M. flexor digitorum longus (FDL) [1,2,3]. It was shown that a special designed minimal shoe (Nike FREE) increases the range of motion on the metatarsophalangeal joints (MPJ) and the ankle joint in normal walking and modifies the plantar pressure distribution in a way close to barefoot walking on grass. In a pilot study using wire EMG technique the muscle activity of the FHL was shown to be significantly increased during walking in the minimal footwear in comparison to walking in traditional running shoes. If training with the minimal footwear mimics barefoot training one can assume that using the minimal shoe will increase the loading of the foot structures and make them stronger.

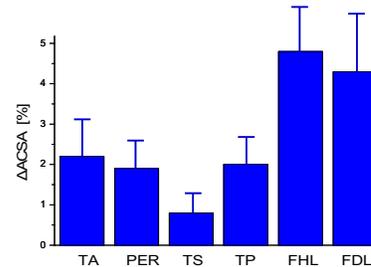

The purpose of the study was to demonstrate the capacity of biological structures to adapt to mechanical stimuli modified through footwear and to quantify effects on strength and morphology of the foot and shank muscles. The research question was to quantify the impact of increased mechanical stimuli on (1) muscle strength and (2) anatomical cross sectional area (ACSA) of intrinsic foot and shank muscles.

### METHODS

The research question was solved by a prospective longitudinal designed approach. The prospective study operated with an experimental ( $n_E=25$ ) and a control group ( $n_C=25$ ) both consisting of male and female subjects. The experimental intervention over a period of five months was the use of the minimal footwear in athletes preparatory (warm up) training while the control group used traditional training shoes for the same training programme. The measurement of muscle strength was performed by special custom build dynamometers. ACSA of FHL, FDL, M. triceps surae (TS), Mm. tib. post (TP) and ant.(TA), M. peroneus (PER) at the greatest circumference of the shank and ACSA of four of the intrinsic foot muscles (M. abductor hallucis, M. quadratus plantae, M. abductor digiti minimi, M. flexor digitorum brevis) were estimated by MRI (Siemens Symphony, 1.5 Tesla).

### RESULTS AND DISCUSSION

The muscle strength changes through the intervention showed a significant ( $p<.01$ ) increase of the MPJ flexors in the experimental group; no significant change in the controls.

**Figure 1:** Relative increase of ACSA of six extrinsic foot muscle through the five months intervention (Mean and SEM); experimental group ( $n_E=25$ ).

**Table 1:** Changes in MPJ flexor strength [N], subtalar inversion strength [Nm], plantar and dorsi flexors strengths [N]. Means and SEM. \*:  $p<.05$ , \*\*:  $p<.01$ .

	Experimental group		Control group	
	Pre	Post	Pre	Post
MPJ flexor strength	232 (10.9)	279 (11.6) **	228 (11.1)	237 (11.6) ns
Inversion moment	18.0 (1.4)	21.8 (1.6) *	17.5 (1.3)	17.7(1.2) ns
Plantar fl. strength	1065(72.2)	1254(73.2) *	1296(68.0)	1242(63.1) ns
Dorsi fl. strength	432(18.0)	460(18.9) *	415(20.6)	419 (14.8) ns

Plantar flexion strength increased only significantly ( $p<.05$ ) in the experimental group. The maximum supinator muscles torque increased for the experimental group ( $p<.05$ ) and showed no effect on the control group. While for the Mm tibialis anterior, peronei, tibialis posterior and triceps surae no significant changes in the ACSA were found, the ACSA of the Mm flexor hallucis and flexor digitorum increased by approximately 4% and by 5% for the Mm abductor hallucis and quadratus plantae in the experimental group.

### CONCLUSIONS

The use of minimal footwear was related to changes in muscle strength and morphology. It was demonstrated that the footwear increased mechanical stimuli on the tendon muscle units. The muscle strength capacity of those muscles which were more intensively used by the minimal shoe increased significantly. Muscles which were similar activated in both conditions did not respond. One can conclude that footwear technology impacts the mechanical loading as well as the biological response of the loaded tissues.

## AN INVESTIGATION OF EXTERNAL LOADING PATTERNS APPLIED DURING MAXIMAL GRIP

A.K. Kanellopoulos, M.K. Gíslason, N.K. Fowler  
 Bioengineering Unit, University of Strathclyde; email: [asimakis.kanellopoulos@strath.ac.uk](mailto:asimakis.kanellopoulos@strath.ac.uk)

### INTRODUCTION

The external loads applied to the fingers have been previously measured using different gripping tools in several wrist orientations [1],[2],[3]. Uniaxial or planar forces applied to a grip tool are typically measured in order to examine the force distribution across the digits. These kinetic studies have not been concurrent with kinematic measurement and there is therefore little information on the external moments generated at the finger joints during whole hand grip.

The aim of the current study was to investigate the three dimensional externally applied forces and moments on each individual finger during whole hand grip. The variation of the external loading patterns and the finger force distribution was also studied in relation to the orientation of the wrist joint.

### METHODS

A cohort of fifty healthy right-hand dominant adults (25 males, 25 females) were required to provide their maximal gripping force in five different wrist orientations: maximal flexion, extension, radial (RD) and ulnar deviation (UD) and a position of 'functional neutral' (N). A custom-built gripping tool with five independent six-degree-of-freedom force transducers was used to measure the three dimensional forces and moments applied to individual digits during each grip task. The kinetic data was synchronized with an eight-camera VICON (Oxford Metrics) motion analysis system in order to obtain concurrent kinematic data of each finger/thumb segment, the wrist and forearm. These kinematic data were used to express the transducer loads in terms of individual metacarpal axis systems.

### RESULTS AND DISCUSSION

The mean (SD) percentage distribution across the fingers of the applied normal transducer force for the neutral wrist position was found to be: 35% (7.6%) in the index, 30% (6.9%) in the middle, 21% (5.5%) in the ring and 14% (5.9%) in the little finger. These results are comparable with several previous studies [2]. Others suggest however that the middle finger exerts the highest normal force during maximal grip with a neutral wrist [3]. Figure 1 shows the force distribution across the digits in the coronal plane for three wrist positions. It is evident from this figure (and table 1) that during maximal

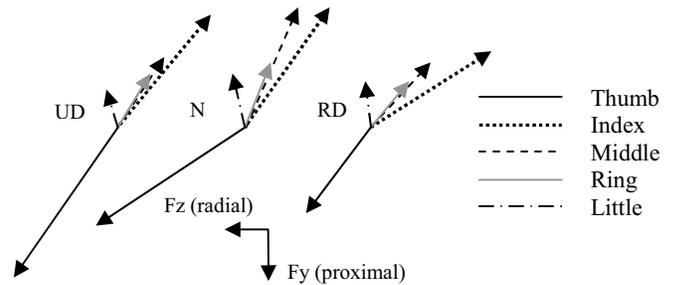

Figure 1: Force vector diagrams showing the force distribution between the digits for three wrist positions in the coronal plane with respect to the metacarpal axis systems.

grip trials there is a significant contribution from shear forces which cannot be neglected.

Table 1 shows how the external loading patterns applied to the index finger (with respect to the metacarpal axis systems) vary with wrist joint orientation in maximal grip. The maximum resultant grip loads are generated in a neutral wrist position. The largest ulnarly directed forces occur during ulnar deviation and this coincides with the largest applied adduction moments. This evidence agrees with current knowledge of hand biomechanics and is clinically important because it explains the contribution of external loading patterns on the development of several deformities in the pathological hand.

### CONCLUSIONS

The three dimensional loading patterns generated during whole hand grip are complex and vary with wrist orientation. Significant shear force components are produced during simple grip activities and these can generate large adduction/pronation moments at the finger joints. These results have important implications for both biomechanical modelling and joint implant design.

## TREADMILL VERSUS OVERGROUND RUN TO WALK AND WALK TO RUN TRANSITION SPEED IN UNSTEADY STATE LOCOMOTION CONDITIONS

<sup>1</sup>P. Malcolm, <sup>1</sup>M. Lenoir, <sup>2</sup>P. Aerts, <sup>1</sup>V. Segers, <sup>1</sup>D. De Clercq

### INTRODUCTION

Recently it has been argued that the transition between walking and running is a gradual process instead of a distinct event [2]. If this is true then transitions should preferably be studied in a protocol with gradually changing speed. Furthermore it has been found that the magnitude of acceleration has an effect on the transition speed. The easiest way to impose such a constant acceleration is by the use of a motor driven treadmill. Although the mechanics of treadmill locomotion and overground running do not fundamentally differ, various kinematical [1], physiological and perceptual differences exist. It might be possible that one or more of these differences affect the run to walk transition (RWT) or the walk to run transition (WRT).

The purpose of this preliminary study was to determine whether treadmill versus overground locomotion differ in transition speed in a protocol with gradually changing speed.

### METHODS

4 female subjects (height:  $170.8 \pm 2.3$  cm) performed several RWT's and WRT's at 3 constant accelerations ( $\pm 0.05$ ,  $\pm 0.07$  and  $\pm 0.10 \text{ms}^{-2}$ ) on a motor driven treadmill and an overground walkway. They were instructed to change from walking to running or vice versa when it felt most natural to them.

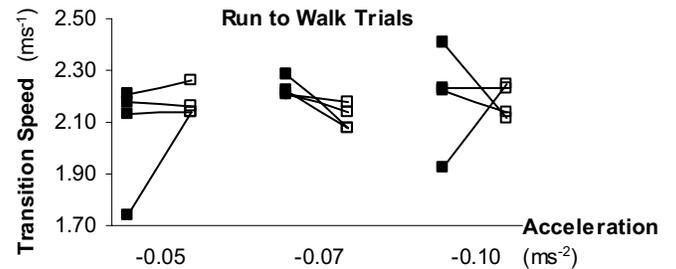

In the treadmill protocol transition speed was defined as the average speed of the treadmill belt during the transition step. The transition step was defined as the first step with a double stance phase in a RWT or the first step with a flight phase in a WRT. In the overground protocol the constant acceleration was imposed by means of a row of flashing lights which the subjects had to "follow" as closely as possible. The transition speed was defined as the average forward speed of a marker at C7 during the transition step. This speed was obtained from motion analysis (Qualisys, 240 Hz).

In each condition 3 trials were retained. Statistical analysis was done in MS Excel 2002 and SPSS (11.0)

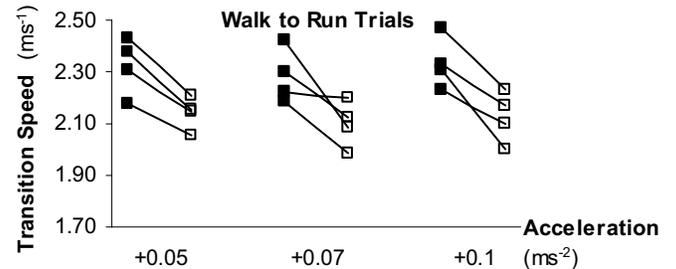

### RESULTS AND DISCUSSION

Visual inspection of the results showed that intra subject variability was acceptable so further analysis could be done with average values of each subject. The average transition speed of each subject is shown in two scatter plots: one for the RWT's (figure 1) and one for the WRT's (figure 2). In figure 1 we see no systematic relation between the average RWT speed in the overground condition and the treadmill condition. From figure 2 however it seems that all subjects started running sooner (i.e. at a lower speed) when they performed a WRT on the treadmill. Non parametric analysis with a Wilcoxon test showed a trend towards significant differences

between the overground condition and the treadmill condition in all three WRT accelerations. ( $p = .068$ ,  $Z = -1.83$ )

**Figure 1:** RWT transition speed of four subjects in the overground condition (filled squares) and the treadmill condition (open squares)

**Figure 2:** WRT transition speed of four subjects in the overground condition (filled squares) and the treadmill condition (open squares)

These results can probably be linked to the fact that many authors found that on a treadmill subjects tend to change their kinematics to "a pattern that provides them with more security" as a means of avoiding falling off the back of the treadmill [1]. It makes sense that the subjects only alter their transition speed in the WRT condition because the WRT is probably more intimidating than the RWT. In the WRT the subjects face the risk of being thrown off the back of the treadmill if they are unable to match the increasing speed whereas in the RWT they probably perceive this as less likely because the treadmill is slowing down.

### CONCLUSION

The results of this preliminary study should be interpreted with caution, because of the small population. Nevertheless a clear difference in WRT transition speed has been found between treadmill and overground locomotion. We believe that it is worthwhile to continue this research on a larger scale so that we will be able to use more stringent statistical methods and be able to determine if the use of a treadmill can be justified in transition studies with a gradually changing speed protocol.

## POSTURAL GAIT CHANGES ARE SEEN WITH SEVERE, NOT MODERATE, KNEE OSTEOARTHRITIS

<sup>1</sup>Janie Astephen and <sup>1</sup>Kevin Deluzio

<sup>1</sup>Dalhousie University School of Biomedical Engineering

### INTRODUCTION

Knee osteoarthritis (OA) is a very common disease of the musculoskeletal system that is a major cause of morbidity and disability in the world. It is a progressive disorder that involves multiple, interacting biomechanical and biochemical factors, making it very difficult to understand the pathological process of the disease. Although many biomechanical changes with knee OA have been identified (i.e. knee joint loading and orientation), most previous studies have included only patients with severe knee OA. Without data from patients from varying levels of knee OA severity, it is difficult to determine whether these factors are a result of the disease process, or are important to the onset and progression of the disease. Differences in the knee flexion angle during gait with knee OA have been found [2], but simultaneous changes that occur at the other joints in the lower limb have not been explored in previous studies.

Using a multidimensional gait data analysis technique, we compared the postural changes (hip, knee and ankle angles in the sagittal plane) over different levels of knee OA disease severity.

### METHODS

Two patient populations, a moderate knee osteoarthritis (OA) population (n=40) and an end-stage knee OA population (n=38), as well as an age-matched control group (n=40) were included in this study. Disease severity of the moderate knee OA group was based on radiographs, physical exams and functional tests. The severe knee OA patients were within six months of total knee replacement surgery.

Three-dimensional kinematic and kinetic data during gait were collected for all patients using two optoelectronic motion analysis position sensors (Optotrak 3020, Northern Digital, Inc.), and a force platform (Advanced Mechanical Technology, Inc.) embedded in the walkway. These data were combined with specific anthropometric measures in an inverse dynamics model.

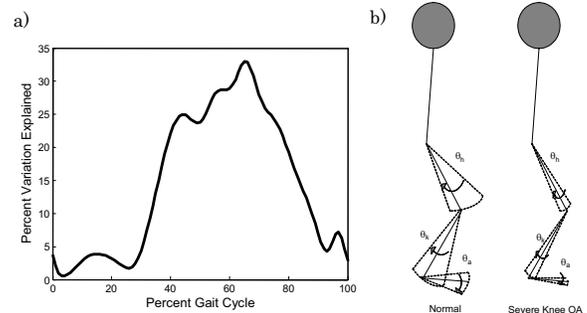

A multidimensional gait data analysis technique [1] that uses principal component analysis (PCA) and discriminant analysis was applied to the sagittal plane hip, knee and ankle angle waveforms to extract the important features of the data that describe differences in sagittal plane posture between the groups.

### RESULTS AND DISCUSSION

A scree plot of the data indicated that the first three principal components (PCs) explained the majority of the variation in the sagittal plane waveforms. A stepwise discrimination procedure indicated that two of these three PCs, PC1 and PC3, contained valuable discriminatory information between the groups. The two discriminatory PCs, combined in linear discriminant functions that represented boundaries between the groups, successfully discriminated between the normal and severe knee OA groups (with a cross-validation error of 9%), but did not discriminate between the normal and moderate knee OA groups.

Postural gait differences are therefore characteristic of severe knee OA gait, and not characteristic of moderate knee OA gait.

The third principal component, PC3, was the most discriminatory feature. This feature had equal contributions from all three lower limb angles, and therefore represented an overall range of motion of the lower limb. This difference is most important from late stance to early swing (approximately 40 – 80% of the gait cycle) (Figure 1a). The severe knee OA group had higher PC3 scores than the normal group, and these higher scores were associated with lower overall ranges of motion in all three joints (Figure 1b). These changes are likely in response to the increased levels of pain during gait that are common with end-stage knee OA. The lack of difference between the normal and moderate OA groups suggests that these postural changes are not involved in the pathomechanics of knee OA. PC1 was interpreted as a difference in the magnitude of the knee flexion angle during early stance, which supports the results of previous knee OA studies. The identification of PC3, however, points to the importance of synergism between the joints of the lower limb during gait.

**Figure 1:** a) A plot of the percentage of the variation explained by PC3 at each percentage of the gait cycle shows that PC3 is most important from approximately 40-80% of the gait cycle. b) Severe knee OA patients exhibited less sagittal plane angular motion in all three lower limb joints during gait than normal subjects.

### CONCLUSIONS

Postural gait changes between normal and severe knee OA subject groups were identified, but no significant postural changes were identified between the normal and moderate knee OA groups. This suggests that the kinematic changes are more a response of the disease than a contributing factor to the onset and progression of knee OA. The most discriminatory feature identified an important synchronicity in the joints of the lower limb that is often not accounted for in gait studies. The results of this study indicate the need for more simultaneous considerations of multiple joints in gait analysis.

## COMPUTATIONAL ASSESSMENT OF ANTEROPOSTERIOR LAXITY FOLLOWING PARTIAL PCL RELEASE IN CRUCIATE-RETAINING TKR

Matthew F. Moran<sup>1,2</sup>, Damon Servidio<sup>5</sup>, Charles M. Davis III<sup>4</sup>, and Stephen J. Piazza<sup>1,2,3,4</sup>

<sup>1</sup>Biomechanics Laboratory and Departments of <sup>2</sup>Kinesiology, <sup>3</sup>Mechanical Engineering, and <sup>4</sup>Orthopaedics and Rehabilitation, The Pennsylvania State University, University Park, PA and Hershey, PA  
<sup>5</sup>Stryker Orthopedics, Mahwah, NJ; E-mail: steve-piazza@psu.edu

### INTRODUCTION

Proper tensioning of the posterior cruciate ligament (PCL) achieved by adequate joint line restoration has been cited as a key determinant of success in PCL retaining total knee replacement (PCR-TKR) [1]. Tensioning of the PCL is thought to be important because it affects anterior-posterior (AP) stability and knee kinematics following PCR. Modifying the joint line following total knee replacement (TKR) could affect PCL tensions and consequently alter stability and function. Joint line elevation commonly follows PCR-TKR [2] and has the potential to tighten the PCL and restrict range of motion (ROM). In cases where PCL tightness limits ROM, a partial PCL release has been advocated [1], but few studies have addressed the effect of this procedure on AP laxity. The purpose of the present study was to create a computational model to investigate the effect of partial PCL release on AP laxity characteristics following PCR-TKR as compared to a posterior cruciate-substituting (PS) knee design. Varying degrees of release and three PCR tibial insert designs (condylar, anteriorly-lipped, and ultra-conforming) were tested for AP laxity. It was hypothesized that partial PCL release would increase AP displacements at higher flexion angles, but an ultra-conforming insert would limit these displacements more than the other two designs.

### METHODS

A forward-dynamic computer simulation of the American Society for Testing and Materials protocol for testing AP constraint (ASTM F1223-04) was created and its output was found to compare well to experimental results obtained for PS knee components [3]. The model for this study incorporated 8 spring-like elements representing the anterior-lateral (AL) and posterior-medial functional bundles of the PCL respectively. Ligament insertions, stiffness, and slack lengths were assigned based on values reported in literature [4, 5]. The natural knee motions reported by Walker et al. were applied to the model and the resulting ligament length patterns were found to compare favorably to experimental values [6]. Anterior-posterior laxity test simulations were run at 0°, 30°, 75° and 90° for all three PCR tibial inserts and for intact PCL, partial AL-PCL release (half of the bundle was released), and complete AL-PCL release. At each flexion angle an 80 N anterior force and 80 N posterior force were applied to the tibial insert and the total AP displacement was recorded. The inserts were under a constant 200 N compressive axial load, the femoral component was free to move in the frontal plane, and contact friction was not modeled.

### RESULTS

With the PCL intact, the design of the tibial insert affected AP laxity measures at smaller flexion angles but did not influence displacements at either 75° or 90° flexion. The standard condylar insert exhibited 70% more and 215% more AP displacement than either the anterior-lipped or ultra-

conforming inserts at 0° and 30° flexion, respectively. AL-PCL release, either partial or complete, affected AP laxity measures at larger flexion angles while having minimal influence at smaller flexion angles (Figure 1). With a partial release of the AL bundle over all angles, the standard condylar and anterior-lipped insert displayed an average displacement increase of 1.2 mm, while displacement for the conforming insert increased by only 0.6 mm. With a complete release of the AL bundle, the standard condylar and anterior-lipped insert displayed an average displacement increase of 3.3 mm, while the conforming insert increased only 1.9 mm.

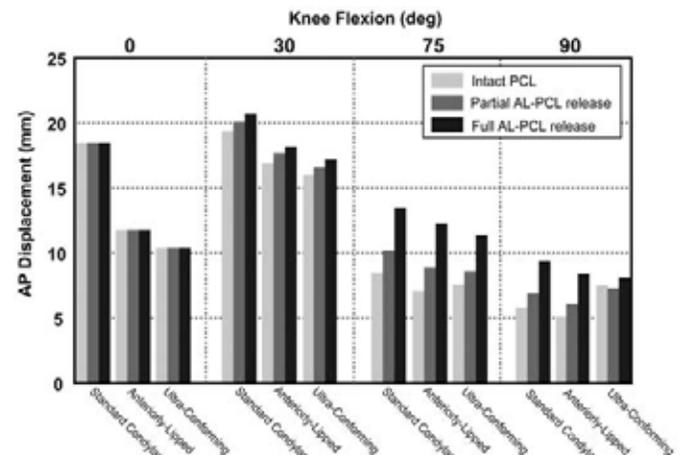

Figure 1: Effect of partial and complete release of the anterolateral (AL) bundle of PCL on AP laxity.

### DISCUSSION

Selective release of the PCL to attain a proper flexion arc substantially increased the maximum AP displacement at 75° and 90° flexion regardless of insert design. At higher flexion angles PCL tension contributes more to AP stability than does insert conformity. When the knee is near full extension and PCL tensions are lower, conforming designs provide a more stable joint. The changes in AP displacement determined in this study are likely to be functionally significant; smaller changes in displacement have been used clinically to differentiate between injured and healthy knees [7].

### 3D-Fiber type distribution in back muscles in small mammals

Nadja Schilling

Institute of Systematic Zoology and Evolutionary Biology, Friedrich-Schiller-University Jena, Germany  
email: nadja.schilling@uni-jena.de, web: www.zoo.uni-jena.de

#### INTRODUCTION

The evolution of the locomotor apparatus in vertebrates is marked by major reorganizations of the trunk's musculature. The plesiomorphic segmental organization was dissolved in the hypaxial but also in the epaxial muscles. In mammals, three epaxial tracts allow for high mobility in all three rotational degrees of freedom as for lateral bending and tilting at symmetrical gaits and for sagittal bending at asymmetrical gaits.

Different roles in stabilizing and mobilizing of the vertebral column were hypothesized for the diverse paravertebral muscles. Large, superficial back muscles are supposed to produce the range of movement, whereas small, deep muscles control the range of movement and especially control segmental motions.

Since metabolic profiles of muscles relate to their function (as shown for limb muscles) it can serve as an indicator of function. Therefore, the aim of the study was to investigate and compare the muscle fiber type distribution in back muscles of different species of small mammals. In order to test current hypothesis on back muscle function the overall, 3D-distribution pattern of fiber types was investigated.

#### METHODS

Adults of 4 small mammalian species (*Galea musteloides* - the cui, *Ochotona rufescens* - the pika, *Rattus norvegicus* - the rat, *Tupaia belangeri* - the tree-shrew) were used for this study. Serial sections were made from the complete backs including the vertebral column to preserve the topographical relationships between muscles and their intramuscular architecture. Only the posterior thoracic and the lumbar regions were used in this study. Samples were quick frozen in liquid nitrogen cooled isopentane.

Sections were made using a kryostat microtome (SLEE, D-knife, 12 µm) and processed for muscle fiber type characterization using alkaline combination reaction based on Ziegan's protocol [1]. As a result, fiber type I (SO) is stained blue, type IIa (FOG) dark brown, and type IIb (FG) light brown. Drawings were made at different cranio-caudal levels from the serial sections.

#### RESULTS AND DISCUSSION

Surprisingly, the overall fiber type distribution pattern was highly similar between the species investigated. Most of the muscles showed a heterogeneous distribution of the different fiber types over the muscle's cross section but also along the cranio-caudal axis. Only few of the muscles showed the same fiber type composition from deep to superficial regions or from cranial to caudal direction.

The highest percentage of glycolytic fibers was present in the m. sacrospinalis (longissimus lumborum et iliocostalis) and in the m. psoas major. Only a few oxidative fibers were observed in the posterior thoracic part of the m. sacrospinalis. The m. psoas major was more or less free of oxidative fibers. The fiber type composition of both muscles make them suitable to generate forces and speed for a wide range of movement.

The highest percentage of oxidative fibers were found in the mm. intertransversarii et interspinales as well as in the mm. rotatores et multifidi. In caudal direction, the proportion of oxidative fibers is decreased in the superficial regions of the mm. multifidi. As inferred from their anatomical position and their high percentage of fatigue resistant, oxidative fibers, these muscles are best suited to maintain segmental stability.

A regionalisation of oxidative fibers was found in the m. quadratus lumborum. Around the huge intramuscular tendon oxidative fibers were distinctly arranged. Especially, in the caudal thoracic but also in the cranial lumbar part this oxidative region was extensive. Towards the caudal region the proportion of the oxidative fibers was decreased. Such regionalisation of oxidative fibers in deep parts of a muscle are well known from limb muscles in so called anti-gravity muscles. These muscles enduringly counteract passive limb flexions due to gravitational force. As a muscles involved in ventilation, the oxidative region of the m. quadratus lumborum is supposed to be involved in inspiration movements.

#### CONCLUSIONS

Diverse back muscles were related to different functions in stabilization and mobilization of the vertebral column. An overall distribution pattern of different muscle fiber types was found in all species under investigation. The major reorganization in the trunk's musculature during the evolution of mammals is suggested to include not only macroscopic changes but also the fiber type distribution pattern.

## KINEMATICAL ANALYSIS OF THE PREPARATORY AND TAKEOFF MOTION IN THE LONG JUMP

<sup>1</sup>Yuya Muraki, <sup>1</sup>Hiroyuki Koyama and <sup>2</sup>Michiyoshi Ae  
<sup>1</sup>Doctoral Program of Health and Sport Sciences, <sup>2</sup>Institute of Health and Sport Sciences,  
 University of Tsukuba, Japan; email: yuya@lasbim.taiiku.tsukuba.ac.jp

### INTRODUCTION

Approach velocity is one of the most important factors in the long jump. However, it is difficult for a jumper to prepare for the takeoff with a minimum loss of approach velocity. The purposes of this study were to investigate motion variability of the preparatory and takeoff motions for skilled long jumpers and to compare their motions between different approach velocity groups.

### METHODS

The last two steps of the approach and takeoff motions of thirty-three skilled male long jumpers (height,  $1.79 \pm 0.06$  m; body mass,  $69.9 \pm 6.9$  kg; and effective jump distance,  $7.78 \pm 0.31$  m) were videotaped with two high-speed VTR cameras (250 Hz) during official competitions. Two-dimensional coordinates were used to calculate linear and angular kinematics of joints and segments and the location of the center of gravity (CG). The VTR images were collected by the Scientific Committee of Japan Association of Athletics Federations.

The preparatory and takeoff motions were divided into three support and two flight phases. Coordinate data were normalized by the body height and the duration of each phase and averaged [1]. Since the takeoff time was set at 100%, the support and flight time of the last two and last steps were 76, 91, 111 and 62%. Coefficients of variation (CV) of the angles of the shank, thigh and torso were determined by the following equation.

$$CV = \frac{SD}{|Mean + 360|} \times 100$$

Subjects were divided into two groups by the horizontal CG velocity at the touchdown of the takeoff phase, i.e. fast group (FG:  $n=14$ ; height,  $1.82 \pm 0.07$  m; body mass,  $71.7 \pm 9.1$  kg; effective jump distance,  $8.01 \pm 0.30$  m) and slow group (SG:  $n=19$ ; height,  $1.78 \pm 0.05$  m; body mass,  $68.47 \pm 4.7$  kg; effective jump distance,  $7.61 \pm 0.19$  m). Student's t-test was used to test significant differences between FG and SG for the angles of the shank, thigh and torso. The significance level was set at  $p < 0.05$ .

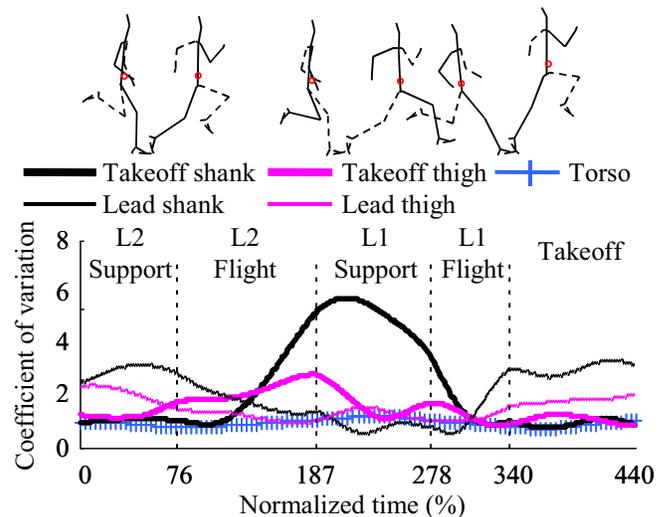

### RESULTS AND DISCUSSION

The horizontal CG velocity at the touchdown of the FG,  $10.38 \pm 0.15$  m/s, was significantly larger than that of the SG,  $9.91 \pm 0.12$  m/s ( $p < 0.001$ ). The FG kept significantly larger horizontal CG velocity than the SG at all instants of all phases ( $p < 0.01$ ).

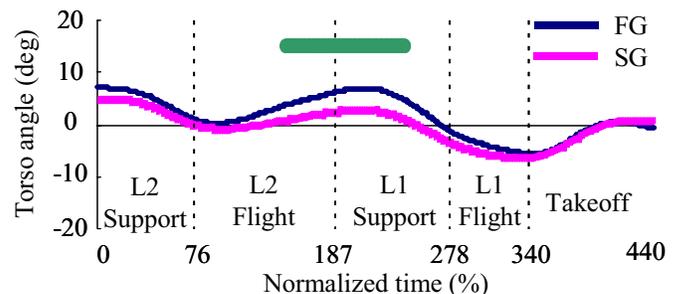

Figure 1 shows changes in coefficients of variation of the shank, thigh and torso angles during the preparatory and takeoff phases. The takeoff leg was identical to the support leg during the second last step. The CV of the segment angles of the leg during the support phase was small. In the flight phase, the CV of segment angles of the swing leg increased during forward swing and decreased during backward swing before the

touchdown. These results indicated that all the subjects moved the support leg in a consistent manner during the support phase but they swung the free leg in more various manner.

Figure 2 shows changes in the torso angle of the FG and SG during the preparatory and takeoff phases. The significant differences were found between the FG and SG only in the torso angle around the touchdown of the last support, which indicated that the FG inclined the torso more forward than the SG. Although the horizontal CG velocity of the FG was larger than that of the SG, there was no significant difference in the decrease of the horizontal CG velocity during the support phase of the last step. These results indicated that a jumper with the torso tilted forward slightly before the touchdown of the last step may minimize the loss of the horizontal CG velocity during the preparatory phase.

**Figure 1** averaged changes in coefficients of variation of the shank, thigh and torso angles from the last two step (L2 and L1) to the takeoff. Stick pictures showed the averaged preparatory and takeoff motions of all the subjects

**Figure 2** averaged changes in the torso angles of the FG and SG from the last two step (L2 and L1) to the takeoff. Positive value indicated that torso tilted forward. Horizontal bar above the curves showed significant difference between FG and SG ( $p < 0.05$ )

## GROUND REACTION FORCE ASYMMETRIES DURING SUSTAINED RUNNING

### INTRODUCTION

Gait is a complex activity that has served as a major area of research in the biomechanics community. A common assumption in gait analysis and research is that the lower extremities behave symmetrically during able-bodied gait. This assumption may be inaccurate and have significant impact in clinical gait analysis, rehabilitation of patients, and artificial limb design.

Previous research examining running and ground reaction forces have utilized a limited number of footfalls in their analyses of symmetry, and have reached different conclusions. Hamill et al. [1] used ten-trial mean values to examine ground reaction force symmetry during walking and running and concluded that there appeared to be symmetry in ground reaction force parameters. Munro et al. [2] used six trials from each subject to examine ground reaction forces in running and indicated that right-left asymmetries were clearly present in these subjects. The purpose of this study was to examine ground reaction force symmetry during running using 700 pairs of footfalls per subject.

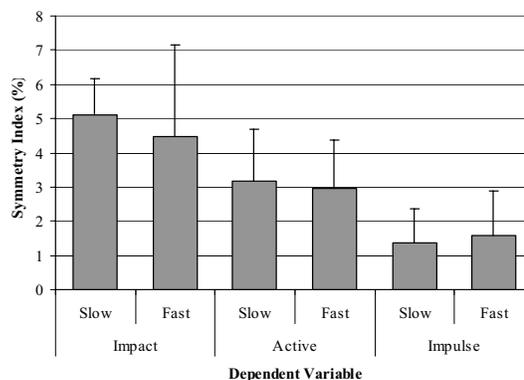

### METHODS

Eight healthy young adult subjects with mean (sd) age 24.6 (3.5) years and body mass 627.0 (61.8) N, with no known musculoskeletal or neurological pathology volunteered for the study. The subjects were all experienced runners.

Vertical ground reaction force (VGRF) data were collected at 250 Hz using a Kistler Gaitway Instrumented Treadmill. Data were collected for two different running trials. Trial one (slow speed) consisted of running at 3, 4 or 5 m.s<sup>-1</sup> for 600 s for male subjects and 2, 3 or 4 m.s<sup>-1</sup> for 600 s for female subjects. Trial two (fast speed) consisted of running at a self-selected velocity for 600 s. Data collection began once the subject was running at the required velocity for each trial.

Data were processed with force and center of pressure data filtered with a 2<sup>nd</sup> order Butterworth filter with a cut-off of 30 Hz. The start and end of footfalls were identified using a 30 N threshold and data below this value were assumed to be noise. To quantify symmetry, a symmetry index was computed [3]. This index computed the difference between right and left limbs of a gait variable divided by the average of this variable.

Statistical differences in the following parameters were assessed using paired t tests: symmetry indices, mean impact peak VGRF, mean active peak VGRF, and mean VGRF impulse.

**Figure 1:** Mean and standard deviation of symmetry index of mean impact VGRF, mean peak VGRF and VGRF impulse.

### RESULTS AND DISCUSSION

Subjects completed an average of 1641.6 (83.2) steps per trial. Paired t-tests indicated significant differences between speeds for mean impact peak VGRF ( $p < 0.001$ ), mean active peak VGRF ( $p = 0.001$ ), and mean VGRF impulse ( $p = 0.008$ ). As the speed of running was increased, there was a significant change in these variables. These results may have significance relative to injury rates in runners.

The symmetry index indicated that all of the subjects demonstrated asymmetrical behavior in mean peak VGRF, mean active VGRF and impulse across all trials. The presence of asymmetry in these variables for this period supports the concept that right and left lower extremities are not symmetrical during sustained running.

Paired t-tests indicated no significant differences ( $p > 0.2$ ) for symmetry indices for impact peak VGRF, active peak VGRF, and VGRF impulse at different speeds (Figure 1).

### CONCLUSIONS

This study provides evidence for the asymmetrical behavior of the lower extremities during running, but did not demonstrate any change in symmetry as running speed is increased.

**INTRODUCTION**

A major challenge in the field of human movement analysis is the interpretation of data acquired. For example, this interpretation could lead to optimization of performances in sport, to better space organization in ergonomics or to define therapeutic planes in medicine. The large amount of data provided by motion capture devices makes interpretation a difficult task for human reasoning [1]. Techniques of artificial intelligence could decrease the subjectivity and give a helpful tool for interpretation. The aim of this study is to provide a method to link a movement with the elements of interpretation of this movement. For application example, toe-walking - considered as a major gait deviation in many diseases - will be linked with its possible clinical causes provided by physical examination.

**METHODS**

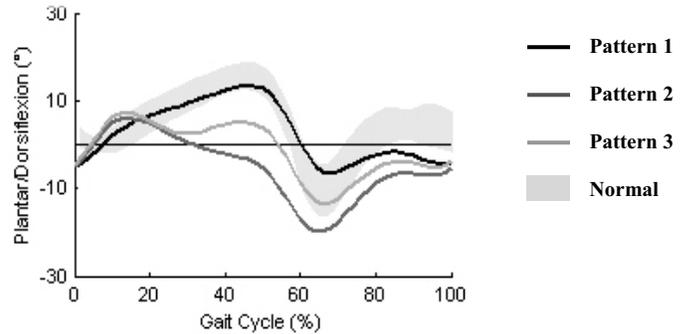

The first step of the method is to extract (from trials) the different patterns or expressions of a considered movement. In order to reach this aim, a fuzzy space-time windowing of variables permitting to quantify the considered movement can be performed. And then a fuzzy c-means algorithm can be used to extract the different expressions of this movement. Each trial is assigned to these different patterns with membership values. Next, each pattern is characterized by the weighted mean of motion analysis data.

The second step is to link these expressions with their possible causes. Literature and experts could provide the different possible causes. Measurements of cause variables - which are interesting in interpretation process - are coded in fuzzy modalities. Fuzzy decision trees are then induced to create “if-then” rules linking expressions of movement with their possible causes. The accuracy of these rules can be evaluated with a stratified ten-fold cross validation.

For application example, toe-walking was explored with this method. A database of 2511 clinical gait analysis containing 11950 trials is used in input to extract the different expressions of toe-walking. Subsequently, toe-walking patterns are linked with their clinical causes. Possible clinical causes are extracted from clinical examination measurements including range of movement, muscular tone and strength which are coded in membership values according to the three modalities: {low, medium, high}.

**RESULTS AND DISCUSSION**

In this clinical example of extraction of knowledge; the first

**Figure 1:** Three ankle gait patterns identified for toe-walkers

step of the method has permitted to extract three different patterns of toe-walking (figure 1). The second step of the method has highlighted clinical possible causes of these three patterns represented by 12 main rules. A rule is a combination of clinical elements leading to one of the three groups. An example of rules, corresponding to the possible causes, is presented on Table 1. The classification accuracy of the rules has been evaluated at 81%. Results were in agreement with literature and clinical gait analysis experts. For a given pattern of a new patient, it is now possible to determine possible causes of this pattern: *abduction approach*. It is also possible to predict the pattern of movement as from clinical measurements: *deduction approach*. Results of this clinical example provide an overview of possibilities of such method. Compared to classical statistical method, this method of extraction of knowledge has the advantage of not considering linear relationship between variables and permits to deal with a large amount of data. Fuzzy coding introduces the notion of vagueness and allows manipulation of language terms as “high” or “medium” rather than numerical values.

**CONCLUSIONS**

This two steps method using fuzzy c-means and fuzzy decision trees is an original method to extract knowledge from motion analysis data. It provides intelligible rules permitting identification of possible movement causes. This artificial intelligence method can be a helpful tool for all the people who have to deal with a large amount of data in the field of human motion analysis and who want to understand which elements influence movement patterns.

### INTRODUCTION

Osteoarthritis (OA) is a progressive degenerative joint disease that often results in significant disability and loss of function. This chronic joint disorder can be particularly debilitating in the knee because it is stressed in activities of daily living including walking. There is a distinctly higher prevalence of medial compartment OA within the diseased population [1]. The adduction moment of the knee is considered to be the mechanical factor most highly correlated with knee OA. However, not all studies have found higher adduction moments in OA patients [2]. In the latter case, the patient severity level was unknown, and comparisons were made at the peak adduction moment only. The purpose of this study was to characterize the changes in adduction moment that are associated with different severities of knee OA. Principal component analysis was used to detect differences in adduction moment waveform magnitude and shape.

### METHODS

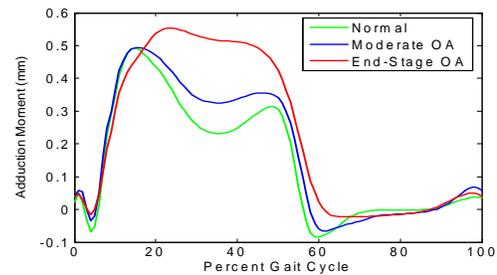

Fifty patients affected with moderate OA, 32 end-stage OA patients and 37 asymptomatic controls underwent a complete 3D kinematic, kinetic and electromyographic (EMG) analysis of the lower limb, with only the kinetic findings being discussed in this abstract. Patient severity levels were established through the Kellgren-Lawrence radiographic grading system [3] (Mod=1-3; End-stage=4). A Joint space narrowing grade [4] difference  $\geq 1$  (medial-lateral) was used to establish predominantly medial compartment OA. The subjects were required to walk along a 5-meter walkway in the laboratory a total of five times at a self-selected pace. The lower limb kinetics were calculated using the three dimensional orientation and position of the markers and the force plate data. The joint moment data was normalized with respect to bodyweight to Newton-meter/kilogram. All adduction moment waveforms were analyzed for group differences using principal component analysis (PCA) [5].

### RESULTS AND DISCUSSION

Descriptives comparing the subject groups indicated that the control group was slightly younger and lighter than the patient groups, while the end-stage OA group walked significantly slower than the other two groups (Table 1).

**Table 1:** Descriptives for moderate OA, end-stage OA and normal subject groups. Values are mean (STD).

	Normals (N)	Moderate OA (M)	End-Stage OA (S)	Significant Diff (p<0.05)
Age (yrs)	50.5 (10.5)	59.7 (8.2)	64.1 (7.7)	N < (M = S)
Weight (kg)	72.9 (14.2)	94.7 (19.1)	94.3 (16.3)	N < (M = S)
Height (m)	1.7 (0.1)	1.7 (0.1)	1.7 (0.1)	NONE
BMI (kg/m <sup>2</sup> )	24.8 (4.0)	31.1 (5.7)	33.2 (5.0)	N < (M = S)
Speed (m/s)	1.3 (0.1)	1.2 (0.2)	0.9 (0.2)	S < (M = N)

**Figure 1:** Mean adduction moment gait waveforms for moderate OA, end-stage OA, and control groups.

Using PCA to compare the adduction moment waveforms between the groups revealed that all three groups were significantly different ( $p < 0.05$ ) with respect to the overall magnitude of the curve during the stance phase (0-60%) (Figure 1). This magnitude difference ( $S > M > N$ ) was represented by PC1. PC2 represented the shape of the adduction moment curve during the first 20% of the gait cycle. The end-stage OA group was significantly different than the other two groups with respect to PC2 ( $p < 0.01$ ). PC3 represented the variation found in the curve during the latter half of the stance phase (20-60%). The shape of the loading vector revealed that this PC was a difference operator contrasting mid-stance to late stance. The end-stage OA group was significantly different than the other two groups with respect to PC3 ( $p < 0.05$ ).

### CONCLUSIONS

The overall magnitude of the adduction moment waveform during gait increases with both disease presence and severity level. End-stage OA patients exhibit a modified adduction moment curve shape when compared to moderate OA patients and asymptomatic controls.

## The Effect of Laterally Wedged Orthoses on Talus Angle

### INTRODUCTION

Laterally wedged insoles are a conservative treatment for medial knee osteoarthritis (OA). These insoles, typically inclined 5-10 degrees, attempt to alter lower extremity alignment and redistribute forces at the knee, potentially reducing knee pain. However, there are conflicting reports of static alignment measured with frontal plane radiographs. A few studies [4,5,6] did not find significant differences in tibio-femoral angle between wedged and non-wedged conditions, whereas another study [7] reported a shift in the mechanical axis, but not in the tibio-femoral angle during one-legged stance.

We previously reported no differences in tibiofemoral angle or mechanical angle with laterally wedged orthoses [3]; however, it is possible that wedged insoles affect ankle alignment as determined by talus position on frontal plane radiographs. The purpose of this study was to determine the effects of laterally wedged insoles on frontal plane talus angle in patients with medial knee OA. It was hypothesized that the talus would rotate medially with the use of a laterally wedged insole.

### METHODS

Eleven males and ten females ( $M_{age} = 61.6 \pm 7.0$  yrs;  $M_{height} = 169.9 \pm 9.8$  cm;  $M_{mass} = 93.9 \pm 18.6$  kg), all diagnosed with medial knee OA of grade II or higher on the Kellgren-Lawrence scale, volunteered to be subjects in this study. Full length laterally wedged foot orthoses were fitted for each subject's affected knee side. Wedging amount ( $9.2 \pm 3.5^\circ$ ) was determined for each subject based on the greatest reduction in knee pain during a lateral step-down task. A two-week period was allowed for accommodation to the orthotic device. Frontal plane radiographs allowed analysis of the affected limb in a bilateral stance with and without the wedged insole in the shoe.

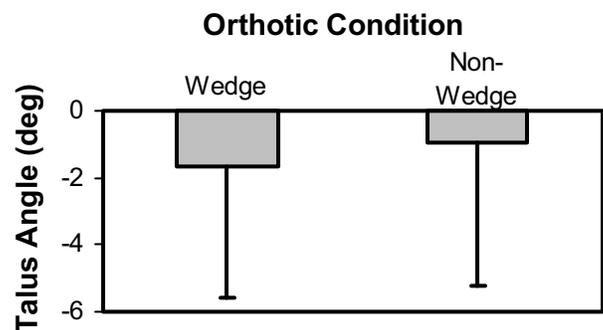

A line was drawn on the radiograph to connect the two most superior articulations of the talus; the angle between this line and horizontal, measured manually with a standard goniometer, defined the talus angle. Positive angles represent a medially rotated (laterally elevated) talus.

A paired samples t-test was used to determine significant differences between wedged and non-wedged conditions for talus angle ( $p < .05$ ).

### RESULTS AND DISCUSSION

Talus angle (Figure 1) for the wedged condition ( $-1.67 \pm 3.93$  deg) did not rotate medially from the non-wedged condition ( $-0.95 \pm 4.25$  deg) as hypothesized ( $p = 0.197$ ). Change in talus angle ranged from -4 to +4 degrees, indicating a highly variable subject response to the wedged orthosis.

Despite wedging of 5-15 degrees, lateral wedging does not seem to affect talus angle during a bilateral static stance. Previously we reported increased subtalar eversion during gait with wedged orthoses, suggesting the calcaneus is altered during the stance phase [1]. Therefore, potential changes in calcaneus alignment do not appear to affect static talus alignment. Additionally, changes in talus angle are not consistent with reductions in frontal plane knee moment [2] or knee pain associated with wedged orthotic use.

**Figure 1:** There were no significant differences in talus angle between insole conditions. Positive angles reflect a medially rotated (laterally elevated) talus.

### CONCLUSIONS

Laterally wedged orthoses did not alter talus angle in subjects with medial knee OA.

## MECHANICAL PROPERTIES OF CANCELLOUS BONE OF THE DISTAL HUMERUS

<sup>1</sup>Cheryl E. Dunham, <sup>2</sup>Sarah E. Takaki, <sup>1,2</sup>James A. Johnson, and <sup>1,2,3</sup>Cynthia E. Dunning

<sup>1</sup>Departments of Biomedical Engineering and <sup>2</sup>Mechanical and Materials Engineering

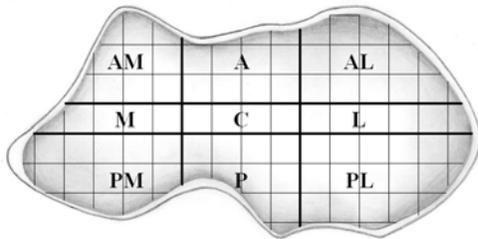

Biomechanical Testing Laboratory, University of Western Ontario, London, Ontario, Canada; email: <sup>3</sup>cdunning@eng.uwo.ca

### INTRODUCTION

Mechanical properties of cancellous bone in the distal humerus are of interest for a number of reasons. An understanding of variations in modulus and strength across several transverse sections may determine optimal fixation techniques and locations for prosthetic components. These results may also suggest optimized surgical procedures to allow better fixation in stronger bone [1,2,3]. An understanding of these mechanical properties is of value in developing finite element models, as well as providing comparative data to validate synthetic bones for implant testing. The objective of this study was to quantify the strength and modulus of distal humerus cancellous bone, and identify any regional variations.

### METHODS

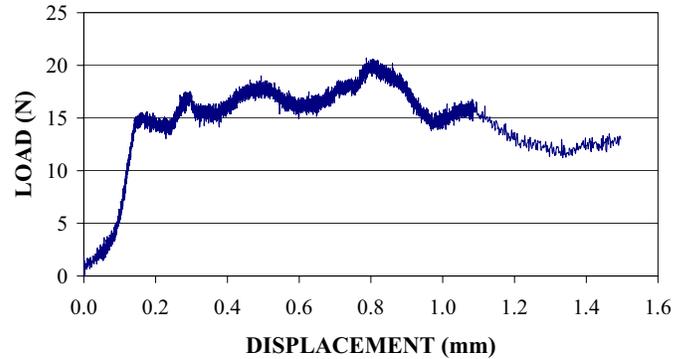

Three consecutive transverse slices (3 mm thick) were sectioned from the distal cancellous region of seven fresh-frozen cadaveric humeri (ages 70-92, mean age 79.4 years). Each slice was marked with a 3x3 mm<sup>2</sup> grid, and subjected to compressive testing using a flat cylindrical indenter (1.6 mm diameter). A servohydraulic testing machine (Inston Corp., Canton, Mass., USA) collected load-displacement data during testing. Indentation modulus and strength were calculated for each test site, and pooled into nine regions defined by anatomical directions (anterior, posterior, medial, lateral and central) for each slice (Figure 1). Results were analyzed using two-way repeated measures ANOVAs to determine differences in strength and modulus among regions and slice levels. All statistical tests were performed with  $\alpha = 0.05$ .

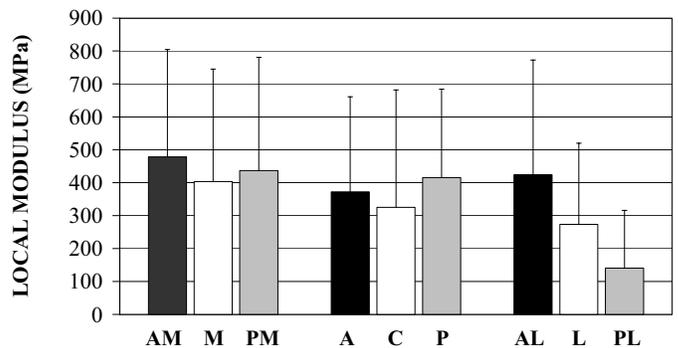

**Figure 1:** Transverse slice showing 3x3 mm<sup>2</sup> test sites and nine regional divisions [defined by anterior (A), posterior (P), medial (M), lateral (L) and central (C) sections].

### RESULTS AND DISCUSSION

Stress-strain curves for the indentation tests were reasonably consistent in shape, with all exhibiting a characteristic yield followed by a slight softening and then a large region of nearly constant load (Figure 2). Mean modulus was found to be 309.8±242.0 MPa (range: 2.9-1041.7 MPa). Yield strength averaged 4.4±2.5 MPa (range: 0.6-16.3 MPa). The highest modulus was found in the distal-most slice ( $p < 0.05$ ). The lowest modulus region was the posterior lateral ( $p < 0.05$ ) (Figure 3). There were no differences in strength among slices or across the nine regions.

**Figure 2:** Representative load-displacement curve for one indentation site.

**Figure 3:** Indentation modulus for the 9 regions of the distal humerus. (See Figure 1 for region definitions.)

### CONCLUSIONS

This study determined the indentation strength and modulus of cancellous bone of the distal humerus at three transverse levels and nine anatomically-defined regions within each cross-section. Mean strength was 4.4 MPa and mean modulus was 309.8 MPa, with large variations both within and among humeri. Cancellous bone modulus decreased with movement from distal to proximal. The posterior lateral region had a lower modulus than the other regions of the distal humerus. The influence of slice depth may be important with regard to the amount of bone removed during prosthetic replacement requiring cancellous fixation. Regional variations in modulus suggest that the posterior lateral region may be an inferior site for screw purchase during fracture fixation.

## SEQUENTIAL LABELLING AND ACOUSTIC EMISSION ANALYSIS OF DAMAGE OCCURRING IN CORTICAL BONE DURING INDENTATION CUTTING

<sup>1</sup> Ger Reilly, <sup>1</sup> Ashkan Safari, <sup>2</sup> David Taylor and <sup>1</sup> Brendan McCormack

<sup>1</sup> School of Mechanical and Electronic Engineering, Institute of Technology, Sligo, Ireland, [reilly.ger@itsligo.ie](mailto:reilly.ger@itsligo.ie)

<sup>2</sup> Trinity Centre for Bioengineering, Trinity College, Dublin, Ireland

### INTRODUCTION

When a surgeon uses a wedge shaped blade or an osteotome to cut cortical bone during an operative procedure the bone will fail by a process of microcracking and primary crack propagation. It has previously been observed that crack propagation is dependent on the direction of cutting relative to the main axis of the bone [1]. It has also been observed that microcracks occurring during fracture release acoustic signals that facilitate real-time monitoring of a cutting process [2].

In these novel studies, we labelled damage accumulation during cutting of cortical bone using sequential chelating dyes [3] and we correlated recorded AE signals during cutting with load-displacement curves.

### METHODS

8mm cubes of cortical bone were located in a chamber and cut using a wedge-shaped blade in longitudinal and transverse directions. Chelating dyes were used at different loading stages. Specimens were sectioned and examined for evidence of damage using UV microscopy post-test.

Similar specimens were also tested using AE monitoring techniques and various AE parameters were recorded and correlated with load curves; number of AE hits, and amplitude of AE signals. A threshold value of 40dB was used to eliminate background noise and low-amplitude signals were amplified by a fixed gain of 40dB with a (0.1-1) MHz band pass filter [4].

### RESULTS AND DISCUSSION

The chelating dyes label the progressive damage occurring during different stages of the cutting process and indicate the extent of the damage zone around the cutting area. The zone is different for different cutting directions; extending longitudinally for longitudinal cutting and confined to lateral regions for transverse cutting as shown in Figure 1. For both cutting directions fracture cracks grow along the lamella interfaces.

Figure 2 shows that the number of recorded AE pulses increased prior to main cutting fracture as previously reported for tensile fracture [5]. High amplitude, high duration signals may be associated with the main crack propagation, as they occurred predominantly during this period of loading.

### CONCLUSIONS

It is difficult to clearly distinguish different stages in the crack growth from current results however there is clearly labelling of damage (flame effect) by all dyes used, indicating damage occurring at different stages of the loading process, and the labelled zone shows the direction of the damage process

occurring relative to cutting. The AE technique is useful for real-time monitoring and prediction of fracture processes, and the increase in AE pulses prior to fracture may be used as an indicator of onset of fracture during bone cutting.

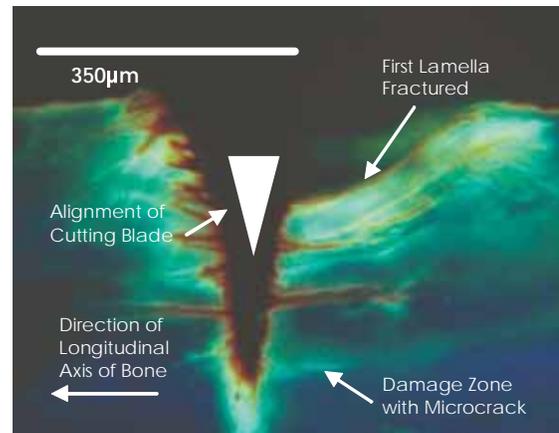

Figure 1: Cutting zone - transverse cutting specimens.

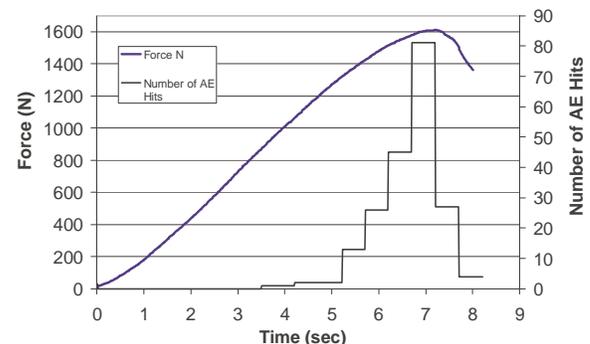

Figure 2: Force and number of AE hits versus time during longitudinal indentation loading.

## VALIDATION OF INTRAMUSCULAR PRESSURE SENSOR IN RAT GASTROCNEMIUS MUSCLE DURING ISOMETRIC CONTRACTION

JL Megesi<sup>1</sup>, TR Jenkyn<sup>1,2</sup>

<sup>1</sup>School of Kinesiology, University of Western Ontario, Canada

<sup>2</sup>Dept. of Mechanical and Materials Engineering, University of Western Ontario, Canada

### INTRODUCTION

The inability to directly measure the internal loads acting within articular joints has been a limitation in biomechanics. Currently, skeletal muscle loads must be estimated from EMG measurements or calculated computationally. Intramuscular pressure (IMP) has been shown to be well correlated with muscle tension and has recently become a feasible *in vivo* measure [1,2]. The sensor used in this study is based on fiber-optic technology and has been used extensively in rabbit [3]. The purpose of this study was to evaluate the performance of the fiber-optic IMP sensor during galvanic isometric contractions in intact rat skeletal muscle.

### METHODS

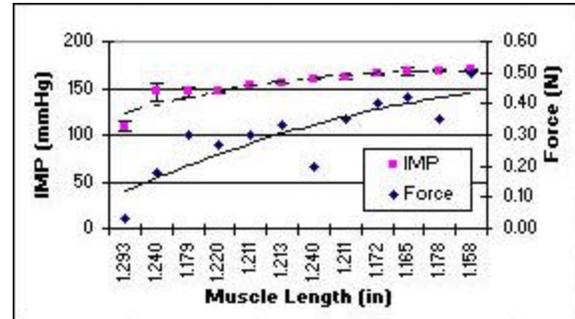

Sprague-Dawley rats (weight 200-300g) were anaesthetized and secured to a custom-made jig with the knee fixed at 90°. Hind limb muscles were exposed, but left intact. The foot was attached to a lever articulating about the ankle from which force was measured. The biceps femoris was reflected and the sciatic nerve exposed. Platinum wire electrodes were placed around the nerve and isometric contractions of the hind limb muscle group were elicited (Grass Instruments, S-88 stimulator). A 360 µm diameter fiber-optic pressure sensor (Luna Innovations Inc., Blacksburg, VA) was inserted into the belly of the gastrocnemius muscle via a 22-gauge needle, parallel to the direction of the muscle fibres. IMP, force and muscle length were measured simultaneously at stimulation levels of 2.4, 3.0, 3.5, 4.0, 4.5, 5.0 and 5.5 volts with at least 1 minute rest between levels to minimize fatigue.

### RESULTS

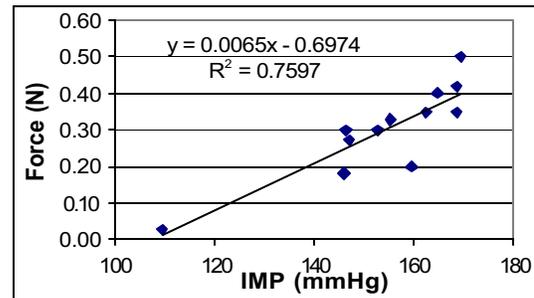

The results of this experiment indicate that the length-tension curve for isometric contractions was mimicked by the length-pressure curve for active conditions (Figure 1). To confirm this finding, muscle force and IMP were plotted against each other and linear regression was performed (Figure 2). There was a strong linear correlation ( $R^2=0.76$ ) between IMP and muscle force.

### DISCUSSION

This study quantified the relationship between IMP and muscle force during galvanic isometric contractions in intact rat skeletal muscle. These findings confirm previous work done in rabbit skeletal muscle [3]. Further work must now be concentrated on the validity of the sensor under dynamic contraction conditions.

**Figure 1.** Relationship between IMP and isometric muscle force for rat gastrocnemius muscle at varying lengths.

**Figure 2.** Relationship between isometric force and intramuscular pressure at various stimulation levels. Force and IMP were well correlated ( $R^2=0.76$ ).

## DYNAMIC SIX-SEGMENTAL FOOT MOTION USING ELECTROMAGNETIC TRACKING SYSTEM

<sup>1</sup>XueCheng Liu, <sup>2</sup>John Thometz, <sup>2</sup>Roger Lyon, and <sup>3</sup>Chris Boudreau

<sup>1</sup>Motion Analysis Lab, <sup>2</sup>Dept. of Orthopaedics, Children's Hospital of WI, <sup>3</sup>Dept. of Biostatistics, Medical College of Wisconsin. Email: xcliu@mcw.edu, web: www.chw.org

### INTRODUCTION

Multi-segmental foot motion during walking has been mostly investigated using passive markers and the Video Motion Analysis System (1,2,3). These foot segments mainly are limited to the hindfoot and forefoot. Since the Electromagnetic Tracking System (ETS) was introduced to our biomechanical and clinical society, one study was conducted to determine the ankle joint kinematics (4). The goal of this study is to develop a newly designed anatomically based six-segmental foot model using the ETS, including the hindfoot, midfoot and forefoot kinematics, and to find out the reliability of intraobserver.

### METHODS

The study was performed on six children with 12 normal feet. Their ages ranged from 9 to 15 years with a mean age of 12 years. The ETS consists of: a long range StarTrak transmitter (Polhemus Inc., Colchester, VT) with 12 sensors, electronics unit and the 6D Skill Technologies' Gait motion capture and software (Skill Technologies, Inc., Phoenix, AZ). There is a two-inch cubic transmitter used as the global reference frame within a maximum radius is 12 ft. Each sensor with half-inch cubic coils compute with 6 degrees of freedom in real-time. The motion is sampled at a rate of 120Hz. A fourth order Butterworth digital filter with a cut-off frequency of 6Hz is also used.

Six sensors were placed on each foot with double stick tape at the following locations: the tibia tuberosity, posterior calcaneus, navicular tuberosity, cuboid tuberosity, middle dorsal shaft of the 1<sup>st</sup> metatarsal bone and dorsal hallux. The children were initially asked to stand in a neutral position, which is defined as a static standing with weight-bearing and their feet paralleling the y-axis of our global reference. Each sensor is used as a local reference frame for the segment to which it is attached and aligned with the global reference during calibration. After defining the neutral position, the subjects walked with 6 sensors on each foot along a 20 ft walkway at their natural speed. Data was captured over a 4 second period and three separate trials were completed for each subject. Four subjects were randomly selected for repeated tests during the same day and by the same staff. Correlation between two times measurements was calculated by Intraclass coefficient (ICC).

We always calculate angles by the distal sensor with respect to the proximal sensor. Hence the Cardan sequence is the angle around the medial/lateral axis first (dorsiflexion/plantarflexion as pitch angle), followed by the angle around the anterior/posterior axis (inversion/eversion as yaw angle), finally the angle around the vertical axis (internal/external rotation as roll angle).

### RESULTS AND DISCUSSION

In the sagittal plane, mean peak dorsiflexion of the hindfoot at the mid stance is 10.4°. The navicular-1<sup>st</sup> metatarsal segment displays mean peak dorsiflexion of 4.9° before toe-off. The 1<sup>st</sup> metatarsal-hallux joint gives mean peak dorsiflexion of 43° at toe-off (Figure 1). In the coronal plane, mean peak inversion of the hindfoot is 5.2° and eversion is 2.9°, whereas the navicular-1<sup>st</sup> metatarsal segment, and 1<sup>st</sup> metatarsal-hallux joint yield smaller range of motion. In the transverse plane, the hindfoot displays dominated external rotation during 1<sup>st</sup> and 2<sup>nd</sup> rocker. The midfoot and forefoot expresses minimal internal rotation during stance phase yet external rotation during swing. In sagittal plane, ICC between two measurements are 0.62 for hindfoot, 0.40 for navicular-1<sup>st</sup> metatarsal segment, and 0.34 for 1<sup>st</sup> metatarsal-hallux joint. In the coronal plane, coefficients are 0.86, 0.52, and 0.79, respectively. In the transverse plane, coefficients are 0.94, 0.66, and 0.72, respectively.

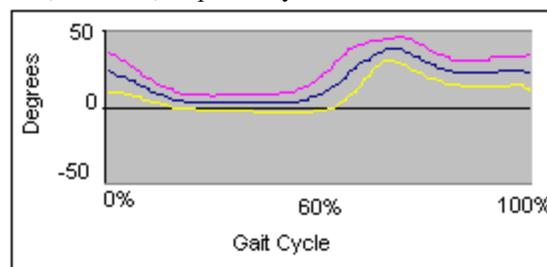

Figure 1. Dorsiflexion and plantarflexion of the 1<sup>st</sup> metatarsal-hallux joint in mean  $\pm$  SD as a function of gait cycle.

### CONCLUSIONS

Our foot model has a moderate to high reliability to determine hind and forefoot rotation. Movements derived from the navicular-1<sup>st</sup> metatarsal enhance our understanding of midfoot kinematics during walking. Further studies are needed to evaluate the interobserver variation across days.

### INTRODUCTION

The most common reason for the aseptic loosening of cementless hip stem is the lack of primary stability as the presence of an excessive relative micromotion at the bone-implant interface [1]. Despite pre-clinical validation has remarkably improved over the last few years, some important factors affecting implant biomechanics have still to be considered. Most of the previous numerical studies on hip arthroplasty were based on the solid model of a composite femur replica. However, subject-specific factors (skeletal anatomy, mechanical properties, implant position) are needed to produce helpful outcomes for clinical practice. In addition, these models were developed using time consuming structured meshes frequently lacking of careful verification and validation phases.

Aim of the present work is the development of a Finite Element (FE) model of an implanted femur taking into account the specificity of subject as well as the planned surgery technique parameters.

Specific aims are the verification of the numerical accuracy of the FE model and the analysis of the predicted relative micromotions compared to experimental results (validation).

### METHODS

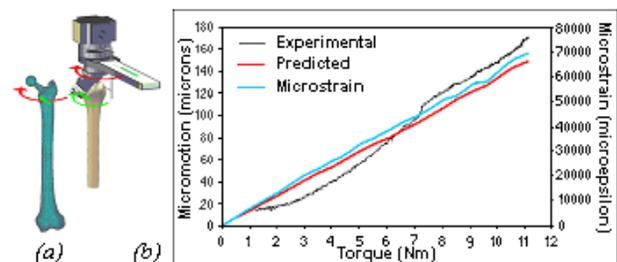

The 3D model of an intact cadaveric femur, taken *in-vivo* for clinical purpose, was generated from the CT dataset using a previously validated procedure. A linear convergence test on seven meshes with increasing refinement levels was performed to ensure the numerical accuracy of the model. Afterward, the position of an anatomic cementless hip stem (ANCAfit, Cremascoli-Wright, Italy) inside the femur was defined by a skilled surgeon using a pre-operative CT based software (Hip-Op, B3C, Italy). Surgical parameters and hip stem geometry were then imported within the FE model. An unstructured mesh was generated for both femur and hip stem consisting of tetrahedral elements (Figure 1a). The coefficient of friction was set to 0.3. Frictional contact was modeled at the bone-implant interface by means of face-to-face contact elements.

The peak compenetration was recorded since it must be very small to get a good level of numerical accuracy. The validation process ensured that the numerical model accurately predict the physical phenomenon it was designed to replicate. This was assessed by comparing the predicted history of sliding micromotion at the femur calcar level to *in-vitro* experimental measurement of Intra-operative Stability Assessment Console (ISAC) [2] replicating the same boundary conditions (Figure 1a). Two indicators were selected to judge the quality of the model: the root mean square error and the peak error of predicted micromotions.

### RESULTS AND DISCUSSION

Over the seven generated meshes, the percentage error in energy norm and the differences in terms of stress, strain and displacement were less than 2.2%. The model that guarantee the best compromise among computational time and accuracy was chosen (40460 elements). The peak compenetration was 3.2 microns, less then previously reported best value [3].

The model predicted the sliding micromotions measured experimentally with an average (RMS) error of 12  $\mu\text{m}$  and a peak error of 21  $\mu\text{m}$  (Figure 1b). The errors are comparable to those reported in studies with synthetic femurs and clearly acceptable for most applications. The different pattern of predicted versus experimental micromotions is explainable through a small volume of very soft cancellous bone in the femoral endosteum that may exceed the yield strain limit, e.g. 0.78% (Figure 1b). This hypothesis is confirmed by other measurements on different cadaveric femurs that have shown a similar pattern of experimental micromotions.

**Figure 1:** (a) FE model and the applied boundary conditions compared to experimental set-up used as benchmark problem; (b) Predicted and experimental micromotions over the applied torque. Peak microstrains over the entire FE model are also reported.

### CONCLUSIONS

Verification and validation are necessary preliminary steps to consider any finite element model predictions of scientific value. Using the method proposed it was possible to assess the confidence of predicting the bone-implant relative micromotions account for the patient and surgeon. Furthermore, unstructured mesh was proved to have the same degree of accuracy of the more time-consuming structured meshes.

## AN ANALYSIS OF LOSSES OF BALANCE DURING TANDEM STANCE ON A NARROW BEAM

<sup>1</sup>Alaa A. Ahmed and <sup>1,2</sup>James A. Ashton-Miller

Biomechanics Research Laboratory

Departments of <sup>1</sup>Biomedical and <sup>2</sup>Mechanical Engineering

University of Michigan, Ann Arbor, MI, USA; email: aaahmed@umich.edu

### INTRODUCTION

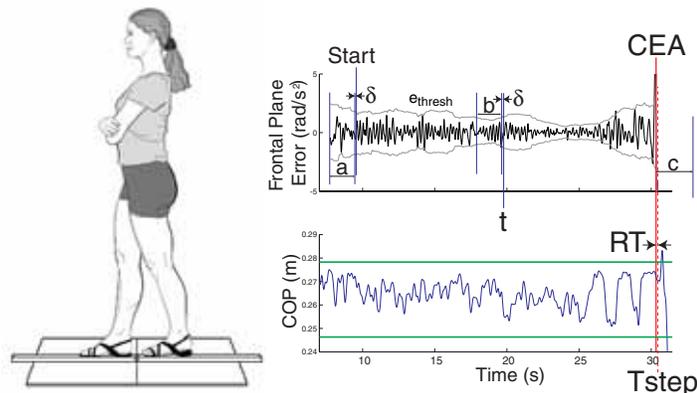

Most falls are preceded by a loss of balance. Given that there are few mechanistic explanations for 'loss of balance', we have hypothesized it to be a loss of effective control, detectable as a control error anomaly (CEA). We have used a model-reference adaptive controller to represent the central nervous system along with a failure detection algorithm to mimic how it makes decisions based on input and output signals obtained during the task [1,2]. In this paper we examine the ability of this method to detect a loss of balance in a three-dimensional, multi-degree of freedom (dof) balancing task: tandem stance on a narrow beam. We hypothesize that a control error anomaly will predict the occurrence of a compensatory step off the beam at least 100 ms, and no more than 2 s, later.

### METHODS

Ten young (18-30 yrs) female subjects were tested. Subjects were asked to stand in tandem (heel-to-toe) stance on a narrow beam (2.5 cm wide) for a maximum of 60 seconds (Fig 1). Each subject performed a minimum of 15 trials.

The human was modeled using eight three-dimensional rigid body segments: trunk, pelvis, right and left feet, calves, and thighs. Twenty-eight optoelectronic markers recorded the segment kinematics; ground reaction forces and torques were also recorded from two force plates to which the beam was bolted. Joint torques were calculated using inverse dynamics.

We considered the joint torques to represent the system inputs, while the segment accelerations represent the 8x3 system

**Figure 1** Left: Subject in tandem stance. Right (top): Algorithm schematic of one of the 22 control error signals analyzed and (bottom) center-of-pressure (COP) in the frontal plane with time of step initiation,  $T_{step}$ , marked by a vertical dotted line. The horizontal lines (bottom figure) delineate the beam outline.

outputs in the three orthogonal planes. The corresponding control error signals were defined as the residuals generated when each of the actual system outputs is compared to the corresponding predicted output of a nominal forward internal model using the given torque inputs. CEA was detected once an error signal crossed a threshold level set at three standard deviations ( $3\sigma$ ) beyond the mean value in a 2-second-wide moving window, **b**, which trailed the current time instant, **t**, by 100 ms ( $\delta$ ). (Fig 1: The threshold calculation begins at 'Start', initially using baseline data in window **a**.) LOB was confirmed by the occurrence of a step within 2 s of, and no earlier than 100 ms from, CEA detection (window **c**). The occurrence of a step was defined as a compensatory response and evidence of CEA perception.

### RESULTS AND DISCUSSION

This is the first test of the CEA hypothesis in a 3D multi-dof balancing task. The  $3\sigma$  algorithm correctly detected a loss of balance in 71.6% of 148 trials by either predicting the step off the beam when one occurred, or by not predicting a step when one did not occur. In this case, the first of the 8 segment control error signals in the frontal plane to reach  $3\sigma$  was used to detect CEA. Similar results were obtained when monitoring control error in either the sagittal (64.9%) or transverse plane (64.2%). Control error within a given plane was a better step-predictor than individual segment control error ( $p < 0.05$ , Table 1), and segments performed equally ( $p > 0.05$ ). Importantly, kinematic signals such as segment and whole-body center of mass (COM) position, velocity and acceleration were significantly less reliable than CEA ( $p < 0.01$ , Table 1). The optimal threshold level for CEA detection was  $3\sigma$ , supporting earlier results in sagittally-symmetric seated [1] and standing reach [2] balance tasks. In contrast to kinematic measures, CEA emphasizes the importance of the control input, and the input/output relationship in the perception of a loss of balance.

### CONCLUSIONS

The results support the definition of a loss of balance as a loss of effective control. Control error is a more reliable predictor of a compensatory response than body kinematics in this three-dimensional, multi-input, multi-output balancing task.

### INTRODUCTION

The objectives of the study were to identify the gait assessment practices currently used in pediatric motion analysis laboratories and to evaluate the need for a standardized approach [1].

Gait analysis is recognized today as an essential tool in clinical rehabilitation [2,3]. Generally, gait analysis is successfully used to assess and to identify motor disability, to develop treatment plans, to evaluate the effectiveness of a treatment and to study clinical and pathological gait. However, because of differences in the equipment, personnel training and the methods used for gathering data, comparing and sharing gait analysis results between gait analysis laboratories is very difficult, if not impossible [4].

A questionnaire was developed in the Pediatric Rehabilitation Department, at the George and Marie Backus Children's Hospital at Memorial Health University Medical Center. Several important issues emerged from the current study. The results of the study highlight the current inconsistency between gait assessment practices of various motion analysis laboratories and the importance of standardization.

### METHODS

A multiple-choice questionnaire assessed the current practices in pediatric motion analysis laboratories, and the perceptions of the staff regarding the standardization of their laboratory's data. The questionnaire had 15 questions regarding motor evaluation tests used for children with motor impairment, methods to determine treatment effectiveness, normative database used, etc.

A consecutive sample of 13 pediatric motion analysis laboratories were recruited out of 15 centers to complete the questionnaire based on availability of pediatric evaluation, testing capabilities and peer recognition. All the participants completed the same questionnaire. Four recruited participants did not answer the questionnaire.

### RESULTS AND DISCUSSION

Currently, to evaluate the results of a gait analysis, diverse resources are used. No two laboratories listed the same protocols as part of their evaluation. Most of the participants are using normative data that is collected on-site. The remaining participants are using data developed by other laboratories.

Four of the participants consider "functionality" as the most essential characteristic of gait for children with motor

impairment. Symmetry, normality, comfort and patient's goals were also considered. Four of the participants are using Gross Motor Function Measure (GMFM) to evaluate motor impairment in children. The remaining participants are using various other evaluation tests: Gross Motor Function Classification System (GMFCS), Pediatric Outcomes Data Collection Instrument (PODCI), etc.

Determining the necessity of a treatment and the treatment's effectiveness varies among participants. These determinations are usually performed using instrumented and observational examinations, as well as other evaluations such as team review, interview with the family, etc.

Determining the optimal duration of a physical therapy treatment is particular for each participant. Multiple criteria are used: specific goals, post surgery assessment, functional potential, severity of motor impairment, patient's ability to cooperate, insurance reimbursement, etc.

Despite the availability of expensive and sophisticated equipment, there is no standardized protocol or series of tests that laboratories agree to as a basis for evaluation. Most of the participants are interested in using a new normative database as reference.

### CONCLUSIONS

Gait assessment practices vary significantly between different laboratories. While developments in technology are rapidly progressing, the tools to standardize the information are lagging. This gap is particularly noticeable in children under the age of eight, where there is little to no normative tools.

Lack of consistency between centers, rapid development of technology, and perceived interest of current laboratories for a common assessment and normalization tools calls for the standardization of data.

**INTRODUCTION**

Proprioception is a sense of position and movement of one's own limbs and body in the absence of vision, termed "limb-position sense" and "kinesthesia," respectively. Proprioception has been shown to diminish with injury, age, and so on. Position sensibility can be measure by many methods. Several different testing techniques have been developed to measure the conscious submodalities of Proprioception. There are 3 submodalities (joint position sense, JPS; Kinaesthesia and sense of tension). The JPS test measures the accuracy of position replication and can be conducted actively or passively in both open and closed kinetic chain position. Variety of equipment and instrument were developed to measure conscious appreciation of Proprioception, such as commercial isokinetic dynamometers, electromagnetic tracking devices, custom-made jigs, and some new device. Recently a functional squat system (FSS) was introduced by MONITORED REHAB SYSTEMS that mimics the movement co-ordination pattern of squat jump, under the control of an external load. This device can be measure Proprioception in actively closed kinetic chain. Compared to some open chain device, it shows more similar to daily activity. Therefore, some test need to investigate the reliability for FSS. The intraclass correlation coefficient (ICC) is used to measure inter-rater reliability. Although Pearson's r may be used to assess test-retest reliability, ICC is preferred when sample size is small (<15) or when there are more than two tests (one test, one retest) to be correlated. Therefore, The purpose of the present study was to compare repeat-measures proprioceptive test in Functional Squat System.

**Figure 1:** Functional Squat System when performed repetitive squat exercises with one leg in standardized pace.

**METHODS**

Eighteen college students participated in this study (male=9, female=9; mean age, 22.1 ±3.5 years). Subject were used FSS in Proprioception test program to measured low extremity in 25, 50 and 75 three different knee joint angel. For intrasession intratester reliability of the figure-of-two measurement, ICC (2,1) and the SEM were used. The ICC (2,1) was based on a subjects ×2-way analysis of variance (Shrout & Fleiss, 1979).

**RESULTS AND DISCUSSION**

The ICC (2,1) for repeat-measures knee proprioceptive test was 0.94 (P< .05). The means, SDs, and SEMs for these measurements and the repeat-measures proprioceptive test are summarized in table 1. the results of the correlations between two test are summarized in Table 2. In order to get an accurate measurements, the reliability coefficients should exceed 0.90 to ensure valid interpretations (Portney and Watkins, 1993). In this study, results demonstrated excellent intrasession intratester reliability and small measurement error for the repeat-measures proprioceptive test.

**Table 1:** Means, SDs, and SEMs, for 3 different knee angles repeat measurement test in FSS.

Measurement	Distance (cm)		
	Mean	SD	SEM
25°	16.04	11.05	5.41
50°	15.81	11.81	7.06
75°	9.22	4.29	3.49

\*Means based on 3 measurements obtained from 25 subjects.

**Table 2:** Pearson Product Moment correlation coefficients ( ) of the relationship between repeat-measures proprioceptive test in FSS.

Measurement	r*
25°	0.89
50°	0.84
75°	0.96

\*p < .001

**CONCLUSIONS**

This study was conducted to determine the intrasession-intratester reliability and criterion-related validity of the repeat-measures knee proprioceptive test. The result shows that the FSS Proprioception test was reliable and valid indirect method of measuring knee Proprioception in individuals with this test.

## Investigation of Shoulder Range of Motion Limits for Application to Ergonomic Analysis

Joshua S. Danker and Matthew P. Reed  
University of Michigan - Ann Arbor,  
email: [danker@umich.edu](mailto:danker@umich.edu), web: [www.HUMOSIM.org](http://www.HUMOSIM.org)

### INTRODUCTION

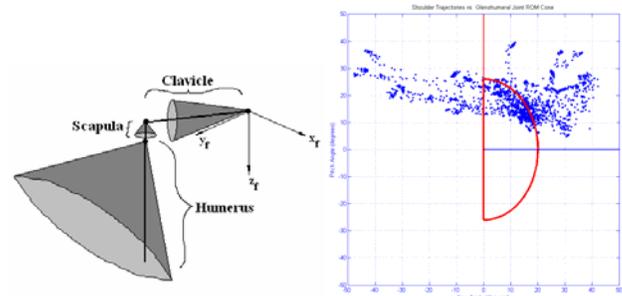

Ergonomic analysis using human figure models requires detailed knowledge of worker postures. Because tendonitis, carpal tunnel syndrome, impingement syndrome, and other musculoskeletal disorders can result from awkward upper extremity postures, accurate simulation of upper-extremity postures is critical for job analysis. Posture-prediction algorithms used in digital human models include joint range of motion (ROM) limits, and these limits affect the ranges of postures that can be applied to the figures. Inaccurate or inappropriate joint ROM may result in inaccurate posture prediction.

Due to its complexity, versatility, and susceptibility to injury, the shoulder is of primary importance in any comprehensive ergonomic analysis of the upper extremities. This abstract describes the first steps of an investigation of the influence of shoulder ROM on work postures, beginning with a comparison of shoulder motions in seated reaching tasks with the ROM data provided by Tumer and Engin [2].

### METHODS

Widely cited data on shoulder ROM [2] were compared with shoulder motions in seated upper extremity reaches measured in the laboratory using motion capture equipment. The experimental data contain the locations of the sternoclavicular and glenohumeral joints calculated from the position and orientation information obtained from electromagnetic transducers (Flock of Birds, Ascension Technologies). Data from 12 men and women seated in a truck seat reaching to a wide range of push-button target locations were used for the current investigation. Because the experimental data provide a single claviscapular segment to approximately the linkage of the thorax to the humerus, the data are not directly comparable to Tumer and Engin's three-segment model (clavicle, scapula, humerus) for which ROM data are provided. To facilitate the comparison, a composite ROM cone was created to define the combined motions of Tumer and Engin's sternoclavicular and claviscapular joint segments.

Figure 1 shows the joint sinus cones from Tumer and Engin along with the three-link shoulder system. A MATLAB simulation incremented the two joints independently through their ranges of motion. The endpoint of the claviscapular segment, the glenohumeral (GH) joint center, was stored for each increment. This cloud of roughly  $5 \times 10^5$  points defined a region of allowable glenohumeral joint center locations relative to the torso for the average joint ROM cones given by Tumer and Engin. The resulting simulated GH locations were compared to the measured GH locations, expressed with respect to an equivalent thorax coordinate system.

**Figure 1:** Diagram of the three-link shoulder complex used by Tumer and Engin [2] (left). Comparison of measured glenohumeral joint locations with respect to the thorax with the combined clavicle-scapula ROM (right).

### RESULTS AND DISCUSSION

GH locations often deviated from the region defined by the Tumer and Engin clavicle and scapula ROM limits (Figure 1). The patterns of deviation persisted even when the data were normalized within subject to a neutral posture. Most of the deviations were in the upper right quadrant, corresponding to reaches to targets in front of and above the shoulder. The greatest GH excursions occurred in near-maximal reaches, precisely the reaches that are of greatest interest for ergonomic analysis. Perhaps unsurprisingly, given the large amount of inter-individual variability in shoulder ROM [1, 3], most of the population may have shoulder ROM that exceeds the average mobility provided by the Tumer and Engin joint sinus cones. The current investigation also suggests that the shape of the shoulder ROM used by individuals for seated reaches varies considerably.

More investigation will be necessary to determine how best to include the large amount of variability in shoulder ROM in ergonomic analyses. If an average ROM limit is used, the figure model may not be capable of motions that many or most people could perform, posing a model credibility problem. Moreover, because individuals with more limited ROM will not always be the individuals most at risk in a particular task, the utility of DHM figure models as a screening and evaluation tool may be compromised without improved methods for incorporating ROM limits.

## THE FIRST METATARSAL AS A FIXED STRUT: NEW INSIGHTS INTO DYNAMIC ARCH FUNCTION

<sup>1,2</sup> Jason Wilken, <sup>2</sup> Charles Saltzman, <sup>1,2</sup> Smita Rao, <sup>1</sup> H. John Yack  
<sup>1</sup> Grad Program in PT and Rehab Science, <sup>2</sup> Orthopaedics and Rehabilitation  
The University of Iowa, email: [jason-wilken@uiowa.edu](mailto:jason-wilken@uiowa.edu)

### INTRODUCTION

The truss and tie rod theory has long provided the framework through which motion of the medial longitudinal arch during loading is viewed [1,2]. Early insights gained from static loading of cadaveric feet resulted in a conventional understanding that describes arch lowering during the stance phase of gait via simultaneous downward motion of the proximal first metatarsal and distal calcaneus. In the process of quantifying the effects of ankle arthroplasty and fusion on dynamic foot function it was observed that arch motion occurred in a manner different than commonly accepted. The purpose of this work is to define the segmental kinematics that expose a new perspective on arch motion during gait in which arch elongation occurs about a stationary first metatarsal.

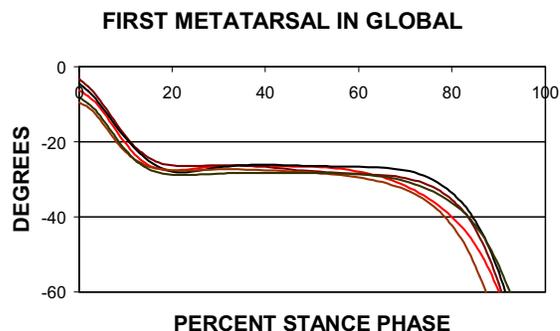

### METHODS

Motion of the first metatarsal in the global (relative to the floor) and of the first metatarsal relative to the calcaneus (arch elongation) was assessed in a total of 23 limbs. Of the limbs tested 7 had undergone ankle fusion, 9 had undergone ankle arthroplasty and 7 had no previous surgical intervention. An Optotrak motion analysis system was used to record the 3-D position of the first metatarsal and calcaneus during gait. Motion of the first metatarsal was tracked with a lightweight marker triad mounted on the first metatarsal, medial to the extensor hallucis longis tendon in a manner similar to Leardini et al. [3]. Hindfoot motion was assessed by two markers on the lateral and one on the posterior aspect of the calcaneus. A digitizing process in conjunction with lateral and AP x-rays of the foot in the patient population, and palpation of the foot in control subjects were used to identify the location of underlying bony geometry relative to each segment's marker triad. Visual 3D (C-motion Inc.) was used to calculate 3-D displacements. The mean of five trials at self selected, 0.9, 1.1, 1.3 and 1.6 m/s were used for variables of interest.

To determine arch kinematics during gait motion of the first metatarsal relative to the calcaneus (arch motion) and sagittal plane angular motion of the first metatarsal in the global (lowering of the proximal end of the first metatarsal) were assessed during stance phase.

### RESULTS AND DISCUSSION

Kinematic patterns and peak values were highly consistent both within and between walking velocities with standard deviation values of less than 1 degree on average. To our surprise arch and first metatarsal kinematics were not significantly different between groups and therefore, grand mean values were used. Once forefoot contact occurs the first metatarsal was found to maintain a nearly static position from  $17.0 \pm 3.3\%$  until  $67.0 \pm 6.4\%$  stance (Figure 1). During this

**Figure 1:** Sagittal plane kinematics of the first metatarsal relative to the floor for five subjects demonstrating nearly static positioning for approximately 50% of stance.

interval the first metatarsal was found to lower only  $1.5 \pm 1.2$  degrees while the arch flattened  $10.5 \pm 3.0$  degrees on average. These data suggest that during the stance phase of gait arch elongation occurs as the calcaneus is pulled up and over the nearly stationary first metatarsal. The elevation and resulting unloading of the calcaneus that produces this motion is substantiated by plantar pressure data in which the calcaneus is unloaded in mid stance

Contrary to the current understanding of normal arch motion, the first metatarsal appears to maintain a nearly static sagittal plane orientation during midstance. These findings are quite robust and exist following surgical interventions and across different walking velocities where the stress on the arch would vary.

### CONCLUSIONS

These data suggest a new insight into medial longitudinal arch motion in which the calcaneus is pulled over a nearly stationary first metatarsal causing arch elongation. This calls into question the current understanding of medial longitudinal arch lowering and may in part explain the mixed results observed with current interventions used to control arch motion during gait.

## THE EFFECTS OF EXTERNAL WEIGHT CARRIAGE ON POSTURAL STABILITY

<sup>1</sup>Michelle Heller, <sup>2</sup>John Challis, and <sup>2</sup>Neil Sharkey

<sup>1</sup>Mechanical and Nuclear Engineering, and <sup>2</sup>Kinesiology, The Pennsylvania State University, University Park, PA, USA  
email: [nas9@psu.edu](mailto:nas9@psu.edu), web: [www.biomechanics.psu.edu](http://www.biomechanics.psu.edu)

### INTRODUCTION

Postural stability has been defined as “the ability to return the body close to the equilibrium point when exposed to a perturbation” [1]. Karlsson and Frykberg suggested that two different mechanisms keep an individual in a stable position: the load-unload strategy and the ankle strategy [1]. Medial-lateral stability is maintained through the load-unload strategy when a person shifts his/her weight from one foot to the other. The ankle strategy is used to maintain anterior-posterior stability by employing the muscles crossing the ankle joint to create a moment to resist loss of balance and is the mechanism of greatest interest when investigating the effect of load distribution on postural stability. Both load carriage and associated muscle fatigue have the potential to decrease a person’s postural stability. Compensatory mechanisms such as increased trunk inclination during load carriage serve to keep the center of mass over the feet, and the degree of flexion is dependent on the magnitude of the external load. This observation illustrates that there may be a correlation between load carriage and stability; such information could be valuable in combating common injuries encountered by military personnel.

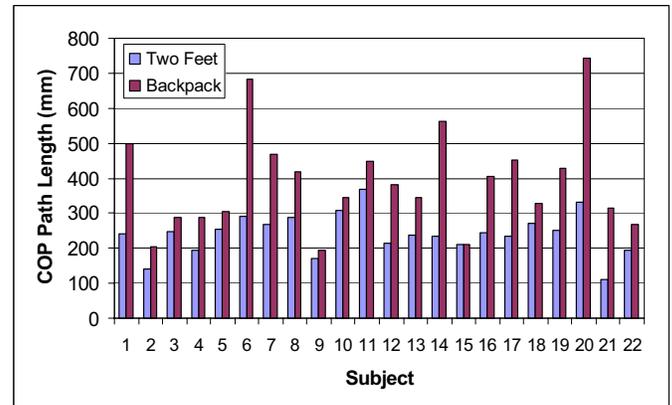

Kinematic changes of load carriage include a greater degree of knee flexion after heel strike [2], decreased transverse pelvic and thoracic rotation, decreased phase shift between pelvic and thoracic rotation, increased hip excursion [3], and increased musculoskeletal stiffness [4]. The changes in gait kinematics are partially a result of energy-saving mechanisms, but may also function to help increase dynamic postural stability. Static postural control studies may begin to unravel some of these relationships.

### METHODS

Twenty-two female subjects (mean: 20.8 years, S.D.: 1.7 years) with no history of musculoskeletal disorders volunteered to participate in the study. Each subject was asked to stand upright on a Kistler force platform under each of three conditions: one foot quiet standing, two feet quiet standing, and while wearing an 18.1 kg military pack. The subjects were asked to concentrate on an “X” located 1.5 meters from the ground. Data were collected at 1000 Hz in conjunction with a Motion Analysis system. One thirty-second trial was collected for each condition, as LeClair et al. [5] determined this was sufficient to see differences between conditions.

The standing trials involved standing quietly on two feet and the one-foot trials involved standing while one first metatarsal head was placed against the opposite medial malleolus. During the external load condition, the subjects were asked to wear a standard issue military pack, which was obtained from the Penn State ROTC program.

### RESULTS AND DISCUSSION

**Figure 1:** The center of pressure path lengths for each of the subjects indicates more sway under the backpack condition than during quiet standing.

Standard measures of postural stability indicated that the subjects were less stable while carrying the military pack. The data were analyzed using a paired t-test. The center of pressure (COP) path lengths were higher under the load carriage condition than the two foot quiet standing ( $P < 0.001$ ), as shown in Figure 1. The area of the ellipse that included 85% of the data points was calculated for each trial. The COP areas were higher for the load carriage condition ( $P < 0.001$ ). Both of these results indicate more postural sway when carrying an external load. Furthermore, the anteroposterior (AP) and mediolateral (ML) excursions were both greater under the load carriage condition, with  $P = 0.019$  and  $P < 0.001$  respectively. All standard measures of postural stability indicate a decrease in stability when the subjects donned the military pack.

### CONCLUSIONS

Wearing an external load of 18.1 kg, which is less than the minimum load carried by military personnel, reduces postural stability in healthy, young females. This could translate into a higher likelihood of injuries such as ankle sprains in this population.

## VIRTUAL JACK MANIKIN USED TO ASSESS POSTURAL VARIABLES AND VISIBILITY MEASURES FROM THE CAB OF LOAD-HAUL-DUMP MACHINES

<sup>1</sup> Alison Godwin, <sup>2</sup>Tammy Eger and <sup>2</sup>Sylvain Grenier

<sup>1</sup>Queen's Ergonomic Research Group, Queen's University

<sup>2</sup>Biomechanics Ergonomics and Kinesiology Lab, Laurentian University; email:4aag@qmlink.queensu.ca

### INTRODUCTION

Load-haul-dump (LHD) machines were previously shown to have significant visibility deficits within a computer-aided design environment known as Classic JACK [1]. The virtual human simulation program was then used to assess the postural deviations of the head and trunk that may be associated with obtaining a line-of-sight from the cabin of these machines. Since minor retro-fit modifications were insufficient to create a large increase in visibility measures [2], a concept change was tested in the virtual environment for feasibility.

A rotating operator seat has been successfully used to reduce postural deviations for tractor operators and other, sideways-seated machine operators [3,4]. A rotating seat and console was incorporated into the virtual environment to allow testing of a 20° and 45° seat rotation intervention. Postural load variables and visibility measures were evaluated as dependent variables.

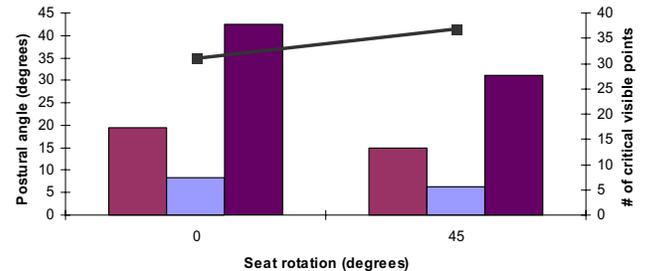

### METHODS

Virtual human operators representing a range of anthropometric sizes (1<sup>st</sup> to 99<sup>th</sup> percentile) were placed in the cab of a 7yd3 LHD machine. A series of movement strategies (n=15) representing typical neck and trunk movements used by actual operators to view specific hazards around their vehicles were developed. These movement strategies were constrained by known biomechanical tendencies (twist developed by thoracic vertebrae and flexion developed by lumbar vertebrae). The virtual hands and feet were constrained to hand controls and foot pedals. A variety of biomechanical variables were collected while the virtual human used their unique movement strategy to view the left-most target point. Selected dependent variables included muscular activity of five trunk muscles (N), compression (N), shear (N), L4/L5 moment (Nm), trunk rotation (°), neck rotation (°), trunk flexion(°) and trunk lateral bend (°). Data was assessed using t-tests to determine if differences existed between the current cab condition and a seat rotation of 20° and 45°. Using the Bonferroni correction, a  $p < 0.0167$  was required for significance.

### RESULTS AND DISCUSSION

There was a lack of statistical significance to demonstrate that a seat rotation will unequivocally reduce the risk factors that may lead to injury for LHD operators. Compression, shear, L4/L5 moment and muscular activity all showed decreasing trends. It was possible to demonstrate that a virtual environment can show decreases in postural load variables when a proposed beneficial solution is tested. All postural angle values decreased as seat rotation increased with a

concomitant increase in visible area available to the operator (Figure 1).

**Figure 1:** Trunk rotation, trunk lateral bend and neck rotation decreased as seat rotation increased from 0 to 45. An advantageous increase in the number of visible critical points was also achieved.

Even without statistical significance, these results can be used by manufacturers to evaluate and refine potential designs and concepts. Limitations to consider before implementation of these types of modifications include the ability to obtain accurate machine representations and validated operator movements.

### CONCLUSIONS

Despite some reservations, this research shows promise for the ability to analyze a virtual human in industrial machinery. Most industrial manufacturers use 3-D programs to design future equipment. It is advantageous to the eventual human user if ergonomic principles and biomechanical considerations can be assessed and refined prior to building prototypes.

## INTRODUCTION

Injuries to the upper extremity region rank second among all reported occupational injuries [1]. Currently, limits are non-existent for low force, repetitive tasks such as Fastener Initiations (FI) performed in the automotive industry. The purpose of the current study was to determine acceptable human tolerance limits values (TLVs) for a fastener initiation task, which is commonly performed in the automotive industry.

## METHODS

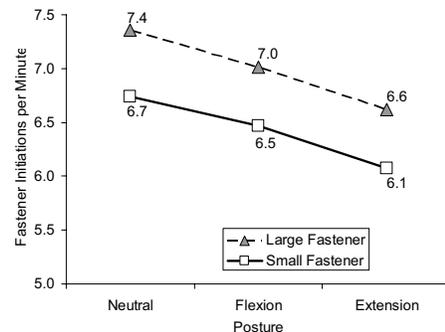

A psychophysical methodology was utilized to examine 24 non-skilled female subjects while performing fastener initiation tasks on a simulation device. The independent variables were: 1) wrist posture: neutral, flexion and extension, and 2) fastener size: large (10 mm depth, 20 mm diameter) and small (5 mm and 10 mm). For each condition, subjects were instructed to complete their maximal acceptable number of FIs over the course of a 60 minute trial. Subjects trained for 2 hours on each condition and were tested for 1 hour (total of 18 hours). The kinematic dependent variables were: 1) average number of 720 degree FIs per minute, 2) average duration of each FI and 3) average number of individual movements (efforts) per 720° FI.

Surface EMG was also used to monitor the muscle activity of forearm (biceps brachii (BB), brachioradialis (BR), flexor carpi ulnaris (FCU), extensor carpi ulnaris (ECU) and hand muscles (thenar (TR) and first dorsal interosseous (FDI)). A repeated measures ANOVA with Tukey's significance post hoc test were used to determine any significance within the measured variables ( $p < 0.05$ ).

## RESULTS AND DISCUSSION

Both Posture and Fastener Size variables had significant main effects on all kinematic variables. Results indicated a 10% decrease in FIs per minute when the small fastener size was used, as well as a 10% increase in the average time to complete each FI when performing the task with the small compared to large fastener. In addition to the fastener size, posture was shown to have a significant effect on the kinematic data. Compared to the extended posture, the average number of FIs/min increased 12% and 7% for the neutral and flexed posture, respectively. In addition, the average duration of each FI was affected by posture with the extension being 12% greater than flexion and flexion being 8% greater than neutral.

The kinematic data used to determine the TLV showed interesting results as the large fastener/neutral wrist condition had the highest number of FIs ( $9.1 \pm 2.6$ ), they were performed with the lowest number of efforts per FI and shortest duration

**Figure 1:** TLV for FI/minute calculated as the values acceptable to 75% of females ( $n = 24$ ).

per FI. TLVs were calculated as those acceptable to 75% of the female subjects (Figure 1). These ranged from 6.1 to 7.4/min depending on the fastener size and wrist posture.

Electromyography data showed that posture, age and fastener size did, in certain instances, demonstrate significant interactions. In particular, posture had an effect on EMG from the BB, BR and TR muscles. The EMG of the BB was at its lowest (% of Maximal Voluntary Exertion (MVE)) during flexion and BR and TR were at their highest during extension. Interestingly, the ECU had the highest activity for all six conditions (mean of 13.5% MVE). This result parallels that of Mogk and Keir (2003), where the ECU higher activation is believed to be due to its role as a stabilizer to the internal and external moments about the wrist joint.

The kinematic and surface EMG data from this study show that both Posture and Fastener Size are important factors that affect the performance and acceptability of FIs. As the Posture variable deviated from neutral, and as the fastener became smaller, a significant decrease in the FIs per minute resulted. Thus, this study provides data to support the need for the design of more neutral hand-wrist human interfaces along with larger objects for the hand to manipulate. Such designs will potentially decrease the risk of musculoskeletal injury and/or increase productivity. Thus, this study has provided recommendations on acceptable human tolerances for the task of fastener initiations used in the manufacturing industry. Furthermore, EMG data provided valuable information regarding forearm and hand muscle activity during a low force, high frequency task.

## ACCURATE PRODUCTION OF PATTERNS OF THE TOTAL MOMENT BY A SET OF FINGERS

Wei Zhang, Naoki Yoshida, Mark L. Latash  
Department of Kinesiology, The Pennsylvania State University, University Park, PA 16802  
email: [mll11@psu.edu](mailto:mll11@psu.edu)

### INTRODUCTION

During isometric force production by an effector, force variability typically increases with the level of force [1]. When several fingers of the hand press down in parallel to produce a required time profile of the total force, there is little variation in the total force variability over a wide range of the total force [2]. This results from force-stabilizing multi-finger synergies. Tasks of accurate total force production are also accompanied by synergies stabilizing the total moment in pronation/supination, even when the subjects are instructed and get visual feedback on the total force but not on the total moment [2]. These findings have been interpreted as consequences of everyday practice with tasks that typically impose more strict accuracy constraints on total moment production. We investigated the relations between the total moment and its variability during the multi-finger production of accurate time profiles of the total moment. We expected the hypothetical multi-finger synergies to lead to complex relations between the moment magnitude and its variability.

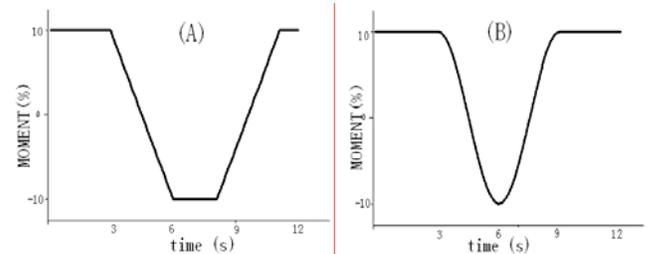

### METHODS

Twelve healthy, right-handed volunteers, six males and six females participated in the experiment. The subjects sat comfortably in a chair and positioned the right forearm on the horizontal board directly in front of the subject. The fingertips of the right hand were placed on unidirectional force sensors spaced to fit the subject's individual anatomy. Changes in the forearm and hand position were prevented by a set of Velcro straps and using a custom-fitted wooden piece placed under the palm. The subjects watched a 17" monitor that showed a target moment time profile and the actual total moment in pronation/supination produced by the normal finger forces with respect to the midpoint between the middle and ring fingers (effort into pronation was considered positive).

After a few practice trials, the subjects were required to follow, as closely as possible, a pattern shown on the screen with the cursor. There were two tasks, the Ramp-Task and the Sine-Task illustrated in Figure 1. Each task required accurate production of a moment profile starting from a certain level into pronation (normalized by subject's index finger maximal force), on average about 20 Ncm, to the same level into supination and then back to the original pronation moment. The total time of a trial was 12 s; the time intervals of moment changes were 3 s each. Twenty-five trials were performed at each task. Average force and moment time profiles and their variance profiles were computed over each set of 12 trials.

### RESULTS

Both ramp and sine changes in the total moment showed two phases, a decrease in the forces by fingers that produced the moment in one direction followed by an increase in the forces of fingers that produced the moment in the opposite direction.

**Figure 1:** The Ramp-Task (A) and the Sine-Task (B). Moment axes are in percent of the product of index finger MVC by its lever arm.

In both tasks, the total normal force produced by the fingers increased over the trial duration such that it was significantly higher at the end of the task (on average, a two-fold increase from 8 to over 16 N) while the subjects produced the same moment as at the trial initiation. No clear relations were observed between total force and its variability and between total moment and its variability. However, moment variance was significantly higher, on average by 70%, when the total moment was close to zero than at its peak values; this was more pronounced during moment changes from pronation to supination. High moments into supination were accompanied by higher variance, on average by 66%, than high moments into pronation.

### DISCUSSION AND CONCLUSIONS

Our observations suggest the existence of complex relations between magnitude of a moment produced by a set of fingers in isometric conditions and moment variability. Apparently there is no simple rule that would predict moment variability based solely on its level. Moment variability depends on the rate of moment change, on the time history of getting to a particular moment value, and it shows differences between the pronation and supination moments. Moment changes from a steady-state to another level and back to the same steady-state are accompanied by an increase in the finger force level, which is not dictated by the task and looks counter-intuitive: It involves unnecessary force production by fingers opposing the required moment. Further studies of multi-finger moment production are needed to resolve these mysteries.

### INTRODUCTION

The mechanism behind medial or lateral tibio-femoral gonarthrosis remains partially unexplained [1]. According to Maquet's theories, the surgical treatment of this pathology seems to give good results [3]. However poor results are observed in more or less 25 % of the cases. It is true that the cartilaginous and osseous lesions of this pathology can explain the long-term pain. The purpose of this work was the development of a new method to record in-vitro tibio-femoral variations of the constraints, during dynamic flexion-extension movement of the knee. Further goals behind this study include analysis of the constraint variations during 3D low femoral osteotomy.

### METHODS

**Specimens:** Five fresh human right lower limbs were used (Age:  $84,2 \pm 8,7$ ; 4 men, 2 women). Each limb was thawed during 24 hours before preparation: - dissection of thigh

muscles; - replacement of muscle tendons by fishing wires for loading (240N on each head of quadriceps and 75N for all flexors). The specimens were placed on a metal bracket allowing their fixing in the hip and femoral bone (Figure 1).

Figure 1: Experimental setup

**Strains gauges (SG):** Six SGs (FCA-1-17,  $\varnothing$  4.5 mm, 120  $\Omega$ , TML) were molded in epoxy resin (LX 112) to obtain sensors that were inserted into the spongy bone of the tibial proximal epiphysis in anterior, posterior and lateral locations of both tibial condyles perpendicular to the cartilaginous surface. The SGs were inserted about 10 mm below the edge of the tibial plateau and below the articular cartilage.

**Data logger:** Twelve gauges amplifiers were built. These modules consist of low-pass filters and different gains to allow increasing of the sensitivity of the SGs. The amplifiers were connected to a Pc-Data acquisition board Dap2003a (DAP, National Instruments).

**Protocol:** Cycles of two movements of leg flexion-extension were applied manually. An 6 DOF-electrogoniometer [2] sampled tibio-femoral kinematics, and allowed to normalize results according to the range of motion. Three repetitions were carried out for each specimen. Intra- and inter-observer reproducibility was studied on one specimen. Three observers performed 10 motion cycles at three intervals of time.

### RESULTS AND DISCUSSION

**Intra- and inter- observer reproducibility:** the Root Mean

Square (RMS) difference to the mean curve was compared. The results show small differences between observers and repetitions, compared to the maximal peak value of 3 N/cm<sup>2</sup> (Table 1).

**Table 1:** Intra- and inter- observer RMS differences for SG 1

	Experimenter 1	Experimenter 2	Experimenter 3
<i>Intra</i> (N/cm <sup>2</sup> )	0.08 to 0.25	0.06 to 0.15	0.05 to 0.09
<i>Inter</i> (N/cm <sup>2</sup> )	0.08 to 0.25		

**Inter-individual variations:** Figure 2 shows the interindividual variability obtained for SG 1. Results also depend on the quality of the spongy bone [4] and the placement of the sensors.

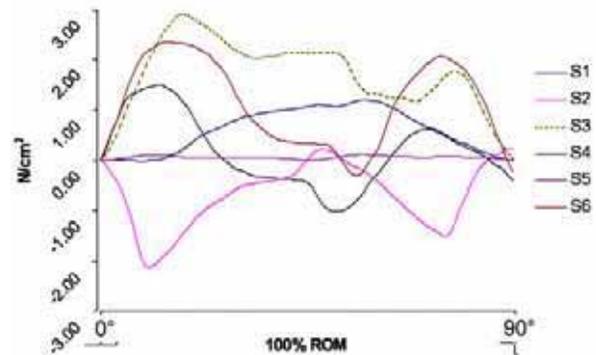

Figure 2: Interindividual variations

### CONCLUSIONS

This study shows the feasibility of analyzing articular constraint variations during dynamic movements. Reproducibility of measurements was satisfactory, and a significant inter-individual variability was found. This reinforces the idea to use this technique to study the changes of joint constraints before and after knee surgical procedures (e.g., osteotomy). Such a study is currently being performed by the authors.

A COMPARISON OF TASK AND MUSCLE SPECIFIC ISOMETRIC SUBMAXIMAL EMG DATA NORMALIZATION TECHNIQUES FOR THE ANALYSIS OF MUSCLE LOADS DURING HYDRAULIC-ACTUATION JOYSTICK CONTROLLER USE.

Taylor Murphy and Michele Oliver  
 School of Engineering, University of Guelph ON; email: taylor@uoguelph.ca

**INTRODUCTION**

Joystick manipulation involves low level, but nearly constant contractions of the shoulder musculature [3]. This combination makes it difficult to choose an appropriate technique for electromyography (EMG) normalization. Results from investigations using maximal voluntary contraction (MVC) normalization techniques are equivocal with some studies observing increases [1] with others finding decreases [4] in reliability. Normalization using MVC methods is also questionable, as it can be difficult for subjects to reliably elicit a maximal contraction. Sub-MVC normalization, on the other hand, has been shown to increase reliability [4]. Further studies [2] have exposed severe compromises (as the result of motion artifacts and contraction type) to the quality of data when a dynamic task is normalized by a single isometric contraction. Moreover, a study of joystick manipulation did not find dynamic normalization procedures to be better than isometric ones [3].

The purpose of this study was to determine an appropriate submaximal isometric electromyography (EMG) normalization technique that will later be used to assess the efficacy of a dynamically moveable armrest for joystick operators.

**METHODS**

The experimental set-up involved a mock-up of a common excavator cab, including a chair and right-hand hydraulic-actuation joystick. Surface EMG data were collected from 3 muscles (upper trapezius – UT, posterior deltoid – PD, and anterior deltoid – AD) using a Noraxon Telemetry (model 500, Noraxon USA Inc) telemetered EMG system (fixed gain of 2000, bandwidth of 10-500Hz, common mode rejection ratio of >100dB at 60Hz, input impedance 2 mega ohms). Six subjects performed three trials of three contraction types consisting of a muscle-specific reference isometric voluntary contraction (mRVC) (one for each of UT, PD, and AD), six task-specific isometric reference voluntary contractions (tRVC) (start, middle and end range of joystick motion), and two dynamic occupation tasks (forwards and backwards joystick motions). The mRVC's were accomplished by holding a 1kg weight in three standardized non-task related positions. Muscle activation levels during tRVC trials were approximately equivalent to activation levels during mRVC trials where force was monitored by strain gauges oriented in a

full-Wheatstone bridge and displayed to subjects on a monitor to allow them to produce a constant level of muscle activation. The average RMS values of the middle 10 seconds of all RVC trials were used as the normalization values. Joystick angles (6 VICON M2 cameras, Oxford, UK) were used to segment the EMG data into 5% intervals of the joystick motion cycle for the forward and backward dynamic trials. After ensemble averaging, and dividing the dynamic trials by the various RMS values, the four normalization procedures were assessed using an inter-subject coefficient of variation (CV) [4].

**RESULTS AND DISCUSSION**

The un-normalized CV's were generally lower than those of normalized ensembles with CV values being consistently higher for backward than forward motions (Table 1). The lowest CV's varied randomly across muscles and normalization methods but remained relatively low throughout. A potential explanation for the low CV values is that joystick motion involves small displacements (approximately 20° for each of forward and backwards motions) and is relatively constrained.

The purpose of normalization is to reduce the variability between subjects, therefore, the low CV values reported for all normalization techniques indicate that one isometric method is not superior to another when normalizing shoulder EMG during joystick manipulation.

**A BETTER IMAGE DEGRADATION METHOD FOR CONVERTING HIGH RESOLUTION CT SCANS INTO FINITE ELEMENT MODELS**

<sup>1,2</sup> Yang, S, <sup>2</sup>Voor, MJ and, <sup>1</sup>Hnat WP

<sup>1</sup>Mechanical Engineering Department of University of Louisville,

<sup>2</sup>Orthopaedic Bioengineering Laboratory of University of Louisville; email: s0yang01@gwise.louisville.edu

**INTRODUCTION**

When performing finite element analysis of voxel-based images converted directly from CT scans, image degradation is often necessary to decrease the size of the finite element model when the model is too large to be solved due to time or memory constraints. The region average (RA, Figure 1: left) image degradation method is widely used. The degraded voxel is generated by combining a particular number of adjacent voxels of the original model and averaging their grayscale values. A voxel expansion (VE Figure 1: right) degradation method is proposed for which the degraded voxel is generated by directly expanding a single original voxel. A reliable method should render high fidelity for the degraded model in three areas: bone indices, image grayscale distribution, and biomechanics.

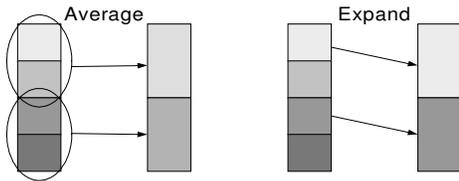

Figure 1: Left: Region average. Right: Voxel expansion

**METHODS**

Three New Zealand white rabbit distal femurs were scanned in a micro-CT system (ACTIS 150/225 FFi-HR CT, BIR Inc., Chicago, IL) with 14µm nominal resolution. A 3.5mm trabecular cube was generated from each of the three image stacks. Models at this size satisfied the continuum assumption for a porous material [1]. The voxel size of each model was then degraded by both methods to 28µm and 42µm which is smaller than 1/4 of the mean trabecular thickness (Tb.Th) as recommended for solution convergence [2]. The trabecular volume fraction, mean Tb.Th, grayscale distribution and apparent stiffness of the degraded models were compared to that of the original models to evaluate the performance.

**RESULTS AND DISCUSSION**

For the trabecular indices calculation, the Otsu method [3] was used to threshold the image stacks. The indices percentage errors for the two methods are shown in Figure 2. The volume fractions of the degraded models rendered by the VE method were essentially unchanged whereas the values from the RA method changed. The mean Tb.Th increased for both methods but significantly less for the VE method compared to RA.

The RA method affects the model grayscale distribution significantly. A distribution comparison between the two methods is shown in Figure 3. The grayscale distribution of the VE rendered model is similar to that of the original model whereas the distribution for the RA rendered model changed.

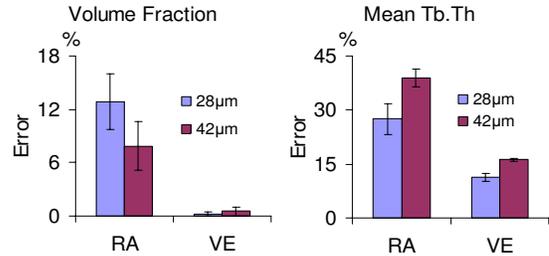

Figure 2: Trabecular indices comparison between two degradation methods

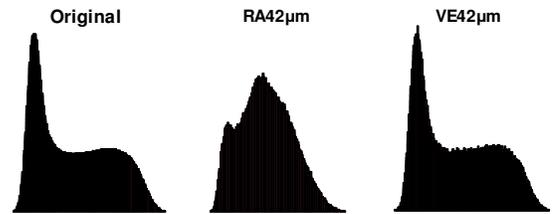

Figure 3: Grayscale distribution comparison between two degradation methods

Six finite element models created by two methods and two degraded levels were evaluated. Homogeneous material properties were assumed and tissue stiffness was set to 10GPa. All models were fixed at one end and a 0.2% axial strain was applied at the other end. Results for the degraded models were compared to the original models (Figure 4).

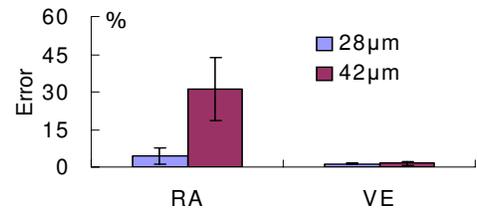

Figure 4: Finite Element Analysis apparent stiffness comparison between two degradation methods

All differences between the VE and RA methods (Vol. Frac., Tb. Th., App Stiff.) were statistically significant except the apparent stiffness for the 28µm voxel size.

**CONCLUSION**

The widely used RA degradation method produced less desirable results than the VE method. The reliability does not decrease significantly as the degraded voxel size increases for the VE method.

## Pseudo-Elasticity and Kinetic Energy Storage: Definitions and Applications to Human Movement

<sup>1</sup> Sam Walcott and <sup>2</sup> Andy Ruina  
<sup>1,2</sup>Theoretical and Applied Mechanics, Cornell University  
<sup>1</sup>Graduate Student; email: scw11@cornell.edu

### INTRODUCTION

Tasks such as throwing and jumping often have a short preliminary phase where movement is away from the target. Traditionally this countermovement is explained by one of four mechanisms: 1) elastic energy storage in soft tissue allows muscular work done in the countermovement to be stored and released, 2) stretch from the countermovement increases the muscle forces in the later movement through force potentiation, 3) because of activation delays, countermovement allows full activation at an earlier time in the forward movement, and 4) stretching muscles in countermovement leads to reflex stimulation and hence higher forces.

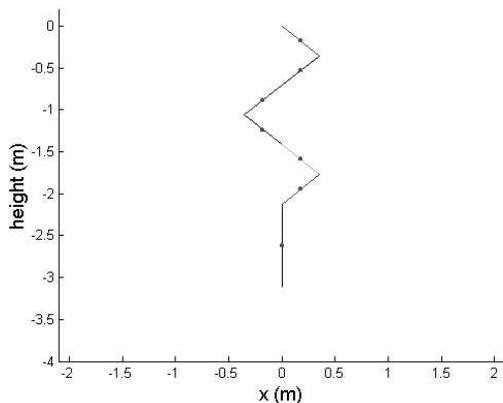

We present an alternative explanation for countermovement that depends on the multi-link nature of the body. The idea, that kinetic energy storage in some links can be used in a manner analogous to elastic energy storage, is foreshadowed in a sketch in [1] in the context of jumping, and is discussed in the context of throwing in [2].

Here, to make the point especially clear in the extreme, we show that a collection of links with no springs whatsoever can behave almost identically to a spring. The idea has long been known at the molecular level where rubber elasticity is explained by the entropic contributions of numerous identical links [3]. Here we show that macroscopic multi-link systems, with no a-priori statistical or thermal inputs, naturally behave as a spring, with the end-point motion putting work in and out of the links almost reversibly.

This multi-link example is not meant to be literally applied to macroscopic biomechanics, but rather gives a cartoon that may apply partially and approximately in normal throwing and jumping tasks.

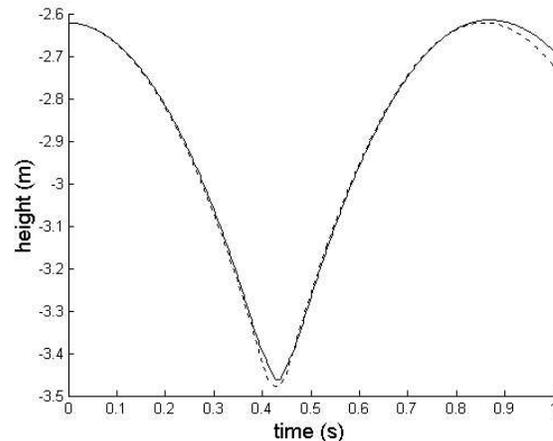

### METHODS

We simulated various multi-link systems that illustrate the ideas. One example is a simple multi-link 2D pendulum with

**Figure 1:** A 2D seven link pendulum with symmetric initial displacement. Gravity points down. The pendulum is anchored to the fixed frame at 0,0.

the last link more massive than the others (Figure 1). When dropped from a typical static configuration the lower mass turns out to move as if it was connected to an appropriate nonlinear spring instead of collection of links (Figure 2). With more degrees of freedom (more links or 3D rather than 2D) the elasticity emulation becomes more accurate.

**Figure 2:** The height of the center of mass of the final link of a 2D seven-link pendulum (solid) and the position of a point mass on a spring in a gravity field (dotted).

### RESULTS AND DISCUSSION

The relatively small number of links required to show this pseudo-elasticity, especially in 3D, suggests the relevance to human motions such as throwing and running.

In throwing, for example, it has long been known that kinetic energy transfer is important – the so-called “kinetic chain”, but here we suggest that this kinetic energy transfer can act like a spring. From the point of view of the ball, the kinetic energy is stored in the arm and then returned to result in a faster, further, or more efficient throw. And, in detail, our model of throwing also illustrates the effect, although the spring analogy is somewhat disguised by the small number of links.

email: c.n.maganaris@mmu.ac.uk

### INTRODUCTION

A well-established adaptation to long-term paralysis is an increase in the speed of muscle contraction and/or rate of force development. This characteristic behaviour has been associated exclusively with transformation of type I muscle fibres to type II muscle fibres due to changes in the expression of relevant myosin heavy chain isoforms [e.g. 1-3]. Information is lacking, however, regarding the degree to which potential disuse-induced changes in the mechanical properties of tendons contribute to the above phenomenon.

To address this issue, we examined in vivo the tensile behaviour of the patellar tendon in spinal cord injured (SCI) and able-bodied (AB) humans.

### METHODS

Six SCI men (age: 36±5 y, height: 186±9 cm, body mass: 80±15 kg; mean±SD) and six age-matched AB men (age: 37±4 y, height: 183±7, body mass: 78±7 kg) volunteered to participate after the study was approved by the local Ethics Committee. The measurements were taken at 90 deg knee angle. Ultrasonography (ALOKA, SSD 5000SV) was used to obtain the patellar tendon resting dimensions and its elongation during isometric contractions of increasing intensity elicited by tetanic (150 Hz) stimulation of the quadriceps muscle [4]. The maximal current used corresponded to 50% of the current producing maximal knee extension torque during femoral nerve stimulation. The patellar tendon forces during contraction were estimated from the torque values produced and moment arm lengths measured on lateral-view pQCT scans (XCT 2000). From the slope of the force–elongation curves produced, the stiffness and Young's modulus of the tendon were calculated in the force region 0–450 N. Independent samples student *t*-tests were used to test for differences in all relevant measured or calculated parameters between the SCI and AB groups.

### RESULTS AND DISCUSSION

The resting length of the patellar tendon was similar in the two groups ( $P>0.05$ ), but the cross-sectional area (CSA) of the tendon was smaller by ~17% ( $P<0.05$ ) in the SCI subjects compared with the AB subjects. Tendon stiffness was lower by ~59% ( $P<0.01$ ) in the SCI subjects compared with the AB subjects. Tendon Young's modulus was lower by ~49% ( $P<0.05$ ) in the SCI subjects compared with the AB subjects (Table 1).

Table 1. The main parameters examined.

Parameter	SCI	AB	P
Tendon length (mm)	44±7	47±6	$P>0.05$
Tendon CSA (mm <sup>2</sup> )	101±23	122±18	$P<0.05$
Stiffness (N/mm)	163±101	401±158	$P<0.05$
Young's modulus (MPa)	77±43	152±76	$P<0.01$

The present results indicate that long-term paralysis deteriorates the intrinsic and structural properties of tendon. A reduction in tendon stiffness means that the changes in contractile speed of the whole muscle-tendon complex underestimate the extent of fibre type transformation in paralyzed muscles.

## SHOULDER-POSITION DEPENDANT ELBOW TORQUE COUPLING DURING ADDUCTION AFTER STROKE

<sup>1</sup>Michael D. Ellis, MPT, DPT and <sup>1,2,3</sup>Jules P.A. Dewald, PT, PhD

<sup>1</sup>Northwestern University, Department of Physical Therapy and Human Movement Sciences, <sup>2</sup>Department of Physical Medicine and Rehabilitation, <sup>3</sup>Department of Biomedical Engineering ; email: [m-ellis@northwestern.edu](mailto:m-ellis@northwestern.edu)

### INTRODUCTION

Previous work [1] has identified abnormal elbow torque coupling during isometric shoulder abduction and adduction of the impaired upper extremity after stroke. Changes in heteronymous (proprioceptive) reflex pathways, that link shoulder and elbow joint muscles [2], may underlie the expression of this coupling due a stroke-induced loss in descending corticospinal input to the spinal cord. In an effort to test this hypothesis, elbow/shoulder torque coupling was measured isometrically in two shoulder positions.

### METHODS

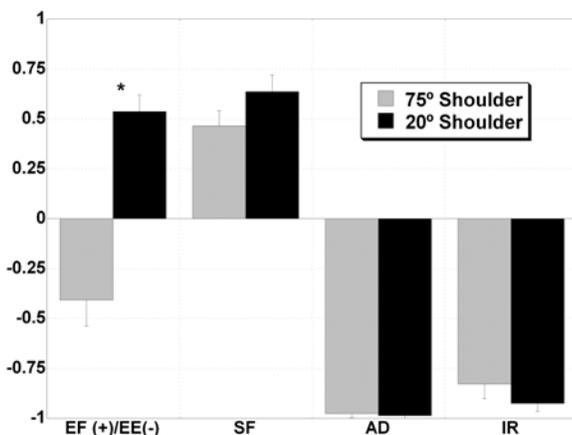

Eleven individuals ranging from 14 to 289 months after stroke participated in the study. All subjects were able to support the upper limb against gravity and demonstrate the ability to generate some concurrent active elbow extension. In each of the two positions studied, the elbow angle was 90° while the shoulder angle (abduction) was either 75° or 20°.

*Single-Task Protocol:* Maximum voluntary torques [1] were measured isometrically at the shoulder and elbow for each shoulder position. Joint torque data was collected concurrently for both the shoulder and elbow while the subject attempted to maximize torque in a primary direction.

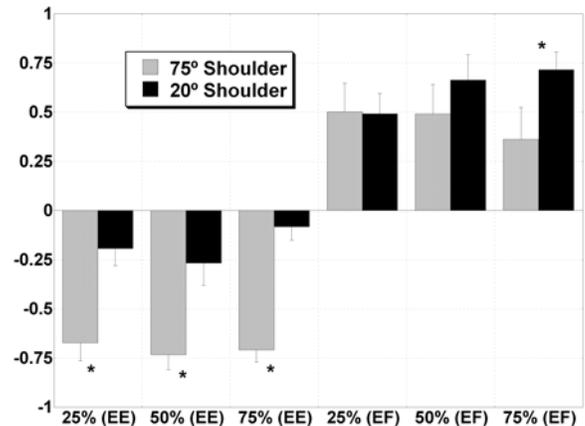

*Dual-Task Protocol:* Subjects maintained various percentages of isometric maximum shoulder adduction (25%, 50%, and 75%) while attempting to maximize either elbow flexion or extension.

### RESULTS AND DISCUSSION

A significant effect of shoulder position was found on elbow/shoulder torque coupling (fig. 1). Specifically, a profound torque direction reversal occurred in the adducted or

**Figure 1:** Normalized maximum shoulder adduction (AD) and coupled elbow flexion (EF)/extension (EE), shoulder flexion (SF), and internal rotation (IR) torques during the single-task protocol for the 75°- and 20°-shoulder positions.

**Figure 2:** Normalized maximum elbow flexion (EF) (+) or extension (EE) (-) torque during various percentages of maximum adduction torque (25%, 50%, and 75%) for the 75°- and 20°-shoulder positions.

20°-shoulder position. This reversal suggests an alteration in the “stereotypical” extension pattern previously described [1] as coupling of shoulder adduction with elbow extension. This phenomena was further examined during a dual-task protocol. Consistent with previous results, [1] subjects generated considerable elbow extension and progressively less elbow flexion during higher levels of adduction in the 75°-shoulder position (fig. 2). However, in the 20°-shoulder position, subjects generated less elbow extension and greater elbow flexion during higher levels of adduction. The effect of shoulder position on joint torque coupling may be explained by position-dependant differences in proprioceptive feedback from shoulder abductor and adductor muscles and/or reorganization at the level of the spinal cord affecting the integration of ascending proprioceptive input.

### CONCLUSIONS

Abnormal torque coupling of shoulder adductors with elbow extensors appears to be dependant upon shoulder position.

## A NEW VOXEL GRAYSCALE BASED 3D IMAGE REGISTRATION VALIDATION METHOD

<sup>1,2</sup> Yang, S, <sup>1</sup>Hnat, WP and <sup>2</sup>Voor, MJ

<sup>1</sup>Mechanical Engineering Department of University of Louisville,

<sup>2</sup>Orthopaedic Bioengineering Laboratory of University of Louisville; email: s0yang01@gwise.louisville.edu

### INTRODUCTION

Registration, or accurately aligning multiple images of the same subject or specimen, is vital to three-dimensional analysis of bone microstructure. Validation is required during development of new registration techniques and for evaluating the performance of existing techniques. Physical landmark methods are usually employed to validate other registration techniques because they have a reputation for accuracy [1]. However, it is difficult to implement a landmark validation method for micro level registrations or to evaluate the registrations with a geometry variance problem caused by bone growth or adaptation.

We developed a new validation technique that can be used without limitations for mono-modality registration validation.

### METHODS

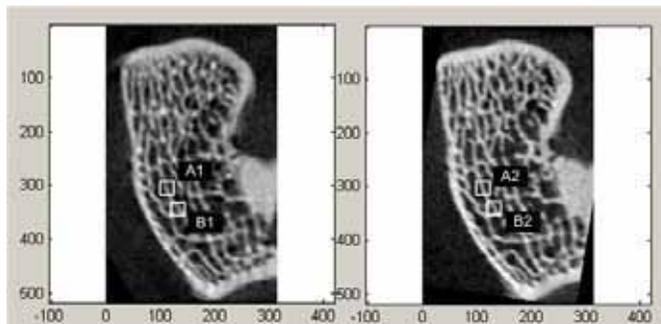

This voxel grayscale based technique takes advantage of the similarity of the net bone formation percentage (%NBF) in the adjacent regions within a bone. A small region,  $A_1$  (Figure 1), from the reference image is selected and the bone volume fraction (BV) calculated. A region  $A_2$ , which has the same size and same position as  $A_1$ , is selected from the registered floating image and the bone volume fraction calculated. The %NBF or volume fraction ratio  $R_A$  is given by

$$\% NBF = R_A = \frac{BV_{A_2} / TV_A}{BV_{A_1} / TV_A} = \frac{BV_{A_2}}{BV_{A_1}} \quad (1)$$

A region  $B_1$  from the reference image, in close proximity to  $A_1$ , is selected together with  $B_2$  in the registered floating image and the %NBF calculated by

$$\% NBF = R_B = \frac{BV_{B_2} / TV_B}{BV_{B_1} / TV_B} = \frac{BV_{B_2}}{BV_{B_1}} \quad (2)$$

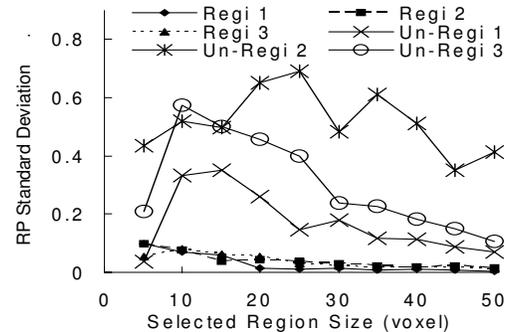

For well registered images with geometry variance, the %NBF should be approximately equal for equation (1) and (2). That is  $R_A/R_B \approx 1$  which is defined as the ratio of percentage (RP). A good image registration will have a RP mean of approximately 1.0 with a small standard deviation.

**Figure 1:** Slices chosen from reference image (left) and corresponding registered image (right).

This method is able to distinguish the registered images from unregistered images for nearly all the selected region sizes

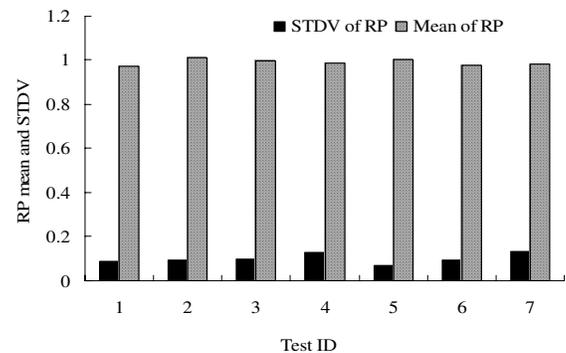

(SRS), as shown in Figure 2, where three registered and unregistered image pairs were tested. The SRS was set to 25 voxels in this study. The distance between  $A_1$  and  $B_1$  was set to 10 voxels which was shown to have no significant effect on the validation results. For each validation, twenty selected region groups were used to stabilize RP and the STDV.

**Figure 2:** validations for registered and unregistered images.

### RESULTS AND DISCUSSION

Seven rabbit distal femurs were scanned, in vivo, at 28 $\mu$ m nominal resolution in a custom open frame micro-CT system (ACTIS 150/225 FFi-HR CT, BIR Inc., Chicago, IL) with 14 or 28 days time-intervals. The images were registered by a custom designed software package using the maximization of mutual information method which is considered to be accurate [1] and then validated. The RP means were all nearly 1.0 and the standard deviations were approximately 0.1 as shown in Figure 3.

**Figure 3:** The RP mean and standard deviation for seven registrations.

This new grayscale based method can be used case by case to validate the registrations where existing techniques do not apply. The minimum registration error it can detect has been shown to be one voxel.

## UNIQUE SOLUTION FOR FEED-FORWARD CONTROL OF NEUROPROSTHETIC SYSTEMS CHARACTERIZED BY REDUNDANT MUSCLES ACTING ON MULTIPLE DEGREES OF FREEDOM

<sup>1,2,3,4</sup> Jose Luis Luján, <sup>1,2,3,4</sup> Patrick E. Crago

<sup>1</sup>Case Western Reserve University, Department of Biomedical Engineering,  
<sup>2</sup>MetroHealth Medical Center, <sup>3</sup>Cleveland FES Center, <sup>4</sup>Cleveland VA Medical Center;

### INTRODUCTION

We previously developed a method for implementing feedforward neuroprosthetic controllers for musculoskeletal systems with multiple degrees of freedom and complex mechanical interactions [1]. These controllers employed inverse models of the musculoskeletal systems under control. Experimental tests showed poorer performance than expected, which we attribute to redundancy of the data used to develop the inverses. The inverse relationship between muscle output and electrical stimulation is not unique (most joints have redundant actuation with non-stationary input-output muscle properties and coupled degrees of freedom) and if left unrestricted, neural networks trained to model the inverse may produce undesirable solutions. To overcome this problem, we automated a method to choose a single optimal inverse prior to network training [2]. Our present work involves obtaining this unique inverse solution and training a controller capable of independently controlling coupled degrees of freedom. We evaluate our solution method by testing the controllers in simulation and experimentally with able-bodied and spinal cord injured human subjects.

### METHODS

For simulation studies, we developed a forward model of static isometric force production at the tip of the thumb, controlled by four extrinsic and intrinsic muscles. This model, which parallels our experimental model, allows us to generate time-varying forces in three directions. Muscle activation is modeled as a nonlinear function of the electrical stimulus. The model includes random noise and a linearly-decreasing fatigue factor that scales the maximum muscle force with every muscle contraction.

Our general approach (Figure 1) is to first create a system model of the time-varying input-output data with a time-invariant artificial neural-network. The system model smoothes the output muscle forces at the tip of the thumb, eliminating their time-variance. The system model also allows us to increase the amount of time-invariant input-output data by means of its interpolation capabilities. We choose unique input-output patterns from this time-invariant data that optimize specific performance criteria, such as minimum co-activation, which allows us to eliminate redundancy and thus obtain a unique solution. We train an inverse-model, static, feedforward, artificial neural network controller (Figure 2) with these optimal input-output data.

Figure 1: Process for obtaining a unique solution.

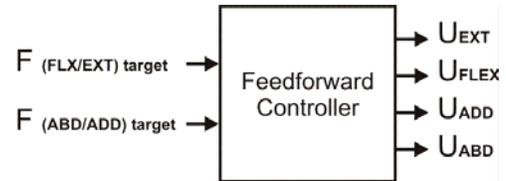

Figure 2: Feedforward controller. The inputs are the target flexion/extension and abduction/adduction forces at the thumb tip. The outputs are the stimulus required for the extensor, flexor, adductor and abductor muscles.

We first study redundancy by stimulating only a pair of antagonists (extensor pollicis longus and abductor pollicis brevis) controlling flexion/extension of the thumb's carpometacarpal joint. We then incorporate coupling to the system by stimulating two additional muscles (flexor pollicis longus and adductor pollicis) allowing us to control abduction/adduction as well.

### RESULTS AND DISCUSSION

We demonstrated the feasibility of this approach with a simplified model of a pair of antagonist muscles controlling a single degree of freedom [2]. The system model eliminated redundancy due to noise, and the optimization produced training data that eliminated mechanical redundancy by optimizing co-contraction. We expect similar results with the more realistic simulation model we are implementing currently, which will be followed by experimental tests. The methodology is general enough that it will be suitable for a wide variety of musculoskeletal systems. The use of neural networks for the controller allows us to improve generalization of muscle stimulation. Furthermore, by allowing independent control of redundant systems with coupled degrees of freedom, the function restored by neuroprostheses can be improved.

## MUSCLE FIBRE LENGTH-TO-MOMENT ARM RATIOS IN THE HUMAN LOWER LIMB

Constantinos N. Maganaris, Vasilios Baltzopoulos and Dimitrios Tsaopoulos  
 IRM, Manchester Metropolitan University, Alsager, U.K.; email: c.n.maganaris@mmu.ac.uk

### INTRODUCTION

The fibre length ( $L$ )-to-moment arm ( $d$ ) ratio ( $L/d$ ) is functionally significant because it determines the active excursion range and the relative contributions of the contractile element and its mechanical advantage to the pattern of the torque-angle relation. Despite their importance, data on  $L/d$  ratios are rather scarce [e.g., 1,2], but suggest that the  $L/d$  ratio in a given muscle-joint is constant between individuals. In the present study we have quantified the  $L/d$  ratio in main human knee extensors and ankle plantarflexors from in vivo measurements of  $L$  and  $d$ . A secondary aim was to examine whether the  $d$  values in the knee extensors and ankle plantarflexors scale with each other.

### METHODS

Twenty-one men (age:  $25 \pm 6$  years, body height:  $182 \pm 8$  cm, body mass:  $79 \pm 8$  kg; mean  $\pm$  SD) without any musculoskeletal injuries in the lower limbs volunteered to participate after the study was approved by the local Ethics Committee. Measurements of  $L$  were taken from the vastus lateralis (VL), vastus intermedius (VI), gastrocnemius medialis (GM), gastrocnemius lateralis (GL), and soleus (SOL) muscles, using ultrasonography [e.g., 3,4]. The sonographs were taken from the central region of each muscle, with the knee fully extended and the ankle at the anatomically neutral position. Measurements of  $d$  were taken at the above joint configuration in the Achilles tendon (AT) and the patellar tendon (PT) using magnetic resonance imaging [e.g. 5,6]. From the measurements taken, the relations between a)  $L$  in each ankle plantarflexor muscle and  $d_{AT}$ , b)  $L$  in each knee extensor muscle and  $d_{PT}$ , and c)  $d_{AT}$  and  $d_{PT}$ , were analyzed with Pearson correlation coefficients.

### RESULTS AND DISCUSSION

The  $L/d_{AT}$  ratios ranged from 0.78 to 1.35 in the GM muscle, from 0.72 to 1.32 in the GL muscle and from 0.61 to 1.1 in the SOL muscle. The  $L/d_{PT}$  ratios ranged from 1.5 to 2.24 in the VL muscle and from 1.1 to 2 in the VI muscle. The  $d_{AT}/d_{PT}$  ratios ranged from 1.21 to 1.61. None of the relations examined was significant ( $P > 0.05$ ), which therefore also precludes that the quantities involved in each relation scaled with each other. The Pearson correlation coefficients obtained ranged from -0.2 to 0.29 (Table 1).

**Table 1.** Relations between the parameters examined.

Relations	r	P
$L_{GM}$ vs. $d_{AT}$	0.059	$P > 0.05$
$L_{GL}$ vs. $d_{AT}$	0.129	$P > 0.05$
$L_{SOL}$ vs. $d_{AT}$	0.092	$P > 0.05$
$L_{VL}$ vs. $d_{PT}$	-0.203	$P > 0.05$
$L_{VI}$ vs. $d_{PT}$	-0.245	$P > 0.05$
$d_{AT}$ vs. $d_{PT}$	0.29	$P > 0.05$

The varying  $L/d$  ratios in the present in vivo study contrast previous findings in other muscle-joint systems [1,2], indicating that  $d$  differences in a given joint between individuals may not always accounted for by differences in muscle length caused by  $L$  differences. It may be the case that in some pennate muscle-joint systems the above inter-subject muscle length differences are primarily accommodated by differences in muscle fibre number and/or cross-sectional area. The present findings indicate that  $L$  may not always scale to  $d$  and need to be accounted when the  $L/d$  ratio of a given muscle-joint system needs to be known, e.g., when seeking a donor muscle to surgically substitute functional loss.

The lack of relation between  $d_{AT}$  and  $d_{PT}$  precludes that these quantities can be predicted from one another when one of these  $d$  values is already known.

### INTRODUCTION

Ankle-foot orthotics (AFOs) are external orthopaedic devices that provide support for foot-drop or ankle instability associated with many neuromuscular disorders. Currently, AFOs are articulated or rigid. Dynamic joint stiffness (JS) can be calculated as the slope of a joint angle vs. moment plot and is an important constraint on the motor control system as it affects the generation of voluntary movements and the displacement resulting from an external perturbation [1]. Understanding JS is essential to orthotic design and the quantitative evaluation of neuromuscular diseases [2]. JS has not been examined experimentally or dynamically with the use of AFOs in human locomotor activities. The effects of dynamically varied AFO stiffness on joint kinematics, kinetics, muscle activation patterns and resultant JS during walking and stepping down from a platform were the focus of this study.

### METHODS

Bilateral AFOs were instrumented with electro-hydraulic disc brakes to allow for computer-adjustable AFO stiffness, which permitted varied external resistance of ankle motion. The study design was prospective, randomized, and was comprised of six healthy adult males. 3D kinematics were acquired using unilateral, lower-extremity active marker placement and a high-speed, motion analysis system (CODAmotion MPX30; Chamwood Dynamics Ltd., UK). Force plate (AMTI; 2000 Hz), electromyographic (EMG) (MA-310; Motion Lab Systems, Inc. Los Angeles, CA, USA; 2000 Hz), and video (200 Hz) data were collected during a minimum of 15 successful walking and 10 step down trials per subject for Shod (shoes only) and 3 AFO stiffness conditions: rigid (Rigid), articulated (Art), and intermediate (Inter). Time-frequency analysis, using wavelets, was used for EMG analysis to identify low (20-38 Hz) and high (128-218 Hz) frequency content of the EMG signals. Multivariate analysis of variance with a *post-hoc* test ( $\alpha=0.05$ ) revealed significant differences.

### RESULTS AND DISCUSSION

During both gait and step downs there were no significant differences in mean resultant ankle or knee joint stiffness, independent of AFO use and AFO stiffness for both tasks. During the stance phase of gait, there was a significant decrease in ankle joint energy production at toe-off when AFO conditions were compared to Shod (Fig. 1). There was also a significant decrease in energy absorbed at the knee joint following heel-strike in the AFO conditions. During the step down task, there was a significant increase in energy absorbed across the ankle and knee joints in all AFO conditions compared to Shod (Fig. 1). The tibialis anterior (TA) muscle showed a significant increase in activation for all AFO conditions for walk and step down trials across all frequency bands (Fig. 2). There was significantly greater recruitment of the lateral gastrocnemius (LG) in all AFO conditions for step downs, but a decrease in activation for the AFO walking trials (Fig. 3). There were AFO condition and frequency dependent changes in EMG signals for both tasks.

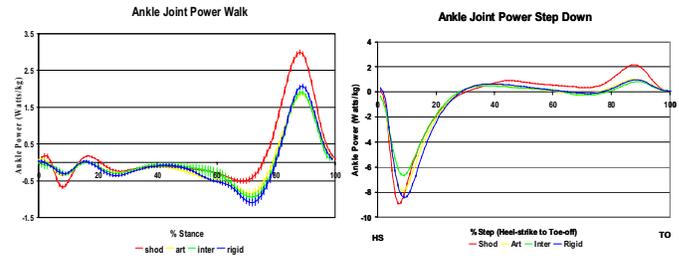

Fig. 1: Mean ( $\pm$ se) ankle joint power for walk (left) and step downs (right) for Shod (red) Art (yellow), Inter (green) and Rigid (blue). N=6

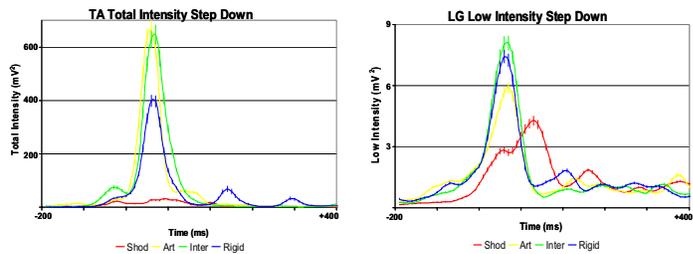

Fig. 2: Mean ( $\pm$ se) TA total intensity (left) and LG low intensity (right) for 200ms pre- and 400ms post-step down for Shod (red) Art (yellow), Inter (green) and Rigid (blue) conditions. N=5

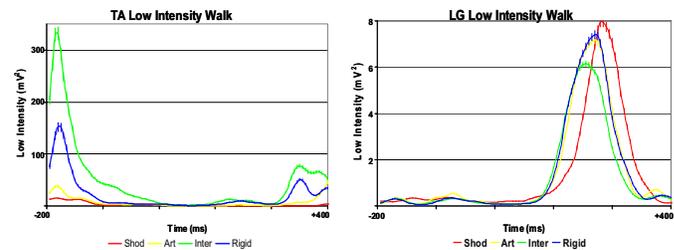

Fig. 3: Mean ( $\pm$ se) TA low intensity (left) and LG low intensity (right) for walking trials for Shod (red) Art (yellow), Inter (green) and Rigid (blue) conditions. N=5

### CONCLUSIONS

Despite changes in AFO stiffness, resultant ankle and knee joint stiffnesses remained unchanged for both walking and step down trials; however, there were changes in muscle activation patterns and mechanical joint energetics. That suggested that a neuromotor and joint dynamics response helped maintain a task-specific resultant joint stiffness. These findings are consistent with JS being a function of task [3] and therefore, task-specific AFO stiffness may be more desirable in clinical populations. Results from this study provide data to help in our understanding of how AFO prescription may affect internal joint mechanics and muscle activation patterns.

## MUSCLE FORCE-STIFFNESS CHARACTERISTICS INFLUENCE JOINT STABILITY: A SPINE EXAMPLE

Steve Brown and Stuart McGill  
 Department of Kinesiology, University of Waterloo  
 email: shmbrown@ahsmaail.uwaterloo.ca

### INTRODUCTION

The muscle force-stiffness relationship has often been modeled as linear, while in-situ muscle research has clearly demonstrated a non-linearity [1,2]. Estimation of rotational joint stability relies on both a muscle's instantaneous pre-perturbation force and stiffness [3]. Under conditions of static equilibrium, a muscle's stiffness will function in a stabilizing manner, while its force can function in either a stabilizing or destabilizing manner depending on the muscle's orientation about the joint.

In joint stability research, it has generally been assumed that a muscle's direct contribution to stability increases with force and activation and theoretically peaks at maximum force and effort. The purpose of this study was to theoretically test this notion, by comparing the joint stabilizing effects of a muscle with a linear force-stiffness relationship to the same muscle after imparting a slight non-linearity into the relationship.

### METHODS

A single muscle (rectus abdominis) was modeled and its individual direct stabilizing potential about lateral bend axis of the L4-L5 spine joint was analyzed. Muscle force profiles were simulated from 0 to 100 percent of maximum. Muscle stiffness was calculated using the following equation from

$$\text{Bergmark (1989): } k_m = q \frac{F_m}{L_m}$$

where:  $k_m$  = muscle stiffness ( $\frac{N}{m}$ )

$q$  = dimensionless multiplier

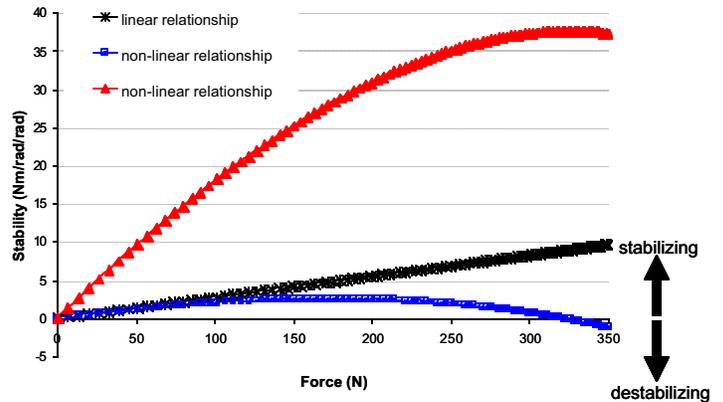

$F_m$  = muscle force (N)

$L_m$  = muscle length (m)

Force-stiffness relationships were developed by adjusting  $q$  through a range of values generally reported in the literature, and to replicate the general form of the non-linear relationship (Profiles 2 and 3) between muscle force and stiffness seen in the literature. Three profiles were examined: 1) linear; 2) non-linear with moderate stiffness magnitudes; 3) non-linear with higher stiffness magnitudes.

### RESULTS AND DISCUSSION

With a linear force-stiffness relationship, stability increased proportional to muscle force; with a non-linear relationship, stability peaked and subsequently decreased at submaximal muscle forces. When considering the lower, as opposed to the higher non-linear stiffness magnitudes, the stabilizing potential of the muscle peaked at a lower muscle force level and actually became negative (destabilizing) at a "critical" stiffness magnitude (Figure 1).

**Figure 1:** Stabilizing contribution of the RA muscle about the lateral bend axis of the L4L5 spine joint in upright standing. The muscle is simulated to have either a linear or non-linear force-stiffness relationship.

The primary concept demonstrated in this proof of principle study is that a muscle's individual contribution to joint stability may not necessarily peak at its maximum force output. Considering a non-linear relationship between force and stiffness and a muscle whose orientation is such that its pre-tension is destabilizing, there may exist a critical force level at which any additional force increase becomes dominant over the corresponding stiffness increase, thereby reducing the muscle's stabilizing potential.

This apparent dichotomy in the muscle force-stiffness relationship, and its effect on joint stability, may provide an explanation for the phenomena of joint buckling under high loading situations. As muscles generate force towards maximum, corresponding stiffness increases taper off, thus reducing the stability margin of safety. Based on this, it appears possible that the likelihood of joint buckling may be lowest during moderate loading conditions, and become higher as loading conditions approach the minimum or maximum of the end loading range.

### CONCLUSIONS

It was concluded that a non-linear muscle force-stiffness relationship greatly alters the individual stabilizing potential of the muscle throughout its progression of force development. A muscle's stabilizing contribution may actually peak at and subsequently decrease above a critical submaximal force level. Incorporating this knowledge into stability models may assist in recognizing unstable events that lead to injury at higher levels of muscle activation.

### INTRODUCTION

To reveal the dynamics of center of pressure (COP) such as the magnitude and direction of displacements between COP points, a stabilogram-diffusion analysis (DFA) was proposed [1]. The DFA assumes a COP profile as a fractional Brownian motion (fBm), and applies the basic relation of a long-memory process, which expresses a typically unbounded process with an unlimited diffusion, to estimate the Hurst coefficient. As COP profiles are usually bounded due to physiological limits, the DFA thus conducted to COP naturally biases the results [2]. We first examined if a COP profile is a fBm signal, and then used a bridge detrended scaled window variance method (bdSWV) to estimate the Hurst coefficient if applicable.

### METHODS

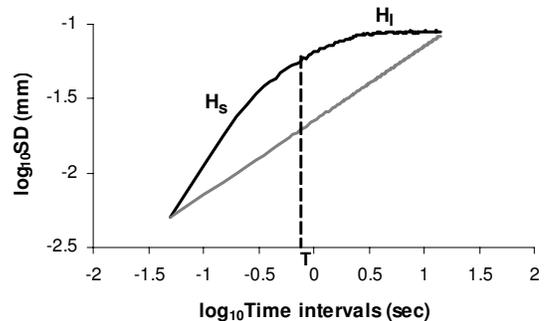

Twelve healthy female college students volunteered in this study. The subjects stood barefoot on a Kistler® 9287 force platform as still as possible in 1) eyes open (EO) and 2) virtual dynamic vision (DV). Three trials were collected for each subject at 100 Hz for 60 seconds. COP data in anterior-posterior (AP) direction were analyzed. Raw data were filtered by a second order Butterworth with cutoff frequency 5 Hz.

A power-law  $q(f) \sim 1/f^\beta$  exists in the Fourier power spectrum of a fBm signal, where  $q(f)$  is the power at a frequency  $f$ , and  $\beta$  is the scaling exponent with  $1 < \beta < 3$ . A power spectral analysis (PSA) was conducted to raw COP data, and  $\beta$  was estimated for the frequencies lower than 1/8 of the sampling rate [3].

A fBm signal obeys the scaling law  $Var(\Delta x) \sim \Delta t^{2H}$ , where  $Var(\Delta x)$  is the variance of the displacement  $\Delta x$ ,  $\Delta t$  is the time interval, and  $H$  is the Hurst coefficient with  $0 < H < 1$ . When  $H > 0.5$ , COP is positively correlated (persistence), i.e., the direction of the past COP movement will be likely continued in the future movement. A higher  $H$  in this context denotes a higher level of persistence. Conversely, when  $H < 0.5$ , COP is negatively correlated (anti-persistence). A lower  $H$  here represents a higher level of anti-persistence [2]. The bdSWV [4] was conducted to the filtered COP data such that 1) data were partitioned into non-overlapping windows in one time interval, 2) a bridge detrending was performed and standard deviation (SD) was calculated within each window, 3) average SD was calculated for each time interval, 4)  $H$  was estimated in the log-log plot of average SD versus time intervals.

### RESULTS AND DISCUSSION

Scaling exponent  $\beta$  (Table 1) was within the range of 1 to 3, indicating that a COP profile is a fBm signal regardless of visual condition. Two linear portions were observed through the bdSWV method irrespective of visual condition (Figure 1) such that the short- and long-term regions were separated by a

**Figure 1:** A representative log-log plot of average SD vs time intervals. T is transition point,  $H_s$  and  $H_l$  is the Hurst coefficient for short- and long-term regions, respectively.

transition point T, which was close to 1 second (Table 1).  $H_s$  was higher than 0.5 and  $H_l$  was lower than 0.5 in both visual conditions (Table 1), similar to the findings by a DFA analysis [1]. Two control schemes may be expected in quiet stance such that persistence dominates in the short-term region while anti-persistence governs in the long-term region [1]. This implies that the postural control system may not use input from the visual, vestibular and somatosensory systems to regulate muscle activities unless the input reaches a threshold.

$H_s$  in DV was significantly higher than that in EO, while  $H_l$  in DV was significantly lower than that in EO (Table 1). Dynamic visions yielded higher levels of persistence and anti-persistence in the short- and long-term regions, respectively. The higher anti-persistence in DV may be due to the increase of the activity of musculature in quiet stance.

### CONCLUSIONS

It was concluded that a COP profile is a fBm signal, and the bdSWV is able to reveal the fractal dynamics of COP profiles.

**JOINT TORSIONAL STIFFNESS CONTRIBUTIONS TO LEG STIFFNESS  
 VARY DURING DROP LANDINGS ONTO ONE OR TWO LEGS**

<sup>1</sup> Steven T. McCaw, <sup>2</sup>Tibor Hortobágyi and <sup>2</sup>Paul DeVita

<sup>1</sup>Illinois State University, Normal,

<sup>2</sup>East Carolina University, Greenville, NC; email: [smccaw@ilstu.edu](mailto:smccaw@ilstu.edu), web: [cast.ilstu.edu/mccaw](http://cast.ilstu.edu/mccaw)

**INTRODUCTION**

Vertical ground reaction force (GRFv) descriptors of landing on one leg are less than twice the two leg landing values[1], suggesting neuromuscular control strategy adjustments according to the number of limbs available to absorb energy. Quantifying leg stiffness and individual joint stiffness allows evaluation of neuromuscular control strategies [2]. When hopping in place, leg stiffness adjustments to alter hopping frequency or height occur primarily by adjusting ankle joint stiffness [2]. Landing differs from hopping since landing does not require a subsequent flight period. Landing research identifies the knee as the primary contributor to energy absorption, but the ankle contribution increases if a “stiffer” landing technique is used [3,4]. The purpose of this study was to compare measures of leg and joint stiffness between one and two leg drop landings. It was hypothesized that higher vGRF values in one leg landing reflect increased leg stiffness. We were also interested in how the individual joint stiffnesses contribute to the altered leg stiffness.

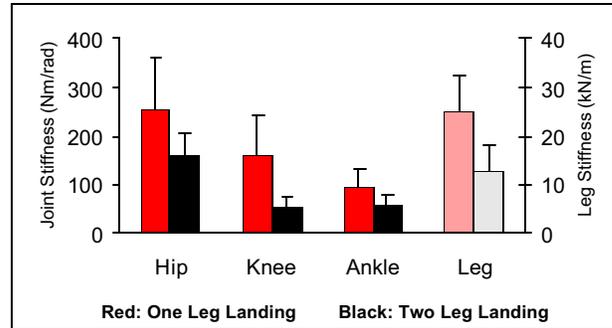

**METHODS**

Eleven physically active females, each accustomed to landing, participated in the study. All landings were performed from a box set at 25% of body height. Ten trial blocks of one leg and two leg landings were collected in random order from each subject. Instructions were to “land comfortably”.

To collect ground reaction force data (GRF), subjects landed with the right foot on a force platform (960 Hz). Markers secured on the right side of the body defining the trunk, thigh, shank and foot segments were digitized with a high-speed infra-red tracking system (240 Hz). Custom software was used to calculate joint torques (JMF) using an inverse dynamic analysis combining the synchronized GRF, kinematic, and subject anthropometric data. Leg stiffness ( $k_{leg} = \text{Peak GRF}_{\text{vertical}} / \text{Leg compression}$ ) and individual joint stiffness ( $k_{joint} = \Delta\text{JMF} / \Delta\text{Joint Angle}$ ) were subsequently calculated [2]. Paired t-tests were used for statistical comparisons ( $\alpha = .05$ )

**RESULTS AND DISCUSSION**

All GRF and kinematic measures were significantly different between one and two legged landings (table 1). Peak GRFv

**Figure 1:** Leg and joint stiffness measures.

values were not twice as high. A more extended body position was used in a one leg landing and the leg compresses less. Joint positions are more extended at contact and less flexion ROM is utilized at all joints when landing on one leg; peak knee flexion is reached in a shorter period of time. All joint and leg stiffness measures were significantly different between one and two leg landings (figure 1). Leg stiffness was ~2 times higher during a one leg landing compared to a two leg landing. The increase in leg stiffness was attained by increasing joint stiffness slightly more than 50% at the ankle and hip, and tripling joint stiffness at the knee.

**CONCLUSIONS**

A twofold increase in leg stiffness during landing on one leg results in GRFv values that are 1.5 fold as high as when landing on two legs. While increased joint stiffness is evident at the hip, knee and ankle, the disproportionate increase in knee joint stiffness suggests modulation of knee joint stiffness is the primary mechanism of adapting to a landing on one leg.

### INTRODUCTION

The architecture of a muscle, characterized by the length (fascicle length) and the angle (pennation angle) of fascicles of muscle fibers, is a primary determinant of its function. Recent in vivo approaches employing ultrasonography have shown that architecture of human skeletal muscles change during contractions even in isometric actions [1-4].

Most previous sonographic studies measured muscle architecture only at the midbelly of the muscle, based on the notion that there is a marked uniformity in architecture throughout a muscle [5]. As for the medial gastrocnemius muscle (MG), however, Kawakami et al. [1] found that pennation angle measurements significantly varied among positions, while fascicle length was constant. In their results, the differences in pennation angles still remained when the muscle contracted. Moreover, Nagayoshi et al. [4], who examined the architecture of the tibialis anterior muscle (TA), reported significant differences in fascicle length measurements between proximal 30% and 50% positions in a relaxed condition, without differences in pennation angles. On the other hand, some researchers claimed that homogeneous architecture at the various sites of muscle belly of MG [2] and TA [3] were found both at rest and during contraction. Thus, whether architectural parameters, such as the fascicle length and pennation angle, differ within a muscle at rest and/or during contraction still remains a question.

The present study aimed to ascertain the uniformity of the architecture of human medial gastrocnemius and tibialis anterior muscles both in the relaxed and contracted conditions.

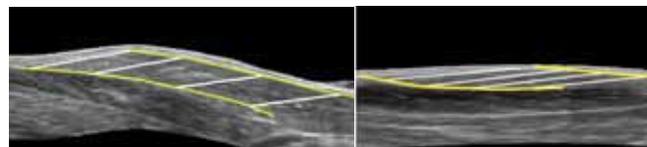

### METHODS

Four healthy men ( $27.8 \pm 2.2$  yrs) volunteered for the measurements. The subject's right foot was firmly attached to an electric dynamometer. The ankle joint was fixed at 0 deg (for MG) or at 30deg dorsiflexion (for TA), and the knee joint was fully extended while the subject was in a prone position and seated position for MG and TA measurements, respectively. During the ultrasound data acquisition, the subject was asked to relax, then to maintain isometric plantar flexion or dorsiflexion at five force levels (20, 40, 60, 80, 100%MVC).

By moving a 7.5MHz, linear, B-mode, ultrasonographic probe (SSD-5500, Aloka, Japan) on the skin along the center of the muscle belly, serial cross-sectional images of muscles were obtained. An electromagnetic position sensor was attached to the ultrasonic transducer to provide position and orientation information for each image acquired. All the serial ultrasonic images (recorded at 30 frames/s) were stored in a computer simultaneously with the positional information, by which,

three-dimensional ultrasound (3D-US) images were reconstructed.

The 3D-US images could be cut at any planes with respect to the muscle orientation. Several planes were taken from different regions over the longitudinal axis of the muscle belly so that fascicles of interest were visualized throughout their lengths. In each image, the fascicle length was measured along the fascicle as the distance between its aponeurotic attachments, and the pennation angle was measured as the angle between the deep aponeurosis and fascicles.

**Figure 1:** Typical examples of reconstructed ultrasound images of the MG (left) and TA (right) at rest condition.

### RESULTS AND DISCUSSION

A preliminary study for 2 subjects showed that the fascicle length of MG was constant throughout the muscle in the relaxed and contracted conditions. On the other hand, fascicle length of TA showed an increasing trend along the center line of the muscle belly towards the distal direction in rest conditions, which remained when the contraction levels increased. The uniformity of fascicle length for MG and the nonuniformity for TA support previous reports [1,2,4].

The pennation angles of MG and TA both differed among various sites. In the relaxed condition, pennation angles were maximal at the middle position and minimal at the extreme ends in both muscles. The site of the maximal values moved proximally with increasing contraction levels. The position-related differences within muscle are similar to a previous finding [1] for MG, while no reports have been made for the nonuniform pattern of TA pennation angles at rest and/or during contraction.

The present results indicate that MG and TA have heterogeneous architecture within muscle that change by contraction, and that they should not be treated by planimetric models.

**ISOMETRIC TRAINING ALTERS MECHANICAL PROPERTIES OF TENDON STRUCTURES.**

<sup>1</sup>Megumi Ohta, <sup>1</sup>Yoichi Katsumata, <sup>1</sup>Koichiro Murata, <sup>2</sup>Hiroaki Kanehisa <sup>3</sup>Yasuo Kawakami and <sup>3</sup>Tetsuo Fukunaga

<sup>3</sup> Faculty of Sport Sciences, Waseda University; e-mail: blessing@akane.waseda.jp

**INTRODUCTION**

The mechanical properties of tendon structures are related to the functional characteristics of muscle-tendon complex (MTC), such as the rate of torque development (RTD) and electromechanical delay (EMD) [1]. On the other hand, resistance training changes the tendon tissues to be stiffer [1, 2], which could result in faster RTD and shorter EMD.

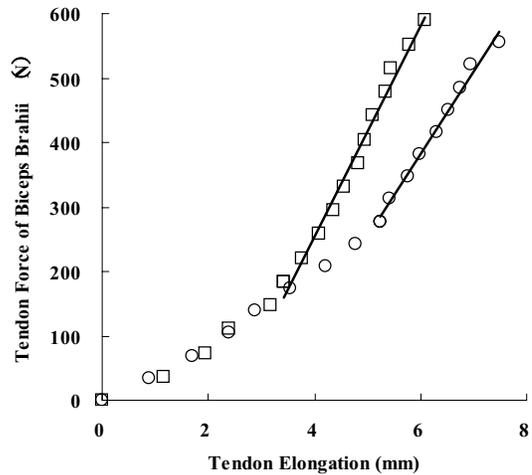

The present study aimed to examine the effect of isometric resistance training on elastic and functional properties of human elbow flexor muscles.

**METHODS**

Nine healthy males (age, 24.4±2.3 years; heights, 172.8±6.7cm; weight, 68.1±8.9kg; mean ± SD) voluntarily participated in this study. They were requested to perform maximal isometric elbow flexion torque at 90° of elbow joint for ten seconds, five times a day (interval between trials was one minute each), five days a week, for six weeks. Before and after the training period, the distal myotendinous junction of the biceps brachii (MTJ) was visualized on the real-time ultrasonic image (Aloka SSD6500). Excursion of the MTJ during ramp isometric elbow flexion was considered as the elongation of the tendon structure. Maximal isometric elbow flexion torque (MVC), RTD, EMD and muscle thickness of elbow flexors were measured before and after the training period. RTD was determined as the rate of torque increase from 0 to 50% MVC. EMD was calculated as the time interval between the onset of electromyogram and torque development.

**RESULTS AND DISCUSSION**

The relationships between the tendon elongation (L) and tendon force (F) before and after the training period are shown in Fig 1. Before the training, the L-F curve consisted of two phases, i.e., phase 1 (Ph1), the region below 40%MVC of force with a large tendon elongation, and phase 2 (Ph2), the region above 40%MVC. The training changed the point

**Figure 1:** The relationship between tendon elongation and %MVC before (○) and after (□) the training.

dividing Ph1 and Ph2 from 40%MVC to 25%MVC. The decrease of tendon elongation in Ph1 may be related with a decreased slack of tendon or joint laxity. The slope of the regression line for the relationship between L and F in Ph2, representing the tendon stiffness as reported previously [1, 2, 3], increased significantly after the training. There were tendencies for RTD to increase and EMD to decrease by the training, which could be attributed to less tendon elongation at the lower force region. However these changes were not significant (Table 1).

### INTRODUCTION

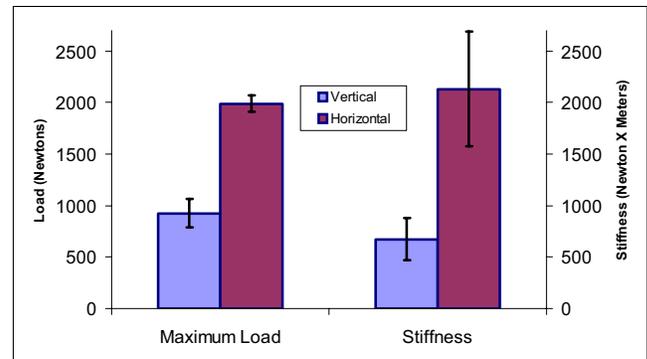

The modified AO tension band method is commonly used for the fixation of transverse patellar fractures. Despite its wide spread use, the orientation of tension bands has not been tested directly. Free body diagrams of a tension band suggest that the vertically oriented figure eight (Fig. 1A) that has traditionally been used does not provide as much compression across the fracture fragments as would a horizontally oriented figure eight (Fig. 1B). Based on the free body diagrams, a simple rotation of 90 degrees of the tension band will more than double the compressive force between fracture fragments. The objective of this study is to experimentally evaluate the mechanical effect of orientation of the patella tension band.

**Figure 1:** Free body diagrams of a vertically (A) and horizontally (B) oriented patella tension band

### METHODS

Tension bands of both orientations were tested on a model constructed to simulate patellar fracture fragments. Two parallel aluminum cylinders were mounted on an Instron 5865 material testing machine (Instron, Canton MA, USA) by perpendicular lag screws. 5.0cm segments of 2.0mm Kirchner wires (K-wires) were inserted perpendicularly into the aluminum cylinders into pre-drilled holes to simulate the free ends of the K-wires in the proximal and distal patellar fragments. The K-wires were located on the anterior slope of the cylinders to simulate the curvature of the anterior surface of the patella. A tension band of 316L 18 G monofilament stainless steel wire was applied to the construct using either in the vertical or horizontal orientation. The ends of the tension

**Figure 2:** Comparison of the experimental maximum load and stiffness values of a horizontally and vertically aligned patellar tension band construct (Mean values and standard deviations are shown).

bands were twisted until each specimen had a pre-tension of 40N. The cylinders were then distracted on the material testing machine at a rate of 25 N/sec to a preload of 250N and held for ten seconds to allow tension to equalize throughout the tension band. The load was then increased at a rate of 50 N/sec until failure of the wire. Maximum load, stiffness, and mode of failure were recorded for fifteen trials of each wire orientation.

Limited cyclic testing was also performed using this model. The tension bands were subjected to 50 cycles consisting of increasing the load from the preload (250N) to 500N and back to the preload in four seconds. Five samples were tested in each orientation. Statistical comparisons between both models were performed using Student's t-test.

### RESULTS AND DISCUSSION

In load to failure testing the horizontal construct was found to have a significantly higher maximum load and stiffness than the vertical construct ( $p < 0.0001$ , Figure 2). Cyclic testing showed significantly less extension for the horizontal figure eight, with a mean value of 1.1 mm, than for the vertical figure eight, with a mean value of 2.7 mm ( $p < 0.0001$ ). For both constructs, over 80% of the extension was seen in the first fifteen cycles.

There is much debate over the proper method of patellar fracture fixation including methods with screws, and a combination of screws and wires. This study strengthens the position of tension bands in patellar fracture fixation and may require that this improved method be evaluated against other methods in use.

### CONCLUSIONS

Overall, the results from this study confirm the theoretical advantages of the horizontal figure eight tension band compared to the vertical orientation

## HEELSTRIKE DYNAMICS DURING 6 MINUTE WALK TEST AMONG END STAGE KNEE OA PATIENTS

### INTRODUCTION

Osteoarthritis (OA) is one of the most common chronic conditions among older adults with the knee joint being the most commonly affected joint. Symptoms of the disease involve gait alterations and difficulty completing activities of daily living. The involvement of mechanical factors in OA is widely recognized. Heelstrike phenomenon can reflect abnormal loading patterns that standard kinematic variables are unable to detect.

This study investigated the effect of performing a 6 minute walk on gait speed, vertical velocity of the ankle marker just prior to heelstrike, and maximum ankle vertical displacement during swing.

### METHODS

Data from thirteen subjects recruited for a larger overall research project were collected and analyzed. All subjects signed a consent form approved by an IRB. Our study population consisted of 6 men, and 7 women, ages 54 to 70 years old ( $61.38 \pm 6.25$ ). Patients were diagnosed with unilateral end stage knee OA and scheduled for TKA. Only subjects capable of walking at a velocity greater than 0.75m/s for 6 minutes were included in this study to limit the influence of speed on gait parameters.

Each patient was asked to perform a 6 minute walk along a 35 meter loop and was instructed to cover as much distance as they could in 6 minutes. One side of the walkway was instrumented with an 8-camera motion tracking system (Hawk system; Motion Analysis Corp.) Patients had reflective markers placed on their body in a Helen Hayes marker arrangement. Markers trajectories were recorded while walking and data for the first and last loops (beginning and end of the 6 minute walk) were retained for analysis. Motion data were collected at 100 Hz.

Gait speed (GS) was calculated as an average over one loop, for the first and last loops. Maximum ankle vertical displacement ( $Z_{max}$ ) during swing prior to heelstrike for the affected leg (i.e. limb not scheduled for surgery) was considered for analysis. Vertical velocity of the ankle marker was derived from marker vertical displacement data, and the the peak, occurring prior to heelstrike ( $\dot{Z}_{max}$ ) for the affected leg, was retained for analysis.

Paired t-tests were used to assess the differences in these parameters, between the beginning and end of the 6 minute walk, for the involved limb.

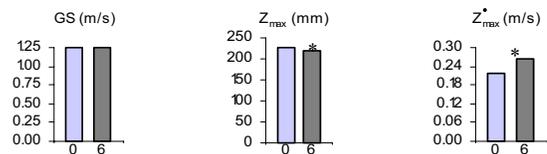

### RESULTS AND DISCUSSION

No significant difference was found in gait speed ( $p=0.72$ ) between the beginning and end of the 6 minute walk (figure1).

Significant differences were found for the vertical velocity of the ankle marker prior to heelstrike ( $p=0.012$ ), and the maximum vertical displacement of the ankle during swing ( $p=0.019$ ) between the beginning and end of the 6 minute walk (figure1). Means, standard deviations and t-test values are reported in table 1.

**Table 1:** Mean, standart deviation and t-test value for GS,  $Z_{max}$ , and  $\dot{Z}_{max}$  at the beginning and the end of the 6 min walk.

	Mean	Std Dev	t-test
GS <sub>0</sub>	1.25 m/s	± 0.30	P = 0.72
GS <sub>6 min</sub>	1.24 m/s	± 0.27	
$Z_{max}$ 0	226 mm	± 22	P = 0.019
$Z_{max}$ 6 min	220 mm	± 21	
$\dot{Z}_{max}$ 0	0.219 m/s	± 85	P = 0.012
$\dot{Z}_{max}$ 6 min	0.265 m/s	± 75	

**Figure 1:** GS,  $Z_{max}$ , and  $\dot{Z}_{max}$  at the beginning and the end of the 6 min walk. (\*  $P \leq 0.05$ ).

While gait speed remains unchanged, between the beginning and end of the 6 minute walk test, subtle changes in GS,  $Z_{max}$ , and  $\dot{Z}_{max}$  are noticeable. At the end of the 6 minute walk, the vertical velocity of the ankle marker prior to heelstrike increases and patients don't lift their ankle as high in preparation for heelstrike. Gill et al. [1] in a study among healthy adults demonstrated that higher heelstrike ankle vertical velocity and lower ankle rise in preparation for heelstrike are associated with higher loading rate at heelstrike. These findings suggest that in order to maintain their gait speed throughout the 6 minutes, patients develop compensatory mechanisms modifying their loading pattern, possibly due to fatigue. These subtle changes are not noticeable with usually reported gait variables but as suggested by Gill et al. [1], can be responsible for large differences in impulse loading experienced at heelstrike and cause one's knee OA condition to worsen.

The results of this study may need to be interpreted with caution, at this time, since the sample size is still somewhat small. Subject recruitment, however, is continuing. Future investigation in this area hopes to establish means for utilizing these biomechanical variables as fatigue indicators, which could help assess end stage knee OA treatment outcomes.

### INTRODUCTION

An individual with a complete thoracic-level spinal cord injury (SCI) experiences a loss of voluntary control to the lower extremities, the pelvis, and a portion of the trunk. These limitations may make it difficult or impossible to perform seated tasks such as reaching, lifting, and pulling. A prototype functional neuromuscular stimulation device was developed to activate the trunk muscles for added stiffness during seated tasks. The particular studies described here involved evaluation of one-handed and two-handed reaching tasks using the Stimulation for Improved Trunk Stability (SITS) system prototype. The hypothesis was that using the SITS system would result in increased postural stability when compared to reaching tasks performed without stimulation.

### METHODS

Subject #1 was a 34 year-old male with a T3 level complete injury, and Subject #2 was a 38 year-old male with a T6 level complete injury. The SITS system consisted of a control module that interfaced with an Octostim muscle stimulator. Adhesive surface electrodes were placed on the skin over the paraspinal muscle mass just lateral to the vertebral column. During one-handed reaching, three conditions were tested while seated in a wheelchair: unconstrained (U), constrained (C), and constrained with assistance from the stimulation system (SITS). Compensatory movements such as hooking an arm around the wheelchair frame were allowed in the U condition. Use of the non-dominant arm was deterred in the C condition by having the participant hold his arm to the side of his body. The two-handed reaching tasks were tested using the U and SITS conditions. Reflective markers were tracked by a Motion Analysis video system, and the wheelchair wheels were positioned on four load cells. Video data were used to determine object trajectory, targeting accuracy, and trunk displacement.

One-handed reaching tasks involved moving a 1 kg mug between nine targets on a table. Targets were located at 60% (6), 90% (9), and 120% (12) of seated reach (measured with trunk vertical) at the midline (M) and half the shoulder width to the left (L) and right (R). For example, L6R6 indicates moving from the left 60% to the right 60% target. A successful movement was defined as the final object position being within 80% reaching distance from the target. Five repetitions of six reaching combinations for three conditions (U, C, SITS) were performed over two days (180 trials). For the two-handed reaching tasks, the table was removed, and the mug was manipulated through a series of movements. The three tasks were moving and holding the object: 1) above the head, 2) at eye-level with arms extended, and 3) with the arms extended on the dominant side of the body. Five repetitions of the three two-handed tasks for two conditions (U, SITS) were performed over two days (60 trials).

**Figure 1:** One-handed reaching success. Arrows indicate movements where the SITS system appeared beneficial.

### RESULTS AND DISCUSSION

Combining data for one-handed reaching tasks, the percentage of successful movements was highest for the U condition (92%), followed by the SITS (89%) and C (84%) conditions. Similarly, trunk displacement was minimized in the U condition (1.8 cm), followed by the SITS (2.6 cm) and C (3.1 cm) conditions. Figure 1 shows representative data from Subject #1 for the percentage of successful movements as a function of reaching combination. When combining data for the two-handed reaching tasks, trunk displacement did not show differences between the U and SITS conditions. Wheelchair center of pressure displacements were reduced for the SITS condition (7.4 cm) as compared to the U condition (10.8 cm). Maximum wheelchair center of pressure velocities were also reduced for the SITS condition (68.1 cm/s) as compared to the U condition (84.5 cm/s) indicating that the task was more controlled with the stimulation than without.

Compensatory movements such as arm hooking (U condition) may be ergonomically unfavorable. One goal of designing the SITS system was to provide enough trunk stability that compensatory movements would be unnecessary. The SITS system appeared to be helpful for the one-handed combinations that involved reaching to the right or left (Figure 1). In addition, the SITS system may have been most beneficial for two-handed reaching tasks, particularly those that involved lifting an object over the head. Center of pressure data supported observations that the SITS system provided additional postural stability to maintain targeted two-handed reaching postures. Overall, the participants continued to reach most effectively with the U condition, while the SITS system provided additional lower back stiffness that resulted in consistent improvement over the C condition.

**BIOMECHANICAL ANALYSIS OF JUMPING COMPARING LOW- AND HIGH- ACL INJURY RISK GROUPS: IDENTIFYING POSSIBLE MECHANICAL RISK FACTORS**

Jennifer J. Jeansonne, Vanessa A. West, and Jennifer R. Hoenig  
 Southeastern Louisiana University, Hammond, LA, USA; email: jjeansonne@selu.edu

**INTRODUCTION**

It is well known and documented that anterior cruciate ligament (ACL) knee injuries occur more frequently in women, at a rate of 4-8 times that of men [1]. Of the 30,000-100,000 ACL injuries reported in various years, most injuries were a result of a non-contact mechanism and sports such as soccer, basketball, and volleyball, report the highest prevalence of ACL injuries especially when compared to males in the same sports [2, 3]. Research associated with knee injuries in females has observed hormonal, neuromuscular, and anatomical differences in men and women [4]. What has not been reported is why certain groups of athletes have a higher incidence of injury than others, or if it is due to training and teaching techniques. If dancers and cheerleaders also jump, why are they less likely to injure their knees? The purpose of this study was to compare kinematics and kinetic data from low- and high- ACL injury risk groups, and controls, to identify possible mechanical risk factors.

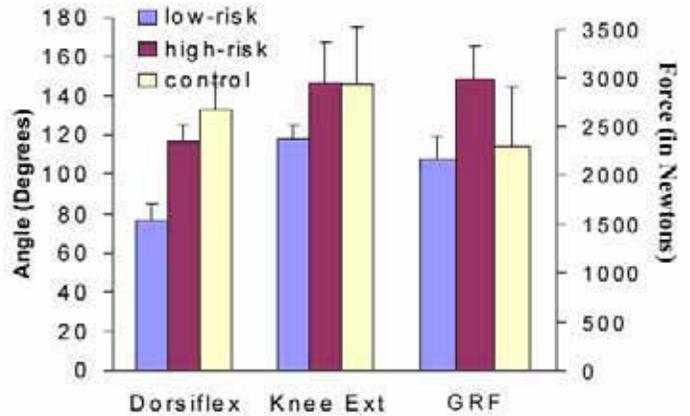

**METHODS**

Thirty-six female collegiate undergraduates volunteered for this study; however, only 32 (m=20±2.3yrs) completed the study. Subjects were placed in one of three groups: high-risk (volleyball players, n=11), low-risk (dancers & cheerleaders, n=12), and controls (non-athletic, n=9). All participants completed an informed consent and medical questionnaire.

Each participant performed 3 vertical jumps at maximal effort with joint markers on the right and left legs placed at the hip, knee, ankle, heel and toe. Each participant faced the same direction and had only the right foot on the Bertec force platform when jumping. The jumps were videotaped using three cameras, two anteriorly and one posteriorly positioned relative to the subject. The video was digitized and then filtered and processed to calculate flexion/extension at the knee and ankle, knee varus/valgus, jump height, and jump time using Peak Motus® 8. The force data was synchronized with the kinematics data to calculate peak forces during the loading and landing phases of the jump. The force plate collected at 600 Hz, while the cameras collected data at 60 Hz.

**RESULTS AND DISCUSSION**

A 3 X 9 (group X measure) ANOVA found significant differences (p<0.05) between the groups for all but 2 of the dependent measures (Table 1). Post-hoc tests revealed the high-risk group to be significantly different from both the controls and the low-risk group for the kinematic measures (dorsi/plantarflexion at load & land, knee flexion at load & land, & jump time) (Figure 1), while the low-risk group was significantly different from the high-risk and controls for the kinetic measures (GRF at load & land). Measures of knee varus and valgus were not significant.

**Figure 1:** Maximal dorsiflexion, knee extension and ground reaction force during the landing phase of the jump.

This study revealed several differences between the three groups. The high-risk group was observed to load the least out of the three groups (knee angles: loading 120 deg, landing 147 deg), yet had longer jump times (0.48s vs. 0.42s). This is possibly due to training, needing to get to the net and quickly jump high to spike or block the ball. This landing style transmits a high amount of force to the knee and puts excessive stress on the ACL. The high-risk group also had higher GRF (loading: 2128 N, landing: 2979 N) than the low-risk group (loading: 1936 N, landing: 2165 N). These high forces could be attributed to the higher prevalence of ACL tears. The similar GRF for loading and landing in the low-risk group could be due to their training and teaching. Dancers are taught to go through the same flexion/extension path and depth during loading and landing. This could indicate why they have fewer ACL injuries compared to the high-risk group. The low risk groups must make jumps look smooth and symmetrical, while the high-risk athletes have a responsibility to make an athletic play regardless of how it looks.

**CONCLUSIONS**

Prevention programs have been developed to retrain females' firing patterns, increase hamstring strength, and improve jumping and landing mechanics to reduce the number of incidences and risk of injury. The research presented here supports the need for preventative jumping programs to decrease the ground reaction forces during landing and increase joint flexion, to reduce risk factors.

## A TIME-FREQUENCY APPROACH USING WAVELETS TO STUDY WEEK-TO-WEEK VARIABILITY IN BLOOD FLOW OSCILLATIONS

<sup>1</sup>Yih-Kuen Jan, PhD, PT; <sup>1</sup>David M. Brienza, PhD and <sup>2</sup>Michael L. Boninger, MD

<sup>2</sup>Department of Physical Medicine and Rehabilitation, University of Pittsburgh; email: yij2@pitt.edu

### INTRODUCTION

Laser Doppler flowmetry has been used extensively to quantify skin perfusion response to compressive loading (1). The study of blood flow responses is confounded by temporal variability in blood flow measurements (2). Several methods have been reported to compensate for temporal variability in baseline blood flow measurements. However, the success of these methods in reducing temporal blood flow variability has been mixed. Spectral analysis has been shown to be useful in isolating the effects of distinct control mechanisms to various stimuli in the microcirculatory system (1). However, the sensitivity of spectral analysis to temporal blood flow variability has not been reported. This study investigated the effectiveness of a wavelet analysis technique in reducing week-to-week variability in blood flow measurements.

### METHODS

Ten healthy subjects were brought into the laboratory on three occasions separated by  $7 \pm 2$  days for measurements of baseline and thermally induced maximal sacral blood flow for three consecutive weeks. Blood flow over the sacrum was recorded during 10 minutes of rest to establish baseline flow followed by 15 minutes of incremental heating from  $35^{\circ}\text{C}$  to  $45^{\circ}\text{C}$ . Laserflo Blood Perfusion Monitor 2 (BPM<sup>2</sup>, Vasamedics, Eden Prairie, MN) and Softip pencil probe (P-435, Vasamedics) were used to measure capillary blood perfusion (ml/min per 100g tissue). A temperature control module (TCO, Vasamedics) with heater probe (P-422, Vasamedics) was used to heat the skin to  $45^{\circ}\text{C}$  to obtain a maximal skin blood flow response. Laser Doppler blood flow was sampled at 20 Hz using a 16-bit data acquisition card (PCI-MIO-16XE, National Instruments, Austin, TX).

Wavelet analysis was used to decompose blood flow signals into frequency components determined to be associated with metabolic (0.008-0.02 Hz), neurogenic (0.02-0.05 Hz), myogenic (0.05-0.15 Hz), respiratory (0.15-0.4 Hz) and cardiac (0.4-2.0 Hz) control mechanisms (1). Analysis methods were used to study relative contributions in each characteristic frequency band to total blood flow (1). The rationale for designation of frequency range for each characteristic frequency band's control mechanism is described in Geyer et al. (1).

Maximal blood flow ratio was defined as the ratio of baseline blood flow to thermally induced maximal blood flow at  $45^{\circ}\text{C}$ . The coefficient of variation (CoV), independent of units of measurements, was used to analyze the impact of inherent skin blood flow variability on various normalization methods by comparing its magnitude between total skin blood flow at baseline, power within each characteristic frequency band at baseline and baseline skin blood flow normalized to the maximal blood flow according to the ratio method.

### RESULTS AND DISCUSSION

The CoV for the blood flow signal power in each individual frequency band at baseline (CoV range from 0.08 to 0.15) were smaller than that of blood flow at baseline (0.28) or maximal blood flow ratio (0.41) ( $p < 0.05$ ) (Figure 1). The maximal blood flow ratio method failed to reduce variability in baseline blood flow.

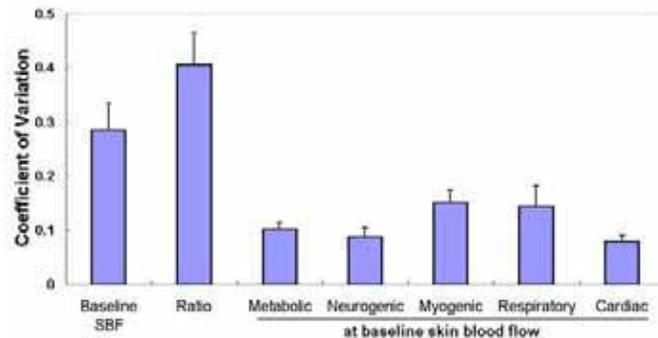

Figure 1. Comparisons of coefficients of variation of skin blood flow at baseline, maximal blood flow ratio method, and five characteristic frequency bands isolated from baseline blood flow in three consecutive weeks (values are mean  $\pm$  S.E.).

### CONCLUSIONS

Our study suggests that wavelet analysis is effective in reducing temporal blood flow variability. To best of our knowledge, this is the first study published using wavelet analysis to investigate temporal variability of laser Doppler blood flow measurements. However, time-frequency approaches have been used widely in the study of heart rate variability. We postulated that the study of skin blood flow variability has great potential to advance understanding of blood flow control mechanisms and to provide early detection of pathological changes in the skin (i.e. foot ulcers in diabetes mellitus, survival of free flap and stage I pressure ulcer).

**The relationship between leg length and velocity of center of gravity during contact phase in the long jump**

<sup>1</sup>Kenji Ohishi, <sup>1</sup>Tetsunari Nishiyama and <sup>2</sup>Kazuhisa Anraku

<sup>1</sup> Human Performance Laboratory, Nippon Sport Science University, <sup>2</sup>Physical Training School of Japan Defence Forces  
 e-mail: kenji@nittai.ac.jp, web: http://www.nittai.ac.jp/

**INTRODUCTION**

The take-off velocity of the center of gravity (CG) is one of important factors in the performance of the long jump. The horizontal velocity of CG gained by approach run was decelerated during the contact phase. Therefore, it is important to study the mechanisms of velocity changes during the stance phase. We examined the relationship between the changes of the CG velocity and leg length of the take-off leg during foot contact phase.

**METHODS**

Ten male long jumpers and ten male no-athletes participated in this study. The long jump movement during foot contact phase of take-off was recorded in the sagittal plane at 250f/s using high-speed video camera (nac, inc.). Two-dimensional coordinates of each marker on whole-body of subjects were obtained using MOVIAS software (nac, inc.). The kinematics data were smoothed two-order digital Butterworth low-pass filter with a cutoff frequency of 8Hz.

The horizontal and the vertical velocity of CG and the leg length were calculated from the coordinates. The leg length is defined as the distance from the CG to the point of metatarsophalangeal joint. The leg length was normalized to the length at the take-off. And, horizontal velocity of the CG was normalized to the horizontal velocity of the CG at the touchdown.

**RESULTS AND DISCUSSION**

The mean long jump distance was 6.99(6.31-7.33) m in the athlete, and 4.97(4.33-6.13) m in the non-athlete.

The %leg length was decreased in the first half of foot contact phase, then it was lengthened during the last of phase. The first half was defined as the period from touchdown to the appearance of shortest %leg length, and the latter half was defined as the period from the appearance of shortest %leg length to take-off.

Figure show the relationship between  $\Delta$  %horizontal velocity at the latter half and %horizontal velocity at the take-

off. In all the members, there was the significant relation. This result show that the increase of  $\Delta$ %horizontal velocity at the latter phase approaches the velocity of approach run. However, there was no correlation in the athlete and no-athlete groups.

The relationship between velocity of CG and  $\Delta$ %leg length was show in the table. And, there was the correlation on  $\Delta$ %leg length at the latter half and it at the first half. In all the members and athlete group, there was the significant relation in  $\Delta$ % horizontal velocity at the latter half and  $\Delta$ %leg length at the same phase(p < 0.05). The significant relation could not be observed between other elements.

From these results, there was no relation on  $\Delta$ %leg length and  $\Delta$ velocity of CG in many phases. However, the  $\Delta$ %leg length affects the  $\Delta$ %horizontal velocity of CG at the take-off, which  $\Delta$ %leg length will be considered as one element of the performance decision.

## INITIATION AND PROPAGATION OF FATIGUE MICROCRACKS FROM A DEFECT IN A CEMENTED TOTAL HIP ARTHROPLASTY

Jihui Li<sup>1</sup>; Gang Qi<sup>1,2</sup>

<sup>1</sup>Dept. of Biomedical Engineering, <sup>2</sup>Dept. of Mechanical Engineering. The University of Memphis, Memphis, TN 38152  
 E-mail: [jihui@memphis.edu](mailto:jihuili@memphis.edu) Web: [http://www.me.memphis.edu/mar\\_lab/mar\\_lab/home.htm](http://www.me.memphis.edu/mar_lab/mar_lab/home.htm)

### INTRODUCTION

Voids/defects in cement mantle or at interfaces were reported as a major source of fatigue microcracks (MCs) that occurred in cemented total hip arthroplasty (THA) [1,2]. Presently, it is difficult to monitor the progression of MC activities in real time. In this work, we presented a case study to reveal the initiation and accumulation of MCs from a proximal defect in a cemented THA, using acoustic emission microcrack graphs (AEMG) technique [3].

### METHODS

A series of standard hand mixed cemented THA specimens were prepared using Spectron stem, Palacos R cement and Sawbone femurs. In X-ray examination, one specimen with a proximal defect of  $6.5 \times 2.5 \times 14.0$  mm (in anterior-posterior, medial-lateral and distal-proximal direction, respectively) was identified (Fig. 1a) and selected to study the influence of the defect on MCs activities. The specimen was subjected to 5 million cycles of fatigue loading (267/2670 N at 2 Hz) on a MTS machine. MC signals were detected by an AE system and their locations were calculated. Six virtual sections (A1 to A6, 5 mm thick each) were selected from the defect area (Fig.1b). MCs that occurred in each section were counted and plotted onto the anterolateral quadrant (Fig.1c) to visualize the initiation and accumulation of MCs (a process called AEMG [3]). After the experiment, the specimen was sectioned at seven locations (A-G in Fig.1a) for SEM inspections.

### RESULTS AND DISCUSSION

The AEMG and the number of MCs of virtual sections in the first three hours (Fig.2) indicated that the fatigue damage initiated from the lower lateral end of the defect (section A4) 4 seconds after test started. The damage spread to the surrounding area of the defect (A2-A5) immediately and the number of MCs increased dramatically. Damage propagation (evaluated by number of MCs) decreased as the test proceeded, but with three recover periods which started from the 12<sup>th</sup>, 18<sup>th</sup> and 22<sup>nd</sup> days, respectively (Fig. 3c). Most MCs accumulated around the middle-lower defect (A3-A5). SEM observed a continuous debonding at cement-stem interface next to the defect at physical section A (Fig.3a). A large amount of cement debris could be identified in the debonding (Fig.3b). This indicated the MCs in the middle and final fatigue process was caused mainly by the grinding between damaged interfaces instead of the damage propagation. No MCs located along cement-bone interface and on either side of the defect. Few insignificant MCs were detected in other physical sections.

### CONCLUSIONS

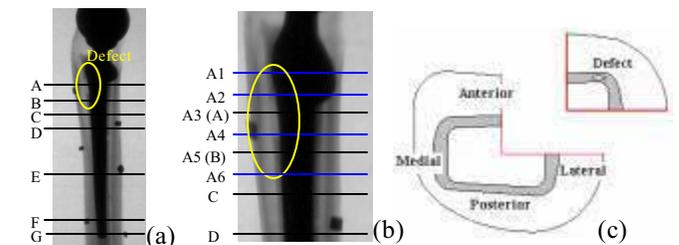

AEMG analysis indicated that defect was indeed the key reason of fatigue MCs. These MCs initiated at the lower lateral end of the defect and propagated upward to the surrounding area. Damage propagation was slow down then and interface grinding became the major source of MCs.

## OPTIMISED TUMBLING PERFORMANCES THAT ARE ROBUST TO PERTURBATIONS

Mark A. King and Maurice R. Yeadon

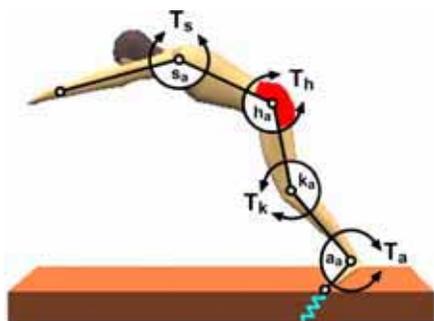

Loughborough University; email: M.A.King@lboro.ac.uk, web: www.lboro.ac.uk

### INTRODUCTION

Determining optimum tumbling performance in artistic gymnastics has previously focused on maximising somersault rotation in simulations, with a double straight somersault being possible [1]. Gymnasts may develop their optimum performance in a different way, however, since their technique must have some robustness to perturbations. Therefore using an optimisation criterion that merely maximises somersault rotation in a simulation is unlikely to give a realistic solution. In particular there is no guarantee that such an optimum simulation will be robust to small perturbations of the touchdown conditions and the technique used. The aim of this paper is to determine the effect of incorporating perturbations of technique into the optimisation of simulated tumbling performance.

### METHODS

A planar five-segment model was developed with torque generators at each joint for simulating the foot contact phase in tumbling. The elastic properties of the interface between the feet and tumbling track were represented by horizontal and vertical massless damped linear springs (Figure 1).

**Figure 1:** A five segment simulation model of the foot contact phase in tumbling.

The model was customised to an elite gymnast by determining subject-specific segmental inertia and joint torque parameters. Anthropometric measurements of an elite gymnast were taken and segmental inertia parameters were calculated using a mathematical model [2]. Torque measurements were taken during eccentric-concentric movements at the ankle, knee, hip and shoulder joints using an isovelocity dynamometer (KinCom 125E), with crank angular velocities ranging from 20°/s to 250°/s, in order to express torque as a function of joint angle and angular velocity [3].

A performance of a double layout somersault was used to provide initial conditions for simulations. Maximising

rotation potential (angular momentum  $\times$  flight time) subject to a flight time constraint (greater than the actual performance) produced sufficient somersault rotation for a double straight somersault [3]. This original optimised simulation was then perturbed by varying the initial conditions (body orientation  $\pm 3^\circ$ , linear momentum  $\pm 3\%$  and angular momentum  $\pm 3\%$ ), and the onset activation times ( $\pm 20$ ms) of the knee and hip torque generators in order to determine its robustness to perturbations. Two modified optimisations were then carried out with the perturbations to the initial conditions and the onset activation times included in the optimisation procedure (lowest rotation potential score chosen for each combination of parameters and simulations with flight times less than that of the actual performance discarded).

### RESULTS AND DISCUSSION

The optimisation for robustness to perturbations of initial conditions had 4% less rotation potential than the original optimisation while the onset time optimisation had 3% less rotation. Perturbing the initial conditions for the original optimised simulation and the two robust optimisations resulted in maximum reductions in rotational potential of 5%, 5% and 5% respectively. Perturbing onset times to the torque generators resulted in reductions in rotation potential of 3%, 2% and 1% respectively. The flight times for the perturbed original optimisation were as much as 6% less than in the actual performance while the flight times for the perturbed robust optimisations were all greater than the actual flight time. In summary, including perturbations within the optimisation procedure resulted in simulations that had less rotation potential but were more robust (in terms of rotation potential and flight time) to perturbations than the original double straight optimum simulation.

### CONCLUSIONS

When maximising performance it is important that the robustness of the optimum simulation to perturbations is considered and is included in the formulation of the optimisation procedure used. Failure to do this can result in maximal solutions that are unrealistic and not achievable. In the development of such gymnastic skills it is likely that robustness and consistency are an inherent part of optimised performance. Considerations of robust and consistent performance may therefore have parallels in both motor learning and evolution.

## Different Motor Planning During Eccentric and Concentric Elbow Muscle Contractions

Yin Fang, Vloděk Siemionow and Guang H. Yue  
 Biomedical Engineering Dept. The Cleveland Clinic Foundation  
 Email: [fangy@bme.ri.ccf.org](mailto:fangy@bme.ri.ccf.org)

### INTRODUCTION

Eccentric contractions are characterized by greater force production but lower muscle activation, depressed monosynaptic reflex excitability, reduced ability to fully activate the working muscle, motor unit recruitment strategy altered from the “size principle”, reduced stability of the movement, and greater susceptibility to muscle tissue damage. The results of many studies suggest that the CNS may control concentric and eccentric muscle actions differently though direct evidence is few. The purpose of this study was to measure electroencephalography (EEG)-derived movement-related cortical potential (MRCP) during the two types of muscle actions and determine if the level and timing of cortical activation differ between eccentric and concentric human elbow flexor contractions.

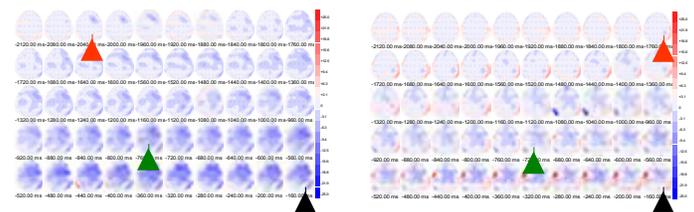

### METHODS

Eight right-handed men ( $29.13 \pm 2.36$  years old, range 26-31 years) participated in the study performed on Kin-Com isokinetic dynamometer. They performed 40 maximum voluntary concentric contractions (when exerting elbow flexion force against the lever arm and rotating it toward the body) and 40 eccentric contractions (when lever arm rotating away from the body). Surface EMG signals were recorded from the biceps brachii (BB), brachioradialis (BR), triceps brachii (TB), and deltoid (DT) muscles. Scalp EEG signals were simultaneously recorded by a 64-channel NeuroScan EEG system. The force, EMG, and EEG data were trigger-averaged across the 40 trials and movement related cortical potential was derived. Two dimensional MRCP mapping was draw based on the mean value of the entire group.

### RESULTS AND DISCUSSION

The force exerted by the subjects during eccentric MVCs ( $210.63 \pm 94.68$  N) was significantly higher ( $P < 0.05$ ) than the force during concentric MVCs ( $184.06 \pm 87.07$  N). The EMG of the major elbow flexor muscles (BB) during eccentric

contraction ( $321 \pm 175 \mu\text{V}$ ) was significantly lower ( $P < 0.01$ ) than the EMG of the muscle during concentric contraction ( $447 \pm 264 \mu\text{V}$ ). A majority of electrodes showed a greater NP for eccentric than concentric movements in the brain potential maps (Fig 1). Detailed analysis suggested there is a bigger brain activation area for eccentric than concentric movements, and the activation starts earlier (from MRCP start to EMG start) when compared with concentric movements (Fig 2).

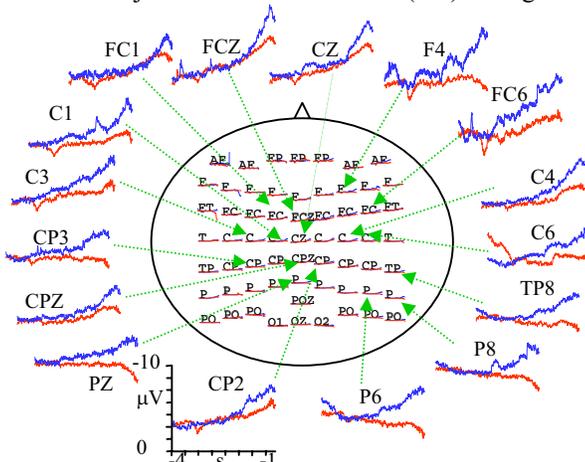

**Figure 2:** Group average of topographical maps of cortical potential ( $\mu\text{V}$ ) showing spatial and temporal distributions of electrical activity at the cortical surface for eccentric (left panel) and concentric (right panel) contractions. Red arrow: MRCP onset; Green arrow: EMG onset; Black arrow: Movement onset;

Our data imply that the level of cortical activation was substantially higher and the preparation time was significantly longer for eccentric than concentric tasks during the specific planning and execution phases of the controlling process. Several factors related to distinct eccentric characteristics might contribute to these different cortical activities. It is well known that eccentric muscle contractions induce greater tissue damage than do concentric muscle activities [1]. The adaptive changes following repetitive eccentric training may be an indication of CNS-modulated adaptations to protect muscle from further injury [2]. The unusual brain activities could be the results of such adaptation. Eccentric contraction is also more difficult to control than concentric ones, represented by greater force fluctuation and more EMG spiking [3]. Greater voluntary effort is required when a person performs a motor task that is more difficult to control. Associated with this difficulty is that the motor unit pool cannot be fully activated during maximal voluntary eccentric contraction [4]. This incapability to fully activate motor units could also related to some mechanism protecting muscle tissue from damage, since more force would be generated while the motor unit pool was fully activated.

## METHODS TO MEASURE STATIC COEFFICIENT OF FRICTION BETWEEN HAND AND OTHER MATERIALS

Na Jin Seo, Thomas J Armstrong, Philip Drinkaus  
University of Michigan; email: [najins@umich.edu](mailto:najins@umich.edu)

### INTRODUCTION

The friction between hand and other materials affects our ability to grasp and manipulate objects. Friction data are needed for the design of tool/consumer products, job analysis, and workstation design. This coefficient of friction is difficult to measure consistently, because it is affected by many factors including: contact force, hydration [1], area of contact, contaminants [2], and direction [3]. The purpose of this study is to develop a simple method of measuring the static coefficient of friction between skin and other materials so that this information can be readily calculated in the field.

### METHODS

The proposed method is referred to as the “tilt” method. A flat plate is held in the hand. The hand is then tilted at a steady rate until the plate begins to slide. The static coefficient of friction ( $\mu_s$ ) is equal to the ratio of the shear (friction) force ( $F_f$ ) to the contact (normal) force ( $F_n$ ) just before the object starts to move.

$F_f$  is equal to  $W\sin\theta$  and  $F_n$  is equal to  $W\cos\theta$ , where  $W$  is the weight of the plate and  $\theta$  is the angle of the plate with respect to the horizontal at the time the plate begins to slide. It can be shown that  $\mu_s$  is approximately equal to  $\tan\theta$ .

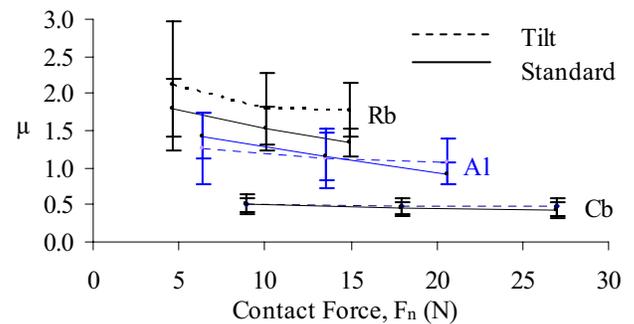

The standard method entails holding the flat plate on the hand as in the tilt method, but the plate is attached to a force transducer. The subject then increases the horizontal force on the plate until it begins to slide. The  $\mu_s$  is then calculated as the ratio of the  $F_f$  (measured by force transducer at the time the plate begins to slide) to its weight.

Independent variables for the tilt method were: contact area (fingertips vs. flat palm), materials (rubber (Rb), aluminum (Al), cardboard (Cb)), and plate weights (10, 20, 30N). The average  $F_n$  and shear force buildup rate ( $dF_f/dt$ ) at which slippage occurs were calculated for each condition (subjects pooled). The  $F_n$  values ranged from 4.2–27N. The  $dF_f/dt$  values ranged from 0.8–5.4 N/s. Using the results from the tilt method, the appropriate  $F_n$  and  $dF_f/dt$  were chosen for each material and contact area, and used for the standard method. The dependent variable was  $\mu_s$ . Subjects were allowed to practice tracking a constant  $dF_f/dt$  by following a bar indicator.

5 university students (3 males, 2 females) volunteered to participate. To remove possible contaminants, subjects washed their hands with soap and rinsed with tap water. They dried their hands with paper towels and air dried for 15 minutes. Each condition was tested 3 times, and trials were randomized.

### RESULTS AND DISCUSSION

The  $\mu_s$  measured by the tilt and standard method for each  $F_n$  and material is shown in Figure 1.

**Figure 1:** Static coefficient of friction from “tilt” and standard method between palmar skin and three different materials for different  $F_n$ 's (contact area and subjects pooled, Rb: rubber, Al: aluminum, Cb: cardboard).

Analysis of variance revealed that the  $\mu_s$ 's from the tilt and the standard methods were not statistically different ( $p>0.05$ ).

The  $\mu_s$ 's decreased with increasing  $F_n$  ( $p<0.05$ ), as observed in the previous studies [1,2,3]. The relatively high  $\mu_s$ 's ( $2.11\pm 0.88$ , for the tilt method with Rb) may have resulted from the low  $F_n$ 's tested.

The  $\mu_s$ 's of fingertips were lower than those of the flat palm. This difference was statistically significant for Rb and Al, while only a trend was observed for Cb. This trend that a narrower skin contact area tended to have a lower  $\mu_s$  than a wider contact area under clean skin condition was also observed in [2], even though a different material and kinetic coefficient of friction were investigated in [2].

In this study, the  $\mu_s$ 's for Al and Cb were found  $1.15\pm 0.37$  and  $0.48\pm 0.12$ , respectively ( $F_n$ , contact area, method pooled). These values were higher than those calculated from the regression model in [1]: 0.39 and 0.30 for Al and paper, respectively ( $F_n$  pooled). This could be due to the difference in skin contact area, since only an index finger and a thumb were used in [1]. Higher values for  $dF_f/dt$  and  $F_n$  in [1] (15N/s and 22–39N, respectively) could also be the reason for the large difference in  $\mu_s$ 's between the two studies. The  $dF_f/dt$  was controlled in this study. However, the effect of different  $dF_f/dt$  on  $\mu_s$  needs to be investigated.

The tilt method is easy to perform, and can be performed in the field. This provides timely, relevant information about  $\mu_s$  in the workers' environment.

## TEMPERATURE-DEPENDENT MECHANICAL PROPERTIES OF HUMAN SOLEUS MUSCLE FIBERS

Sampath K. Gollapudi<sup>1</sup> and David C. Lin<sup>1,2,3</sup>

### INTRODUCTION

Temperature-dependent mechanical properties of different skeletal muscle fibers (slow and fast) are related to the differences in their crossbridge kinetics [1]. Previous studies have employed complex multi-state crossbridge models for analysis of temperature-dependent mechanical properties, mostly in isometric condition and for shortening contractions. There has been no study of the variations in contractile properties during lengthening contractions at different temperatures. This study will record the lengthening and shortening force-velocity (F-V) data from human type I fibers at different temperatures to examine the variations in these properties within the context of a simplified Huxley's two-state crossbridge model [2]. Also, this study will serve as the experimental basis of how to utilize data obtained at lower temperatures to extend the model to *in vivo* temperatures.

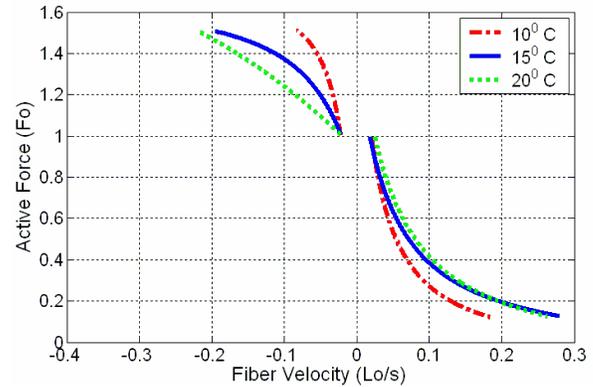

### METHODS

Single fibers were chemically skinned and dissected free from biopsies of human Soleus muscles. Institutional Review Board approval was obtained for these procedures. Fibers were attached between the force transducer and motor hooks via aluminum foil T-clips. The initial sarcomere length of all fibers in relaxing solution was set to 2.2  $\mu\text{m}$ , and each fiber is maximally activated in a  $\text{Ca}^{++}$  solution at a specific test temperature (10, 15, and 20<sup>o</sup> C). A perturbation was then applied as a linear change in force (force ramp) for both lengthening and shortening contractions to measure the F-V behavior. For this study, a total of 15 type I fibers have been measured. Each fiber was later analyzed by gel electrophoresis for myosin heavy chain type.

### RESULTS AND DISCUSSION

Figure 1 shows the averaged F-V curves for human Soleus fibers during lengthening and shortening contractions across all trials at 10<sup>o</sup> C (n=5), 15<sup>o</sup> C (n=5) and 20<sup>o</sup> C (n=5). In all these fibers, a good homo geneity of the sarcomere pattern was maintained after repeated activations. These experimental curves clearly demonstrate that the mechanical properties of both shortening and lengthening contractions are quite sensitive for changes in temperature. A temperature rise from 10<sup>o</sup> C to 15<sup>o</sup> C causes an increase of ~43% in the maximum shortening velocity during shortening and an increase of ~135% during lengthening, thereby affecting the muscle's peak power production. A similar trend can also be observed among these properties at higher temperature steps.

By simulating the Huxley's crossbridge model for these ramp perturbations, it is possible to estimate the model parameters (crossbridge attachment rate,  $f$  and detachment rate parameter,

**Figure 1:** Averaged F-V curves at 10<sup>o</sup> C, 15<sup>o</sup> C and 20<sup>o</sup> C. Positive velocity is shortening.

g) [3]. These analyses provide valuable information about how crossbridge kinetics at the microscopic level influences macroscopic behavior. Also, these data at lower temperatures can be used to extrapolate *in vivo* function at physiological temperature. Furthermore, this study can be extended to investigate the temperature-dependent mechanical behavior of fast (Type II) fibers. These data would be critically important in understanding the differences of distinct muscle fiber types at both the microscopic and macroscopic levels [4].

### SUMMARY

Mechanical properties of human Soleus (type I) muscle fibers are found to be highly-temperature sensitive. Specifically, both the lengthening and shortening force-velocity relationships were found to vary with the test temperature. These data will be used with a simplified crossbridge model to tie the temperature controlled biophysical experimental data to macroscopic force predictions. A need to further extend this study to *in vivo* temperatures is also justified in order to better understand the differences in contractile properties among various fiber types.

## FUNCTIONAL FATIGUE DECREASES THREE-DIMENSIONAL MULTIJOINT POSITION REPRODUCTION IN OVERHEAD ATHLETES

Brady Tripp, Tim Uhl, Carl Mattacola, Cidambi Srinivasan, Robert Shapiro  
University of Kentucky; E-mail: brady\_trippl@yahoo.com

### INTRODUCTION

The sensorimotor system (SMS) is responsible for providing the awareness, coordination and feedback to maintain stability and function. Therefore, acuity of this system is a major component of injury-free athletic performance. Evidence suggests that muscular fatigue [1,2] and injury [3] compromise SMS function in the upper-extremity. However, investigations of joint position sense often employ methods that hamper our ability to apply results to functional activity. The purpose of this study was to examine the effect of functional fatigue on unconstrained, multijoint position reproduction of the upper-extremity. We measured position reproduction acuity of the upper-extremity as a functional unit and acuity of four individual joints.

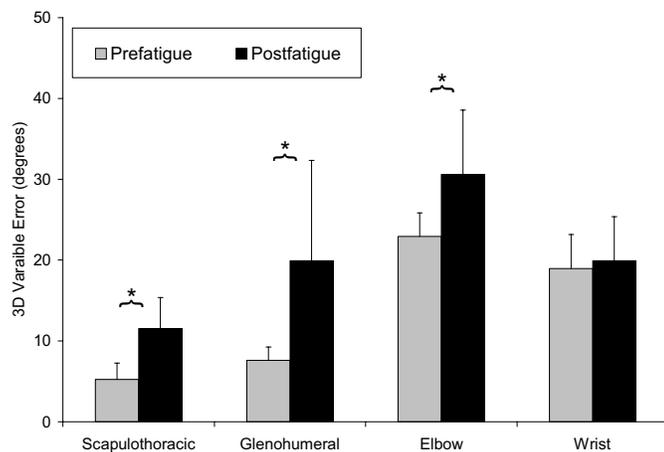

### METHODS

We used a single-session repeated-measures design. Subjects consisted of 16 healthy male NCAA baseball players ( $21.0 \pm 1.6$  years,  $175.8 \pm 10.2$  cm,  $82.8 \pm 4.3$  kg). We recorded position of the throwing-side thorax, scapula, humerus, forearm and hand using an electromagnetic tracking device (Ascension Technology, Burlington, VT, USA) and MotionMonitor software (Innovative Sports Training, Chicago IL). We blindfolded subjects and tested their ability to reproduce two self-selected upper-extremity positions (arm-cock and ball-release) before and after a fatigue protocol. Subjects were in a single-knee stance position for the testing and throwing protocol. Subjects identified a target position followed by three-reposition trials. The functional fatigue protocol was a single bout of throwing a baseball at a target with maximum velocity (1 every 5 seconds). After every 20 throws, subjects rated their local (upper-extremity) exertion level on the Borg Rating of Perceived Exertion scale [4]. We considered subjects fatigued after reaching a level greater than 14. Immediately after the throwing protocol, we retested

participants in the same manner as pre-fatigue measures. Post-testing began within 1 minute after completion of the throwing protocol and both positions were completed within 3 minutes. We calculated 3-dimensional variable error scores (3DVE) to represent overall reposition acuity for each arm position using hand position in relation to the thorax. We calculated additional 3DVE scores for each individual joint (scapulothoracic, glenohumeral, elbow and wrist).

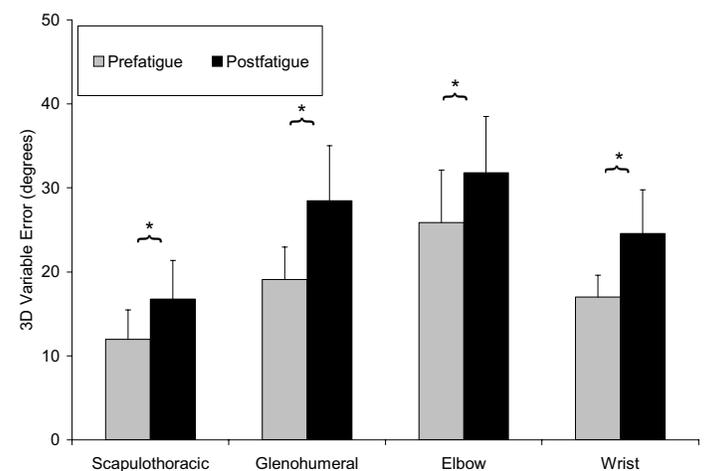

### RESULTS AND DISCUSSION

Subjects were fatigued after  $62 \pm 28$  throws. We used Wilcoxon matched-pairs sign-rank tests to compare pre-fatigue to post-fatigue error scores. Fatigue had a significant effect on position reproduction acuity (increasing 3DVE scores) for the arm-cock ( $12.4$  to  $24.1$ mm) and ball-release positions ( $20.8$  to  $41.7$ mm) ( $P < .001$ ). Comparisons of pre-fatigue 3DVE scores for scapulothoracic, glenohumeral, elbow and wrist joints with post-fatigue reveal decreased acuity for both the arm-cock (Figure 1) and ball-release (Figure 2) positions.

**Figure 1:** Comparison of pre-fatigue to post-fatigue acuity scores (3DVE) for the arm-cock position.

\* Significant difference between conditions ( $P < 0.05$ )

**Figure 2:** Comparison of pre-fatigue to post-fatigue acuity scores (3DVE) for the ball-release position.

\* Significant difference between conditions ( $P < 0.05$ )

### CONCLUSIONS

Using multijoint, 3-dimensional measures and a functional throwing protocol, we demonstrated fatigue reduced 3D position reproduction acuity in both positions tested and at multiple upper-extremity joints. Our results indicate that after prolonged throwing, SMS deficits affect the entire upper-extremity and may put multiple joints at risk for injury.

## THE MECHANICS OF JUMPING VERSUS STEADY HOPPING IN YELLOW-FOOTED ROCK WALLABIES

### INTRODUCTION

Previous work has suggested that a musculoskeletal design that favors elastic energy recovery, like that found in wallabies and kangaroos, may be constrained in the ability to generate mechanical power [1]. Yet rock wallabies regularly make large jumps while maneuvering through their environment. The goal of our study was to explore the mechanical power requirements associated with jumping in yellow-footed rock wallabies and to determine how these requirements are achieved relative to steady speed hopping mechanics. As jumping can be a high power activity, we hypothesized that yellow-footed rock wallabies would be able to generate substantial amounts of mechanical power.

### METHODS

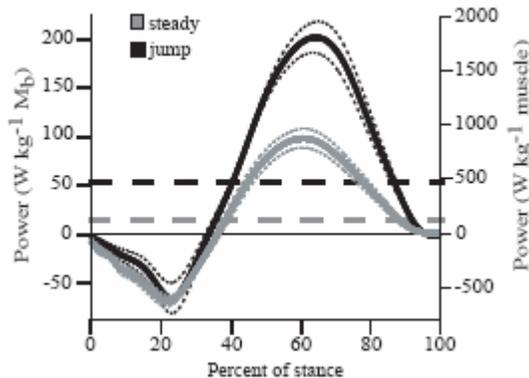

Four adult yellow-footed rock wallabies, *Petrogale xanthopus* (one male and three female, ranging from 5.10 to 5.50 kg body mass) were trained to hop through a straight runway with no obstacles and through a runway containing a jump 1.10m high. High-speed video recordings (Photron Fastcam-X 1280 PCI) and ground reaction force measurements from a runway mounted force platform (Kistler type 9286AA) were used to calculate whole body power output and to construct a simple mass-spring type model to determine whole limb mechanics. The combined mass of the hind limb extensor muscles was used to estimate muscle mass-specific power output.

Changes in mechanical energy and whole body power outputs were calculated via integration of the vertical and horizontal ground reaction forces [2]. The legs were modeled as a spring in series with a linear actuator and the body was considered to be a point mass located at the ilium point, which was a proxy for the position of the CoM. The actuator in this model can only produce positive work, and it is assumed that all of the negative energy associated with leg spring compression is recovered elastically. Leg stiffness was determined at the point of maximum leg compression.

### RESULTS AND DISCUSSION

Net extensor muscle power outputs averaged  $155 \text{ W kg}^{-1}$  during steady hopping and  $495 \text{ W kg}^{-1}$  during jumping (Figure 1). The highest net power measured reaching nearly  $640 \text{ W kg}^{-1}$ . As these values exceeded the maximum power producing capability of vertebrate skeletal muscle [3], it was determined that back, trunk and tail musculature likely played a substantial role in contributing power during jumping. Inclusion of this musculature produced a maximum power output of  $452 \text{ W kg}^{-1}$  muscle.

Similar to human high-jumping, rock wallabies used a moderate approach speed (not significantly different than

**Figure 1.** Mean power output during stance normalized to body mass ( $M_b$ , left axis) and hind limb extensor muscle mass (right axis). Horizontal dashed lines represent the net power produced during stance.

steady hopping) and a relatively shallow leg angle of attack ( $45\text{-}55^\circ$ ) during jumps [4]. Leg stiffness increased nearly twofold in jumping (steady:  $2.98 \text{ kN m}^{-1}$  vs. jumping:  $5.50 \text{ kN m}^{-1}$ ), which facilitated the transfer of horizontal kinetic energy into vertical kinetic energy. Time of contact was maintained during jumping despite greater leg stiffness and smaller leg excursions by a substantial extension of the leg, which kept the foot in contact with the ground. Additionally, rock wallabies appeared to minimize potential pitching moments by adjusting their leg angle to match the angle of ground reaction force vector.

### CONCLUSIONS

Our results clearly show that rock wallabies are capable of producing very high power outputs. For the jumps recorded in this study, estimates of muscle mass-specific power output ( $450 \text{ W kg}^{-1}$  muscle) suggest that all of the musculature of the legs, back and tail were recruited to produce jumps and that power output is near the maximum expected for vertebrate skeletal muscle. However, whether this comes at the expense of tendon and aponeurosis strain energy savings by rock wallabies during steady level hopping requires a more detailed kinetic analysis of their level hopping mechanics.

## ARM FRACTURE IN CHILDREN'S FALLS

<sup>1</sup>Peter L. Davidson, <sup>1</sup>David J. Chalmers and <sup>2</sup>Barry D. Wilson

<sup>1</sup>Department of Preventive and Social Medicine, <sup>2</sup>School of Physical Education

University of Otago, Dunedin, New Zealand; email: peter.davidson@ipru.otago.ac.nz, web: www.otago.ac.nz/ipru/

### INTRODUCTION

Arm fractures in children are a significant public health problem in New Zealand and other industrialized nations. Computer simulation has been used to model the risk of arm fracture in children as a function of fall height, surface stiffness and damping, child age and fracture history; taking into account physical properties of children such as body weight, arm stiffness, bone density and bone size [1]. This 'biomechanical impact model' generated a 'Factor of Risk' (FR) ratio of the impact force to the fracture force. The model was validated using data gathered for an epidemiological case-control study of falls from playgrounds [2]. The FR values were found to be significantly associated with the actual fracture probability (FP) and an 'injury risk curve' was generated to predict fracture probabilities for given values of FR [3]. The purpose of the current study was to use the biomechanical impact model and the injury risk curve to predict distal radius fracture for a series of playground fall scenarios. This study assessed the risk relationship between child age, equipment heights and surfaces currently used in playgrounds in New Zealand and other countries with the aim of providing information on which to recommend measures for reducing arm fractures in falls from playground equipment.

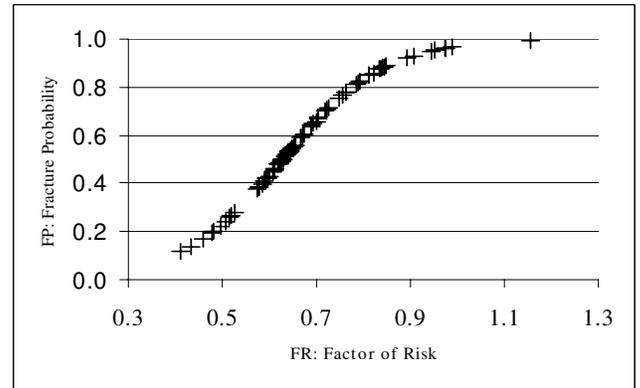

Figure 1: Injury Risk Curve [3].

### METHODS

Playground fall scenarios were defined by child age (5, 9 and 13.5 years of age), fall height (0.5 to 3m at 0.5 m intervals), and surface type. The surface types are listed in Table 1. These scenarios were chosen to represent the range of fall situations that are expected to be encountered at typical playgrounds. FR values were generated for each of the fall scenarios using the biomechanical model, with FR being the estimated impact force (based on the child's age and mass; fall height and surface impacted) divided by the estimated fracture force (based on the child's age and fall height dependent strain rate). The biomechanical model is a rheological two-mass model with the wrist and shoulder joints represented as linear spring and damper elements [1, 4]. The impact properties of children's joints were derived from a gymnastic study of head-first wrist impacts [5] and surfaces were modeled as linear or exponential springs [3]. Presented here are analyses conducted for the high-frequency force component representing the initial hand impact. FP values as a function of FR were derived from the injury risk curve (Figure 1) [3].

### RESULTS AND DISCUSSION

The fall scenarios for a child aged 9 are listed in Table 1. Surfaces are listed in order of decreasing risk. Earth, grass, rubber mats and dry 15cm deep bark chips produced very similar risks. Wet bark produced a lower risk compared to dry bark, likely due to an increased energy absorbing capacity. The scenarios for ages 5 and 13.5 years of age produced similar pattern of results but with lower and higher values respectively, compared to 9 years of age. Risk increased dramatically with fall height with 3m falls having a high probability of arm fracture. Due the limitations of the case-control study upon which the injury risk curve was based; the model is limited to falls onto a single arm and that are serious enough to require attention (medical or reassurance) by a caregiver.

### CONCLUSIONS

This study showed that non-rigid surfaces typically used playgrounds give similar risks of fracture and this risk reached high values for 3m fall heights. This study demonstrates how the biomechanical model is a valuable tool in evaluating interventions aimed at reducing arm fractures in children.

## INTRODUCTION

In this study, we propose a new method to simulate human gait motion when muscles are weakened. The method is based on the enhanced version of 3D linear inverted pendulum model that is used for generation of gait in robotics. After the normal gait motion is generated by setting the initial posture and the parameters that decide the trajectories of the center of mass and angular momentum, the muscle to be weakened is specified. By minimizing an objective function based on the force exerted by the specified muscle during the motion, the set of parameters that represent the pathological gait was calculated. By using our method, it is possible to find out the general idea how an impairment of a muscle can affect biped gait. By doing further concise modeling of the musculoskeletal and development of techniques to import parameters from individual humans, it will be possible to use the proposed method for analysis, diagnosis, and rehabilitation training of patients with impairments at the muscles. The effects of weakening the gluteus medialis were analyzed. Important similarities were noted when comparing the predicted pendulum motion with data obtained from an actual patient

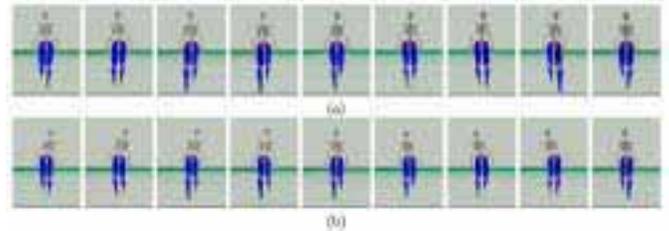

## METHODS

The 3D Linear Inverted Pendulum Mode [1], a method to plan biped locomotion of robots, was enhanced so that angular momentum can be generated around the center of mass. Since angular momentum is consistently generated around the center of mass when human perform gait motion, this function is essential to generate gait motion similar to humans. This model is called Angular Momentum inducing inverted Pendulum Model (AMPM). Using AMPM, the human gait was modeled. We then introduce a method to combine using the musculoskeletal model with AMPM. A musculoskeletal model based on Delp's data [2] was prepared to estimate the muscle force by using static optimization [3]. The gait motion was first modeled using AMPM, and then the motion was tuned by changing the parameters that define the behavior of AMPM by optimizing a criteria based on the musculoskeletal dynamics.

## RESULTS AND DISCUSSION

To examine the validity of the method proposed in this paper, we have generated normal and pathological human gait motion using our method, and compared the kinematical and dynamical data with those by humans. A set of AMPM parameters that produce a gait motion with a step length of 0.6 m and velocity of 1 m/s were used. By minimizing an objective function based on muscle dynamic, the effects of

weakening the gluteus medialis, was simulated. As the optimization proceeds, features known as lateral trunk bending appears in the motion. The trunk swings from one side to the other, producing a gait pattern known as waddling. During the double support phase, the trunk is generally upright, but as soon as the single support phase begins, the trunk leans over the support leg, returning to the upright attitude again at the beginning of the next double support phase.

**Figure 1** The trajectory of the AMPM-generated motion before (a) and after (b) the optimizing an objective function based on gluteus medialis.

The method proposed in this study has the following advantages compared with previous methods:

- Since the gait motion is described by the AMPM parameters, there is no need to specify all the input parameters of the muscles. As a result, the computational cost for the optimization is much less than previous methods.
- As the balance of the human body model is explicitly kept by using the AMPM model, the optimizer only needs to search for the optimal set of parameters in terms of muscle force, and hence does not need to go through a large number of trials to generate the balanced motion.

## ADAPTIVE CHANGES IN LOWER LIMB COORDINATION IN RESPONSE TO UNILATERAL LOADING DURING TREADMILL LOCOMOTION

Jeremy W. Noble and Stephen D. Prentice

Gait and Posture Lab, Department of Kinesiology, University of Waterloo, Waterloo, ON, Canada.  
email: [jwnoble@uwaterloo.ca](mailto:jwnoble@uwaterloo.ca)

### INTRODUCTION

In order for the Central Nervous System (CNS) to effectively control the movement of the limbs during locomotion it must have sufficient knowledge of the mechanical properties of the lower limb. With this knowledge the CNS is able to coordinate actions at the three major joints of the lower limb to provide safe and effective locomotion. Previous studies have manipulated limb mechanics by placing an additional mass on the lower limb and reported the changes in limb kinematics and kinetics [1,2]. However none of these studies have examined the resulting disruptions in interjoint coordination in the lower limb when the mechanical properties of the limb were altered. The goal of this study was to determine how interjoint coordination is affected during the adaptation to addition of mass to the limb, and its subsequent removal.

### METHODS

Participants (n=8) were instructed to walk on a treadmill moving at 1.56 m/s for three 5 minute trials (PRE, WEIGHT, POST). During the WEIGHT condition a 2 kg mass was placed at the centre of mass of the leg segment of the left lower limb. Bilateral limb and trunk kinematics were obtained from an OPTOTRAK system (Northern Digital Inc., Waterloo ON) and infrared emitting diodes placed on anatomical landmarks defining a seven segment representation of the limbs and trunk.

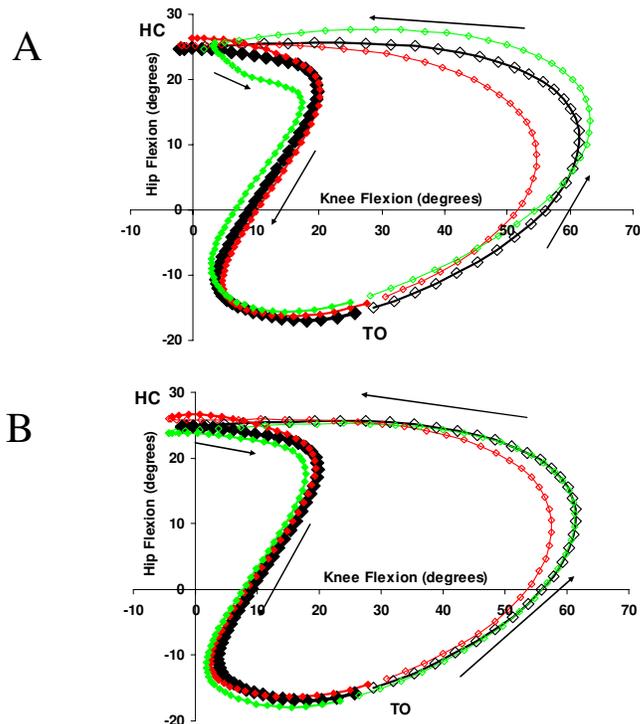

Segment and joint kinematic time histories were determined using the conventions described by Winter [3] and net joint moments the sagittal plane were calculated at the ankle, knee and hip joints during the swing phase using standard inverse dynamics [3]. Time series data from the WEIGHT and POST conditions was then averaged into bins of five consecutive strides so that the time course of the adaptation to the mass could be analyzed. In order to investigate interjoint coordination between the hip and knee joints knee vs. hip angle plots were determined for each stride.

### RESULTS AND DISCUSSION

During the PRE condition the Hip vs. Knee angle graphs were similar to those previously reported [4]. With the added mass, there was decrease in knee flexion during the swing phase of the first bin of 5 strides although the range of hip motion was similar to the PRE condition. Once accustomed to the mass the swing phase of the angle-angle plot approached that which was observed in the PRE condition however knee flexion never fully returned to that observed in the PRE condition.

When the mass was removed the peak angles observed at both the hip and knee joints during the swing phase were greater than the PRE condition. There was also a period of additional hip extension during early stance. This extra hip extension

during weight acceptance diminished over the first 25 strides of the POST condition.

**Figure 1:** Hip vs. Knee Angle Plots comparing the first (A) and 25<sup>th</sup> (B) bins of the WEIGHT (Red) and POST (Green) to the mean of the PRE (Black) condition.

### CONCLUSIONS

Adaptive changes in knee-hip coordination were observed primarily during the swing phase when the mass would have the greatest effect. Early exposure to the weight (or its removal) brought a disruption to the normal coordination between the knee and hip which returned close to PRE coordination within 25 strides. Additional changes in the coupling between the knee and hip during weight acceptance following the removal of the mass would indicate the influence of swing limb mechanics upon the actions of weight acceptance.

## ANKLE MUSCULAR ACTIVITY DURING LANDING IN VOLLEYBALL PLAYERS WITH FUNCTIONAL INSTABILITY

Eneida Yuri Suda<sup>1,2</sup>, Carla Sonsino Pereira<sup>2</sup> and Isabel de Camargo Neves Sacco<sup>2</sup>

<sup>1</sup> Centro Universitário Capital, Physical Therapy Course

<sup>2</sup> Physical Therapy, Speech and Occupational Therapy Department, School of Medicine, University of São Paulo – São Paulo – Brazil; email: yurisuda@usp.br

### INTRODUCTION

The ankle sprain is one of the most common injuries in athletes, particularly in sports in which participants frequently jump and land on one foot like the volleyball. 90% of ankle injuries in volleyball occur during landing after a blocking maneuver. The most common complication following ankle sprains is functional ankle instability (FI) that has been defined as a tendency for the foot to give away after an ankle sprain with no evidence of ligament injuries [1]. The pathogenesis of FI is considered to be multifactorial, with mechanical, muscular, and sensorimotor factors playing a role [2]. The purpose of this study was to compare the muscle activation patterns of selected ankle muscles of volleyball athletes with and without FI performing a landing after the blocking maneuver. We believe that subjects with functional ankle instability present different patterns of muscular activation when compared with normal ones.

### METHODS

Nine subjects were studied (age 24.1±3.1 years). Four had complaints of FI with no clinical evidences of mechanical injury and were considered as the functional instability group (FIG). Five subjects had no complaints about instability and had no history of lower limbs injuries and were considered as the control group (CG). All subjects were professional or recreational volleyball players. Surface electromyography were collected from peroneus longus (PL), tibialis anterior (TA) and gastrocnemius lateralis (LG) muscles while subjects performed a jump in the volley blocking. Electrodes were placed on the muscle belly, far away from the innervation zone [3]. The task was performed 8 times and a synchronized electrogoniometer signal placed on the ankle allowed the recognition of the landing phase. The RMS values and temporal variables in linear envelopes, both normalized by each subject's maximal voluntary isometric contraction (MVIC), were obtained for each muscle. The linear envelope's variables obtained were TA maximum peak, TA minimum peak, PL maximum peak and GL maximum peak. Groups were compared using t test for independent samples when normal distribution was present, and Mann-Whitney tests when the data was not normal. We adopted p value lower than 0.05.

### RESULTS AND DISCUSSION

**Table 1:** RMS values (% of MVIC) and linear envelope variables (% of movement cycle) for TA, PL and LG muscles of CG and FIG.

Muscle	RMS			Envelope variables	Linear envelope variables		
	CG	FIG	p		CG	FIG	p
TA	83,51±7,8	66,73±3,7	0,002*	TA max peak	20,56%±1,429%	13,22%±1,85%	0,009*
PL	45,12±3,07	49,11±3,45	0,301	TA min peak	39,66%±2,256%	44,96%±3,979%	0,56
GL	48,7±3,99	44,2±3,81	0,504	PL-max peak	14,47%±1,653%	14,06%±1,912%	0,165
				LG-max peak	13,90%±1,695%	3,125%±1,564%	0,000*

Results are displayed in Table 1. The RMS values showed significant differences in TA muscle activation between groups but not in the PL or LG muscles. The PL is a potentially critical muscle in preventing ankle sprains injuries as a protective mechanism to balance inversion [4], but interestingly we observed a significant difference only in the TA muscle: a lower activation in FIG subjects. TA is also an important muscle in preventing ankle sprains by impeding excessive plantar flexion, a primary mechanism in ankle sprain injuries since the inversion movement has a plantar inversion component associated [4]. The linear envelope variables showed that TA has an earlier peak of activation in FIG subjects; therefore this TA activation is statistically lower than the CG. A study showed a decrease in onset latency for the TA muscle after 8 weeks of proprioceptive training [5]. Although our subjects hadn't been specifically trained, they are active athletes and this pattern may be due to a compensatory learning. We can also observe that subjects in FIG had an earlier LG peak of activation than the control ones. This activation can help individuals to diminish impact during landing and it can also be due to a compensatory pattern. If the LG is activated earlier, the TA as an antagonist also has to be active earlier in order to counteract the LG action. This GL earlier activation can also predispose the individuals with FI to an inversion sprain since a more plantar flexion position during landing can predispose the individual to an inversion sprain.

### CONCLUSIONS

Our results showed that individuals with FI have a muscle activity pattern that predisposes to an ankle inversion sprain since subjects in FIG showed a lower TA activation during landing when compared to controls. Besides that subjects with FI also showed an activation pattern probably compensatory, with TA and GL muscles activating earlier.

### INTRODUCTION

Musculoskeletal disorders in the neck and shoulder regions of female computer users are a major occupational concern in the European countries and the incidence of disorders increases with age and hours of work per week. It has been reported that neck shoulder cases (NS-cases) compared to neck shoulder controls (NS-controls) have a significantly lower muscle strength and a lower muscle activation measured as a lower EMGrms value at the same relative force demand [1]. This finding supports the pain adaptation model supposed to protect the painful muscle from further activity by an inhibitory effect of pain. In contrast, another study has reported an increased trapezius activity during computer tasks in the NS-cases compared to controls evaluated from the total number of motor unit action potentials (MUAP) per second [2]. Such an activity pattern would be in agreement with the vicious circle theory suggesting a pain induced increase in activity in the painful muscle. The aim of the present study was to investigate if the results of a decreased muscle strength and lower activation in a large field study of subjects with and without neck-shoulder pain can be supported by an analysis on single motor unit (MU) level during a typing and editing task in a sub sample of the study population.

### METHODS

Two groups of computer users were recruited: 88 NS-cases, who reported trouble in the neck and/or shoulder region for more than 30 days during the last year, and 164 NS-controls who reported trouble in the neck and/or shoulder region for no more than 7 days during the last year. Their mean (SD) values were: age 53 (5) years, height 1.66 (0.06) m, weight 70 (14) kg with no significant difference between NS-cases and NS-controls. An adhesive electrode array composed of eight linearly arranged bar electrodes (size 1x5 mm, 5mm inter electrode distance) was placed on right upper trapezius muscle attempting a position distal to the endplate zone without covering the tendon. Measurements started with a bilateral MVC of the trapezius muscle during shoulder elevation and a 30% MVC test. Further, the subjects performed a 10 min typing and editing task. EMGrms was calculated using an inter electrode distance of 20 mm. On a sub sample of 11 cases and 19 controls MUAP were detected in the typing and editing composite EMG signals with a wavelet based method, separating action potentials from the background noise. MUAP rate is defined as the total number of action potentials divided by the total activity time. A MU was defined when at least 20 action potentials could be allocated to the same MU. Of the total number of action potentials a fraction of 20.8 (19.2) % for cases and 30.8 (18.1) % for controls, could be clustered into single MU.

### RESULTS AND DISCUSSION

In the large group of NS-cases and NS-controls a significantly lower MVC was found for the NS-cases (mean 310 (122) N) compared to the NS-control (mean 364 (122) N). In the sub sample the corresponding values were 400 (88) N and 395 (136) N with no significant difference. During the 30% MVC test a significantly lower EMGrms was found both in the large group (NS-cases =194 (105) $\mu$ V vs. NS-controls 256 (169) $\mu$ V) and in the sub sample group (NS-cases= 195 (77)  $\mu$ V vs. NS-controls= 248 (93) $\mu$ V). However, in the more functional typing and editing task similar levels of EMGrms were found in NS-cases and NS-controls. This was supported by the more detailed muscle activity analysis in the sub sample. From the right trapezius muscle a total of 4938 (2836) and 4852 (3480) MUAP per subject was detected in NS-cases and NS-controls, respectively. MUAP rate, the combined measure of MU number and firing rate, was similar, being 10.8 (6.1) MUAP per sec in NS-cases and 11.7 (5.3) MUAP per sec in NS-controls. A total of 22 MU were defined for NS-cases and 44 MU for NS-controls giving a mean of 2 MU per subject in both groups. For each subject mean values of the properties of the detected MU were calculated. Table 1. presents the results as group mean (SD). Only MUAP area was significantly different between the groups.

Table 1.

	NS-Cases	NS-Controls
No. of MUAP per MU	612 (560)	915 (820)
MU Activity duration (s)	312 (173)	258 (163)
MUAP Area (mV*s)	0.774 (0.382)*	1.136 (0.762)
MUAP MPF (Hz)	112 (13)	107 (15)

\* indicates significant difference between cases and controls ( $p < 0.05$ )

### CONCLUSIONS.

In the present study lower muscle activation, measured as EMGrms, in NS-cases compared to NS-controls was found both in the large study group and in a sub sample during a 30%MVC. In contrast, for the more functional typing and editing task, neither EMGrms nor MUAP rate, could confirm a lower level of activation in NS-cases. The significantly smaller MUAP area for NS-cases may indicate a selective recruitment of smaller MU or a pain related change in properties such as fibre diameter of the low threshold MU for the NS-cases.

## QUANTIFYING UPPER LIMB MOTOR CONTROL: THE PEG IN HOLE TEST

Germano T. Gomes, Farshid Amirabdollahian, Garth R. Johnson  
CREST, University of Newcastle  
email: [G.T.Gomes@ncl.ac.uk](mailto:G.T.Gomes@ncl.ac.uk), web: <http://www.ncl.ac.uk/CREST>

### INTRODUCTION

The *I-match* project ([www.i-match.org](http://www.i-match.org)), funded by the European Commission under the Information Society Technologies program, is a three-year project that began in 2002. It focuses on quantifying user's upper limb performance and skills in order to aid in selecting the most suitable interface for use with an assistive device. Within this project a new technique, the 'Peg in Hole Test' was developed making use of virtual reality and haptic robotics in order to access motor control.

The Peg-in-Hole assessment is essentially a 3D movement task presented in a virtual space (Figure 1). It has a simple geometry and objective. It consists of a table with two cylindrical holes and one cylindrical peg that is to be placed in the holes alternately using the hand. It is inspired by the validated, used in clinical assessment, Nine-Hole-Peg-Test [1].

### METHODS

The PHANToM haptic interface (SensAble Technologies, USA) was used. It offers 3 active and 3 passive degrees of freedom. The orientation of the virtual peg follows that of the PHANToM stylus in real-time. Shadow cues are used to provide better depth perception and a novel collision detection algorithm was developed, allowing for multiple contacts points between the peg, the table and holes and the walls thus adding realistic touch feeling. The peg insertion and removal is preceded by a guiding arrow and a beep sounds at each successful peg insertion. It is possible to modify, on the fly, the peg diameter, peg height and weight, hole diameter, separation between holes and clearance (peg vs. hole).

A pilot study involving 12 healthy subjects (6 females, 6 males, age  $32 \pm 8$ ) was conducted. Subjects were instructed to (starting from mid-position) insert the peg into the left hole, remove it and insert it into the right hole as quickly as possible while trying to minimise the collision with the table and the walls of the holes. This was performed 20 times (10 cycles) before moving to the next experimental setting.

Two virtual tables were selected: one with a separation between holes of 50mm and the other 150mm. The diameter of the holes was set at 20, 30 and 40mm. Two peg weights were used: one with simulated weightless (0 N) and the second with a weight of 0.981N (~100g). The virtual peg diameter was set constant at 10mm. These combined variables made for a total of 12 different testing conditions.

Data was logged at an average sampling frequency of 1000Hz. Forces, positions, orientations and velocities were recorded. In order to exclude learning effects, only 5 full cycles were analysed (cycles 4 to 8) for each of the 12 settings.

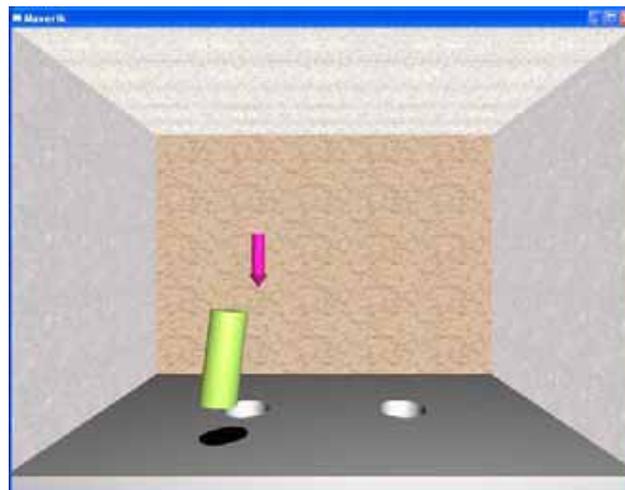

Figure 1: The Peg-in-Hole test

### RESULTS AND DISCUSSION

The following results were calculated from the 144 tests: time of each full cycle, time of left-to-right and right-to-left half-cycles, FFT, spread of velocities, collision energies, spread of positions at mid-travel and at insertion for right and left holes, deviation of Y positions from a straight line and deviations from Fitts law [2].

All frequencies were below 0.5Hz and corresponded to the gross movement (no tremor). Adding weight appeared to lower collision energy. The accuracy and repeatability of the movements were analysed using the distribution of positions (error and STD) at bottom of right and left holes ( $z=0$ ), these varied with the clearance and the side considered.

X-Y plots showed a consistent double arched pattern clearly different from the expected shortest projected path (straight line fits produced  $RMSE > 0.8$ ). Fitts 'law' failed to apply, the movement time did not correlate linearly to index of difficulty.

### CONCLUSIONS

It appears that a more compressive measure of "difficulty" of a task must be introduced. Real world human arm movement tasks are in nature 3D, have a goal, might involve obstacle avoidance and eventually face collisions. The Peg-in-Hole test, despite its simplicity, has embedded in its design all of these factors and as such can be a powerful tool in studying and accessing general upper limb movement. A single compounded factor involving collision energy, duration of collisions, repeatability, accuracy and cycle time of the movement may prove to be a more realistic measure of quality or difficulty of these movements.

## A MUSCULOSKELETAL MODEL OF POSTURAL CONTROL AT THE ANKLE

Christopher J. Hasson, Jeff L. Gagnon, Richard E.A. van Emmerik, and Graham E. Caldwell

Biomechanics and Motor Control Laboratories, University of Massachusetts, Amherst, USA; E-mail: cjhasson@excsci.umass.edu

### INTRODUCTION

Changes in postural stability associated with the aging process may be due to alterations in neural, skeletal and muscular characteristics. The effects of such changes are difficult to study experimentally, as they typically occur over a long time period. Therefore, many have studied postural control using analytical or numerical models, such as the simple inverted pendulum [3]. However, most models do not incorporate specific representation of the individual muscles involved in the balance process. The purpose of this paper is to describe a musculoskeletal model for studying control of sagittal plane postural sway at the ankle [3]. Development of this model will allow the study of how age-related changes in muscular properties will affect postural control.

### METHODS

For initial testing of the model, experimental data were collected on a single male subject undergoing voluntarily upright sway in the sagittal plane at a frequency of  $\sim 1/3$  Hz for 20 s. Center of mass motion (CoM) was measured in 3-D with an eight-camera Qualysis™ system, center of pressure (CoP) was measured with two AMTI™ force platforms, and muscle activity of the right limb soleus (SO), gastrocnemius (GA), and tibialis anterior (TA) muscles was recorded with a Delsys™ electromyography (EMG) system. Segment lengths were measured, and their masses and inertial characteristics were estimated with standard anthropometric scaling.

The musculoskeletal model was comprised of two segments representing the feet and rigid body, linked by a frictionless hinge ankle joint, confined to sagittal plane movement. The model's segment anthropometrics were matched to the subject. The equations of motion for the model were found with Autolev™, and can be expressed in general form as:

$$A(\theta)\alpha = B(\theta, \omega) + gC(\theta) + F_A + F_C$$

where  $\theta$ ,  $\omega$  and  $\alpha$  are vectors of segment angle, angular velocity and angular acceleration respectively;  $A(\theta)$  is the inertia matrix;  $B(\theta, \omega)$  is the vector describing Coriolis and centrifugal effects;  $gC(\theta)$  defines the gravitational effects; and  $F_A$  is the net ankle joint torque.  $F_C$  represents foot-floor constraint forces, modeled with a series of 21 spring-damper elements along the length of the foot [1]. The ankle torque was generated by three Hill-type models representing the SO, GA, and TA muscles. Each Hill actuator consisted of non-linear series elastic and contractile components, with model parameters drawn from the literature. The experimental EMG signals were rectified, smoothed, and scaled to use as control signal shape templates for the Hill models. Muscle lengths and moment arms were computed using subject-scaled polynomial functions of joint angle modeled from SIMM™.

A variable step-size Runge–Kutta–Merson integrator was used to simulate the model motion, using initial conditions from the experimental data. A differential evolution genetic algorithm [2] was used to find the control signal scaling levels ( $\lambda$ ), which

maximized the time the model was able to remain upright. The same  $\lambda$  was used for SO and GA. Model performance was assessed by comparison of CoM and CoP time series with experimental data. Model sensitivity was studied by changing maximum isometric force ( $P_0$ ) values in the Hill muscle models using five different literature sources (Table 1).

### RESULTS AND DISCUSSION

The model was able to stay upright for the entire 20 s trial, indicating that the muscle models, control signals, and foot-floor interaction were realistic. The shape of the model's CoM and CoP motion closely matched the experimental data, with the major difference being that the model did not “lean back” as far as the subject (Figure 1).

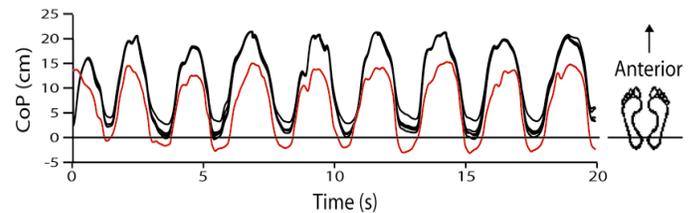

Figure 1. Experimental (thin / red) and model (Mod 1 to Mod 5; black) CoP sagittal displacement referenced to the ankle joint.

Optimized  $\lambda$  values (Table 1) and simulation performance were sensitive to the  $P_0$  values used for the Hill actuators. With increases in the absolute TA  $P_0$ , the model leaned back farther as measured by its CoM minimum ( $r = -.94$ ). Weaker relationships were found between the SO ( $r = -.57$ ) and GA ( $r = -.70$ )  $P_0$  values and the model CoM minimum. Although the TA  $P_0$  values had a large range (1253 to 3114 N), the optimized  $\lambda$  values did not (0.72 to 0.82). The SO / GA  $\lambda$  values varied more (0.48 to 0.75). This suggests that the model results were dictated by the dorsiflexor TA. With a weaker TA, the model kept its CoM farther in front of the ankle joint to prevent unstoppage backward sway that would result in falling. Future work on age-related changes in muscular properties will focus on the inclusion of subject-specific parameters using MRI and ultrasound technology.

Table 1. Optimization parameters and results.

	Actuator	Mod 1	Mod 2	Mod 3	Mod 4	Mod 5
$P_0$ (N)*	SO	8367	8674	6976	5377	5898
	GA	5039	4854	4850	2869	3116
	TA	3114	2867	2303	2295	1253
$\lambda$	SO, GA	0.49	0.48	0.53	0.75	0.70
	TA	0.72	0.74	0.82	0.73	0.80

\*Model  $P_0$  sets [Mod 1 to Mod 5] drawn from studies in the literature.

## GROUND REACTION FORCES DURING LEVEL WALKING WITH AND WITHOUT LATERAL HEEL WEDGE ORTHOTICS

David A. Wallace, and Rod A. Harter  
 Sports Medicine Laboratory, Oregon State University, Corvallis OR  
 email: [wallaced@onid.orst.edu](mailto:wallaced@onid.orst.edu),

### INTRODUCTION

Osteoarthritis (OA) affects an estimated 21 million Americans and is responsible for more than 7 million physician visits per year. Knee OA is a debilitating condition that frequently transforms physically active individuals into sedentary persons. Heel wedge orthotics are designed to mechanically lower the magnitude of the tibiofemoral joint loads in order to reduce pain and disability in knee OA patients. Heel wedge orthotics have been shown to effectively reduce knee pain<sup>1</sup> but few studies have compared the ground reaction forces of both medial and lateral orthotics. The purpose of this study was to characterize the effects of medial and lateral heel wedge orthotics on peak ground reaction forces during level walking.

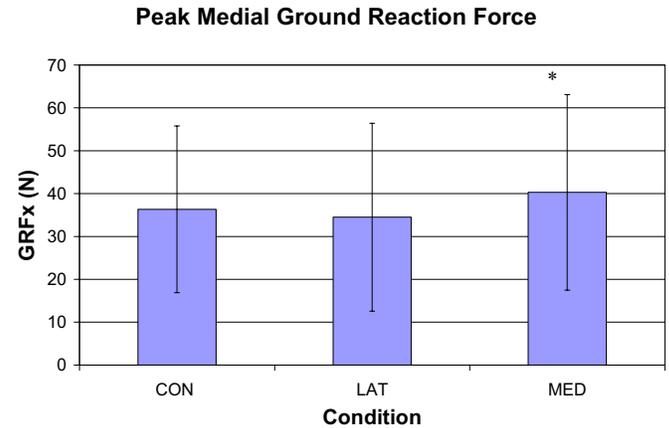

### METHODS

Ten healthy volunteers (6 females, 4 males; mean age, 24 ± 7 yr) with no history of knee injury participated in the study. Three-dimensional kinematic data (6-camera, Vicon Motion Systems, 120 Hz) and ground reaction forces (2 Kistler force plates, 1080 Hz) were collected as subjects ambulated at a self-selected pace along a 10m walkway. Each subject was tested under 3 conditions (10 trials per condition): lateral wedge (LAT), medial wedge (MED) and no wedge (CONTROL). The order of testing was selected randomly.

Peak ground reactions forces in the medial (GRF<sub>x</sub>), anterior (GRF<sub>y</sub>) and vertical (GRF<sub>z</sub>) directions were analyzed from the initial contact to mid-stance phase of the gait. Force data was filtered using a second order recursive Butterworth filter with a 50Hz low-pass cutoff frequency. For reach direction of force, a repeated measures ANOVA was used to detect differences between three conditions. When appropriate, Bonferroni *post-hoc* tests were employed to determine significant differences between pairs of the three conditions.

### RESULTS AND DISCUSSION

Peak GRF<sub>x</sub> was significantly higher in the MED condition compared to both the LAT (p=.0005) and CONTROL conditions (p=.0025). Although the LAT condition tended to be lower than the CONTROL, no significant differences were determined (p>0.05). There were no significant differences between conditions found in either peak GRF<sub>z</sub> or peak GRF<sub>y</sub> (p>0.05).

\* Significant difference between MED and both CON and LAT

### CONCLUSIONS

These data suggest that heel wedge orthotics can effectively alter ground reaction forces during gait. In the current study, the application of a medial heel wedge created a much larger medially directed force during the initial loading phase of gait thus potentially increasing the varus joint torques of the lower extremity. However, in agreement with previous studies, the orthotics did not reduce vertical peak forces.<sup>2</sup> Previous studies have suggested that lateral heel wedge orthotics reduce the varus joint torque at the knee.<sup>3</sup> These findings suggest the mechanism by which this occurs is through a change in the medial/lateral ground reaction force rather than by a reduction in the magnitude of the vertical ground reaction force.

## EXPLANATION OF THE BILATERAL DEFICIT IN HUMAN VERTICAL JUMPING

Maarten F. Bobbert, Wendy W. de Graaf and Jan N. Jonk

Institute for Fundamental and Clinical Human Movement Sciences, Vrije Universiteit, Amsterdam, The Netherlands;  
email: M\_F\_bobbert@fbw.vu.nl

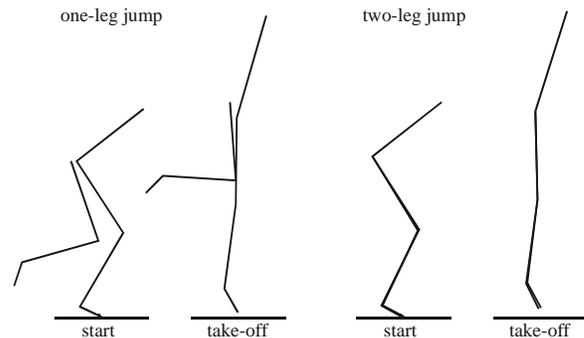

### INTRODUCTION

In the literature, it has been reported that in two-leg jumps, humans achieve less than twice the jump height and work they are able to achieve in a one-leg jump [1, 2]. The seemingly submaximal performance in two-leg jumps has been coined bilateral deficit. It has been speculated that the deficit is primarily caused by a reduction in neural drive to the muscles in the two-leg jump and only secondarily by differences in non-neural factors [1, 2]. The purpose of the present study was to investigate the contribution of differences in active state and shortening velocity to the bilateral deficit in vertical squat jumping. For this purpose, we performed experiments on human subjects and simulations with a forward dynamic model of the musculoskeletal system.

### METHODS

Eight male subjects performed maximum height vertical jumps, pushing off with only their right leg or with both legs together. In the one-leg jumps, the left leg was kept as passively as possible. Except for the position of the left leg, the initial body configuration was the same in both types of jumps (Figure 1). Kinematics and ground reaction forces of the individual legs were collected at 200 Hz, and EMG activity was recorded at 1000 Hz from soleus, gastrocnemius, vasti, rectus femoris, glutei and hamstrings of the right leg. Off-line, the EMG signals were high-pass filtered, rectified and low-pass filtered at 5 Hz to produce SREMG (Smoothed Rectified EMG). Inverse dynamics was used to calculate work produced by the right and left leg during the push-off.

One- and two-leg jumps were also simulated with a forward dynamic model of the musculoskeletal system [3]. The model had 7 rigid segments (foot, shank and thigh of each of the two legs and a head-arms-trunk segment), and was actuated by 15 muscle-tendon complexes (MTC): soleus, gastrocnemius, vasti, rectus femoris, glutei and hamstrings of the left and right leg, and tibialis anterior, short head of biceps femoris and iliopsoas of the left leg. Each MTC was represented as a Hill-type unit. The model calculated the segmental motions corresponding to stimulation (STIM) input to the muscles. Initial STIM levels were chosen such that static equilibrium was achieved in the starting position, which was close to that of the subjects. Subsequently STIM of each muscle was allowed to switch between "on" and "off" several times, and switching times were optimized to find maximum jump height using a parallel genetic algorithm. Once the optimal solutions had been found for the one-leg and two-leg jumps, we used them to determine the cause for differences in muscle work performed. We estimated the effect of differences in active state by substituting at each MTC length in the two-leg jump the active state at the same MTC length in the one-leg jump, and subsequently re-calculating muscle force and work (this step will be called: correction for active state). The same procedure was followed to estimate the effect of differences in CE velocity (correction for CE-velocity).

**Figure 1:** Average initial and take-off body configurations of the subjects in the one-leg and two-leg jumps.

### RESULTS AND DISCUSSION

No differences occurred between the two types of jumps in the range over which the subjects extended the joints of their right leg (Figure 1). Obviously, in the two-leg jump, greater velocities were reached and the range of motion was traveled in less time than in the one-leg jump. Mean vertical displacement in the airborne phase was 23.7 cm in the two-leg jump and 12.6 cm in the one-leg jump. Work performed by the right leg was 195 J in the two-leg jump and 248 J in the one-leg jump. Ratio's of peak SREMG values in the two-leg jump to peak SREMG values in the one-leg jump, averaged over all subjects, ranged from 0.9 to 1.0 for the different muscles, suggesting that any reduction of neural drive in the two-leg jump was at best minimal. In the simulation model, the work performed by the right leg was 160 J in the two-leg jump and 234 J in the one-leg jump. In the model, the difference in work output of the right leg was, of course, completely caused by non-neural factors. Correction for active state caused the work in the two-leg jump to increase by 24 J, while correction for CE-velocity caused it to increase by 58 J. This shows that the differences in active state and shortening velocity between two-leg jumps and one-leg jumps can have a substantial effect on the force and work output of the muscles.

### CONCLUSIONS

SREMG-results indicate that at best a minimal reduction in neural drive occurred in two-leg jumps compared to one-leg jumps. However, in a two-leg jump, initial active state is lower than in a one-leg jump and less time is available to increase active state. Moreover, the muscles travel their range of shortening at greater speed. In the model, these two factors combined caused the muscles to produce substantially less work in the two-leg jump than in the one-leg jump. It seems that the bilateral deficit in jumping is primarily caused by non-neural factors rather than by a reduction in neural drive.

### INTRODUCTION

Judo is an Olympic sport modality based on a straight combat between two athletes, whose main objective is to dominate the adversary leading him to knock down. The achievement of a good performance requires the development of athletes' equilibrium and muscular force [1]. The role of balance is enhanced by the end of the fight with the disequilibrium of one of the adversaries, followed by his immobilization or giving up. According to the judo techniques, athletes are constantly subjected to unexpected movements imposed by their adversaries with the objective of creating opportunities to break their equilibrium to define the combat [2]. This modality leads the athlete to develop new sensorial-motors strategies and mental abilities that contribute to improve his postural control [3]. This study aimed to test the hypotheses that athletes of this modality presents better postural control in responses to unexpected perturbation than a healthy and recreationally active young group.

### METHODS

Ten skilled male judo athletes and ten healthy and recreationally active young male adults (age and weight matched) participated in this study. Subjects were asked to stand still on an AMTI force plate. Using a resistant non-extendable thread we applied at the subject's upper mid spine (i.e., at the level of the inferior border of the scapulae) an external posterior perturbation (EPP) by means of halters equivalent to 6% of the subject body weight. Three trials of 40s were collected with data acquisition beginning 2s prior to the EPP. After observing that the subject reacquired apparent stability with EPP, the EPP was then unexpectedly released. Postural control was analyzed in 8 intervals of 1s each (T1 to T8) starting at the moment of EPP release. Analysis of variance was used to compare mean of COP speed and COP displacement for T1 to T8 and maximum COP displacement during T1. The  $\alpha$  level was preset at p less than 0.05 and post-hoc (Tukey HSD test) were conducted when necessary.

### RESULTS AND DISCUSSION

Athletes showed better postural control than control group. In the first second (T1) after EPP release ANOVA showed that athletes presented COP speed 16.4% lower than control group ( $p=0.01$ ) (Fig. 1). Intragroup analysis showed similar COP displacement from T2 to T8 for control group. However, in athletes, COP displacement was higher during T2 than others intervals (Fig. 2). Summarizing (1) both groups presented similar reflexive response to the perturbation with no inter-groups difference in the maximum COP displacement in T1, (2) the athletes presented lower COP speed in T1 and (3) athletes were slower to bring the COP backward ( $T1 \neq T2$ ,

$T2=T3=...T8$ ). These results reveal better postural control of the athletes than the control group after the perturbation

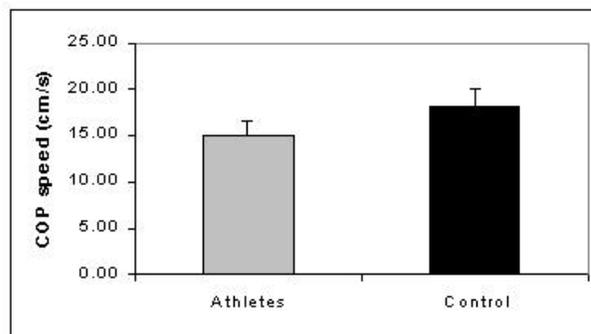

Figure 1: Mean of COP speed for athletes and control group in the T1.

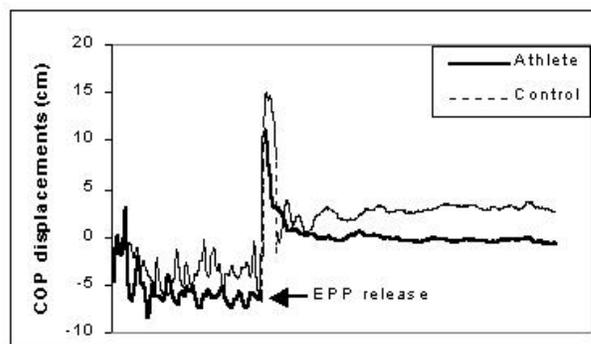

Figure 2 – Example of athlete and control subject postural control. Athlete (dark line) and control subject (light line) cop displacement during trial 2 and 3 respectively.

### CONCLUSIONS

Athletes presented better postural control in response to unexpected perturbation compared to healthy and recreationally active young male adults.

### INTRODUCTION

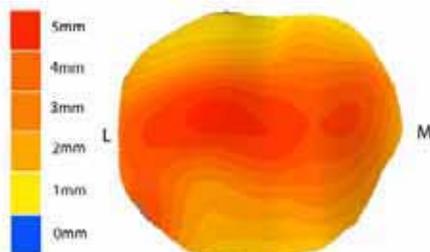

Patellofemoral pain is a common and debilitating knee disorder. Increased stress in the articular cartilage may lead to stimulation of pain receptors in the subchondral bone. Thinning of the articular cartilage is one possible mechanism leading to increased cartilage stress. We tested the hypothesis that subjects diagnosed with patellofemoral pain have thinner patellar cartilage than control subjects.

Magnetic resonance imaging (MRI) has been used to accurately and non-invasively measure cartilage thickness [1,2]. Patellar cartilage thickness has been estimated in pain-free control subjects using MRI [3]. However, comparisons of cartilage thickness between control subjects and individuals with patellofemoral pain have previously not been performed.

### METHODS

Sagittal plane MR images were obtained from 10 pain-free control subjects and 10 subjects with patellofemoral pain. All subjects were between the ages of 20 and 35 to minimize the effect of osteoarthritis on cartilage thickness. Equal numbers of male and female subjects were present in each group. Subjects were imaged while lying supine with the knee in full extension, minimizing cartilage load and deformation. Images were acquired with a 1.5T scanner (GE Healthcare, Milwaukee, WI), using a standard knee coil and a 3D fat-suppressed spoiled gradient echo MR sequence, with a scan time of approximately 15 minutes. The following scan parameters were used: TR: 60ms, TE: 5ms, Flip Angle: 40°, Matrix Size: 256x256, FOV: 12cmx12cm, slice thickness: 1.5mm, Sections: 60.

The subchondral bone and articular cartilage boundaries of the patella were manually segmented using custom software to generate 3D point clouds representing the cartilage surface. Triangulated surfaces were created of the subchondral bone boundary (Geomagic, Raindrop Geomagic, NC). Cartilage thickness was determined by computing the minimum distance between the subchondral bone surface and the articulating cartilage surface, along the surface normal vectors of the subchondral bone (Figure 1). The peak and average thicknesses of the cartilage were computed and compared

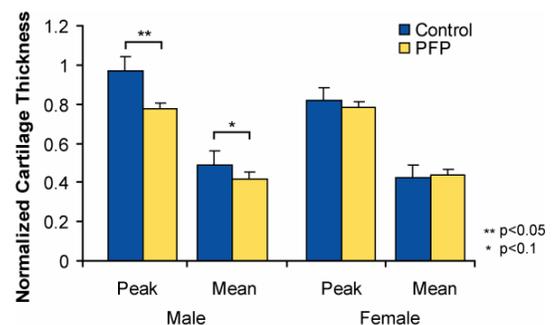

**Figure 1:** Cartilage thickness distribution on patella of a female volunteer.

between subject groups. To account for differences in subject size, we normalized the thickness measurements by scaling according to  $(\text{body mass})^{0.45}$  [4]. The significance of the differences was evaluated using a one-tailed t-test.

### RESULTS AND DISCUSSION

We found that the average peak thickness among control subjects was  $5.8 \pm 1.6$  mm while the average mean thickness was  $2.9 \pm 0.7$  mm. These results are comparable to previous measurements of patellar cartilage thickness in active, healthy subjects made using MRI ([1], peak = 5.8-5.9mm, mean = 2.8-2.9mm). The average peak thickness among subjects with patellofemoral pain was  $5.2 \pm 0.7$  mm while the average mean thickness was  $2.9 \pm 0.3$  mm. Compared to the control subjects, the male subjects with patellofemoral pain had significantly lower peak cartilage thickness both before and after normalization ( $p < 0.05$ ) and showed a trend towards a lower mean cartilage thickness ( $p < 0.1$ ). There were no significant differences in cartilage thickness between the female control and patellofemoral pain subjects both before and after normalization (Figure 2). When both genders were pooled, there was a trend for the patellofemoral pain subjects to have a smaller normalized peak cartilage thickness than the control subjects ( $p < 0.1$ ).

**Figure 2:** Comparison of Peak and Mean Cartilage Thickness between Subject Groups

These data suggest that thin cartilage may be correlated with patellofemoral pain in male subjects. Future studies that examine patellar and femoral cartilage thickness on a larger group of subjects are required to confirm this finding.

### INTRODUCTION

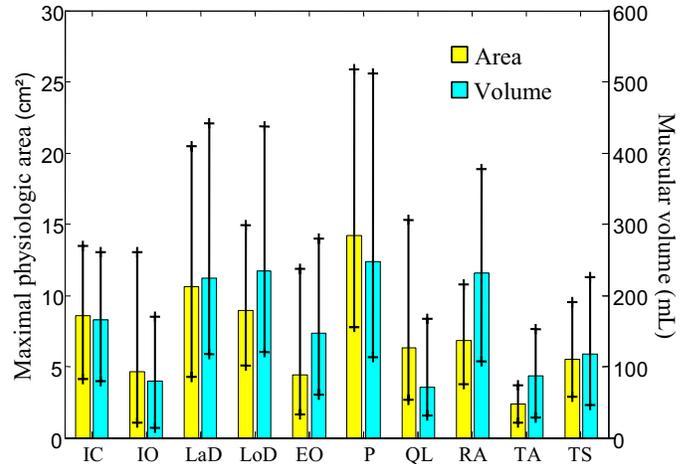

Biomechanics models of the lumbar spine need specific muscular geometry data as maximal physiological area, centroid location of muscular areas in the intervertebral plane and muscular line of action or contraction. Those geometry data are usually acquired for supine subject. However, a significant difference exist when considering muscular centroid locations between the supine and the upright position [1]. The aim of this study was to characterize personalized muscular geometries of asymptomatic subjects in upright position and their related parameters in the L3/L4 intervertebral plane.

### METHODS

19 asymptomatic subjects were recruited. Two exams were performed. First, a stereoradiographic exam consisting of two full spine X-Ray (frontal and lateral views) in standing position into a calibrated device was done [2]. With a specific software, the 3D personalized reconstruction of the vertebrae (T1-L5), the pelvis and the ribs of the subject in upright position were obtained. Then, ten MRI axial slices were obtained from T9-T10 to L5-S1 levels and the femoral heads. The muscles outlined on the MRI were the Rectus Abdominis (RA), the External Oblique (EO), the Internal Oblique (IO), the Transversus Abdominis (TA), the Psoas (P), the Transverso Spinalis (TS), the Longissimus Dorsi (LoD), the Iliocostalis (IC) and the Latissimus Dorsi (LaD). The outlined muscles were then reconstructed and repositioned into the 3D spine reconstruction coordinates system using a specific technique based on muscles geometry adaptation regarding skin configuration in standing position and muscular bone attachment points [3]. A personalized volume reconstruction in standing position of each studied muscle was obtained between T9-T10 level and the femoral heads. Muscular volumes and intersection areas between the muscular reconstructions and the L3/L4 intervertebral plane were evaluated on left and right muscles. The centroid location of the muscular area was calculated with regard to the intervertebral disc centre. The orientation of the muscular line of action was quantified. The maximal physiologic area was evaluated as the maximal area of the intersected volume by a normal plane to the muscular line of action.

### RESULTS AND DISCUSSION

The trunk muscles volumes and maximal physiologic area are shown in Figure 1. The largest muscles volumes were the Psoas (242 mL) and the RA (255 mL). The smallest volume was obtained for the QL (69 mL). The biggest variation between subjects was observed for the left Psoas (77%). The Psoas had the highest maximal physiologic area with 14 cm<sup>2</sup>,

**Figure 1** Maximal physiologic areas and muscular volumes (mean, min, max).

followed by the LaD (11 cm<sup>2</sup>) as well as the IC and the LoD (9 cm<sup>2</sup>). A maximal physiologic area inter subject variability of 34% was observed for the LoD and the RA. The IO, LaD and RA had a high inter subjects variability for the postero-anterior centroid position (6.5-7.1 cm). The inter subject variability of the lateral centroid position for the IO, the LaD, the EO and the TA was between 4.6 and 6.8 cm. As for orientation of muscle line of action, variability between subjects could reached 46° for the LaD in the sagittal plane and 25° in the coronal plane. Furthermore, the TA had 70° of variation in the coronal plane. The muscles TS, Psoas and LoD had few variations between subjects for the area centroid position and the line of action orientation. Our data were in accordance with the few available data in the literature [4, 5].

### CONCLUSIONS

The proposed muscular geometry in the L3/L4 plane took into account the muscular geometry shape and the muscular fiber orientation. A wide inter variability among subjects was observed, which underlined the need to personalized the muscular geometry for trunk muscular modelization.

## REGIONAL VARIATION OF BONE STRAIN CREEP OF VERTEBRAL BODY DURING REPETITIVE LOADING – AN IN VITRO PORCINE BIOMECHANICAL MODEL

Chun-Kai Chiang, M.S., Yuan-Chuan Tsai, M.S., \*Jaw-Lin Wang, Ph.D.  
 Institute of Biomedical Engineering, National Taiwan University, Taipei, Taiwan, ROC  
 e-mail: [jlwang@ntu.edu.tw](mailto:jlwang@ntu.edu.tw), web: [biomech.bme.ntu.edu.tw](http://biomech.bme.ntu.edu.tw)

### INTRODUCTION

The compressive fracture of osteoporotic vertebra is the consequence of accumulated micro fracture caused by the mechanical repetitive loading. However, how the micro fracture or strain accumulated during repetitive loading within the vertebra is not well understood yet. The purpose of this study is to explore the distribution and progression of strain and strain field of vertebral body during repetitive loading.

### METHODS

Seven fresh-frozen thoracic porcine spinal motion segments (T10/T11/T12) were used in the experiments. All ligamentous, capsular, and intracapsular structures were preserved. The T10 and T12 were mounted in polyester resin casts with the T11 vertebral body aligned. The surface of vertebral body was cleaned with alcohol. Two 3-axial strain gages rosettes (Kyowa KFG-1-120-D17-11N50C2, Kyowa Electronics Instruments Co., Ltd., Tokyo, Japan) were mounted at the anterior and posterior sites of T11 vertebral body.

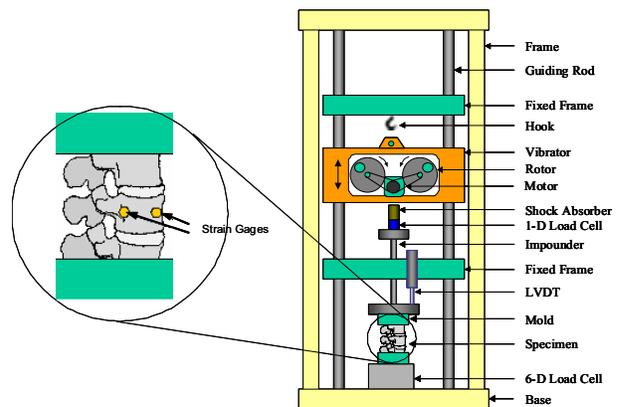

A “drop-tower type” impact testing apparatus was used for the testing (Figure 1). The vibrator was guided by two rods to give a vertical motion. The energy of the vibration was produced with the two eccentric rotors droved by a motor. The energy was transmitted to the specimen through the impounder. The fixed frame, which is fixed to the guiding rode, is used to align the vertical movement of impounder. The specimen was mounted vertically below the impounder with a uni-axial load cell (Kistler 9021, Kistler Instrumente, Winterthur, Switzerland).

The magnitude of external loading was 200N compression and 100N tension from peak to peak. The loading frequency was 5 Hz, and the loading period was five hours; hence 90,000 cycles in total were applied. We recorded one second data every 5 minutes. Sixty sets of data were collected through the loading period. Signals of two strain gages rosettes and axial forces were recorded at 10 kHz sampling frequency. The signals were then low pass filtered at 250 Hz frequency using Butterworth filtering algorithm. The two principal strains at anterior and posterior sites of vertebral body were calculated from the measurement of two strain gage rosettes.

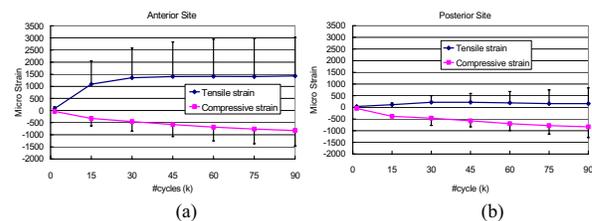

### RESULTS AND DISCUSSION

The tensile strain of anterior site reached equilibrium after 30,000 cycles ( $1500 \mu\epsilon$ ), while the compressive strain kept progression through out the loading period ( $820 \mu\epsilon$  max) (Figure 2a). The tensile strain of posterior site reached equilibrium after 30,000 cycles ( $200 \mu\epsilon$ ), while the compressive strain did not reach steady state even after 90,000 cycles loading ( $850 \mu\epsilon$  max) (Figure 2b). We found that the compressive principle strain of both site of vertebral body did

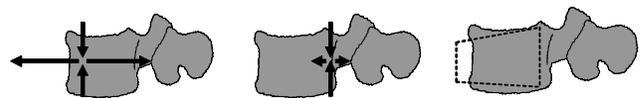

not reach the steady state even after 90,000 cycles of loading, while the tensile strain reached steady state at about 30,000 cycles of loading. The magnitude of the tensile principle strain is two times as large as the magnitude of the compressive principle strain at anterior site of vertebral body. It showed that tensile strain induced by the long-time fatigue loading maybe the reason for the wedge compressive fracture of vertebral body (Figure 3).

**Figure 1:** The schematic plot of testing apparatus.

**Figure 2:** Principal strain of vertebral body at (a) anterior site, and (b) posterior site.

## ANKLE JOINT DORSIFLEXION: ASSESSMENT OF THE TRUE VALUES

John Weir and Nachiappan Chockalingam  
 Faculty of Health and Sciences, Staffordshire University, Stoke-on-Trent, ST4 2DF, UK  
 email: [jweir40@eircom.net](mailto:jweir40@eircom.net); [n.chockalingam@staffs.ac.uk](mailto:n.chockalingam@staffs.ac.uk)

### INTRODUCTION

The amount of ankle joint dorsiflexion required for human ambulation is claimed to be 10 degrees [1,2,3,4,5]. Motion of a reduced quantity has been referred to in the literature as “equinus” and the widely accepted theory is that when equinus is present abnormal foot function occurs. Clinical experience suggests that the majority of patients evaluated, display an amount of ankle joint dorsiflexion during stance, which falls short of this figure. However, patients presenting within the clinical environment normally complain of some discomfort and therefore may not be a good representation of the normal population. One of the main purposes of this study is to determine how and when this arbitrary figure of 10 degrees became established and accepted as the norm and is it in fact a correct figure.

### METHODOLOGY

Fifteen subjects consisting of 8 men and 7 women, aged 19-49 years (mean 27.07), with a body mass ranging between 51.5-126 kg (mean 71.96), height ranging between 161-189 cm (mean 173) and no known gait abnormalities were recruited from a population of university students. All subjects reported to have a passive ankle joint motion of between 12.2 and 25.6 degrees. Ethical approval was sought and received from the university ethics committee. As a result of the prescribed exclusion criteria, one male subject was eliminated from the study (ankle surgery due to fracture). All subjects were supplied with a written explanation of the study and gave a written consent.

A three dimensional opto electronic motion analysis system consisting of five infra-red cameras, sampling at a rate of 60 Hz was employed for data collection and analysis (Motion Analysis Corp, Santa Rosa, CA). Reflective skin markers were placed on predetermined anatomical landmarks. Once the markers were placed on the subject, they were asked to stand on a dynastat weight bearing goniometer (Dynastat, Stafford, UK), with their ankle joint maintained at 90 degrees, whilst their subtalar joint was placed in neutral position [6]. The positioning of the subject in neutral was performed by the same researcher (JW). Two trials of data were taken for each subject whilst they were in this position. The information from this data was later used as a zero reference point to correct the walking data for subtalar neutral position during data analysis. The markers were used to define a segment coordinate system for each limb segment, 3 markers per segment i.e. foot, shank, thigh. This set up allowed for analysis of motion between the foot and leg for each subject. While the data was collected for several trials, three trials were chosen at random for each subject to

measure the dorsiflexion values. The 3D co-ordinates were smoothed using a Butterworth filter ( $F_c = 7\text{Hz}$ ) and all foot angles were expressed relative to the subtalar neutral position. Data were subjected to analysis for similarities using the co-efficient of multiple correlation (CMC) [7].

### RESULTS AND DISCUSSION

Results (Table 1) show ankle joint dorsiflexion values of between 12 degrees and 22 degrees dorsiflexion with a wide variation between subjects. Data from a particular subject was discarded due to errors in analysis.

**Table 1:** Maximum values for ankle joint dorsiflexion/plantarflexion

Subject No:	Max Dorsiflexion (degrees)		Max Plantarflexion (degrees)		Typical CMC Values
	Mean	St.Dev	Mean	St.Dev	
1	14.07	0.25	-12.33	1.10	0.983
2	14.70	0.11	-3.79	1.11	0.755
3	12.43	1.18	-12.24	2.11	0.732
4	17.31	2.07	-6.03	3.69	0.823
5	17.85	0.34	-4.02	2.15	0.989
6	18.93	0.52	-3.68	1.03	0.955
7	21.97	1.36	-1.48	1.19	0.914
8	16.97	0.34	-7.61	2.59	0.989
9	13.77	0.15	-3.77	0.66	0.992
10	17.67	0.38	0.58	3.83	0.917
11	13.37	0.26	-6.11	0.50	0.757
12	20.39	0.82	3.69	1.76	0.773
13	22.53	0.29	0.44	1.51	0.941

The results appear to show ankle joint dorsiflexion in normal subjects is greater than the value traditionally espoused by clinicians for walking. This may have clinical implications. More research is needed to determine the effect of terrain, footwear and muscle length on the measurements.

## C-LEG KNEES DO NOT IMPROVE STANCE PHASE KNEE FLEXION OR WALKING EFFICIENCY IN OLDER TRANSFEMORAL AMPUTEES

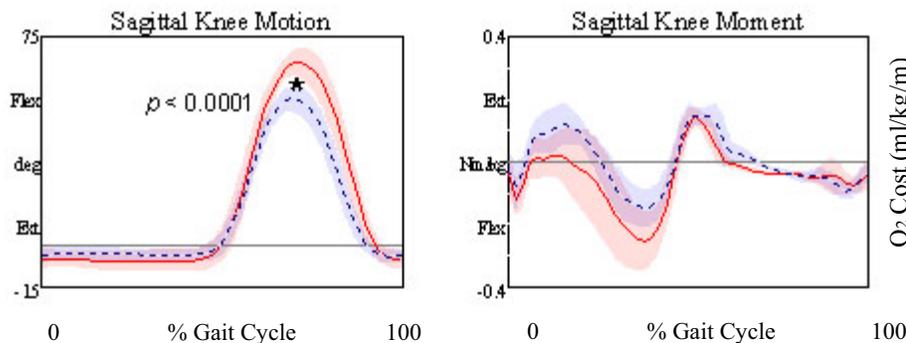

Michael Orendurff, Ava Segal, Martin McDowell, Glenn Klute, Rhonda Williams, Aaron Turner, Jan Pecoraro, Joseph Czerniecki  
Motion Analysis Laboratory, Rehabilitation Research and Development, Seattle Veterans Hospital  
Seattle, Washington USA email: [michael.orendurff@va.med.gov](mailto:michael.orendurff@va.med.gov), web: [www.seattlerehabresearch.org](http://www.seattlerehabresearch.org)

### INTRODUCTION

Microprocessor-controlled prosthetic knees are hypothesized to improve stance phase knee flexion, sagittal knee moments and walking efficiency for transfemoral amputees. Few rigorous examinations of the kinematic, kinetic and energetic<sup>1</sup> improvements in transfemoral amputee gait have been published in peer-reviewed journals. The goal of this study was to compare the differences between the C-Leg (Otto Bock, Minneapolis, MN) and Mauch knees in stance phase knee flexion, knee extensor moment and gait efficiency across walking speeds in older, experienced transfemoral amputees.

### METHODS

Eight traumatic transfemoral amputees (age  $48.5 \pm 13.2$  years; Ht  $172.5 \pm 4.2$  cm; Wt  $80.1 \pm 10.5$  kg) gave informed consent to participate in this IRB approved protocol. Subjects were all previous long term Mauch swing and stance (SNS) users. Each subject was evaluated following a 3-month acclimation period in the C-leg and the Mauch SNS prosthetic knees with identical sockets; order of knee type was randomly assigned. Full body gait kinematics and kinetics were collected at each subject's self-selected walking speed (SSWS) using a 10-camera Vicon 612 system and Plug in Gait (Lake Forest, CA.). Peak knee flexion in single limb stance, peak knee flexion in swing and peak knee extensor moment in early stance was extracted using Event Analyser (Vaquinta Software, Southampton, UK). Later, oxygen consumption (ml/kg/min) was measured at 0.8, 1.0, 1.3 m/s and SSWS overground with a Sensormedics VmaxST mobile metabolic system (Loma Linda, CA) with seated rest between speeds. Oxygen consumption was converted to net oxygen cost (ml/kg/m) by subtracting resting levels and dividing by walking speed to estimate gait efficiency. Overground speed was enforced using a velocity-detecting cart pushed parallel to the subject by an investigator. Oxygen data was monitored in real time and the trial continued until 2 minutes of steady state metabolic data was collected, usually within 8 minutes. Knee flexion in stance and swing, knee extensor moment in early stance, and oxygen cost for the C-Leg versus the Mauch SNS were compared using repeated measures mixed effects ANOVAs.

**Figure 1:** Sagittal prosthetic knee motion, moment across the gait cycle for the C-Leg (dashed blue line) and the Mauch SNS (solid red line). Shaded area is  $\pm$  1SD.

### RESULTS AND DISCUSSION

There was no significant difference observed between stance phase knee flexion with the C-Leg or Mauch SNS knee; both knees remained in full extension through terminal stance phase. The C-Leg had lower (more normal) peak knee flexion during swing phase compared to the Mauch SNS ( $54.2 \pm 4.2$  vs.  $59.1 \pm 8.1$ ;  $p < 0.0001$ ). The peak knee extensor moment in early stance showed no significant difference between the knee types ( $p < 0.59$ ), although the moment was shifted slightly toward extensor (closer to normal) in the C-Leg knee. Oxygen costs at each of the 4 walking speeds were not statistically different with the C-Leg compared to Mauch SNS knee ( $p > 0.19$ ), indicating that the subject's gait was not more efficient with the C-Leg. This is consistent with previous literature<sup>1</sup>.

### CONCLUSIONS

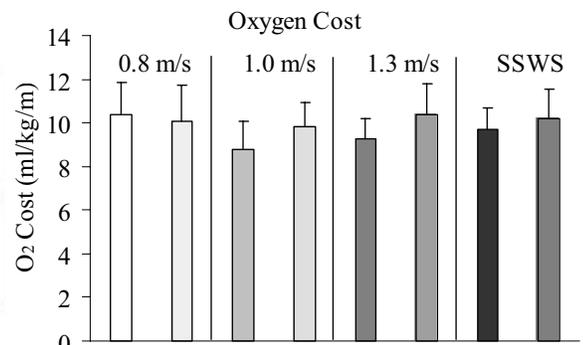

Older, experienced transfemoral amputees did not demonstrate significant improvements with the C-Leg despite a 3-month acclimation period. Even with the long acclimation period, these subjects were not able to take advantage of the eccentric knee flexion feature during early stance phase. This may be related to the subjects' previous long-term use of a Mauch SNS limb. Many subjects commented that they still found it difficult to break the habit of providing extensor force to the prosthetic limb in stance phase. Subjects described the C-Leg as having better stumble recovery and therefore fall prevention, although this was not explicitly measured in this study. Despite the lack of significant improvements observed in the kinematics, kinetics or energetics, 7 of the 8 subjects chose to keep the C-leg as their primary limb after the study was completed.

## Mitochondrial Adaptation During Rehabilitation and Its Importance in Musculoskeletal Modeling

<sup>1</sup> Sherry L. Di Jorio, <sup>2</sup>Michael B. Vergason, <sup>1,3</sup>Gary T. Yamaguchi and <sup>1,4</sup>James T. Ryaby

<sup>1</sup>Harrington Department of Bioengineering, Arizona State University; email: sherry.dijorio@asu.edu

<sup>2</sup>Department of Chemistry and Biochemistry, Arizona State University; <sup>3</sup>Exponent Inc.; <sup>4</sup>OrthoLogic Corporation

### INTRODUCTION

Musculoskeletal models are widely used in assessment and predication of rehabilitation or surgical outcome. In many of these models [1,2], muscle parameters such as specific force are considered constant throughout the healing process. We hypothesized that muscle properties change during healing. This change may be significant enough to alter model outputs and therefore render the model invalid if the changes are not taken into consideration.

### METHODS

8-10 month old male Sprague-Dawley rats (n=105, 500 grams mean weight) were divided into five groups: Control, Sham, Fracture Only (Fx), Tenotomy only (Ten), or Fracture plus Tenotomy (FxTen). Prior to treatment, all animals underwent two weeks of treadmill training. In the Fx group, mid-diaphyseal fractures in the right femur were made as described by Bonnarens and Einhorn [3]. The Ten group had the patellar tendon completely severed just proximal to the patella, rendering the knee extensors ineffective. Animals in the sham group had a knee incision and exposure of the femoral condyles. Food and water were given ad libitum.

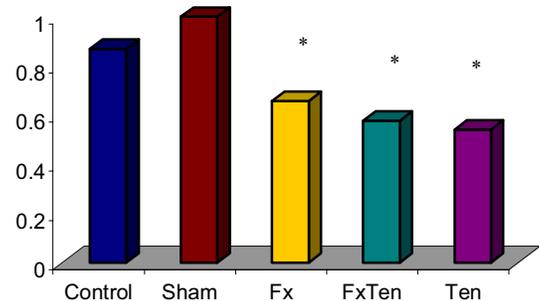

A subset of the animals walked on a forceplate-fitted rodent treadmill wearing reflective markers. Measured ground reaction forces and joint angles were used as inputs to a dynamic 3D musculoskeletal model of the hindlimb.

Animals were euthanized after 2, 4, 6, and 8 weeks. Contralateral knee flexors were harvested (semitendinosus and biceps femoris- caudal head) along with both femurs. Muscles were immediately placed in liquid nitrogen. To determine presence of mitochondrial adaptation, the method of Srere [4] was used to quantify the activity of citrate synthase (CS). CS activity was statistically compared using ANOVA, with  $\alpha=0.05$ . All animal procedures were approved by the Arizona State University IACUC committee.

### RESULTS AND DISCUSSION

CS activity, and indicator of oxidative capacity, is directly proportional to the amount of mitochondrial activity in the muscle [5], and its activity has been shown to decrease in association with decreased ability of the muscle to produce force [6]. The decrease in CS activity associated with fracture, tenotomy, or both indicates a potential need to adjust muscle properties in musculoskeletal models whose purpose is to assess movement capability during fracture or muscle injury rehabilitation.

Mean CS activity was significantly greater in control and sham animals than in animals receiving fracture, tenotomy, or

**Figure 1:** Normalized mean 8-week citrate synthase activity in semitendinosus. \*Mean is different from control and sham,  $p < 0.05$ .

both ( $p < 0.05$ ) (Figure 1). A common pattern is seen at all time points analyzed.

Kinetic and kinematic gait analysis shows that there is indeed a difference in the gait of animals that have undergone femoral fracture, patellar tenotomy, or both ( $p < 0.05$ ). Differences arise in ground reaction forces, knee and ankle joint angles, and stride characteristics. Dynamic musculoskeletal modeling of measured rat gait calculates a significantly different joint reaction force at the knee as the specific force in the knee flexors is changed. To accurately model muscle force during rehabilitation, direct experimental evidence relating mitochondrial content to specific force is needed.

### CONCLUSIONS

Femoral fracture, patellar tenotomy, or both significantly reduce CS activity in the knee flexors, indicating a reduction in those muscles' ability to produce force. Because the gait of these animals is significantly different from normal rat gait, there is a need for musculoskeletal models to be individualized and customized. Based on these results, specific force can be treated as an adjustable parameter.

## JOINT STIFFNESS REQUIREMENTS IN A MULTI-SEGMENT STANCE MODEL

Leonard A. Rozendaal, A.J. “Knoek” van Soest

Institute for Fundamental and Clinical Human Movement Sciences, Amsterdam/Nijmegen, The Netherlands

email: [l\\_rozendaal@fbw.vu.nl](mailto:l_rozendaal@fbw.vu.nl)

### INTRODUCTION

Currently, there is a vivid debate on the control mechanisms involved in human stance, in which the required and available ankle joint stiffness play a key role. Ankle stiffness values are typically discussed in the context of a one-segment stance model. Considering other joints as well, in particular the knee and the hip, it is found that the ankle stiffness should be substantially higher than the one-segment model suggests.

### METHODS

In an  $n$ -segment model of the standing human moving in the sagittal plane, the gravitational potential energy  $U_g(\varphi_1, \dots, \varphi_n)$  can be expressed as a function of the joint angles  $\varphi_i$ . The Hessian (second derivative matrix) of  $U_g$  is  $\mathbf{G}$ , the joint stiffness matrix due to gravity, which typically has negative values. The joint stiffness matrix  $\mathbf{K}$  due to intrinsic muscle-tendon properties and reflexive control, when symmetric, can be considered the Hessian of an elastic energy potential function  $U_k(\varphi_1, \dots, \varphi_n)$ . A quasi-static requirement for stability is that the Hessian of the total potential energy, i.e.,  $\mathbf{G} + \mathbf{K}$ , has all positive eigenvalues. We consider only local control of the joints, where  $\mathbf{K}$  is a diagonal matrix with local joint stiffness values  $K_i$  at the diagonal. At the boundary of the region of stabilizing  $K_i$  the eigenvalues of  $\mathbf{G} + \mathbf{K}$  become zero. Hence this boundary can be found by determining the combinations of  $K_i$  for which  $\det(\mathbf{G} + \mathbf{K})$  equals zero. Analytical expressions can be obtained for systems up to at least order 3.

Besides these boundaries, as scalar measures we use the minimum required stiffness: 1) when all joint stiffnesses are equal,  $K_i = K_0$ ; 2) when all joint stiffnesses exceed their single-joint requirement by the same amount,  $K_i = -G_i + \Delta K_0$ . Here  $G_i$  is the gravitational stiffness for joint  $i$  when all other joints are considered fixed. Model parameters are based on Winter (1979); resulting values of the  $G_i$  are indicated in Table 1.

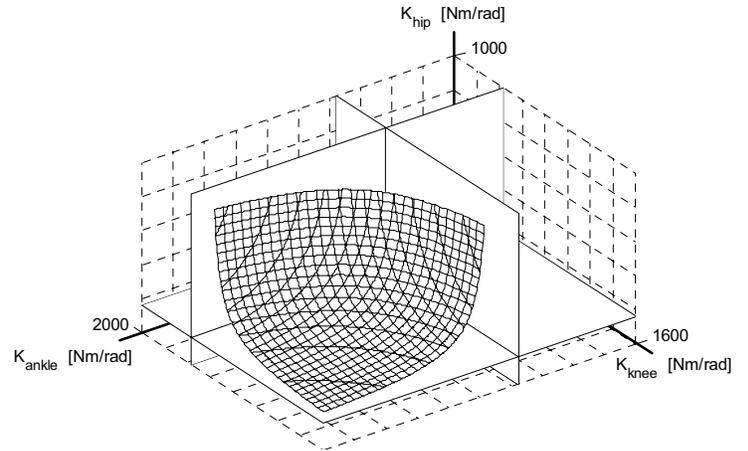

**Table 1 (left).** Gravitational stiffness per joint, in Nm/rad.

**Table 2 (right).** Measures for the required joint stiffness in several multi-segment stance models. All values in Nm/rad.

joint	$G_i$	model	$K_0$	$\Delta K_0$
ankle	-754	ankle	754	0
knee	-432	ankle-hip	794	160
hip	-160	ankle-knee	1054	432
neck	-8	ankle-knee-hip	1106	528
shoulder	25	ankle-knee-hip-neck	1106	529
		ankle-knee-hip-shoulder	1107	532

### RESULTS AND DISCUSSION

In a one-segment model, stability requires that  $K_{ankle} + G_{ankle} > 0$ ; i.e., the ankle joint stiffness must be at least 754 Nm/rad. However, in a two-segment ankle-hip model stability is not guaranteed when  $K_{ankle} > 754$  Nm/rad and  $K_{hip} > 160$  Nm/rad, the single-joint requirements for each joint separately. The actual stability boundary is an arm of a hyperbola with  $K_{ankle} = 754$

**Figure 1.** Joint stiffness requirements for the ankle-knee-hip model. The straight planes represent the single-joint requirements, i.e.,  $K_{ankle} > -G_{ankle}$ ,  $K_{knee} > -G_{knee}$ ,  $K_{hip} > -G_{hip}$ . Joint stiffness combinations at the near side of the curved surface actually result in quasi-statically stable stance.

Nm/rad and  $K_{hip} = 160$  Nm/rad as asymptotes. As a result of the interaction between segments, typically both joint stiffnesses must exceed their single-joint requirement considerably to obtain stable stance (see Table 2). Only when one of the joints has a very high stiffness, its influence on the other joint can be ignored. When the knee is included instead of the hip, the interaction effect is stronger, as  $G_{knee}$  is larger than  $G_{hip}$ . In a three-segment ankle-knee-hip model, the stability boundary becomes a hyperbolic surface in a three-dimensional joint stiffness space (Figure 1). The numerical measures indicate that the stiffness requirements are heightened further in this case (Table 2). Modeling the head or the arms as additional segments separate from the trunk has only a minimal effect.

### CONCLUSIONS

Inclusion of additional joints in a stance model substantially increases the local stiffness requirements for the joints already present. Assuming equal stiffness for all joints, in the ankle-knee-hip model the ankle stiffness must be at least 1106 Nm/rad, compared to 754 Nm/rad in the conventional single-segment stance model. Hence, stabilizing the inverted multi-segment pendulum of the standing human appears to be even more challenging than assumed previously.

**THE EFFECT OF LOWER EXTREMITY FATIGUE ON SHOCK ATTENUATION DURING LANDING**

Kristian M. O'Connor, Evan Coventry, Barbara A. Hart, Sarika K. Monteiro, Jennifer E. Earl and Kyle T. Ebersole  
 Department of Human Movement Sciences

University of Wisconsin - Milwaukee: [krisocon@uwm.edu](mailto:krisocon@uwm.edu), web: [www.uwm.edu](http://www.uwm.edu)

**INTRODUCTION**

The forces that are imposed on the body due to landings must be absorbed primarily in the lower extremity. Muscles assist in the absorption of these impact forces [1], and it has been shown that a fatigued muscle decreases the body's ability to attenuate shock from running [2]. The purpose of the study was to determine the effect of lower extremity fatigue on shock attenuation and joint mechanics during a drop landing. It was hypothesized that lower extremity fatigue would cause a decrease in the shock attenuation and alter joint mechanics.

**METHODS**

Ten active, non-pathologic male participants, 19 to 27 years of age, were recruited for participation. Each participant took part in a fatigue landing protocol (FLP) that was similar to that utilized by Madigan & Pidcoe [3]. The FLP included cycles of a drop landing, a maximal countermovement (CM) jump, and five squats repeated until exhaustion. Accelerometers attached to the skin were used to measure tibia and head accelerations. Shock attenuation was calculated through a transfer function [4]. Sagittal plane lower extremity kinematics were collected using an electromagnetic tracking system and kinetics were collected using a force plate. A repeated-measures ANOVA ( $p < 0.05$ ) was performed on each of the dependent variable across the cycles of the FLP.

**RESULTS AND DISCUSSION**

The power output for the CM jumps performed in each cycle significantly decreased from  $1197 \pm 273$  W to  $805 \pm 182$  W. This indicated that the FLP elicited fatigue, and the individual joint work values indicated that the knee experienced the greatest decrement in performance (Figure 1a), as was anticipated. However, there were no significant changes in tibia and head acceleration or in the shock attenuation (Table 1). The range of motion at the ankle significantly decreased as the FLP progressed, but the knee and hip ranges of motion were not significantly different (Table 1). Hip joint work significantly increased, and ankle work showed a decreasing trend, consistent with a distal to proximal redistribution of joint work (Figure 1b). The total work done by the lower extremity remained approximately constant throughout the FLP, which was expected since the drop height remained constant. Interestingly, the knee joint work during landing was not significantly different from the beginning to end, even though the corresponding jump performance dramatically worsened at the knee.

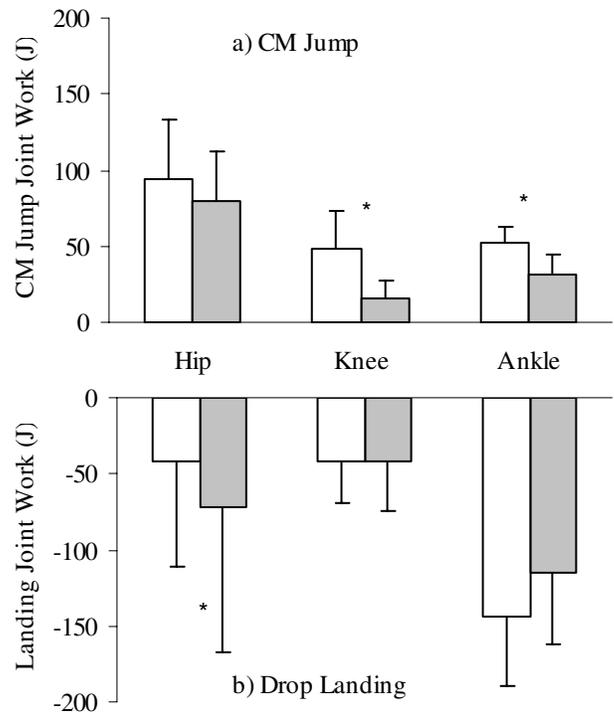

Figure 1. Group mean net joint work for the a) countermovement jump and the b) drop landing for the first (white bars) and last (gray bars) cycles. \* indicates significant difference ( $p < 0.05$ ).

**CONCLUSIONS**

This change in work distribution is thought to be a compensatory response to utilize the larger hip extensors that are better suited to absorb the mechanical energy of the impact. The results suggested that the lower extremity is able to adapt to fatigue though altering kinematics at impact and redistributing work to larger proximal muscles.

## THREE DIMENSIONAL KNEE JOINT KINEMATICS AND LOWER LIMB MUSCLE ACTIVITY OF ANTERIOR CRUCIATE LIGAMENT DEFICIENT KNEE JOINT PARTICIPANTS WEARING A FUNCTIONAL KNEE BRACE DURING RUNNING

Daniel Théoret, M. A., and Mario Lamontagne Ph. D.

University of Ottawa,

email: dtheo087@uottawa.ca, web: [www.biomech.uottawa.ca](http://www.biomech.uottawa.ca)

### INTRODUCTION

Knee braces have been found to provide limited stability to the ACL deficient (ACLD) knee in situations where the knee is loaded during sporting movements [1,3]. The increased laxity in the joint requires the patient's body to compensate for the ACLD by also altering muscle recruitment patterns, such as the hamstrings and quadriceps to adequately stabilize the knee during such activities [4,5]. Different adaptation strategies have been found between patients that can cope with the injury and patients that cannot. One of the expected changes can be muscle activation characteristics of the injured knee during strenuous activity with and without a functional knee brace.

### METHODS

A group of 11 ACLD male participants (mean: 33.5, ± 7.7 yrs, 89.1, ± 12.5 kg, 185.7, ± 7.8 cm) took part in the experimentation. At the time of the testing session, all participants exhibited full knee range of motion and no pain during walking. Three dimensional (3D) kinematic and electromyography (EMG) data were collected for ten consecutive gait cycles during running on a treadmill under both braced (B) and unbraced (UB) conditions. Video was collected using the SIMI\* Motion system (SIMI\* Reality Motion Systems GmbH) from four digital video cameras (JVC GR-DVL9800) set at 60 Hz. EMG data was collected at 1000 Hz (Bortec Biomedical Ltd.) for vastus lateralis and medialis, biceps femoris, semitendinosis, lateral and medial gastrocnemius muscles. Statistical analysis of both the EMG and 3D kinematic data using one-way Anova (p=0.05) focused on comparisons between the braced and unbraced conditions.

### RESULTS AND DISCUSSION

Fairly similar flexion/extension knee joint patterns were observed between the braced and non-braced conditions. Bracing significantly reduced (p<0.05) the peak abduction angle, and the total range of motion during running (Table 1). The internal/external rotation curve for the braced condition showed a significantly (p<0.05) lower range of motion than in the unbraced condition (Table 1). Bracing also prevented the ACLD knee from going into internal rotation during the

running cycle. Overall analysis demonstrated that bracing reduced the overall range of motion of the knee joint in the frontal and transverse planes but did not affect the motion in the sagittal plane for ACLD participants during running.

Comparisons of muscle activity between the braced and unbraced conditions revealed some changes in timing and amplitude characteristics of the EMG signal. Muscle activity (measured as the area under the LE EMG curve) increased for all the muscles in the braced condition. This increase in LE EMG was not significant most likely because of high variability within participants. Our results showed a tendency that at heel-strike, the EMG amplitude of the quadriceps (vastus medialis and lateralis) decreased while hamstrings (biceps femoris and semitendinosis) increased in the braced condition.

### CONCLUSIONS

The findings of this study suggested that bracing significantly affected the kinematic profile of ACLD patients during running. Although no significant differences were observed for the EMG variables, tendencies were noted both in terms of muscle activity and timing, especially for the semitendinosis muscle. The tendencies in EMG activity changes caused by the brace to the semitendinosis muscle were not however in accordance with the added mechanical restrictions expected while wearing a functional knee brace. This led us to believe that the brace had a proprioceptive effect on the injured limb, resulting in added active muscular stability. These findings are therefore in accordance with the phenomenon of a proprioceptive contribution of the functional knee bracing [2]. We must point out that the sample size might have a large influence in the statistical difference in the EMG findings.

## COMPARISON OF DRESSAGE RIDER POSTURE WHEN MOUNTED ON DIFFERENT HORSES

Laurelyn E. Keener<sup>1</sup> and Morris Levy<sup>2</sup>

<sup>1</sup>Dept. of Biology

<sup>2</sup>Biomechanics Laboratory, Dept. of Health Physical Education and Recreation

University of Minnesota Duluth

E-mail: keen0070@d.umn.edu

### INTRODUCTION

The equine sport of Dressage subjectively judges how well a horse and rider move together. Dressage experts believe that a horse cannot move at its potential without the optimal level of balance and communication with the rider.

Measurable differences can be observed in the kinematics of multiple horses when ridden by a professional vs. amateur rider [2]. The availability of measurable horse-rider interactions would further benefit Dressage training, instruction and judging. Therefore, the purpose of this study was to compare rider posture with two horses, and to assess the resulting effect on the horses.

### METHODS

Two well-conditioned Dressage horses, accustomed to the arena in which data collection occurred, were fitted with identical 17.5-inch Dressage saddles and their usual Dressage bridles. Ten adult amateur Dressage riders rode both horses. All riders had at least 4 years of riding experience and 50 hours of formal Dressage education. Two calibrated pan and tilt cameras were positioned 15 meters apart to gather position-time data as the horses trotted along a 12-meter track.

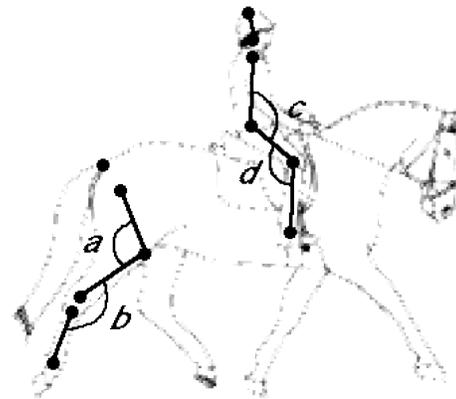

Reflective markers were placed on the following landmarks of each rider: top of the head, jaw, shoulder, hip, knee and ankle. Markers were also placed over palpable skeletal regions along the horses' right hind limbs to aid in later identification of joint angles. Each rider was given a 5-minute warm-up period with the horse. Five consecutive trials of each horse-rider combination were filmed. All pairs were filmed within a five-hour period, and their order was randomized.

Using Peak Motus® Pan and Tilt Software, one stride cycle, beginning with the right hind limb in perpendicular stance phase, from each trial was captured and digitized. The average stifle-, hock-, hip- and knee- angle ranges were calculated to assess horse movement and rider posture. Figure 1 illustrates the angles of interest from which comparisons were made.

### RESULTS AND DISCUSSION

Table 1 described the average angular ranges of riders and horses. Separate paired t-tests ( $\alpha = 0.05$ ) were used to compare the rider hip and knee angle ranges while riding two different horses. The hip angle ranges changed significantly

( $t_9 = 2.50$ ,  $p = 0.0337$ ), while the knee angle ranges remained similar between horses ( $t_9 = 0.064$ ,  $p = 0.95$ ). Paired comparisons of horse angular ranges revealed significant differences for both the stifle and hock ( $t_9 = 11.10$  and  $6.78$ , respectively;  $p < 0.0001$ ). These results suggest that riders change their movement, adjusting to the movement and potential aptitude of the horse in relationship to the skill involved (trotting action in this case).

**Figure 1:** Outline of horse and rider shown for orientation purposes. Horse and rider marker placement and joint angles ( $a =$  stifle,  $b =$  hock,  $c =$  hip and  $d =$  knee).

### CONCLUSIONS

Dressage, a sport based on qualitative observations, would benefit from quantitatively defining desirable interaction characteristics. In analyzing joint angles of ten riders on two horses, we found that a rider's hip kinematics vary when riding horses whose movement patterns are different. Thus, when teaching and judging a pair, the rider position must be flexible depending upon the horse's gaits.

## RUPTURE PRESSURES FOR HUMAN AND PORCINE EYES UNDER STATIC AND DYNAMIC LOADING

<sup>1</sup>Eric Kennedy, <sup>1</sup>Katherine Voorhies, <sup>1</sup>Amber Rath, <sup>2</sup>Frederick Brozoski, and <sup>1</sup>Stefan Duma

<sup>1</sup>Virginia Tech – Wake Forest, Center for Injury Biomechanics,

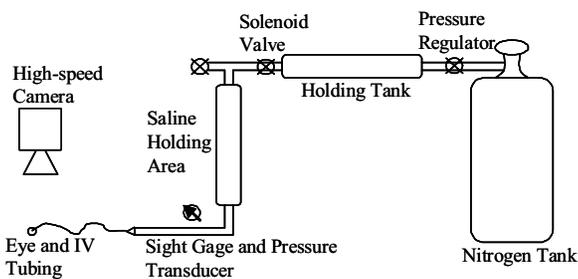

<sup>2</sup>United States Army Aeromedical Research Laboratory; email: eric\_kennedy@vt.edu, web: www.CIB.vt.edu

### INTRODUCTION

More than 30,000 people lose sight in at least one eye every year in the United States alone [1]. Among the severe injuries that can result in the loss of an eye is globe rupture. Previous studies have attempted to determine the rupture pressure of both human and porcine eyes; however, no studies have been conducted at a dynamic rate. Porcine eyes are frequently used as human eye surrogates in ocular research due to their anatomical similarities. Since biological tissue typically displays viscoelastic behavior, it is hypothesized that the rupture pressure of the eye will be directly affected by the pressurization rate of the eye. Therefore, the purpose of this study is to determine the static and dynamic rupture pressure of human and porcine eyes.

### METHODS

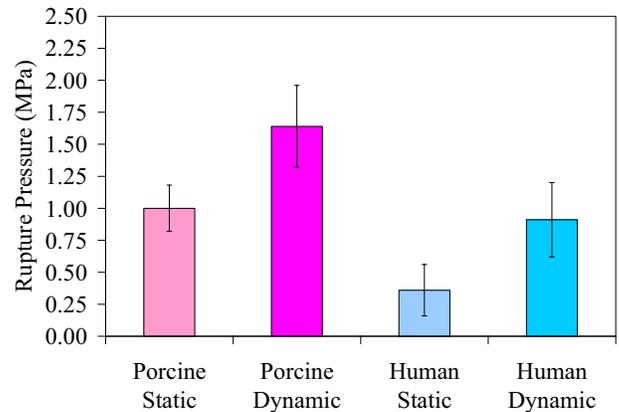

A pressure system was developed to internally pressurize the eye with physiological fluid via a needle inserted through the optic nerve. Static testing was accomplished by increasing the internal pressure of the eye by approximately 0.02 MPa/second, using 10 human and 10 porcine eyes until the eyes ruptured at their maximum static pressure. The dynamic testing of 10 human and 10 porcine eyes was accomplished by setting the initial pressure to release at 2.8 MPa, resulting in a loading rate of approximately 2.77 MPa/second, and measuring the pressure at which the eyes ruptured.

**Figure 1:** Schematic of eye pressurization system used for both static and dynamic tests.

### RESULTS AND DISCUSSION

Globe rupture occurred primarily at the equator for both static and dynamic tests. The average loading rate under static loading was  $0.02 \pm 0.01$  MPa/second while the average loading rate for dynamic tests was  $2.77 \pm 0.58$  MPa/second. Static test results displayed an average rupture pressure for porcine eyes of  $1.00 \pm 0.18$  MPa while the average rupture pressure for human eyes was  $0.36 \pm 0.20$  MPa. Porcine eyes under static loading were found to be significantly stronger than human eyes ( $p = 0.01$ ). For dynamic loading, the average porcine rupture pressure was  $1.64 \pm 0.32$  MPa, and the average rupture pressure for human eyes was  $0.91 \pm 0.29$  MPa. Again, the porcine eyes were found to be significantly

**Figure 2:** Averages of results of rupture pressure testing with standard deviations. Porcine eyes ruptured at a higher pressure than human eyes ( $p = 0.01$ ). For both human and porcine eyes, dynamic rupture pressures were higher than static rupture pressures ( $p = 0.01$ ).

stronger than the human eyes ( $p = 0.01$ ). Additionally, the dynamic rupture pressures for both porcine and human eyes were significantly higher ( $p = 0.01$ ) than their respective static rupture pressures.

### CONCLUSIONS

Both human and porcine eyes exhibit large viscoelastic effects when loaded dynamically. The viscoelastic behavior of the eye under dynamic loading is consistent with that seen in other biological tissue [2]. Under dynamic loading the human eye can withstand approximately 150% more pressure before rupture than under static loading, while under the same circumstances the porcine eye can withstand approximately 64% more pressure before rupture. This behavior proves that previously determined material characteristics of the eye from static tests will lead to inaccurate predictions of the rupture pressure of the eye, both human and porcine. Finally, due to differences in their response versus human eyes, separate criteria must be utilized to interpret results of porcine eye tests versus human eye tests.

### INTRODUCTION

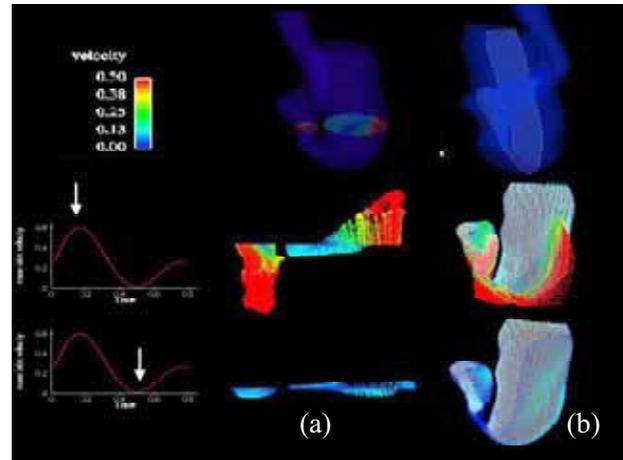

Patients with ESRD “end stage renal disease” require haemodialysis. Its most desirable form of vascular access is the arterio-venous fistula. We propose an investigation protocol to understand the correlation between hemodynamic changes in this very specific blood vessel and the associated clinical complications. Realistic 3D reconstruction geometry of the fistula is the result of segmenting CT angiography images. Then the geometrical model is treated with industrial computation fluid dynamics software for blood flow simulation.

### METHODS

A non pathologic fistula realized in 1987 is the base for this study. CT images are therefore acquired using “Lightspeed Ultra CT, General Electric” & the smartPREP technology. The images are then exported in a DICOM format. Vessel contour segmentation is the output of the region growing algorithm to be finally reconstructed into a three dimensional volume by applying “NURBS”. This volume is introduced into Gambit 2.1® (Fluent, Lebanon, NH, USA) to produce the biomechanical model. At the entrance of the fistula (arterial side), a straight tube of sufficient length is added to allow the blood flow profile development. The volume is perpendicularly divided into seven sub-volumes taking into consideration the vascular central axis as a reference. Each face of the sub-volumes has been meshed with a 524 quadrilaterals at the input & at the output. A boundary layer at the wall of four rows has been added to calculate the velocity gradients & wall shear stress. The Cooper algorithm is implemented to propagate into the volume meshing it with hexahedral mesh of total number 150 288[1]. The blood flow in the vessels of the meshed biomechanical model is calculated using Navier-Stokes equation solved using Fluent 6.1® (Fluent, Lebanon, NH, USA). The post treatment and interpretation of the results are affected using Ensith7.6® (CEI, Apex, NC, USA). In such vessels the blood is considered a Newtonian fluid of viscosity 0,004 Pa.s and density of 1050 kg/m<sup>3</sup> [2]. In our study, a non stationary flow of a cardiac frequency 76 beats/ minute with a period of (0,8 sec) is applied. The entrance velocity follows the physiological curve presented in the literature [3].

### RESULTS AND DISCUSSION

As a result of the numerical simulation, the non stationary flow enables flow pattern visualization during the cardiac cycle in the artery, anastomosis & vein. Figure 1a & 1b shows respectively an axial & a sagittal plane of the arterio-venous fistula at two different cardiac instants.

**Figure 1:** (a) velocity profile axial plane. -(b) velocity profile sagittal plane of the anastomosis

In the axial plane we can notice the parabolic velocity profile in the artery. Whereas in the vein, we see a partial inversion of the velocity profile at the systolic peak. At the beginning of the diastole, there is low velocity. For the sagittal plane we can see a jet towards the external wall of the vein due to the acceleration at the anastomosis, which produces constraints over the wall of the vein and noticeable recirculation phenomena at the low velocity zone at the interior.

We validate our results by comparing it to an Echo-Doppler examination for the same patient. We measure the flow at the artery and visualize approximated velocity profiles at different cross-sections. The obtained flow representation is less accurate than our method. In addition our simulation allows wall shear stress calculation which can not be obtained in the Doppler study.

### CONCLUSIONS

The simulation indicates the risk zones, weak shear rates & views of the recirculation zone. The obtained flow representation is more precise than the Doppler velocity measurements. Therefore our method represents for the clinicians an additional tool to prognostic and diagnosis. Indeed low constraints may predict atherosclerosis generation and high constraints may lead to potential changes in the venous shape serious structural changes

### INTRODUCTION

Primary stability achieved by press-fit is critical for the long-term success of cementless hip stems [1]. It is recognized that micromotions over 30-150 micron prevent osteointegration and lead to implant failure [2]. Conversely, excessive press-fit can cause intra-op fractures [3]. A device able to intra-operatively assess stem stability was developed and validated [4]. It consists of an angular sensor and a torsional load cell, which are embedded in a real-time torque wrench. The device is manually operated by the surgeon, who can use this quantitative information to decide whether more press-fit is needed.

This device could successfully discriminate between stable and unstable stems intra-operatively [4]. The goal of the present work was to find a correlation between rasp and stem stability. This could provide the surgeon with a quantitative information concerning the quality of the femoral canal just prepared before inserting the stem, thus enabling a prediction of the implant stability possibly achievable.

### METHODS

The device [4] is meant to measure a stem/femur relative rotation when a torque is applied. It incorporates two high accuracy transducers, an RVDT angular sensor and a torsional load cell. A custom designed connector allows an easy and rigid insertion of the device in the stem neck modularity. As a reference point for the angular probe, a Kirschner nail is driven anteriorly on the greater trochanter prior to the insertion of the device. All the electronics is hosted in a cavity machined inside the handle. Data acquired (sampling frequency 200Hz) are recorded in a separate memory, for post-op evaluations. The surgeon interface, located in the upper side of the handle, is composed by: (i) a display, for the visualization of the stem size; (ii) four buttons to select a function of the device; (iii) two bi-colored series of LEDs, indicating the amount of torque applied and the extent of micromotion achieved.

Three composite and two embalmed re-hydrated cadaveric femurs were tested. An experienced surgeon prepared the femurs to be implanted, in a single session and following the standard surgical protocol. The tests were performed as follows: a first torque-micromotion acquisition was made with the last rasp used by the surgeon to prepare the canal still inserted into the femur. The measurement device was connected to the rasp and the angular and torsional data were acquired when a torque (up to 20Nm) was manually applied. Five to ten repetitions were performed on each femur. The same measurement protocol was repeated with the corresponding stem inserted and press-fitted in the femoral canal. Data were acquired and processed.

### RESULTS AND DISCUSSION

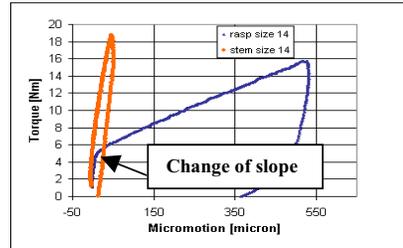

Fig.1 Typical torque-micromotion curves for the rasp and the stem on the same femur

Observing the increasing part of the torque-micromotion curve (Fig.1), the stem micromotions increase linearly, while the rasp shows a highly non-linear trend (with a pronounced “knee” corresponding to a sudden increase of the micromotion rate). Thus it was decided not to directly compare the rasp-stem motion patterns, but to search for a parameter of the rasp curve to correlate with the stem-micromotion.

The best-correlated rasp-parameter was the level of torque corresponding to the slope change in the torque-micromotion curve. This rasp parameter presented a linear trend if plotted against the stem micromotion (Fig.2), thus showing the presence of a good correlation ( $R^2 > 0.93$ ) between rasp and stem stability.

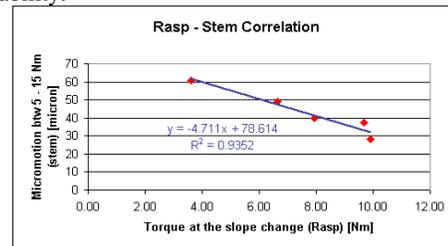

Fig.2 Correlation between rasp and stem stability

### CONCLUSIONS

The aim of the present work was to investigate if it was possible to evaluate the quality of the femoral canal and predict the stem stability, by using the torque wrench, prior to the stem implantation. The correlation tests yielded satisfactory results. The rasp and stem stability seems to be strictly related.

## CHARACTERIZATION OF INTRALIMB COORDINATION DEFICITS IN CHRONIC STROKE PATIENTS

<sup>1</sup> Mark Dohring, PhD <sup>1</sup> Karen Sng, and <sup>1,2</sup> Janis J Daly, Ph.D.

<sup>1</sup> Louis Stokes Cleveland Department of Veterans Affairs Medical Center,

<sup>2</sup> Department of Neurology, Case Western Reserve University School of Medicine

### INTRODUCTION

Many stroke survivors experience deficits in coordination that cause gait deficits. Normal gait is dependent on intralimb coordination among hip, knee, and ankle joint movements. Although the presence of intralimb coordination deficits were noted in stroke survivors, a credible quantitative measure has not been reported. The purpose of this study was: 1) quantitatively characterize intralimb coordination in stroke survivors with persistent gait deficits; and 2) determine whether quantification of intralimb coordination discriminated improvement following an innovative treatment with or without functional neuromuscular stimulation (FNS) using intramuscular (IM) electrodes (FNS-IM).

### METHODS

Twenty-nine stroke survivors (0.23 to 14.92 yrs post stroke) and three healthy controls were enrolled in the study. The study was conducted under the supervision of the Louis Stokes Cleveland Department of Veterans Affairs Medical Center, Committee for Human Subject Protection (VAMC,IRB). Informed consent was obtained.

Subjects were randomly assigned either to Group 1, FNS-IM or Group 2, No-FNS. Both groups received conventional gait training and body weight supported treadmill training for 1½ hours/day, 4 days/week for 12 weeks. Group 1 (FNS-IM) had implantation of up to 8 electrodes for paretic muscles. An 8-channel research stimulator delivered the FNS patterns that were custom-designed for each individual.

A VICON 370 V3.5 was used to acquire pre-treatment and post-treatment hip and knee joint kinematic data during over-ground walking. No FNS was activated during the testing.

Hip and Knee angle consistency across multiple steps was analyzed using a vector analysis method [1]. Incremental change in hip and knee angle between frames of a step was used to define a vector in hip-knee angle space. The directions of these vectors were used to define the angular component of correspondence (ACC) across multiple steps for each limb. Comparisons were made for stroke vs. control and FNS-IM vs. no FNS-IM.

### RESULTS AND DISCUSSION

According to ANOVA model analysis (summarized in Tables 1, 2, and 3, below), there was a significant difference in intralimb coordination for the following: stroke vs. control (both limbs); involved limb vs. uninvolved limb for the stroke survivors; and involved limb pre-treatment vs. post treatment for the FNS-IM group.

The results indicated that the ACC measure successfully differentiated intralimb coordination between controls and stroke survivors for both limbs and between the involved and uninvolved limbs in stroke survivors, meeting the first goal of this study. The ACC also discriminated an improvement following treatment in the FNS-IM group, meeting the second goal of the study. There was no gain detected for the non-FNS-IM group.

## ESTIMATING THE AXIS OF A SCREW MOTION FROM NOISY DATA — NEW METHOD BASED ON PLÜCKER LINES

<sup>1</sup> Koon Kiat Teu, <sup>2</sup>Wangdo Kim

<sup>1</sup>School of Mechanical & Production Engineering, Nanyang Technological University, Singapore

<sup>2</sup>Biomechanics Laboratory, Legacy Clinical Research & Technology Center; email: wkim@biomechresearch.org

### INTRODUCTION

Screw axis has been employed to describe joint kinematics mainly in clinical assessments. It is intuitive that the geometry of the screw axis of a spatial displacement can be fully and easily studied using Plücker's coordinates that define the line directly [1]. One of the fundamental problems in calculating screw axis is noisy data. The new algorithm presented in this paper takes advantage of set of line patterns, which are derived from point data using dual number relationship. The method involves mapping a set of lines to the corresponding lines after movement. The mapping of vectors is made possible by the use of dual transformation matrix. The dual transformation matrix (DTM) has been shown to be effective means of three-dimensional *line* transformation in displacement analysis [2].

### METHODS

The method in this paper involves obtaining the DTM from coordinated points. This method has been mentioned in [2]. After solving for DTM  $[\hat{R}]$ , we solve for the dual vector associated with DTM using the eigenvector.

$$[I - \hat{R}]\hat{V} = 0, \quad (1)$$

and seek solution other than  $\hat{V} = 0$ . This is easily done if we separate it into the pair of vector equations comprising the primary and dual component respectively

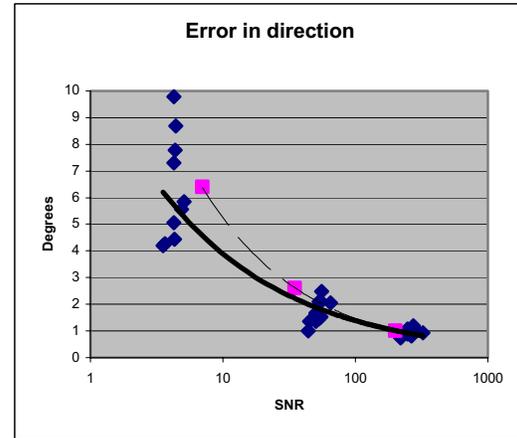

$$\begin{aligned} [I - R]V &= 0 \\ [I - R]W &= [D]V \end{aligned} \quad (2)$$

Where  $[D]$  is the skew-symmetric matrix defined by  $[D]V = d \times V$  for any translation and we used the property of  $[R]V = V$ .

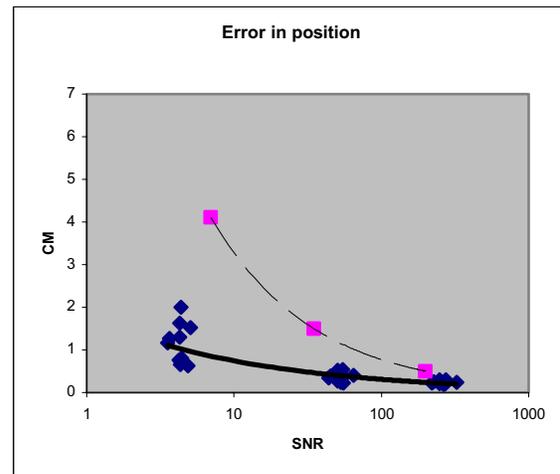

The proposed method was tested on simulated data. The simulations follow closely to that of [4].

### RESULTS AND DISCUSSION

The simulation results in [4] ("new" and "FHA" method) were used as references for the proposed algorithm. The results of the "new" methods were superimposed to our simulation results in Figure 1 and 2 as a comparison. The general trend of the error follows that of those reference methods. The errors in direction and position were lower when there's significant noise. For skin movement artefact simulation, the estimation of the position using the proposed method was better. The error in direction is reasonably good and follows closely to that of the "FHA" method. The simulation results showed that the proposed method worked well, especially in estimating the direction of the screw axis when noise is present. The mapping of vectors gives a better estimate of the rotation than mapping of points data. The results are highly significant as they demonstrate an advantage of using line instead of points.

**Figure 1:** Mean error in the estimated direction of the axis plotted against the SNR (Signal To Noise Ratio). The solid lines correspond to the presented method and the dotted lines to the "new" method.

**Figure 2:** Mean error in the estimated position of the axis plotted against the SNR

### CONCLUSIONS

In our study, the estimation of screw axes from a set of Plücker lines clearly outperforms the conventional methods using points data. This opens the range of new practical applications of Plücker lines in bio-kinematics situation. The method provides an alternative analysis tool for estimation of screw axes and can be applied to any actions such as gait analysis in clinical setting to estimate the screw axis.

## MECHANICAL PERFORMANCE OF ARTIFICIAL PNEUMATIC MUSCLES TO POWER AN ANKLE-FOOT ORTHOSIS

<sup>1</sup>Keith E. Gordon, <sup>1,3</sup>Gregory S. Sawicki and <sup>1,2</sup>Daniel P. Ferris  
<sup>1</sup>Departments of Movement Science, <sup>2</sup>Biomedical Engineering, <sup>3</sup>Mechanical Engineering  
University of Michigan, Ann Arbor, MI; email: [kegordon@umich.edu](mailto:kegordon@umich.edu)

### INTRODUCTION

A powered ankle-foot orthosis could be very useful for investigating neuromechanical control of human locomotion. Plantar flexor muscles are critical to the generation of forward velocity and support of the center of mass during human walking. The purpose of this study was to quantify the mechanical performance of a pneumatically powered ankle-foot orthosis that assists plantar flexion during the stance phase of walking.

### METHODS

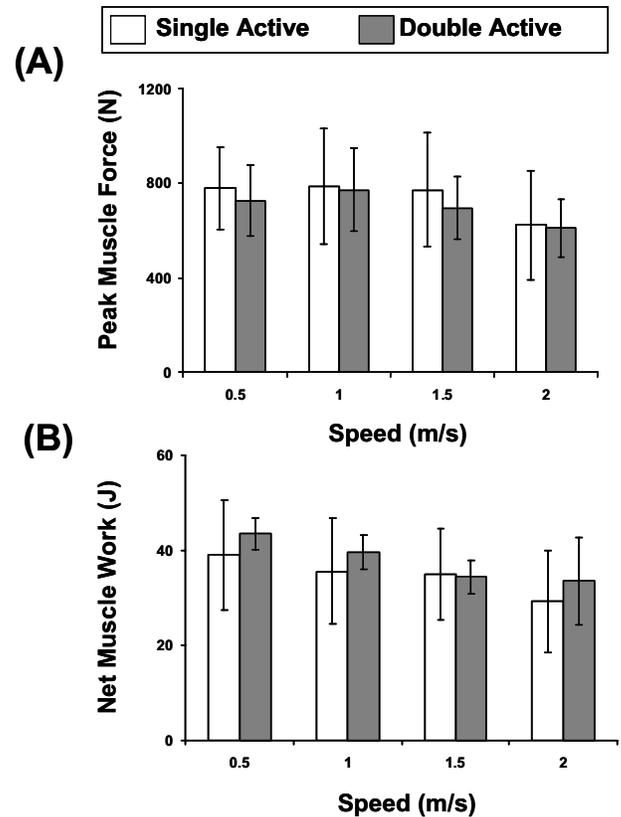

Three subjects walked at a range of speeds (0.5-2.0 m/s) wearing a unilateral ankle-foot orthosis (~1.5 kg) with either one or two artificial muscles working in parallel (Figure 1). Foot switches on the ball of the foot activated the artificial pneumatic muscles (6.2 bar) using on-off control. We hypothesized that two artificial muscles would provide greater torque and mechanical work than one artificial muscle.

**Figure 1: Powered Ankle-Foot Orthosis.** Left) Orthosis fit with a single artificial muscle. Right) Orthosis fit with two parallel artificial muscles to provide plantar flexor torque.

### RESULTS AND DISCUSSION

Contrary to our hypothesis, the orthosis produced similar total plantar flexor torque and net work independent of the number of artificial muscles (Figure 2). The orthosis generated 57% of the peak ankle plantar flexor torque during stance and performed ~80% of the positive plantar flexor work done during normal walking. The similarity in torque and work between single and double muscle conditions can be explained by the artificial muscle force-length properties. Peak artificial muscle force will decrease linearly as artificial muscle length decreases during contraction. Subjects altered their ankle kinematics between single and double muscle conditions. During the double muscle condition subjects increased plantar

**Figure 2:** A) Peak artificial muscle force (mean  $\pm$  s.d.). B) Net artificial muscle work (mean  $\pm$  s.d.). Double muscle data is the sum of both muscles.

flexion resulting in shorter artificial muscles lengths. At shorter artificial muscle lengths, the peak artificial muscle force was less.

Positive work performed by the orthosis on the ankle joint (torque-angle) was about 29% less than work performed by the artificial muscles (force-length). Compliance in the muscle attachment brackets and orthosis shell resulted in the artificial muscles shortening without concomitant changes in joint angle.

### CONCLUSIONS

These findings emphasize the importance of human testing in the design and development of robotic exoskeleton devices for assisting human movement. In this study, subjects modified their joint kinematics when walking with the powered orthosis, resulting in similar joint kinetics between conditions.

<sup>4</sup>Advanced Wound Healing Center, Temple University School of Podiatric Medicine, Philadelphia, USA

email: [wkim@biomechresearch.org](mailto:wkim@biomechresearch.org)

### INTRODUCTION

A method of 3D optical technique for quantifying wound size is presented. More traditional measures of the wound length and width fail to account for irregular wound shape. A reliable and accurate wound size assessment is needed to objectively evaluate efficacy of various wound care modalities.

### METHODS

A special platform was constructed to position the wand of the laser scanner and a digital camera in a common coordinate system when the ulcer surface is scanned. Using a FastSCAN laser scanner (Polhemus, Colchester, Vermont, USA), the ulcer's rim curvature map [1-2] is computed. Utilizing a specified rim curvature value, the wound edge is detected and processed via a cubic spline smoothing. The digital photo is, then, transformed into the same coordinate system as the laser scanner to qualitatively verify the wound boundary. The wound dimensions are reconstructed by interpolating the surface regions outside the ulcer using a second order polynomial fitted to the points outside the ulcer boundary. The averaged difference between the reconstructed surface and the scanned ulcer surface is taken as the mean ulcer depth. The volume is the product of area and the mean depth. Using this technique, a venous status ulcer at the lateral malleolus was scanned ten times during one month period. Three repeated measurements are made for each session.

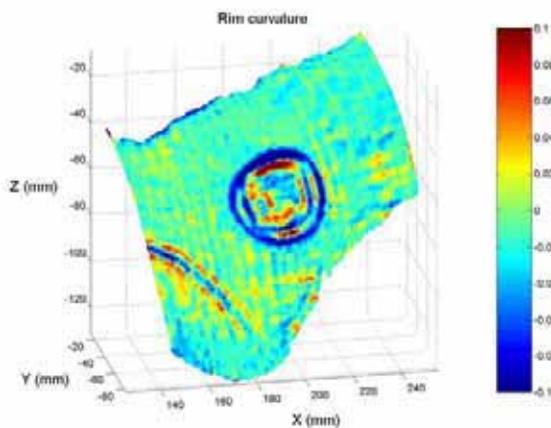

Figure 1: The rim curvature map of the ulcer.

### RESULTS AND DISCUSSION

From the map of rim curvature (Fig. 1), the ulcer boundary can be readily delineated. Calculated wound depth, area, and volume are shown in Fig. 2 with the maximum, minimum and mean values of the three independent measurements. While there is slight increase in area, the ulcer depth and the volume

have decreased over time, which are in agreement with the clinical observation.

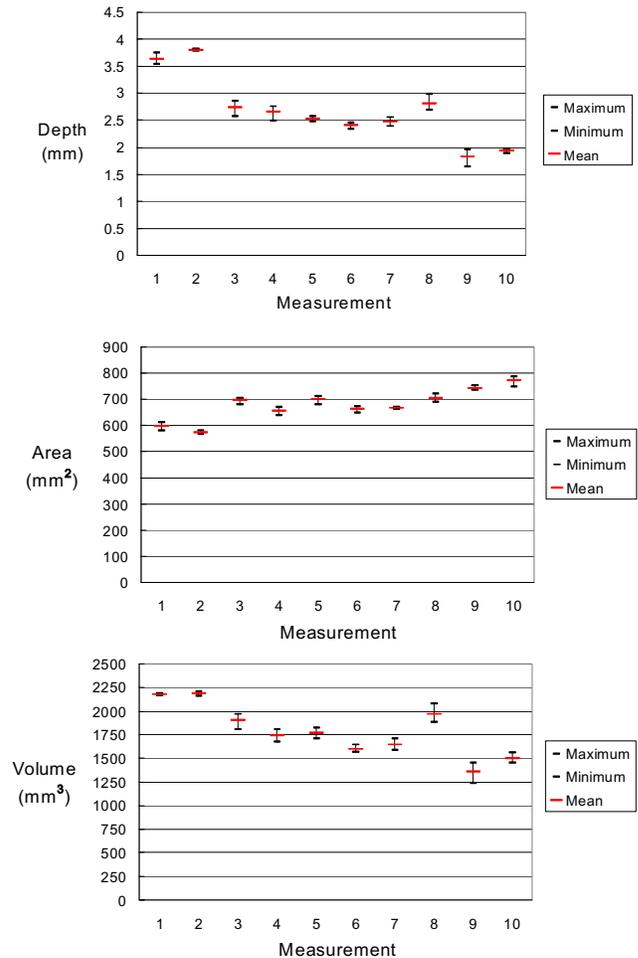

Figure 2: Calculated dimensions of the ulcer over a month.

### CONCLUSIONS

The surface scanning aided by rim curvature maps and photograph is shown to be a potentially viable non-contact method of wound measurement. Additional studies are needed to test its reliability, accuracy, and utility of this technique in wound related studies.

## TARGET ACQUISITION BY PILOTS WEARING VARIOUS HEAD-SUPPORTED MASSES DURING SIMULATED FLIGHT

<sup>1</sup>Stuart Fraser, <sup>2</sup>Nabih Alem

<sup>1</sup>UES, Inc. at U.S. Army Aeromedical Research Laboratory, Fort Rucker, Alabama, USA, <sup>2</sup>U.S. Army Aeromedical Research Laboratory, Fort Rucker, Alabama, USA; email: [stuart.fraser@us.army.mil](mailto:stuart.fraser@us.army.mil)

### INTRODUCTION

The modern U.S. Army helicopter helmet has evolved from a simple crash protection device to a mounting platform for advanced technologies, greatly increasing the effective combat power of the pilot. Current helmet designs are capable of supporting such devices as night vision goggles (NVGs), forward looking infrared (FLIR) display and weapon aiming systems. All of these devices add weight and displace the center of gravity (CG) of the helmet system forward to head and neck CG. This increased helmet load relative to the head and neck CG adds biomechanical stress to the neck and upper body of the pilot, which ultimately could lead to decrements in performance, including such tasks as searching for targets. To date, the relationship between the head-supported loads and the CG of the system and the effects on the pilots in low-G maneuvers has not been explored systematically. This paper investigates the effects of mounting additional mass on the helmet and displacing the CG location on the ability of a pilot to acquire targets placed throughout an NUH-60 helicopter cabin.

### METHODS

To simulate various helmet weight moments, an HGU-56/P aviator helmet was modified to include fixtures that consisted of graduated rods extending forward relative to the direction the pilot was facing. This allowed for the addition of various weights at different distances. In addition to these modifications, a head motion tracker was attached to the top of the helmet using Velcro®. Within an NUH-60 flight simulator, five liquid crystal display targets were placed around the subject; and a computer controlled the presentation of targets and integrated information from the motion tracker, requiring the pilot to actually face the target to successfully 'acquire' it. The pilots flew a 2-hour flight pattern, with 5-minute blocks of target acquisition repeated six times. The time and accuracy of the acquisitions were recorded.

### RESULTS

Multivariate analysis of variance was performed on the effect of the helmet on the acquisition times (Figure 1). The results showed that for targets lower left, upper left, upper center and upper right of the pilot, helmet mass had a significant effect, but center of gravity location did not. Post-hoc analyses showed that increasing mass increased acquisition time for these targets, except for the lower left target; where increasing mass decreased acquisition time. Comparisons of target-hit ratios were compared across all subjects for all targets, with no significant differences discovered. Also, there were no

significant effects observed when testing for the effect of flight time on target hit ratios.

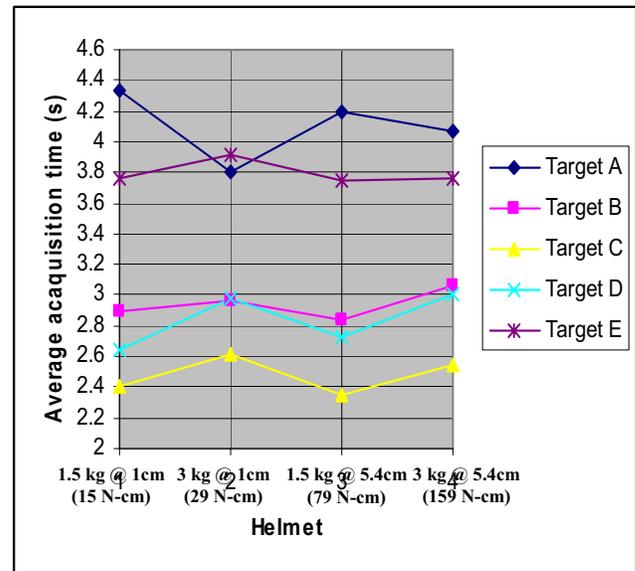

Figure 1: Average acquisition times by helmet and target

### DISCUSSION

At six 5-minute intervals throughout a 120-minute flight, pilots were tasked to acquire targets placed throughout the cabin by pointing their helmet at the active target as quickly as possible. These tasks were repeated while the pilot wore four different head supported mass configurations. Overall, changes in helmet configuration did have a significant effect on target acquisition time, and it was the mass component of the system that produced the most significant effects in this aspect of performance. Helmets of greater mass (even if there was a lesser overall weight moment) performed worse on targets above the shoulders of the pilots, whereas a target on the center console of the aircraft performed better with the additional mass. The performance of the pilots in acquiring targets over the course of a 2-hour session did not change significantly. These results would indicate that reducing the mass of the helmet should be a priority in enhancing the effectiveness in pilots' head motion to detect and focus on targets in their environment.

**LOWER EXTREMITY JOINT WORK IS LARGER IN ASCENDING VS. DESCENDING GAITS**

Paul DeVita, Joseph Helseth, Brandon Noyes and Tibor Hortobagyi  
 Dept of Exercise and Sport Science, East Carolina University, Greenville, NC, USA  
 email: [DeVitaP@mail.ecu.edu](mailto:DeVitaP@mail.ecu.edu)

**INTRODUCTION**

Metabolic rate (i.e. rate of O<sub>2</sub> consumption) is ~3-fold higher walking up vs down stairs and inclines [1,2]. This difference is attributed to the lower metabolic efficiency of generating muscle force through shortening vs lengthening contractions. Two reports however showed that mechanical work from joint powers is ~1.4 to 2.0-fold larger in stair ascent vs descent [3,4]. We also reported that this joint work was only 6% less than the change in potential energy (PE) in stair ascent but was 24% less than the change in PE in stair descent despite equivalent changes in total body PE in these gaits [5].

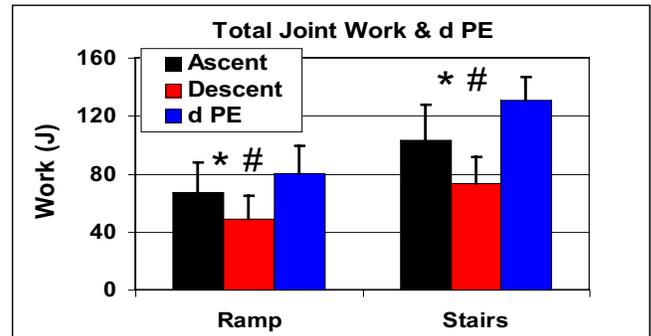

These data lead to a generalized hypothesis about mechanical work through joint powers in ascending and descending gaits. We hypothesize that lower extremity muscles will produce more mechanical energy during gait tasks in which humans raise their center of mass compared to the energy they absorb in gait tasks in which humans lower their center of mass. The purpose of this study was to compare joint work in stair and ramp ascent and descent gaits.

**METHODS**

Ground forces and sagittal plane kinematics were obtained from 34 young, healthy volunteers (mass: 69 kg) as they ascended and descended a 4-step stairway and a 10° ramp. The kinematic and force data were combined through inverse dynamics to calculate lower extremity joint torques during the stance phases. Joint power and joint work were calculated as the product of the torque and angular velocity at each joint and as the area under the power-time curves, respectively. We assume that work from joint powers is produced by muscle force since joint powers are derived from joint torques. Total work was assessed by summing the work performed at each joint. Changes in PE (d PE) were calculated as the change in total body PE per step up or down the ramp and stairs. All descent values were negative but are shown in absolute values for comparison purposes. 2-way ANOVA with specific comparisons was used to compare sample means, p<.05.

**RESULTS AND DISCUSSION**

Total joint work was 28% lower in descent vs ascent in both gaits (figure 1, table 1). The mean vertical displacements per step were 12 and 20 cm on the ramp and stairs yielding d PEs of 82 and 132 J of work. Total joint work in ascent and descent were 17% and 40% lower than d PE on the ramp and 22% and 44% lower than d PE on the stairs (all p<.05).

**Figure 1:** Total joint work and d PE on the ramp and stairs. Descent values in |J|. \* Ascent > Descent, p<.05, # Ascent & Descent < d PE, p<.05.

While both gaits had less joint work in descent, the pattern of responses across the individual joints varied between gaits. Stair descent vs ascent had similar decreases at each joint (~10 J). Ramp descent vs ascent had large decreases in hip and ankle work (~25 J) but a large increase in knee work (35 J).

By ignoring work due to ligament forces we may be slightly overestimating muscle work. We also did not report swing phase energetics. Based on predicted masses of the limbs we estimate that 13 J and 20 J of work were needed to displace the limb on the ramp and stairs which account for ~75% of the difference between joint work and d PE in the ascending gaits but only 36% in descending gaits. We suggest the unidentified work in descending tasks is produced by other tissues including bone, cartilage and spinal discs. Results suggest the higher metabolic cost of ascending gaits is partially due to larger contributions from muscles in these tasks.

**CONCLUSIONS**

Despite the limitations, the results suggest lower extremity muscles produce more mechanical energy during gait tasks in which humans raise their center of mass compared to the energy they absorb in gait tasks in which humans lower their center of mass despite equivalent changes in total PE.

## BONE MECHANICS FROM FINITE ELEMENT MODELING AND MICRO-COMPUTED TOMOGRAPHY: VALIDATION OF AN ORTHOTROPIC MATERIAL MODEL WITH FUSED DEPOSITION MODELING

<sup>1,2</sup> Renfeng Su and <sup>1,2</sup> Steven Boyd

<sup>1</sup>Department of Mechanical and Manufacturing Engineering, University of Calgary, Alberta, Canada

<sup>2</sup>Calgary Center of Innovative Technology, Alberta, Canada; email: [skboy@ucalgary.ca](mailto:skboy@ucalgary.ca), web: [www.enme.ucalgary.ca/~skboyd](http://www.enme.ucalgary.ca/~skboyd)

### INTRODUCTION

Bone diseases such as osteoporosis result in bone loss and weakened bone micro-structure and could lead to spontaneous fractures. Detection of bone micro-structural changes and their impact on bone mechanics is important for the successful treatment of bone diseases and progression of joint injuries.

It is commonly postulated that local mechanics (tissue stress or strain) is related to stimuli for bone remodeling [1]. A micro finite element ( $\mu$ FE) solver was developed in our lab to numerically predict the local stress and strain in bone structure [2,3]. Micro-computed tomography ( $\mu$ CT) can provide high resolution image data suitable to the  $\mu$ FE solver and allows non-destructive, three-dimensional morphological and mechanical analysis of bone. With newly developed in vivo  $\mu$ CT,  $\mu$ FE simulation of bone mechanics can be evaluated over time. However, it is important that  $\mu$ FE models be validated for numerical accuracy. This is problematic because it is difficult to perform experiments on 1:1 scaled bone.

A method has been developed to validate  $\mu$ FE models using rapid prototyping: fused deposition modeling (FDM). FDM prototypes can be built based on  $\mu$ CT image data and scaled up so that local stress values can be measured in an experimental setup using strain gauges for comparison with  $\mu$ FE models to estimate accuracy.

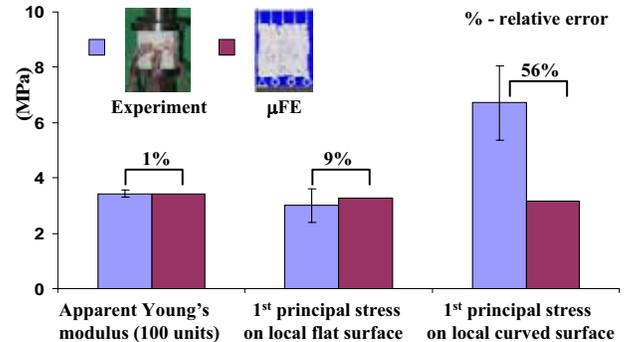

### METHODS

Five identical FDM prototypes were manufactured (FDM Titan, Stratasys, Minnesota, U.S.A) based on a  $1.7 \times 1.7 \times 1.7 \text{ mm}^3$  volume of trabecular bone scaled to 30:1. Two rosette strain gauges were mounted on each prototype: one on a flat and one on a curved surface. Uniaxial compression ( $1\% \epsilon$ ) was performed on the five prototypes. Two data acquisition systems were used for recording. Apparent stress ( $E_{app}$ ) and local 1<sup>st</sup> principal stresses calculated from rosette readings were obtained experimentally.

The  $\mu$ FE model is based on the same trabecular bone image data used for the prototypes, and boundary and loading conditions mimicked the experiments. The material properties used were the orthotropic properties of FDM material which were previously determined experimentally [4]. Our in-house  $\mu$ FE solver was upgraded to solve this orthotropic model. Results from  $\mu$ FE (stress results in elements in a  $3 \times 3$  region corresponding to each gauge were averaged) were compared to experimentally measured strains.

### RESULTS AND DISCUSSION

The FDM Titan machine was tested for volumetric reproducibility (five models; 0.1% error), and the FDM

**Figure 1:** Comparison of experiment and  $\mu$ FE results at both global (left) and local levels (middle/right) on a trabecular bone model.

prototype volumes were matched to the  $\mu$ FE mesh volumes. The  $\mu$ FE model predicted  $E_{app}$  measured experimentally within  $<1\%$  (Fig. 1). The local 1<sup>st</sup> principal stress calculated by  $\mu$ FE was within 9% of experimental data on the flat surface and 56% on the curved surface (Fig. 1). The accuracy of our in-house  $\mu$ FE model at the apparent level (1%) indicates that global orthotropic material properties can be predicted well based on digital FE models. The error of prediction on the curved surface was largest due to the jagged hexahedron mesh used, as well as due to the problems of attaching strain gauges to curved surfaces. The reduced error in local stress measurements on the flat surface is due to the reduced effect of jagged surfaces in that region of the  $\mu$ FE model.

### CONCLUSIONS

The prediction of trabecular bone mechanical properties by our in-house  $\mu$ FE solver is more accurate at the apparent level than local level. This result is expected, and smoothing these  $\mu$ FE models may reduce these local errors (work in progress). The results presented here reinforce that  $\mu$ FE models used to predict bone remodelling based on local stress/strain should account for the large errors that may occur on the model surface.

## VARIATIONS IN SCAPHOLUNATE GAP WITH VARIOUS TYPES OF LIGAMENOUS SECTIONING

<sup>1</sup>Haoyu Wang, <sup>2</sup>Frederick W. Werner, <sup>2</sup>Walter H. Short, <sup>2</sup>Jason K. Green

<sup>2</sup>SUNY Upstate Medical University, email: [wernerf@upstate.edu](mailto:wernerf@upstate.edu)

### INTRODUCTION

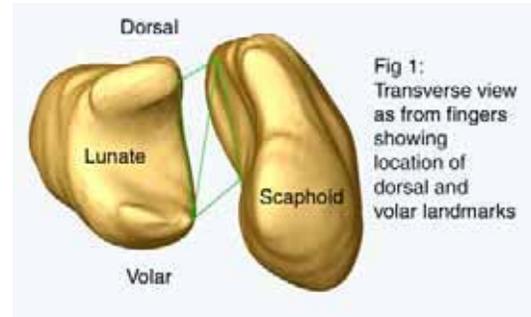

Instability of the scapholunate joint is frequently manifested by wrist pain but determining which ligament or ligaments are torn is difficult. Most studies agree that the scapholunate interosseous ligament (SLIL) is the primary stabilizing structure. However, there are secondary stabilizing structures such as the dorsal intercarpal (DIC) and dorsal radiocarpal (DRC) ligaments. Pre-surgical determination of which structures are damaged would be of value to the surgeon when attempting to repair the torn ligaments. The purpose of this study was to determine if various gap patterns between the scaphoid and lunate could be related to which ligaments were ruptured. A secondary purpose was to determine which wrist position might best differentiate these effects.

### METHODS

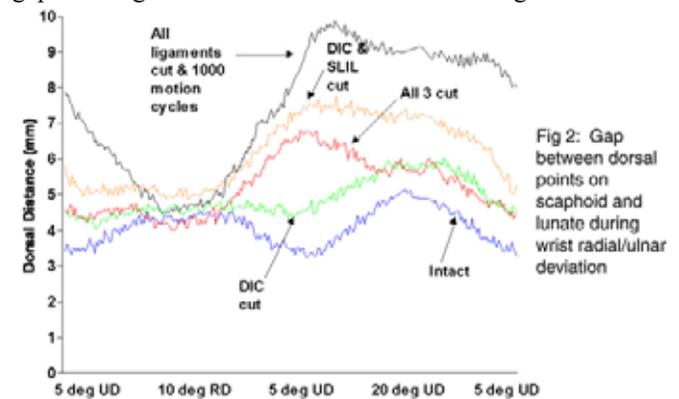

Ten cadaver forearms were evaluated. Fastrak motion tracking sensors were attached to the scaphoid, lunate and third metacarpal to measure angular and translational motion of these bones. Each wrist was physiologically moved using a wrist joint simulator through repetitive cyclic flexion/extension of the wrist (30° extension to 50° flexion) and wrist radial/ulnar deviation (10° radial deviation to 20° ulnar deviation). Carpal bone motion data were collected in the intact specimens, and in 5 arms after sequentially sectioning the DRC, the DIC, and the SLIL. In five additional arms, data were acquired after sequentially sectioning the DIC, the SLIL, and the DRC. Data were again collected after 1000 cycles of flexion/extension motion following complete ligament sectioning to mimic continued use after injury. 3D animated models were created of each wrist, based upon serial CT scans to aid in analyzing the data. The experimental kinematic scaphoid and lunate data were used to drive the animated motions. Two anatomical landmarks were identified on the lunate (dorsal lunate, volar lunate) and two on the scaphoid (dorsal scaphoid and volar scaphoid). Using the models and kinematic data, the distances between the dorsal points and between the volar points were determined during each motion (fig 1) for each level of ligament sectioning using customized CAD software. Additionally, a projected quadrilateral area was computed from these four points.

### RESULTS AND DISCUSSION

Sectioning of only the DRC (1<sup>st</sup> group of arms) or only the DIC (2<sup>nd</sup> group of arms) caused no increase in the gap between

the bones (fig 2, table 1). Subsequent sectioning of the SLIL caused an average 35 to 55% increase in the dorsal and volar gaps during flexion/extension and an average 10 to 40%

increase during radial/ulnar deviation. Even though the gaps during wrist flexion/extension were greater than during radial/ulnar deviation, the wrist angle during flexion/extension at which the largest gap occurred varied among arms. Typically the gap increased the least in wrist extension. However, during radial/ulnar deviation, the largest gaps were consistently observed in ulnar deviation. With cyclic motion, the gaps increased, especially during the radial/ulnar deviation motion.

### CONCLUSIONS

Following wrist ligament injury, detection of major gap changes, between the scaphoid and lunate, may be best detected in wrist ulnar deviation.

### INTRODUCTION

Current finite element (FE) models of the human lower extremity lack accurate viscoelastic material properties of the knee ligaments, which are needed for computational evaluation of pedestrian injuries [1]. Medial collateral ligament (MCL) is the most frequently injured ligament in lateral impacts. Therefore, the accuracy of the viscoelastic mechanical properties of the MCL FE model is of crucial importance in modeling pedestrian impacts [2]. The focus of this work is to determine the global viscoelastic material properties of MCL using a representative human MCL tested under dynamic and quasi-static loadings.

### METHODS

The bone-MCL-bone specimen was extracted and its ends were potted in the fully extended position. The proximal potting cup was rigidly fixed and the distal cup was pulled along the longitudinal axis of tibia. First, the specimen was subjected to a ramp-and-hold test with constant tensile ramp of 3 mm in 30 ms and approximately 600 seconds hold time. The second test was a quasi-static test to failure on the same specimen. In both tests the time histories of force and displacement were recorded. For identification of the material properties, the components of the UVA-GM FE model [2] were used (Figure 1). The insertion sites were modeled using tied contact between bones and ligament. The material model was assumed as transversely isotropic quasi-linear viscoelastic (QLV). The direction of anisotropy (of collagen fibers) was defined in the material definition as the element normal along the insertion sites. First, the quasi-static test was simulated. The material coefficients were optimized using LS-Opt [4], assuming the quasi-static test data as the target values and defining minimization of the root-mean-square (RMS) error as the objective function. The range of values of hyperelastic coefficients ( $C_1$ - $C_5$ ) used in the optimization process were defined based on the reported data in [5]. The viscoelastic properties of the ligament were then determined from the dynamic ramp and hold test. A three-term Prony series was considered for the relaxation behavior. The long-term Prony coefficients ( $S_3$  and  $T_3$ ) were estimated directly from the relaxation data. The two additional Prony coefficients ( $S_1$ ,  $T_1$ ,  $S_2$ , and  $T_2$ ) were determined by considering both the ramp and hold periods and the same FE optimization procedure described above was conducted.

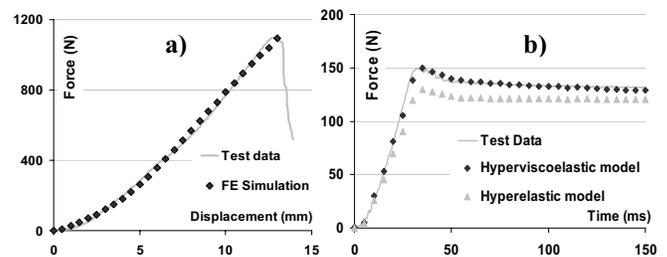

**Figure 1:** FE Simulation of the MCL Tensile Tests

### RESULTS AND DISCUSSION

The material coefficients obtained by FE optimization are provided in Table 1. The results of the simulations of quasi-static failure tests and dynamic ramp-and-hold tensile tests of MCL in comparison with experimental data are shown in Figures 2-a, and 2-b respectively. In the dynamic test with 0.1 mm/ms displacement rate, approximately 15% increase in the peak dynamic force was observed, which suggests that tissue viscoelasticity plays certain role in the response during impact scenarios. The elastic stress-strain relationship in a cubic sample of MCL in tension along the collagen fibers with optimized parameters was compared with the corridor provided in [5]. The current material model was slightly stiffer at strains above 13%. This material model was determined by assuming a homogeneous anisotropic material for the whole MCL and optimizing its global tensile properties. However, MCL is inhomogeneous particularly at the insertion sites, which could explain the difference observed in its local (anterior-central two-third region) and global properties.

**Table 1:** Optimized MCL material properties

<b>K</b> (GPa)	<b>C<sub>1</sub></b> (MPa)	<b>C<sub>3</sub></b> (MPa)	<b>C<sub>4</sub></b> -	<b>C<sub>5</sub></b> (MPa)	<b>S<sub>1</sub></b>
3.75	7.85	0.25	60.4	307.5	0.15
<b>S<sub>2</sub></b>	<b>S<sub>3</sub></b>	<b>T<sub>1</sub></b> (ms)	<b>T<sub>2</sub></b> (ms)	<b>T<sub>3</sub></b> (ms)	<b>λ</b>
0.026	0.348	100	11710	162633	1.055

**Figure 2:** FE Simulation of the MCL Tensile Test

### CONCLUSIONS

The global viscoelastic material properties of an MCL specimen were derived by FE optimization. Results showed that tissue viscoelasticity increases the peak dynamic force by 15%. Studies of more specimens are underway and will be reported in the future.

## EFFECTS OF EXAGGERATED PRONATION AND SUPINATION ON LOWER EXTREMITY MECHANICS DURING A CUTTING MANEUVER

Jennifer E. Earl, Sarika K. Monteiro, and Kristian M. O'Connor  
 Department of Human Movement Sciences

University of Wisconsin – Milwaukee; email: [jearl@uwm.edu](mailto:jearl@uwm.edu), web: [www.uwm.edu](http://www.uwm.edu)

### INTRODUCTION

The mechanism of non-contact ACL injury is commonly associated with a position of knee valgus and tibial external rotation which occurs during sudden twisting or cutting. The literature is contradictory about how foot pronation relates to knee motion and ACL injury. While excessive pronation has been identified as a risk factor [1], this motion is typically coupled with tibial *internal rotation*, and it is tibial *external rotation* that is observed at the time of injury. The purpose of this study was to determine how exaggerated pronation or supination influenced lower extremity kinetics and kinematics during a side cutting maneuver.

### METHODS

Ten active college-age males, with no current lower extremity impairment, volunteered to participate. Three-dimensional kinematic data were collected at 200 Hz and ground reaction force data were collected at 1000 Hz. Subjects ran 4.5-5.0 m/s, and watched for a visual cue to run straight ahead, cut 45° to the left, or stop quickly. This design was intended to elicit an unanticipated cutting response, which has been shown to differ from anticipated cutting maneuvers [2]. The right leg of all subjects was tested. Only the cutting trials were analyzed.

Subjects wore custom-made running shoes: a pair with a neutrally-posted midsole, a pronated pair with an 8° lateral rearfoot wedge, and a supinated pair with an 8° medial rearfoot wedge [3]. Five trials of each activity (run, cut, stop) were collected in each of the three shoes, for a total of 45 trials.

Three-dimensional hip, knee, and ankle joint kinematics and kinetics were calculated. Peak joint angle and moment data were extracted from the stance phase and analyzed using repeated measures ANOVA ( $p < 0.05$ ).

### RESULTS AND DISCUSSION

The pronated shoe caused a significant change in ankle mechanics. Peak ankle eversion angle ( $f_{2,18}=3.51$ ,  $p=0.05$ ), and ankle inversion moment ( $f_{2,18}=10.96$ ,  $p<0.001$ ) were significantly increased in the pronated shoe. It was expected that any change that occurred at the ankle would be transferred up the kinetic chain and result in changes at the knee and hip. However, no significant changes in either knee or hip

kinematics were seen. Joint angle patterns observed in this study are similar to those previously reported [4,5]. The pronated shoe did cause the knee external rotation moment to be significantly lower ( $f_{2,18}=5.03$ ,  $p=0.02$ ), and there was a trend that the pronated shoe also caused the knee varus moment to be lower ( $p=0.10$ ) (Table 1). This indicates that in the pronated shoe there was less demand on the knee joint to maintain transverse plane stability.

These findings seem to contradict the theory that excessive pronation increases the stress at the knee during a cutting maneuver, and is therefore a risk factor for ACL injury. The pronated shoe with its lateral wedge seemed to provide an inclined push-off surface that re-oriented the ground reaction force vector in such a way that the stability of the knee was enhanced.

These findings may not be directly related to the mechanics of an individual with anatomical excessive pronation. These individuals would not have the benefit of the angled push off surface that existed in the pronated shoe design. The supinated shoe, however, could have approximated the effect of a posted orthotic, which did not lead to significant differences in kinematics or kinetics as compared to the neutral shoe.

### CONCLUSIONS

The shoe that exaggerated pronation enhanced the transverse plane stability at the knee, and caused less rotational torque on the knee joint. Additional research is needed to identify if this pattern is consistent in females, and if anatomical pronation causes the same effect.

## fMRI BRAIN IMAGING DURING SIX DOF MECHANICAL MEASUREMENTS OF UPPER LIMB ISOMETRIC CONTRACTIONS

<sup>1</sup>Daniel M. Krainak, <sup>1,2</sup>Todd B. Parrish, and <sup>1,3</sup>Julius P.A. Dewald

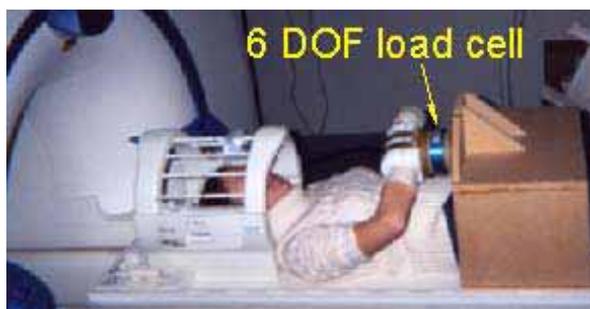

Northwestern University <sup>1</sup>Department of Biomedical Engineering, <sup>2</sup>Department of Radiology,  
and <sup>3</sup>Department of Physical Therapy & Human Movement Sciences; e-mail: [krainak@northwestern.edu](mailto:krainak@northwestern.edu)

### INTRODUCTION

A six degree of freedom (DOF) load cell technology is used to measure joint torques in a functional magnetic resonance imaging (fMRI) environment in an unprecedented manner. This system offers substantial improvement over existing methods that monitor at most one DOF during fMRI motor experiments. Developing a functional brain map depends on adequate characterization of motor output. Collecting multiple joint torques and fMRI simultaneously surpasses all current methods used to assign brain areas to motor functions.

### METHODS

A novel system using a non-ferrous six degrees of freedom load cell (JR3, Inc., Woodland, CA) to monitor shoulder and elbow joint torques is developed to conduct functional MRI investigations of the human motor cortices (Figure 1). The subject's arm is surrounded by a fiberglass cast to prevent wrist movement and insure proper joint position [1]. A combination of delrin and garolyte provides an interface

**Figure 1:** Subject position and load cell mounting setup used during function MRI sessions.

surface to evenly distribute the loads generated by the subject across the entire load cell surface. A wooden frame holds the load cell in position. Load cell signals are filtered using 8<sup>th</sup> order low-pass Butterworth filters with a cutoff of 15-Hz and 4<sup>th</sup> order elliptical filters with a sharp 10-Hz cutoff. The filters remove artifacts caused by the gradients and radio frequency signals used in the functional MRI sequence. This system preserves the force and torque information used to calculate joint torques during contractions of the upper limb and provides feedback to the subject. Using a TTL pulse from the MRI system, joint torque samples are synchronized with the MRI recordings.

Functional MR images are collected from a 3.0-Tesla MR scanner (Siemens Trio, 3T) using a 2D gradient echo, echo-planar imaging sequence (TR=2000ms, TE=30ms, FA=80°, voxel=3.4x3.4x3mm<sup>3</sup>, 31-slices, 64x64 matrix). Following the functional imaging an anatomical scan of the entire brain is acquired as a reference image for functional data using an

MP-RAGE T1 weighted 3D gradient echo sequence (TR=2100ms, TE=4.38ms, FA=8°, voxel=1.0x1.0x1.0mm<sup>3</sup>). Visual stimuli for the functional MRI paradigms are observed through an MR compatible mirror mounted on the head coil aimed at a rear-projection screen fitted in the magnet. An event-related protocol using short, low-effort contractions with approximately 30-seconds between tasks is designed to minimize head movement artifacts during analysis [2].

### RESULTS AND DISCUSSION

The technique is verified both with a phantom MRI study and an incremental mass study. No artifact is caused by the presence of the load cell on phantom images. Load cell recordings inside the magnet match load cell recordings outside the magnet for the same masses. A study of shoulder and elbow activation in the motor cortices during elbow flexion and shoulder abduction confirms the feasibility of this measurement technique. An isolated joint torque is difficult to produce voluntarily without cocontraction. Substantial secondary torques are observed while monitoring multiple isometric joint torques during tasks such as elbow flexion and shoulder abduction. Thus, functional activity on the motor cortex may be related in large part to these secondary joint torques. For example, shoulder flexion is prominent during elbow flexion tasks and therefore, accounts for some portion of the neural activity.

### CONCLUSIONS

This methodology offers a unique and novel approach to investigate cortical control of the upper limb. It permits a greater association of cortical activity with the multi DOF nature of motor output. The system records multiple isometric joint torques generated by a subject and enables detailed study of the relationship between elbow/shoulder torques and associated cortical activation sites. To date, neuroimaging motor studies incorrectly associate most observed neural activity with a single motor output measurement consequently not accounting for unmonitored motor events. Assigning cortical regions based on a single DOF measurement grossly undermines the complexity of human movement. By incorporating multiple elbow/shoulder torques, we can better characterize the cortical activation map in both healthy and neurologically impaired subjects.

## DYNAMIC MODELING AND SYSTEM IDENTIFICATION OF FINGER MOVEMENT

Sang-Wook Lee and Xudong Zhang  
 University of Illinois at Urbana-Champaign  
 email: [xudong@uiuc.edu](mailto:xudong@uiuc.edu)

### INTRODUCTION

Biomechanical models for hand movement can aid in various industrial design and clinical evaluation processes. There exist kinematic models for grip posture prediction [1, 2] and inverse dynamic models for estimating muscle forces in static poses or movements [3, 4]. However, a forward dynamic model of finger movement, particularly one that is empirically based and computationally efficient, has been lacking.

This study aims to develop a dynamic model for predicting human finger movements during manipulative actions. The model incorporates a control scheme modulating dynamic stiffness and damping of the fingers to generate desired movements, and parametric system identification allowing empirical estimation of the parameters characterizing the dynamic properties.

### METHODS

The database for model development was from an experiment in which an anthropometrically diverse group of 28 subjects performed grasping motion tasks. Joint angular profiles derived were found to be of sigmoidal shape, which were then represented compactly by parametric hyperbolic tangent functions [4]. A constrained non-linear optimization was formulated to determine the parameter values of hyperbolic tangent functions best fitting the joint angular profiles.

A proportional-derivative (PD) control scheme was proposed to govern the system dynamics. The torque at joint  $i$  ( $i=1, 2, 3$ ) was computed as:

$$T_i = -K_i^p(\theta_i - \theta_i^f) - K_i^d(\dot{\theta}_i - \dot{\theta}_i^f), \quad T_i \leq M_i^{max} \quad (1)$$

where  $\theta_i$  denotes the angle of joint  $i$ ,  $\theta_i^f$  the joint angle in terminal posture,  $K_i^p$  the proportional feedback gain,  $K_i^d$  the derivative feedback gain, and  $M_i^{max}$  the upper limit of torque value generated at joint  $i$ .  $K^p$  and  $K^d$  characterize two main movement-specific properties: dynamic joint stiffness and damping.  $M^{max}$  corresponds to the torque maximum, i.e., the peak value of torque profile. In forward solutions given the parameter values, the 4<sup>th</sup>-order Runge Kutta method was employed.

The controller parameters were estimated in an optimization routine that minimized the discrepancy between the model-predicted and measured movement profiles. The discrepancy was represented as the difference between two sets of profile attributes: response time, peak velocity, and peak acceleration. These attributes are in fact the parameters in the aforementioned hyperbolic tangent functions fitting the measured profiles. The optimization routine iteratively estimated the control parameters resulting in model response that best matched the measurement. It should be noted that the movement speed affects the parameter values (e.g., faster

movement requires greater feedback gain and torque values). To remove the effect of speed, the obtained control parameters were normalized using a linear regression model. This parameter estimation scheme was applied to the movement database to determine the speed-scaled  $K^p$ ,  $K^d$  and  $M^{max}$  values.

### RESULTS AND DISCUSSION

The mean and standard deviation values of  $K^p$  and  $M^{max}$  are shown in Figure 1.  $K^d$  values showed a similar pattern across the digits as  $K^p$  (means for digit 2 to 5 were 6.9, 6.4, 6.1 and  $2.5 \times 10^{-3}$  N s m/rad, respectively). The grand mean RMSE (SD) value for 336 model-reproduced joint angular profiles was  $4.88^\circ$  ( $3.75^\circ$ ).

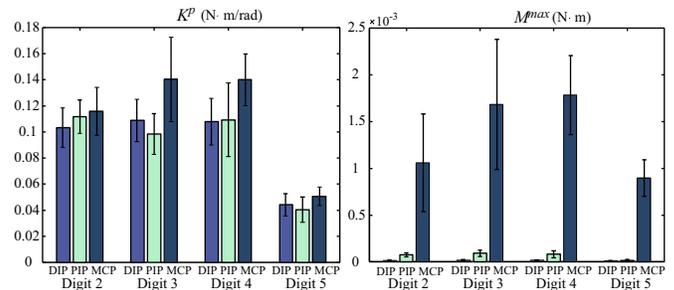

Figure 1: Mean and SD of estimated  $K^p$  and  $M^{max}$  values.

Estimated active joint stiffness  $K^p$  values were in a comparable range for digits 2 to 4, but were considerably smaller for digit 5. This can be considered as a reflection of the difference in anthropometric properties. A similar pattern was exhibited by  $K^d$  values. The  $K^p$  and  $K^d$  values for MCP were slightly greater than those for DIP and PIP, while the  $M^{max}$  values of the MCP joints were 10-100 times greater. These results are consistent with the understanding that most physical work in grasping motion is done by MCP flexion. They also are corroborated by an invasive EMG study [5] that discovered significantly higher levels of muscle activation associated with MCP flexion during grasping motions.

The proposed model enables computationally efficient and physically interpretable prediction of finger movement, owing to the simple control and parametric system identification scheme. Potential applications include computer-aided design of hand-operated products, clinical diagnosis of hand-related disorders or impairment.

### INTRODUCTION

Osteoporosis is a common clinical problem affecting more than 24 million people in the United States <sup>1</sup> and is a “systemic skeletal disease characterized by low bone mass and micro-architectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture.” <sup>2</sup>. Vertebral compression fractures (VCFs), the most common osteoporotic fractures, lead to significant and progressive physiologic and functional limitations <sup>3</sup>, that are compounded when subsequent VCF occur with serious long term consequences. There is up to a 30% age-adjusted increase in mortality and a 9% loss in lung function with each vertebral fracture <sup>4,5</sup>. Subsequent VCF may result from the continued osteoporotic process, from altered load transfer to adjacent levels as a result of altered biomechanics or a combination of both. This study was designed to investigate whether bone mineral density significantly alters adjacent level load transfer following polymethylmethacrylate augmentation, a minimally invasive technique used to treat VCF.

### METHODS

11 spines were used to obtain 21 five level segments composed of 12 upper thoracic (T3-7) and 9 lower thoracic segments (T8-T12). The segments underwent DEXA scanning to determine their bone mineral density (BMD). The segments were divided into two groups based upon BMD, a normal group (11 segments, mean BMD  $1.0 \pm 0.1 \text{ gm/cm}^2$ ) and an osteopenic/osteoporotic group (10 segments, mean BMD  $0.8 \pm 0.1 \text{ gm/cm}^2$ ). The superior and inferior vertebrae (T3, T7, T8 and T12) were fully embedded in polyester resin, and strain gauges (SGs) were applied to the anterior vertebral shells of T3, T7, T8 and T12, while force sensing resistors (FSRs) were inserted into the centers of the same vertebrae. Both the SGs and the FSRs were connected to signal conditioning equipment for data collection. The multilevel segments were biomechanically tested non-destructively in compression and flexion, a defect in the intermediate vertebrae (T5 and T10) was created using either inflatable bone tamps (osteoporotic segments) or bone drill and curettes (normal segments) to ensure a reproducible location of the initial VCF,

the VCF was then reduced and augmented and the non-destructive testing in compression and flexion was repeated. Measurements of stiffness, superior and inferior adjacent level strain, superior and inferior centrum load were taken from all the tests and compared using general linear modeling with two groups of multilevel segments (high and low BMD). The significance level was set at 0.05 with 95 % confidence interval limits with post hoc least significant difference tests.

### RESULTS AND DISCUSSION

The osteoporotic segments had significantly lower compressive stiffness than the normal segments, but there were no significant differences between the two groups in adjacent level load transfer (Table 1). In both groups there was higher adjacent level load transfer following fracture augmentation (strain  $p = 0.10$ , centrum load  $p = 0.41$ ) and flexion created a greater load transfer than compression (strain  $p = 0.001$ , centrum load  $p = 0.54$ ). Osteoporosis significantly reduced compressive stiffness from the reduced bone mass and deterioration of bone micro-architecture. Osteoporosis affects trabecular bone of the centrum to a more significant degree than the compact woven bone of the vertebral shell resulting in the reduced centrum load but increased strain at the adjacent levels.

### CONCLUSION

Augmentation of osteoporotic multilevel segments does not alter segment biomechanics.

### INTRODUCTION

Three groups of factors are known to explain muscle endurance: (1) anatomical factors (muscle mass and composition, capillary-zation), (2) physiological factors (hormones, enzymes, energy stores), and (3) neuromuscular activation patterns (NMAP). However, NMAP (variable activation of motor units within and between muscles, etc.) has rarely been quantified using indices derived from surface electromyography (EMG). This would help to estimate the role of NMAP when muscles fatigue. The aim of this study was thus to quantify the relationship between the NMAP of synergist muscles and fatigue using different EMG indices.

### METHODS

Seventy-four subjects (43 males and 31 females; age: 20-55 yrs) performed 3 maximal voluntary contractions (MVC) and a fatigue test while standing in a static dynamometer measuring L5/S1 moments [1]. Surface EMG signals were collected from 4 pairs of back muscles (multifidus at the L5 level, iliocostalis lumborum at L3, and longissimus at L1 and T10). The fatigue test, assessing absolute endurance (90 Nm load), consisted of repeating an 8-s cycle extension task (1.5 s ramp to reach 90 Nm + 5 s plateau at 90 Nm + 1.5 s rest). For all subjects, a familiarization session (MVCs + 10 min. fatigue test) was followed by a test session (MVCs + fatigue test to exhaustion or 60 min). A subsample of 31 subjects (19 males and 11 females) performed a 3<sup>rd</sup> session, but the fatigue test was performed to exhaustion using a relative load (41% MVC), thus assessing relative endurance.

*Strength* was defined as the peak MVC while our fatigue criterion was defined as the time to reach exhaustion either during the absolute (*Tend<sub>abs</sub>*) or relative (*Tend<sub>rel</sub>*) fatigue test. For each plateau, the time-series of the RMS amplitude (125 ms) of the EMG signals were computed. The EMG RMS time-series (first 5 min) were used to quantify NMAP between back synergists using 2 types of EMG indices (Ind1 and Ind2 adapted from [2]), both accounting for the effect of fatigue on EMG RMS (linear trends in the EMG time-series were removed). Ind1 basically reflects the variation in EMG activity of each muscle while Ind2 quantify the alternating activity between 2 muscles. Ind2 being the proportion of time of alternating activity (*P<sub>ALT</sub>*) times the amplitude of this activity, *P<sub>ALT</sub>* was also studied separately. For Ind2 and *P<sub>ALT</sub>*, various pairs of muscles (homolateral and contralateral) were assessed.

### RESULTS AND DISCUSSION

*Tend<sub>abs</sub>* values of subjects (27 males and 27 females) who reached exhaustion before 60 min (median = 14.4 min; range: 2.7-56.7 min), *Tend<sub>rel</sub>* values (median = 8.7 min; range: 2.0-24.3 min) as well as Ind1 and Ind2 indices (not *P<sub>ALT</sub>*) were first

log-transformed to obtain normal distributions. From the **absolute endurance protocol (load = 90 Nm; session 2; n = 54 subjects)**, the associations (Pearson correlation) between the EMG indices and *Tend<sub>abs</sub>* were all significant ( $P < 0.05$ ) and ranged between -0.29 and -0.61 (positive sign for *P<sub>ALT</sub>*). Higher Pearson correlations were observed between the EMG indices and *Strength* (range: -0.38 to -0.81; positive sign for *P<sub>ALT</sub>*). Stepwise regression analyses revealed that the EMG indices (2 to 4 selected depending on the model) can explain 57% of *Tend<sub>abs</sub>* and 68% of *Strength*. From the **relative endurance protocol (load = 41 % MVC; session 3 ; n = 31)**, few EMG indices (6/38) were significantly correlated to *Tend<sub>rel</sub>* and only three correlated with *Strength*. In the regression models, EMG indices explained only 29% of *Tend<sub>rel</sub>* and 22% of *Strength*. To verify whether Ind1, Ind2 and *P<sub>ALT</sub>* were sensitive to the progression of fatigue, these indices were computed for each 25% interval of the absolute fatigue test to exhaustion (n = 54 subjects). The one-way ANOVAs for repeated measures (4 time-intervals) showed, but only for Ind1 and Ind2, a significant ( $P < 0.05$ ) increase across intervals (fatigue effect).

It can be speculated that *P<sub>ALT</sub>* was more specific to measure alternating activity while Ind1 and Ind2 was more sensitive to EMG amplitude variations due to the recruitment of motor units (due to force or fatigue increase). In fact, the negative association between Ind1 and Ind2 indices and *Strength* during the absolute endurance protocol showed that Ind1 and Ind2 increase proportionally with the relative load. Hence, *Strength* being a predictor of absolute endurance ( $R^2 = 0.31$ ), negative associations between these indices and *Tend<sub>abs</sub>* were expected. During the relative endurance protocol, the relative load being equal across subjects, the relations between the EMG indices and *Tend<sub>rel</sub>* or *Strength* almost disappeared, except for some *P<sub>ALT</sub>* indices. The differential effect of fatigue on Ind1-Ind2 versus *P<sub>ALT</sub>* suggest that EMG amplitude variability increased but alternating activity was stable as fatigue progressed.

### CONCLUSIONS

The quantification of NMAP using surface EMG is complex but can reveal relations with the strength and endurance of an individual, particularly during an absolute endurance protocol.

## NOVEL APPROACH FOR STUDYING HUMAN RESPONSE TO WHIPLASH-LIKE PERTURBATIONS

James P. Dickey, Loriann M. Hynes, Christopher D. Jackson  
Human Biology and Nutritional Sciences,

### INTRODUCTION

Whiplash is a common and disabling condition with a significant associated health and economic burden. Much biomechanical research has attempted to understand the mechanism of this injury, and therefore enable strategies to lessen the severity and prevalence of whiplash injuries. This research has identified several primary sites of injury during whiplash including the facet joints [1] and musculature [2]. While the facet joint contribution can be studied using in vitro experimental approaches [1], in vivo human testing is necessary in order to evaluate the physiologic muscle responses to whiplash-type perturbations. To date the human testing experiments have either used experimental impacts with entire automobiles [3, 4], or have applied accelerations to sleds guided by rails [5-8]. Previous experiments have determined that awareness of the impact timing [7], impact direction [5] and head rotation [6] modulate the muscular response, however previous investigations have not been able to eliminate the subjects' awareness of the impact direction; the nature of the automobile setup, or the orientation of the rails, has provided clues about the impact direction. Placebo "collision" experiments show that the physiological and psychological factors strongly influence the observed responses to perturbations [4]. Accordingly, as the majority of rear-end collisions are unexpected, experiments must incorporate unknown timing and direction in order to gain insight into "typical" responses to whiplash impacts. The purpose of this paper is to describe the novel experimental system that we have developed for applying low-velocity whiplash-like perturbations in arbitrary directions.

### METHODS

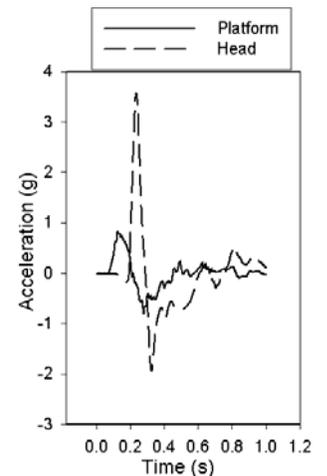

We have assembled a novel experimental system for performing human studies using low-velocity whiplash-like perturbations. This system consists of an automobile seat, leg rest, and seatbelt restraint system mounted on a six degree-of-freedom parallel robotic platform. The six degree-of-freedom capacity make this system ideally suited for applying perturbing motions in any direction. Preliminary efforts have been limited to developing appropriate motion pathways for producing the whiplash-like perturbations, and for developing the necessary associated instrumentation. To date we have concentrated on anterior accelerations/displacements, simulating rear end impacts.

### RESULTS AND DISCUSSION

The robotic testing platform, showing the platform, automobile seat, seatbelt and footrest is shown in Figure 1. We have determined, through experimentation, that the system is limited to translations less than 20 cm, velocities less than 0.8 m/s (3 km/hr) and accelerations less than 1 g. Pilot testing has determined that platform motions with 1 g peak accelerations (peak acceleration at 0.05 s) result in head accelerations of less

**Figure 1:** Automobile seat mounted on robotic platform. The platform motion has been programmed to simulate whiplash-like perturbations.

**Figure 2:** Platform and Head accelerations during whiplash-like perturbation.

than 4 g (Figure 2). These perturbation parameters are similar to one previous study [8], and less severe than the low-velocity impacts that are frequently reported in the literature (either 4, 8 or 9.3 km/hr) [2-6]

### CONCLUSIONS

We have assembled a powerful and versatile testing platform for evaluating the biomechanics of whiplash-like perturbations. This system offers unparalleled flexibility due to the ability to translate and/or rotate in any direction. Accordingly, this system is ideally suited to assess the biomechanical effects of low-velocity whiplash-like perturbations due to impacts in different directions, or combinations of directions, more closely simulating real-world (unexpected) impact situations.

### INTRODUCTION

High resolution computed tomography (micro-CT) is a powerful research tool for the study of the detailed structure of cancellous (trabecular) bone [1, 2]. In vivo scanning of only small animals such as rats has been described [3-5]. There are obvious advantages to scanning larger animals using similar techniques so that greater volumes of bone and larger implants can be studied. The objective of this investigation was to demonstrate the successful scanning of a live rabbit distal femur and obtaining accurate high-resolution micro-CT images of 3-D trabecular architecture. A volume fraction comparison was made from in vivo micro-CT images to in vitro micro-CT images on the same femurs after excision to ensure the in vivo scanning produced accurate results.

### METHODS

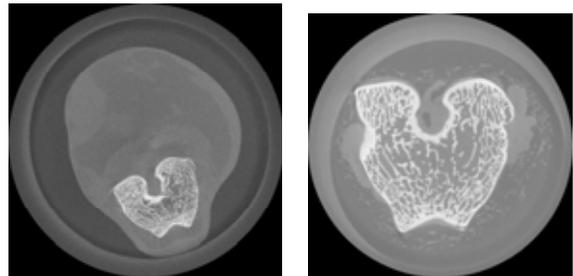

Two six-month-old New Zealand White rabbits (weight: 4-5 kg) were used. All procedures were approved by the university institutional animal care and use committee. The rabbits were anaesthetized with 37.5 mg/ml of Ketamine and 5mg/ml of Xylazine). It took approximately 10 to 20 minutes for the rabbit to be sedated. A rabbit holder was custom made for this scanning procedure. It consists of three sections include the top column of 2.25 inches in length and 40.055 inches in diameter, the second column of 9.22 inches in length and 21.6 inches in diameter and the last column is similar to a tube which has 12.00 inches in length and 2 inches in diameter.

The rabbit was situated in the holder resting its front legs against the top column of the fixture. The right hind leg was resting in flexion and the left hind leg was extended into the transparent column and held in place with a strap. Fabric padding was placed around its head and neck to provide anatomical support in its seating position. The holder was then placed on the specimen manipulator in a custom open architecture micro-CT scanner ((ACTIS 150/225 FFi-HR CT, BIR Inc., Chicago, IL) (Figure 1).

**Figure 1:** Scanning a live rabbit distal femur 28-micron nominal resolution. Scans were performed in two rotations with a total radiation exposure time of approximately six minutes.

The specimen manipulator is rotated around the z-axis and raised or lowered along the z-axis. The best nominal resolution obtained in scanning a live rabbit distal femur in this arrangement is a voxel size of 28 microns. After in vivo scanning, the femurs were excised and scanned again in vitro in a smaller specimen holder at 14-micron nominal resolution. These two sets of data were registered and compared using VG StudioMAX (Volume Graphics, Heidelberg, Germany) to allow direct comparison.

**Figure 2:** Examples of in vivo (28 micron) and in vitro (14 micron) slice images from the same rabbit femur.

### RESULTS

The volume fractions calculated for these two rabbits are 0.25 vs. 0.262 and 0.37 vs. 0.374 (in vivo micro-CT scanning vs. in vitro micro-CT scanning) respectively. The accuracy of in vivo micro-CT scanning is well within 5% of the in vitro method.

### DISCUSSION AND CONCLUSIONS

Our studies have demonstrated that the volume fraction from in vivo micro-CT images matches the in vitro micro-CT images. These accurate high-resolution images show the true trabecular architecture can be further utilized in obtaining other trabecular measurements such as trabecular thickness and in analyzing the changing mechanical properties of trabecular structure in micro-FEA on living animals.

## METABOLIC COST OF GENERATING FORCE DURING HUMAN LEG SWINGING

Jiro Doke and Arthur D. Kuo

Department of Mechanical Engineering, University of Michigan, Ann Arbor, MI, U.S.A.

email: [jdokeh@umich.edu](mailto:jdokeh@umich.edu)

### INTRODUCTION

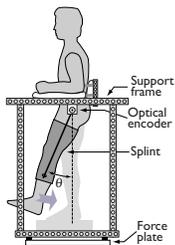

When people walk at a particular speed, they choose a step frequency that is the least metabolically demanding [1]. This optimal selection of preferred step frequency can be attributed to determinants such as the cost of stance leg push-off during step to step transitions [2] and the cost of swinging the legs quickly. Sharp increase in metabolic cost during one-legged isolated leg swinging has been seen [3]. We hypothesized two potential causes to the cost of leg swinging: *work hypothesis* and *force/time hypothesis* [3]. According to the work hypothesis, the metabolic cost would increase proportionally to the positive mechanical work performed on the leg, which is assumed to be continuously fueled by the muscles. With the force/time hypothesis, the muscles are generating short bursts of forces, which result in a metabolic cost that is proportional to the force but inversely proportional to the duration of the bursts. Force/time hypothesis has been shown to better predict the preferred speed-step frequency relationship than the work hypothesis [4].

The purpose of this study is to test the force/time hypothesis on the metabolic cost of fast leg swinging. In order to isolate the effect of the work hypothesis, we maintained a constant rate of positive mechanical work over all swing frequencies. If the metabolic rate increases in spite of constant positive work rate, then we can conclude that work hypothesis has little contribution to the increase of metabolic cost at high frequency leg swinging.

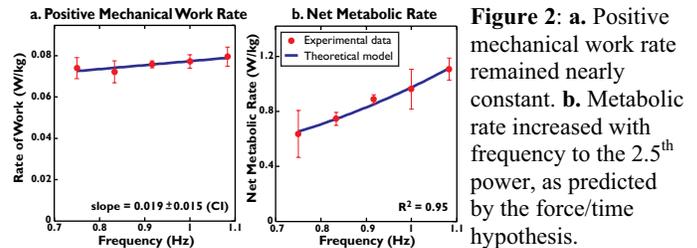

### METHODS

We measured the mechanics and metabolics of swinging a single human leg, using a frame inside which subjects stood on one leg and swung the other leg at prescribed amplitudes and frequencies (Figure 1). The amplitude was set at 50 degrees at the lowest frequency of 0.75 Hz and decreased with higher frequency, in order to assure a constant rate of positive mechanical work. We measured ground reaction forces, swing leg angle, and oxygen consumption rate, which we used to estimate the metabolic rate.

Six male subjects (aged  $29.8 \pm 4.9$  yrs., mean  $\pm$  s.d.) consented and participated in this study. They performed single-leg swings at five different frequencies ranging from 0.75 Hz to 1.08 Hz. Each frequency trial lasted six minutes, and the last three minutes were used for analysis in order to ensure steady state metabolic rate.

**Figure 1:** The apparatus consisted of a metal frame with back and arm rests for support, and a raised block for single-leg standing. The subject was securely strapped inside, and the leg angle was measured by an optical encoder at the hip. The whole frame was placed on top of a force plate.

**Figure 2:** a. Positive mechanical work rate remained nearly constant. b. Metabolic rate increased with frequency to the 2.5<sup>th</sup> power, as predicted by the force/time hypothesis.

We created a theoretical model that consisted of a simple pendulum representing the swing leg, with the equations of motion

$$\ddot{\theta} + \omega_n^2 \theta = T,$$

where  $\omega_n$  is the pendular natural frequency and  $T$  is the hip torque. Assuming a sinusoidal motion with amplitude  $A$  and frequency  $\omega \triangleq 2\pi f$ ,

$$\theta(t) = A \cos \omega t.$$

In leg swinging, force/time cost is defined as a cost proportional to hip torque amplitude and inversely proportional to swing period [3]. With a constant positive work rate, the force/time hypothesis yields a metabolic rate prediction of

$$\dot{E} \propto f^{2.5}.$$

### RESULTS AND DISCUSSION

The metabolic rate increased substantially by 74.3% from 0.75 Hz to 1.08 Hz, despite the nearly constant positive mechanical work rate (Figure 2). Moreover, the metabolic rate increased with frequency to the power of 2.5, as predicted by our force/time model ( $R^2 = 0.95$ ). The rate of positive work had a slope of  $0.019 \pm 0.015$  (95% confidence interval) W/kg. If the work hypothesis was to hold, the cost would amount to a mechanical to metabolic efficiency of 1.5%. Assuming a typical efficiency of about 21% in isolated muscles [5], the result suggests a weak link between mechanical and metabolic work.

### CONCLUSIONS

We isolated the effect of muscular work by keeping the positive work rate constant. There was a substantial increase in metabolic rate. This strongly suggests that the work hypothesis alone does not explain the increase in metabolic cost during high frequency leg swinging. Instead, the increase is better explained by the force/time hypothesis, which credits the cost to muscles generating short bursts of force.

**SONOGRAPHIC MEASURES OF GASTROCNEMIUS LENGTH WITH TWO-JOINT PASSIVE MOVEMENTS**

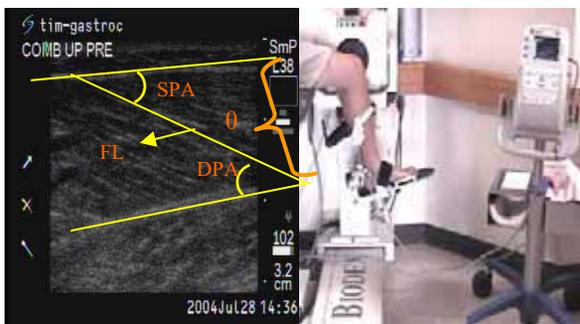

Timothy J. Brindle, Jeri L. Miller, Maria K. Lebedowska, and Steven J. Stanhope  
 \*\*Physical Disabilities Branch, National Institutes of Health, Bethesda, MD 20892  
 email: Tbrindle@cc.nih.gov, web: http://pdb.cc.nih.gov/

**INTRODUCTION**

In-vivo ultrasound is a non-invasive method to identify gastrocnemius (GAST) length changes with passive and active movements.[1-3] Predicted ratios of ankle movement, relative to knee movement, can be varied to generate conditions where the GAST will homogeneously elongate, shorten or where the GAST will heterogeneously maintain its length.[4] The purpose of this study is to determine, with 95% confidence, the feasibility of sonographic imaging to derive quantifiable measures of GAST length in order to identify conditions when the GAST homogeneously shortens, elongates, or a condition when there are heterogeneous or minimal changes in GAST muscle length during knee and ankle movements.

**METHODS**

Ten subjects were seated on a Biodex (Biodex Inc., Shirley NY) with their legs positioned in a custom-made foot/ankle apparatus, controlled by a linear actuator (Ultramotion, Inc, Mattituk, NY), that passively extended knee and plantar flexed ankle, respectively. A 7.5 MHz linear transducer (SonoSite, Bothell, WA) imaged the mid-third of the GAST in the longitudinal plane. The transducer array was set in a jig, attached to the Biodex arm, and held in place with an elastic wrap to maintain image planes of site GAST targets during

**Figure 1:** A) Ultrasound image with angles to calculate: SPA, IPA, and  $\theta$ . B) Biodex and Linear actuator, with custom foot plate to move the knee and ankle.

data acquisition.[1] As the knee was extended ( $60^{\circ}$ - $20^{\circ}$  at  $2^{\circ}/s$ ) the ankle rotated ( $0^{\circ}$ - $6.4^{\circ}$  at  $0.32^{\circ}/s$ ) for med GAST measurements or rotated ( $0^{\circ}$ - $10.8^{\circ}$  at  $0.54^{\circ}/s$ ) for lateral GAST measurements. Off-line ultrasound measures, acquired every  $10^{\circ}$  of knee angle ( $\alpha$ ) included: muscle fiber length (FL); superficial and deep pennation angle (SPA, DPA) and the angle between the superficial and deep aponeuroses ( $\theta$ ).(Fig.1) Commercial software enabled calculation of muscle fiber length (Carnoy, Schols, P.&E. Smets.2001) and pennation

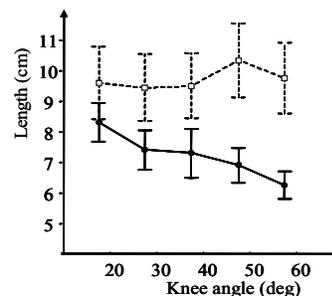

**Table 1: Lateral GAST Pennation angle:**

	<b>Knee Angle (deg)</b>				
	<b>20</b>	<b>30</b>	<b>40</b>	<b>50</b>	<b>60</b>
<b>SPA</b>	6.4+/-3.8	6.5+/-4.1	6.2+/-3.6	5.7+/-3.6	5.4+/-2.9
<b>DPA</b>	10.3+/-3.2	11.1+/-4.1	10.1+/-4.1	9.1+/-4.1	7.7+/-3.2
<b><math>\theta</math></b>	5.7+/-2.3	5.6+/-2.3	5.1+/-2.1	4.5+/-2.3	3.6+/-1.9

angle(Photoshop8,Adobe,Seattle,WA). Mean values from three trials for each condition were used to calculate a linear regression, with 95% confidence interval, and descriptive data for each movement (Statistica,StatSoft,Ltd. Tulsa, OK).

**RESULTS AND DISCUSSION**

Med GAST FL increased ( $p<0.05$ ) as the knee extended (FL=  $9.1-0.05\alpha$ :  $r=-0.32$ ). Lat GAST demonstrated a non-significant trend ( $p=0.051$ ) to shorten with knee extension (FL= $9.2+.014\alpha$ :  $r=0.052$ ). (Figure 2) Greater variability of the lateral GAST FL data warrants reporting pennation angles. (Table 1) During knee extension, increased pennation angles support the trend of GAST shortening during combined knee and ankle movements.

**Figure 2:** Mean med GAST ( —■— ) and mean lat GAST ( ---□--- ) FL, with 95% confidence interval, relative to  $\alpha$ .

Because sonographic techniques are highly user-dependent, future reliability studies are needed to determine accuracy of quantification of muscle length data for estimating forces and muscle function involving two joint movements.

**CONCLUSIONS**

This is the first study to use sonographic techniques to identify how two joint movements affect GAST muscle fiber length. Homogeneous elongation of the GAST was demonstrated at the predicted ratios of knee and ankle movement. However, heterogeneous changes in the GAST length are apparent with the reported insignificant trend of FL measures. Shortening of lateral GAST would occur with increased plantar flexion velocity, relative to given knee movements.

## EFFECTS OF DIFFERENT PROFILES OF LATERAL WEDGING ON KNEE ADDUCTION MOMENTS DURING THE LOADING PERIOD OF THE GAIT CYCLE

<sup>1</sup> Richard K Jones, <sup>1</sup> Christopher Nester and <sup>2</sup> Jim Richards

<sup>1</sup> Centre for Rehabilitation and Human Performance Research, University of Salford, UK

<sup>2</sup> Allied Health Professions Unit, Faculty of Health, University of Central Lancashire, UK

email: [r.k.jones@salford.ac.uk](mailto:r.k.jones@salford.ac.uk), web: [www.healthcare.salford.ac.uk/crhpr](http://www.healthcare.salford.ac.uk/crhpr)

### INTRODUCTION

The aim of lateral wedging is to force the foot into pronation. This will have the effect of altering the centre of pressure and the ground reaction force line of action, which will theoretically modify the loading at the knee joint. This is especially important in conditions such as medial compartment osteoarthritis where off loading of the affected medial compartment is desirable by moving the knee into this position will relieve the pain in this compartment.

The use of lateral wedging has been reported since the first study by Yasuda and Sasaki in 1987[1]. However, there is still a dearth of literature available on biomechanical variables during walking with lateral wedging. A recent study [2] investigated the effects of different elevations of wedging in a group of individuals with no pathologies. They found that laterally wedged insoles significantly reduced the knee joint adduction moment compared with the no wedged insole. However, it is not known if the insoles were inside the shoe or attached to the outside, and also a very simple marker set were used which could bring errors into the calculation of frontal plane motion and moments. It has been clinically shown that wearing a laterally wedged insole provides some perceived pain and function benefit for OA patients, although the guidelines for prescription of the insole such as the degree of incline to use has not been thoroughly studied in respect of controlled shoes and insoles.

The purpose of this study was to assess the effect of wearing two different degrees of lateral wedging on the knee joint adduction moment during loading in healthy adults.

### METHODS

Twelve, healthy, male subjects participated in the study. Subjects performed ten walks whilst wearing standard shoes (ECCO Zen) and standard insoles (slimflex). Three conditions were investigated: a) no wedge b) 5 degree wedge, c) 8.5 degree wedge. The insoles were all manufactured by a podiatrist with a full sole up to the metatarsal heads on the lateral border of the insole. Data was collected using eight camera Qualisys Proreflex MCU240 system with bilateral force collected using two Kistler force platforms. Markers were located on the calcaneus, 1<sup>st</sup> metatarsal, fifth metatarsal, 2<sup>nd</sup> metatarsal, with clusters of four on the shank, thigh and pelvis. Anatomical reference frames were based on the ISB standardisation protocol [3]. Hip joint centre was calculated with the functional hip joint method [4].

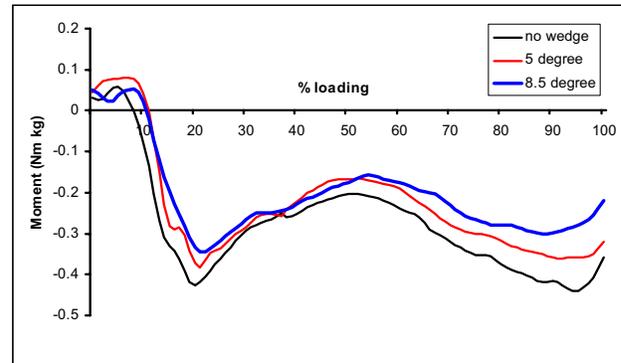

Figure 1: Knee adduction moment in the three wedges N=12)

Data were exported to Visual 3D where 3-dimensional coordinates were interpolated, and low pass filtered using a Butterworth 4<sup>th</sup> order filter at 6 Hz. Analog data was filtered at 25 Hz. The knee adduction moments were calculated and the peak moments during loading were identified between heel strike and the contralateral heel strike. A one way analysis of variance was performed with an alpha level of 0.05 with a Bonferroni adjustment.

### RESULTS AND DISCUSSION

The data for the knee adduction moment was significantly lower for both the 5 degree and 8.5 degree lateral wedging in both limbs during the loading period of both limbs.

### CONCLUSIONS

It can be seen from the data presented in this paper that lateral wedging on a standard insole changes the adduction moment of the knee joint during walking. This has implication for the future study on medial compartment osteoarthritis where three conservative treatment options will be evaluated against standard surgical procedures in the aim at reducing pain and increasing functional independence.

## A SIMPLE MATHEMATICAL MODEL OF KARATE FRONT KICK

Jiro Doke and Arthur D. Kuo

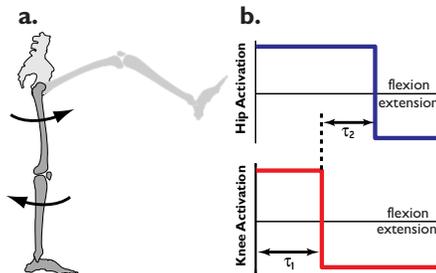

Department of Mechanical Engineering, University of Michigan, Ann Arbor, MI, U.S.A.  
 email: [jdokeh@umich.edu](mailto:jdokeh@umich.edu)

### INTRODUCTION

A front kick is one of the most common forms of kick in karate. From observation, the hip and knee joint of the kicking leg go through a sequence of flexion and extension. Experimental studies have shown that, kinematically, the kick starts with hip and knee flexion, then the knee starts to extend, and the hip extends slightly at impact [1]. The front kick is often taught as a maximal effort technique, and we might superficially expect the hip and the knee muscles to be activated with a bang-bang control. However, torque and EMG data has shown the muscles to be not maximally active. We created a simple mathematical model to test whether bang-bang control is the optimal technique and to examine the effects of activation and coordination on kicking performance.

### METHODS

We derived a simple, two-segment model with anthropomorphic inertial properties to simulate a closed stance front kick (Figure 1a). The hip and knee joints were actuated by a simple Hill-type muscle model with force-velocity dynamics. We activated the muscle model with an adjustable, constant activation level during flexion and extension phase, with no activation dynamics. Coordination was controlled by two timing parameters (Figure 1b). The first timing was the time from the beginning of the kick to when the knee torque switched from flexion to extension. The second timing was the time from the knee switch timing to when the hip torque switched from flexion to extension. We performed a forward-dynamic simulation, with a terminating condition of 60-degree knee flexion angle. We noted whether the kick terminated with the foot in the target area, which was an area of about 4 mm<sup>2</sup> around the hip height level. As a performance measure, we used horizontal foot velocity at kick completion. For each combination of joint activation levels, we optimized about the switch timings to find the maximum final horizontal foot velocity.

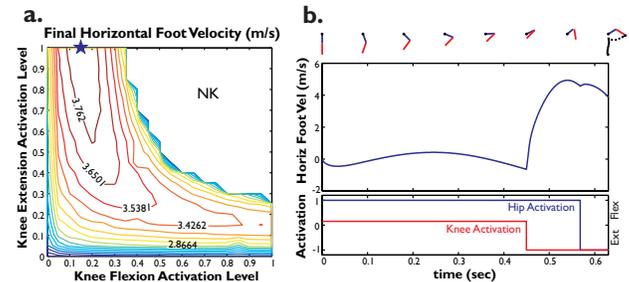

**Figure 1:** a. Simple two-segment karate front kick model. b. The torques at the hip and the knee are activated with specified activation levels and switch timings.

### RESULTS AND DISCUSSION

We found that the hip needed to be fully activated in both flexion and extension, and the knee had to be maximally extending to achieve maximum performance. However, the knee had an optimal flexion activation level that was not maximal (Figure 2a). Maximum final horizontal foot velocity of 3.874 m/s was achieved at only 15% knee flexion activation and 100% knee extension activation. High activations at the

knee caused the knee joint to rotate too fast and kick below the target. At lower knee flexion activations, maximum horizontal foot velocity was achieved at an intermediate activation level (i.e. in the range of 0% ~ 35%, Figure 2a “star”). This optimality arises from the kinematic coupling between the thigh and the shank. At 15% knee flexion activation, the knee is optimally flexed for increasing the horizontal foot velocity during the latter half of the kick. For knee extension, greater activation resulted in increased the foot velocity. These results agree with observations of human kicks, which show relatively low knee joint activity in the flexion phase, but greater activity in the extension phase [2]. Furthermore, a parametric study showed that hip parameters, such as maximum hip torque and velocity, played a greater role in improving kick performance than did knee parameters.

A qualitative analysis of the optimal kick revealed that hip extension torque just prior to kick termination increased the horizontal velocity of the foot (Figure 2b), which can be observed in human data [2]. As the knee straightened, the foot velocity decreased, and this suggested that foot impact should occur before the knee is fully extended, ideally, when the velocity is at its local maximum.

**Figure 2:** a. The optimal kick is indicated by a star, with final horizontal foot velocity of 3.874 m/s. The “NK (no-kick)” region is where no successful switch timing combination was found. b. Horizontal velocity profile of the foot during an optimal kick.

### CONCLUSIONS

We simulated a karate front kick using a model with simple muscle activation mechanics. We reduced the degree of freedom of the complex kicking motion in order to study the essence of the movement. We found the hip to have a more significant role in kicking performance, and the knee had to be moderately activated during flexion in order to ensure target placement and high horizontal foot velocity. Hip extension just before impact also increased foot velocity. These results resemble what has been observed in experiments, and moreover, give insights to coordination of joints in performing an effective kick.

## Influence of loads to of the joint moments and muscle force repartition in sprint cycling test

Inès Benkhémis, Mathieu Boucher

<sup>1</sup>Laboratoire de mécanique des solides UMR-CNRS6610, Université de Poitiers, 86962 Futuroscope-Chasseneuil Cedex, France.

email: [ines@etu.univ-poitiers.fr](mailto:ines@etu.univ-poitiers.fr) web : [www-lms.univ-poitiers.fr](http://www-lms.univ-poitiers.fr)

### INTRODUCTION

The pedalling technique requires a complex muscular activation which depends on a few factors like the frequency, the loads [1]. The aim of this preliminary study is to compare the muscular force obtained when using the physiological cross-section area (PCSA) during a sprint test performed by a road and a track cyclists.

### METHODS

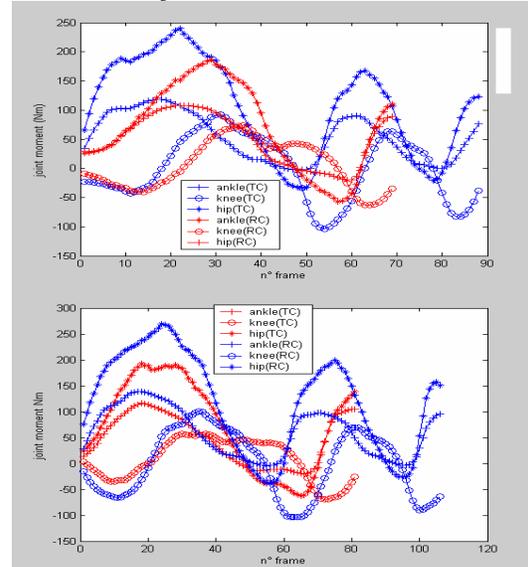

The cycling tests were realized in laboratory conditions seated on a bicycle (Monark 824) equipped with clipless pedals fixed to a 6-axis sensor (Médicaptureur Ex114-45-200). The two subjects (road cyclist: 70kg, 1.75m and track cyclist: 55kg, 1.65m) performed sprints on the ergo-trainer against a 2 and 8kg load. The motion was recorded at 50 Hz by an optoelectronic system (Saga3<sup>rd</sup>). We analyze the first pedalling cycle for each test. The lower limb is considered as a planar 3 degree of freedom. The moment arm and the PCSA values used are taken from [2]. The joint moment at ankle, knee and hip are obtained by the resolution of the inverse Dynamic equations and the muscular force by the minimization method.

### RESULTS AND DISCUSSION

The first result indicates that the track cyclist (TC) develops more joint force than the road cyclist (RC). In fact, the figure 1 shows how the joint moments of TC are more important than RC. So, it is logical to obtain the greater muscular force values from the TC. However, the minimum value of the sum of joint moment and the sum of muscular forces are inferior (table 1). In this case we can conclude that the pedalling strategy is different.

The most important muscular force participation is the Long Head Biceps Femoris (BFL: a knee flexor and hip extensor) and the least are the Tibialis Anterior (TA: an ankle flexor) and the Short Head of Femoris (BFS: a knee extensor). At 8kg, the muscular force increases about 19% for TA and BFS and about 10% for BFL of the two cyclists.

Six of the nine low limb muscles fit into the knee. But the knee moments are the least at any load for the two subjects.

**Figure 1:** joint moments for the two cyclists at 2kg (top) and 8kg (bottom)

### CONCLUSION

Our preliminary study shows the importance of the use of the individual muscle force to compare pedalling motion. It is useful to determinate the energy cost per muscle to define a cycling profile. The inferiority in the knee moment needs more investigation and probably to relate it to the height of the seat.

### INTRODUCTION

During sports play quick movements such as cut tasks are believed to place athletes at risk. The ankle joint plantar flexors, responsible for controlling tibial progression during midstance,[1] may play a key role in successfully completing a quick cut task.[2] As planning time is reduced, rapid development of large plantar flexor moments and restraint of tibial progression (dorsiflexion range of motion) during second rocker are expected. Further, we theorized that as planning time decreased the plantar flexor response would show a non-linear increase to control tibial progression. The purpose of this study was to examine the relationship between indicators of ankle plantar flexor function (Table 1) and planning time during second rocker (10-60% of stance) of an unexpected side step cut task.

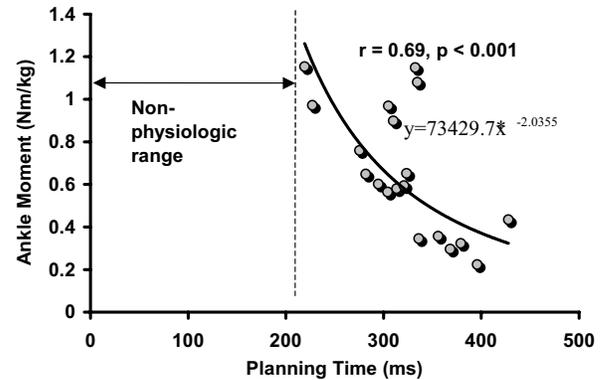

### METHODS

Nineteen healthy subjects ( $22.6 \pm 5.5$  years old,  $172.8 \pm 9.0$  cm, and  $71.9 \pm 14.3$  kg) participated in this study. Data were collected using an Optotrak Motion Analysis System (Northern Digital, Inc.) and force plate (Kistler) integrated with Motion Monitor Software (Innsport Training, Inc.) to generate ankle joint angles, moments and power. Position data were sampled at 100 Hz and force and analogue data at 1000 Hz. Each testing session included expected tasks, straight walking (ST) and 45° side step cut (SS), followed by a set of unexpected straight walking (STU) and unexpected side step cut (SSU) tasks in a random order. For all tasks speed was maintained at 2 m/s using infrared timing gates (Bower Timing Systems, Draper UT). Only the SSU tasks are included in this analysis. Planning time is defined as the interval between the visual cue and initial contact (Figure 1). The relationship between the dependent variables (Table 1) and planning time were examined using SPSS 10.0.

**Figure 1.** Subjects went straight or cut when given a visual cue to turn. Planning time was the interval between an analogue signal synchronized with the light cue and initial contact determined from the ground reaction force data.

### RESULTS AND DISCUSSION

**Figure 2.** The non-linear relationship between peak ankle plantar flexor moments and planning time showed increased moments with decreasing planning time.

**Table 1.** Pearson Product Moment Correlations between Planning Time and Ankle Variables During Second Rocker.

Variable	Mean (SD)	r - value
Planning Time (ms)	321±52	
Dorsiflexion Range of Motion (°)	11.7±4.8	-0.31
Plantar Flexion Moment (Nm/kg)	0.66±0.3	<b>-0.66</b>
Power Absorption Integral (W/kg * %Stance)	6.6±7.8	-0.09

Bold values indicate significance at  $p < 0.05$

The findings of this analysis suggest that the peak ankle plantar flexor moments scale to planning time during an unanticipated cut task (Figure 2). The range of planning times executed during this task varied from  $\approx 200 - 450$  ms (Table 1). The shorter planning times ( $< 350$  ms) are associated with large plantar flexor moments ( $> 0.6$  Nm/kg). These large responses, in some cases equal to the plantar flexor moment at push off, may challenge athletes. The longer planning times ( $\geq 350$  ms) are associated with smaller plantar flexor moments ( $< 0.4$  Nm/kg), suggesting longer planning times have less effect on limb loading. This data supports the view that ankle plantar flexor weakness or poorly timed control of plantar flexor function may impact performance during unexpected cut tasks.

## BIOMECHANICAL DIFFERENCES BETWEEN GENDERS WHEN EXECUTING A LAND AND CUT MANEUVER

Robert Shapiro and Jeff Buhr

Department of Kinesiology and Health Promotion, University of Kentucky  
 email: [rshap01@uky.edu](mailto:rshap01@uky.edu) web: <http://www.coe.uky.edu/biodynamics/>

### INTRODUCTION

It is well documented that the knee is a commonly injured joint in male and female athletes. Many researchers have investigated the significantly higher incidence rate of non-contact ACL injuries in female athletes. [1,2,3]. It has been suggested that females are at risk for an ACL injury because they land with less knee flexion, and greater knee abduction than males while having weaker hip strength. Cutting and landing from a jump are most often identified as the activity at the time of injury. Consequently, investigators have tried to recreate these activities in an effort to define the injury mechanism and deduce factors that cause the injury rate difference between males and females. It has become apparent that a static landing activity, asking a subject to land and hold that position, does not adequately reproduce an authentic sport motion. In an effort to create a more realistic task, investigators have introduced landings followed by a vertical jump, while others have examined the cutting in an unanticipated direction to simulate a sport-related motion. The combination of landing and cutting has yet to be studied in the laboratory setting. The purpose of this study was to attempt to recreate a landing condition that more closely resembled that seen in sport competition and evaluate landing kinematics. In this study landing and cutting were combined into a single event, more closely simulating motions seen in basketball, volleyball and soccer.

### METHODS

Healthy, male (n = 22, age = 23(1.4)yrs, wt = 745(100)N, ht = 1.76(0.05)m) and female (n = 23, age = 22.4(1.5)yrs, wt = 600(69.8)N, ht = 1.65 (0.06)m) subjects provided informed consent prior to participating in this study. Subjects were marked with 37 reflective markers enabling 3-D reconstruction of a rigid linked model of the body. Six Falcon high-speed cameras (120Hz) imaged subjects while two Kistler force platforms measured ground reaction forces (960 Hz). Video and GRF data were synchronized at collection onset. Motion Analysis Corp. Eva software was utilized to obtain marker object-space coordinates. Subjects were imaged in a static position to enable determination of anatomically relevant coordinate systems [4]. Subjects were then instructed to land from a 60 cm platform and cut right, left or remain stationary after impact. The direction of cut was provided immediately prior to the subject leaving the platform. Table 1 provides a list of dependent variables. Three-dimensional kinematic variables were calculated using both KinTrak® and OrthoTrak® software T-tests, p<.05, were used in this preliminary analysis to compare the groups.

### RESULTS AND DISCUSSION

Only kinematic data from the right leg (dominant leg in 44 of 45 subjects) for the land and right cut maneuver are reported

Variable	Male (±SE)	Female(±SE)	P<.05
<b>Angle at Impact (degrees)</b>			
Knee Flexion	22.35 (1.50)	18.42 (1.02)	*
Knee Adduct	6.17 (1.40)	2.84 (1.60)	
Knee Ext Rot	4.23 (0.84)	2.54 (0.80)	
Hip Flexion	18.50 (1.39)	19.12 (1.03)	
Hip Adduct	-3.24 (0.83)	-5.05 (0.88)	
Hip Ext Rot	7.61 (1.03)	9.65 (0.88)	
<b>Maximum or Minimum Angle after Impact (degrees)</b>			
Knee Flexion	93.3 (1.54)	87.9 (1.52)	*
Knee Adduct	-6.17 (1.83)	-13.68 (3.34)	
Knee Ext Rot	5.17 (1.62)	9.56 (1.61)	
Hip Flexion	63.83 (1.73)	64.08 (1.80)	
Hip Adduct	5.68 (1.31)	-2.5 (1.21)	*
Hip Ext Rot	3.87 (1.22)	7.02 (0.99)	

**Table 1:** Comparisons (mean (SE)) of right leg hip and knee angles at impact and maximum range.

here (Table 1). Subjects generally landed in slight knee and hip flexion. Males landed in greater knee flexion and reached a greater maximum knee flexion angle but total range of motion was not different between males and females. Both groups landed with slightly abducted hips and slightly adducted knees. Females remained abducted at the hip while the males obtained an adducted position through the remainder of stance. At the knee both groups moved into an abducted position. This knee motion is similar to that reported by Pollard et al. for a cutting maneuver [2]. No between group differences were observed for knee rotation, knee abduction, hip flexion or hip rotation variables.

### CONCLUSIONS

While the premise that females tend to land with less knee flexion and reach less maximal knee flexion while landing is supported in this study, no differences in knee abduction or rotation were observed. The greater hip abduction angle in females supports the idea that weakness at the hip may prevent females from establishing a safe landing position. With both the thigh and knee abducted, the knee is placed at risk for an injury upon landing as the weight of the body can, given sufficient hip abduction, potentially place a torque at the knee that cannot be actively controlled. Further evaluation of hip kinetics and associated muscle activity is warranted.

## FEEDBACK CONTROL FOR A HIGH LEVEL UPPER EXTREMITY NEUROPROSTHESIS

Dimitra Blana (dimitra.blana@case.edu), Juan Gabriel Hincapie, Edward K J. Chadwick and Robert F. Kirsch  
Department of Biomedical Engineering, Case Western Reserve University, Cleveland OH

### INTRODUCTION

Individuals with C3/C4 spinal cord injury lose voluntary control of almost all muscles of the upper extremity. A neuroprosthetic system that applies electrical stimulation to paralyzed muscles can be used to restore function to these individuals. The controller for this system will generate the appropriate levels of muscle activation, based on the user commands. It also needs to compensate for errors caused by external disturbances and fatigue. This is necessary, because at that level of injury, voluntary correction for errors in the performance of the neuroprosthesis is not possible. In addition, due to the large number of shoulder and elbow muscles that must be controlled in high tetraplegia, purely experimental methods for developing the neuroprosthesis are inefficient and impractical. The goal of this project is to use a model-based approach to develop and test a feedback controller for this system.

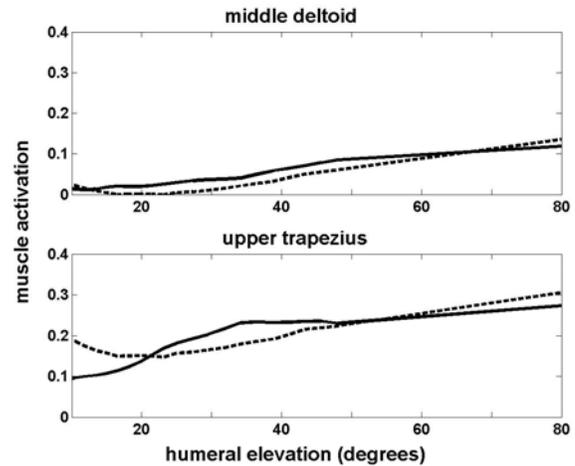

### METHODS

The musculoskeletal model of the shoulder and elbow used in this project is a finite element model built in SIMM (Software for Interactive Musculoskeletal Modeling, Musculographics, Inc.). It includes 28 muscles, six bones and five joints, with a total of 17 degrees of freedom. The morphological and muscle contraction parameters were obtained from cadaver studies performed by the Van der Helm group in Delft [1].

The open-loop controller that calculates the muscle activations required for a desired movement was designed as a static two-layer artificial neural network (ANN). It has a tangent-sigmoidal activation function for the hidden layer and a linear activation function for the output layer. In order to correct for position and orientation errors that are caused by fatigue or external disturbances, such as masses added to or removed from the hand, a feedback loop needs to be added to the previously designed controller. Its role is to model the relationship between error and the changes in muscle activation that will move the arm toward the desired position. Both the open-loop and the feedback parts of the controller are being developed using the musculoskeletal model, which was customized to simulate a person with C3-C4 level spinal cord injury.

### RESULTS AND DISCUSSION

Figure 1 shows the predictions of the open-loop controller, which is an ANN with 20 neurons in the hidden layer, for the activation of two muscles, middle deltoid and upper trapezius, during a humeral abduction movement. The RMS error is 4.47% for the middle deltoid, and 6.05% for the upper trapezius. The performance of the ANN can be improved by optimizing its parameters.

**Figure 1:** The solid lines are the activations calculated by the model, and the dotted lines are the ANN predictions.

When the feedback loop is added, the performance of the overall controller will be evaluated using the model in series with the system. A set of forward simulations will be performed with the output of the controller as input to the model, and the resulting endpoint position and orientation will be compared with the desired ones.

### CONCLUSIONS

The preliminary results show that the ANN can accurately predict the muscle activations needed for a desired posture, and can therefore be used as the open-loop part of the neuroprosthesis controller. It is also demonstrated that the use of a musculoskeletal model can facilitate the development of the feedback controller, by simulating a C3-C4 SCI individual and realistic conditions of fatigue and external disturbances, both for designing and for testing the system.

## FOREARM MUSCLE ACTIVITY DURING THREE HOSE INSERTION TASKS AS MEASURED BY SURFACE ELCTROMYOGRAPHY OF THE FLEXOR DIGITORUM SUPERFICIALIS MUSCLE

D. Christian Grieshaber, Thomas J. Armstrong and Na Jin Seo  
University of Michigan, Ann Arbor, MI  
email: [gries@umich.edu](mailto:gries@umich.edu), web: <http://umrerc.engin.umich.edu/>

### INTRODUCTION

When the physical demands of a task exceed the capacities of the worker performing those tasks can often lead to losses in production, fatigue and sometimes pain or injury to the worker. Hose installation tasks during automotive assembly operations are an example of a physically demanding task. In a recent survey, automotive truck assembly plant workers rated hose insertion tasks as the most physically demanding part of their job [1].

This study examines the effect that insertion method has on subject exertion levels, as measured by surface finger flexor EMGs.

### METHODS

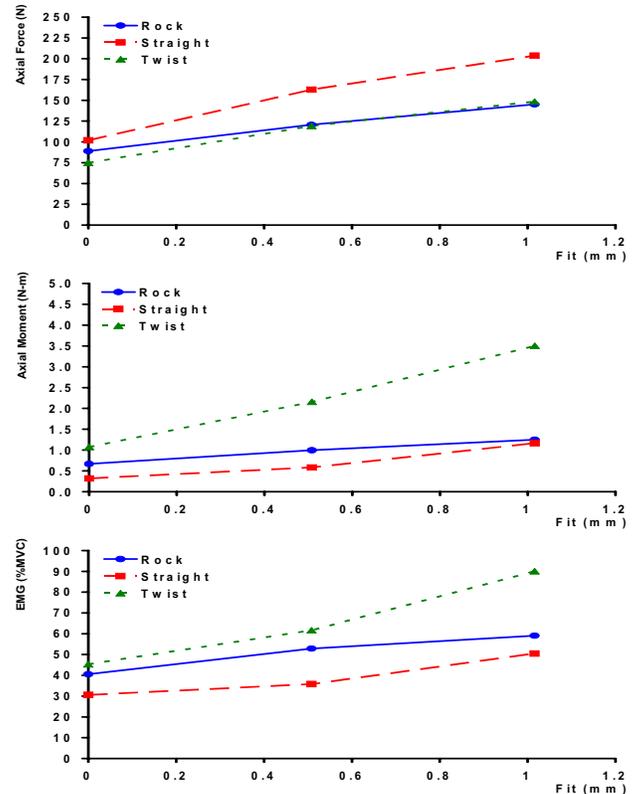

This experiment involved the measurement of insertion loads and EMGs in subjects as they inserted a rubber radiator hose onto a horizontal flange. The hose had an inner diameter of 25.4 mm and a wall thickness of 5 mm. The tasks simulated three insertion methods similar to those observed in field studies of hose installation tasks – Straight Push, Rocking Push and Twisting Push. Surface EMG electrodes (AMBU Neuroline 720 Wet Gel Ag/AgCl) were placed over distal muscle belly fibers of the Flexor Digitorum Superficialis muscle. Exertion levels were normalized using maximum static power grip (MVC) prior to testing.

For straight insertions, subjects were instructed to insert the hose directly onto the flange. For rocking insertions, subjects were instructed to push the hose on while rocking the hose back and forth in either the vertical or horizontal direction. For twisting insertions, subjects were instructed to push the hose on while rotating it about the long axis of the flange.

6 male and 6 female university students volunteered to participate in the experiment. All subjects were free of known upper extremity disorders and gave informed consent prior to testing. The experimental design was approved by the University of Michigan Internal Review Board.

### RESULTS AND DISCUSSION

Axial loads and exertion levels increased with fit and varied by the insertion method used (Figure 1). Axial insertion forces were 35% higher for the straight method (150.0 N) compared to the twist method (110.6 N),  $p < 0.0001$ . There does not appear to be an advantage to using the twisting method over the straight or rocking method, even though the axial insertion force is reduced by 26%. There was a 64% increase in pooled exertion levels for the twisting method over the straight method. The increase in muscle activity is consistent with decreased power grip strength capabilities due to deviations of the wrist during twisting and rocking insertions [2, 3]. It is also possible that tighter grip is required to twist or rock the hose.

**Figure 1:** Average force, moment and EMG recordings for 12 subjects and three insertion methods. Fit is a measure of the amount of interference between the flange and the hose as it is inserted.

### CONCLUSIONS

The greatest muscle activity was recorded while inserting hoses with the twisting method. The straight push has higher axial loading than the rocking push, but allows the subject to work in preferred static wrist posture. Future studies will investigate whether subjects use a tighter grip during twisting and rocking insertions.

## CHANGES IN THE RAT ACL RESULTING FROM SUBFAILURE IMPINGEMENT LOADING

<sup>1</sup>David T. Fung, <sup>2</sup>J. Scott Quinby, <sup>2</sup>Jason L. Koh, <sup>1</sup>Shu Q. Liu and <sup>1-3</sup>Li-Qun Zhang

<sup>1</sup>Depts. of Biomed. Eng., <sup>2</sup>Ortho. Surg., and <sup>3</sup>Phy. Med. & Rehab., Northwestern University; email: d-fung@northwestern.edu

### INTRODUCTION

While many noncontact ACL injuries may have resulted from direct over-stretching of the ligament, the ACL may also be injured due to its impingement against the intercondylar notch. Previous cadaveric studies have shown the ACL to impinge against the lateral wall of the notch during abduction and external tibial rotation at moderate knee flexion [1,2]. How impingement loading may alter the biomechanical properties of the ACL remains unknown. The purpose of this study was to evaluate changes in the force-length relationship of the ACL resulting from impingement, in corroboration with histological examinations on its superficial tissue, in a subfailure impingement injury model in rats

### METHODS

Seven female musculoskeletally mature Sprague-Dawley rats with an average weight of  $370 \pm 60$  g (mean $\pm$ SD) were used in this study. Under anesthesia, both lower limbs were disarticulated at the hip. Soft tissue on the disarticulated limbs was carefully dissected leaving only the ACL intact (Fig. 1a). The lateral tibial condyle of each femur-ACL-tibia complex (FATC) was then removed with a burring tool, allowing the knee to assume excessive abduction.

Each FATC was then mounted on a custom-designed loading apparatus with special clamps to hold the femoral and tibial shafts in a saline bath (Fig. 1b). In the apparatus, a linear motor with a precision of 0.4mm was used to load the ACL. A load cell was connected on one end to the motor shaft with its axis aligned with that of the load cell and, on the other end, to the tibial clamp. The FATC was secured into the apparatus by first fixing the tibia in the tibial clamp with the tibial axis aligned with the motor shaft and load cell axis. The femur was fixed to the femoral clamp, which, in turn, was attached to the multi-degree-of-freedom adjustable arm. Each FATC from each pair was randomly selected to be loaded in one of two knee postures by manipulating the position of the adjustable arm: 1) at  $\sim 30^\circ$  flexion; and 2) at  $\sim 30^\circ$  flexion,  $\sim 15^\circ$  abduction, and  $\sim 5^\circ$  external tibial rotation. Linear movement of the motor directly stretched the ACL longitudinally in the first posture and induced impingement of the ACL in the second.

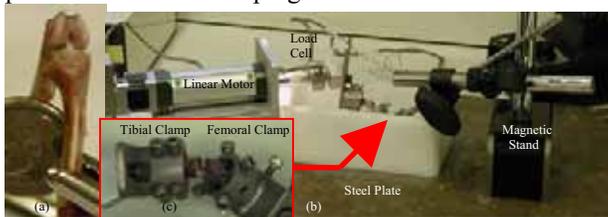

Figure 1. Experimental Setup. An FATC (a) mounted on the loading apparatus (b). Femoral and tibial clamps (c) secure the FATC, allowing the motor shaft the load the ACL cyclically.

Initially, the ACL was loaded cyclically to a minimal load to locate the 'inflection point' on the force-length curve, which established the ACL's normal length. The ACL was then preconditioned by loading the ACL  $10\times$  to 0.28 mm of displacement. Following preconditioning, the ACL was loaded repeatedly  $10\times$  at the same displacement (Sequence 1). The

ligament was given a 15-min rest and loaded cyclically to 0.36 mm of displacement (Sequence 2) for 10 trials of 10 cycles per trial. Subfailure injury, if any, would have occurred during this Sequence, reaching 12% strain in the ligament. Following another 15-minute rest, the ligament was loaded cyclically  $10\times$  again at 0.28 mm of displacement (Sequence 3). All loading was applied at 1 mm/sec. Force-displacement data in Sequences 1 and 3 were plotted separately for impinged and nonimpinged ACL for each pair of FATC's. Using linear regression, the stiffnesses for the impinged ligament ( $k_{1,imp}$  and  $k_{3,imp}$ ) and for the directly-stretched ligament ( $k_{1,ds}$  and  $k_{3,ds}$ ) were determined in Sequences 1 and 3. Differences between the Sequences and between the mode of loading was evaluated statistically (Paired t-test). Significance was established at  $p=0.05$ .

Immediately following Sequence 3, the ACL was harvested and stained with a cell viability assay (Live/Dead® L-3224, Molecular Probes) with Hoechst 33258 added to locate the cell nuclei. Under the fluorescent microscope, live cells show green fluorescence and necrotic cells show red. Images were captured at  $20\times$  magnification and overlaid at randomly selected regions on impinged aspect, and the non-impinged aspect of the impinged ACL, and on the directly stretched ACL. The images of the three regions were compared to assess the effect of impingement.

### RESULTS AND DISCUSSION

Among the seven pairs of ACLs,  $k_{1,imp}$  ( $11.9 \pm 5.7$  N/mm) (mean $\pm$ SD) was significantly greater than  $k_{3,imp}$  ( $9.6 \pm 6.0$  N/mm) ( $p=.014$ ). Insignificant difference was observed between  $k_{1,ds}$  ( $12.9 \pm 7.1$  N/mm) and  $k_{3,ds}$  ( $12.1 \pm 5.5$  N/mm) ( $p=0.20$ ), and between  $k_{1,ds}$  and  $k_{1,imp}$  ( $p=0.67$ ), demonstrating the impingement led to a reduction in the ligament's stiffness. Representative micrographs showed that impingement resulted in the disruption of the tissue organization and cell necrosis on the impinged surface of the ACL (Fig. 2).

Figure 2. Representative fluorescent micrographs showing the directly stretched ACL (a), and the impinged ACL at its nonimpinged aspect (b) and impinged aspect (c).

### CONCLUSIONS

Cyclic impingement loading has shown to decrease the stiffness of the ACL in the ex-vivo rat model, corroborated with reduced cell viability and disrupted tissue organization on the impinged surface of the ACL as observed on fluorescent micrographs. The loads and displacements reached during cyclic loading were within physiological limits. Results from this study contributed to our understanding of ACL injury resulting from impingement at the tissue level.

### INTRODUCTION

Over 100,000 new cases of musculoskeletal disorders (MSDs) reported annually in the U.S. resulted from overexertion or repetitive motion of the upper extremity [1] and cost the health care and insurance systems hundreds of millions of dollars [2]. Despite the prevalence and cost associated with upper extremity MSDs, the underlying mechanisms for these injuries are still not well understood. In the workplace, external forces have been relatively well evaluated, but internal muscular loads are not as easily assessed. Further complicating matters is that, in addition to external forces, laboratory studies have identified several other factors that increase muscle activity in the upper extremity, including the nature of loading, increased task precision and mental demands. Failure to account for these factors by assessing external loads alone in the workplace will likely underestimate muscle load. For example, the addition of a submaximal grip or mental load to maximal shoulder exertions have been shown to interfere with the ability to produce maximal shoulder moment without necessarily reducing muscle activity; this effect was greatest when all tasks were combined [3]. The purpose of this study was to determine the influence of task precision, mental demands and shoulder exertions on forearm and shoulder muscle activity during a grip exertion task.

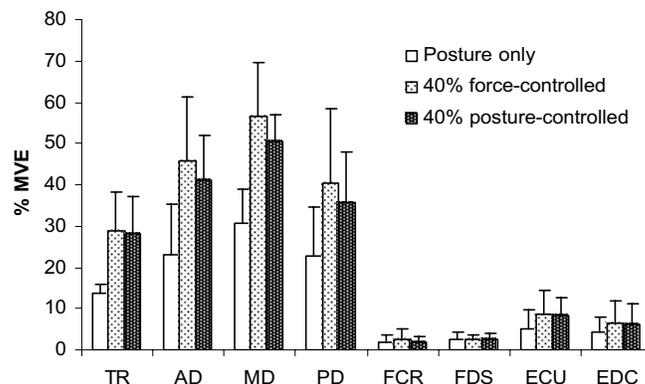

### METHODS

Participants (8 males, 8 females) were recruited from the university community and visited the lab on two occasions. On the first visit, participants were oriented to the protocol and had their maximal grip and shoulder strengths determined. The experimental protocol was conducted during the second visit. In total, there were 4 grip conditions, 3 shoulder loads and 2 mental loading levels. Each of the 24 conditions was repeated 3 times in a randomized block design. Participants were seated with the right arm abducted to 90°. They then exerted grip forces of 0, 30 and 100% MVC while simply maintaining shoulder posture or exerting a 40% MVC shoulder moment. To create the 40% MVC shoulder moment, participants either pushed upwards against a force transducer (*force-controlled*) positioned just proximal to the elbow or supported an equivalent weight (*posture-controlled*) hung from the same location. The 30% MVC grip force was maintained under two levels of precision: high precision required the grip force to be maintained within  $\pm 5\%$  and low precision within  $\pm 10\%$ . The increased mental loading condition was achieved by the simultaneous use of the Stroop test [3]. All forces and linear envelope EMG (3 Hz analog) were collected at 100 Hz. Surface EMG was recorded from 8 muscles on the right upper extremity: trapezius (TR), anterior deltoid (AD), middle deltoid (MD), posterior deltoid (PD), flexor carpi radialis (FCR), flexor digitorum superficialis (FDS), extensor carpi ulnaris (ECU), and extensor digitorum communis (EDC). Each trial lasted 10 s and participants received a

minimum rest of 1 minute between trials and 5 minutes between blocks.

### RESULTS AND DISCUSSION

Preliminary analysis ( $n=3$ ) indicated that maintaining 90° arm abduction while holding the grip dynamometer required shoulder moment of 20-30% MVC. Middle deltoid activity was approximately 30% MVE for these contractions, as previously found [4]. Force- and posture-controlled shoulder exertions at 40% MVC increased trapezius and deltoid activity by 20-25% MVE beyond that required to support the arm alone. Interestingly, for both 40% MVC moments (force- and posture-controlled), forearm extensor muscle activity increased by 2-3% MVE without an increase in grip force (Fig. 1). The need for greater precision in grip force also appeared to increase forearm muscle activity slightly. Based on these preliminary data, there appears to be a slight reduction in deltoid activity between the force- and posture-controlled moments with 0 and 30% MVC grip. The ability to generate a maximal grip exertion was compromised during simultaneous force-controlled shoulder exertions but not in any other condition. This 10-15% MVC reduction in grip force was paralleled by a similar decrease in forearm muscle activity. The findings of this study will improve our knowledge of the interactions of physical and cognitive demands in the workplace and their role in upper extremity MSDs.

**Figure 1:** Muscle activity at 90° shoulder abduction with and without a 40% shoulder moment (no grip force).

## WALKING IN GREATER HIP EXTENSION INCREASES PREDICTED ANTERIOR HIP JOINT REACTION FORCES

### INTRODUCTION

Acetabular labral tears are a recently recognized source of anterior hip pain. Excessive forces have been implicated as one cause of these tears. A clinical sign of a tear is anterior hip pain during late stance phase of gait. We propose that this pain is due, in part, to excessive force on the anterior structures of the hip, especially when the hip is extended. Our hypothesis is supported by the fact that, in patients with this pain, the pain is reduced when the patient is instructed to walk in less hip extension. This gait modification may help to decrease the anteriorly directed force, thus decreasing the pain.

The purpose of this study is to use a 3D dynamic musculoskeletal model to estimate the hip joint reaction forces while walking. We hypothesize that, within subjects, the gait trials with the greatest maximum hip extension will have a greater maximum anterior hip joint reaction force when compared to trials with the least maximum hip extension.

### METHODS

A six degree of freedom, 3D musculoskeletal model of a lower leg was developed to calculate joint reaction forces in the hip, knee, and ankle. Musculoskeletal parameters were adapted from Delp [1]. Kane's Method [2] and AUTOLEV 3.1 (OnLine Dynamics, Inc., Sunnyvale, CA) were used to generate the dynamic equations of motion. The general form of the dynamic equations of motion is:

$$M(\ddot{Q})\ddot{Q} = \bar{T} + \bar{P}(\dot{Q}, \ddot{Q}) + \bar{V}(\dot{Q}, \ddot{Q}) + \bar{G}(\ddot{Q}) + \bar{E}(\dot{Q}, \ddot{Q})$$

where M is the mass matrix, T is the net joint torques contributed by the force in the muscles spanning all joints, P is the torques developed passively in the joints due to viscoelastic damping and passive joint structures, and V, G, and E are the instantaneous segmental torques caused by the inertial, gravitational, and external forces, respectively. Q is the column vector of joint angles. Using kinematic and kinetic data from gait trials, the required segmental torques due to muscles were obtained for each trial. At each time point, a pseudoinverse optimization routine was used to solve for the optimal set of muscle forces [3] to create the needed joint torques. Once the optimized muscle stresses were solved simultaneously across all joints, the model calculated the resulting 3D reaction forces in the hip due to muscular contraction.

The gait data used in this study was collected from 5 healthy college-aged male subjects who participated in a previous study [4]. Each subject walked at a self-selected speed while 3D kinematic and kinetic data were collected. As we were most interested in anteriorly directed joint reaction forces, we only analyzed the terminal stance phase of gait. Within each subject, the reaction forces at the hip for the 2 trials with the most hip extension (MHE) range of motion and the 2 trials with the least hip extension (LHE) range of motion were each averaged. Paired t-tests were used to detect differences ( $p < 0.05$ ).

### RESULTS AND DISCUSSION

The average anterior reaction forces are presented in Table 1. Despite only a 2 degree difference between the MHE and LHE trials on average, ambulating with greater hip extension results in anteriorly directed forces that are significantly higher than ambulating with less hip extension.

**Table 1:** The average maximum hip angle and average anterior joint reaction force for the two groups.

Variable:	MHE	LHE	p
Max Hip Extension Angle (°)	13.5	11.5	0.01
Anterior Joint Reaction (N)	1791	1428	<0.01

### CONCLUSIONS

A 3D musculoskeletal model was modified to estimate joint reaction forces in the hip during ambulation. During gait trials with greater maximum hip extension, anterior joint reaction forces are higher than with less hip extension. Instructing patients with anterior hip pain to ambulate in less hip extension may help to decrease forces on the anterior hip joint and thereby decrease pain.

## AN INTERMITTENT EP-MODEL FOR FAST POINT-TO-POINT MOVEMENTS

Dinant Kistemaker, Knoek van Soest and Maarten Bobbert  
 Institute for Fundamental and Clinical Human Movement Sciences,  
 Vrije Universiteit, Amsterdam, The Netherlands; e mail: [d.kistemaker@fbw.vu.nl](mailto:d.kistemaker@fbw.vu.nl).

### INTRODUCTION

It has been widely acknowledged that the visco-elastic properties of muscles are beneficial to the control of posture and movement. An important class of control models that exploit these properties are equilibrium point (EP) models. Extensions of EP-models for fast point-to-point movements (e.g., co-contraction and ‘virtual’ trajectories) have been proposed to overcome limitations in terms of movement speed. Unfortunately, EP-models and their extensions have often been tested with models that lack a realistic description of the (dynamic) behavior of the muscle-tendon complex. The purpose of this study was to investigate whether EP-models can account for experimentally observed fast single-joint point-to-point movements [1], without making use of ‘virtual’ trajectories. To this end, we used an arm model with muscle models that reproduced the salient dynamical properties of muscles. We also examined intermittent control as a neurophysiologically plausible method to increase maximal movement speed.

### METHODS

The 2D model of the arm (Fig. 1) was actuated by four Hill-type muscles consisting of a contractile element (CE), a series elastic element (SE) and a parallel elastic element (PE). Activation dynamics was modeled to describe the relation between muscle stimulation (STIM) and active state. Feedback of contractile element length ( $l_{CE}$ ) and contraction velocity ( $v_{CE}$ ) was linear, and a 25 ms time delay (denoted by  $\delta$ ) in the feedback loop was adopted using a fifth-order Padé approximation.

**Figure 1.** Schematic drawing of the arm model.  $\varphi_e$  = elbow angle (extension positive).

The desired trajectories were based on experimental data of Gottlieb (1998) and covered  $100^\circ$  in 0.2 s (Fig.2E). In accordance with the experiments, the model was constrained to move in the elbow joint only. The musculoskeletal model was respectively driven by an  $\alpha$ -controller:

$$STIM = STIM_{open}$$

a  $\lambda$ -controller:

$$STIM = k_p[\lambda - l_{CE}(t - \delta)] + k_d[-v_{CE}(t - \delta)]$$

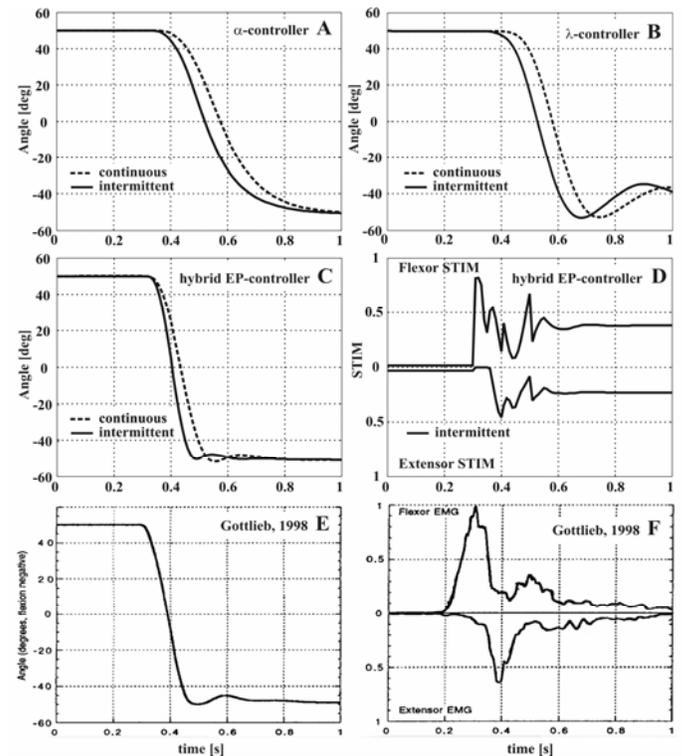

and a hybrid EP-controller:

$$STIM = STIM_{open} + k_p[\lambda - l_{CE}(t - \delta)] + k_d[\dot{\lambda} - v_{CE}(t - \delta)]$$

In these controllers,  $STIM_{open}$  was the open-loop muscle stimulation that created a stable EP with maximal stiffness. Stiffness was calculated using a linearization of the model in an equilibrium point.  $k_p$  and  $k_d$  are feedback gains and  $\lambda$  and  $\dot{\lambda}$  denote desired  $l_{CE}$  and  $v_{CE}$ . In the intermittent controllers  $STIM_{open}$ ,  $\lambda$  and  $\dot{\lambda}$  were updated with a frequency of 10 Hz.

### RESULTS AND DISCUSSION

All implemented EP-models gained maximal movement speed when control signals were sent out intermittently. The implementation of intermittent control was based on experimental studies indicating that humans control their movements with a frequency of 6-10Hz. Maximal movement speed of the  $\alpha$ -controller depended on the stiffness in the EP that was set. The stiffness produced by the present model was in accordance with values reported in the literature. Although  $STIM_{open}$  was chosen such that it maximized stiffness, the  $\alpha$ -controller was not capable of producing fast movements as observed by Gottlieb (1998). The  $\lambda$ -controller was also incapable of generating sufficiently fast movements, because time delays imposed limits on feedback gains to prevent stability problems.

**Figure 2.** Experimental data of Gottlieb (1998) and model simulations with the three different EP-controllers.

The hybrid EP-model was able to accurately reproduce fast movements as observed experimentally [1], albeit only when control signals were sent out intermittently (Fig. 2C). Furthermore, this model showed a stimulation pattern (Fig. 2D) that resembled the observed tri-phasic EMG pattern, indicating that this pattern does not need to be pre-programmed.

## A COMPARISON OF TWO FOOT MODELS USED IN CLINICAL GAIT ANALYSIS

### INTRODUCTION

The location and orientation of talo-crural (TC) and sub-talar (ST) joint axes play an important role in determining foot kinematics and kinetics. The single rigid segment foot model (conventional model) commonly used in clinical gait laboratories contains several significant shortcomings including i) reliance on physical exam based measurements, which are susceptible to significant random and systematic errors [1], and ii) approximating the foot as a single rigid vector [2]. As a result, foot motion data has been widely viewed as a weak link in clinical gait analysis. Other foot models have been proposed, and this study aims to evaluate the clinical usefulness in two proposed foot models: the three-segment foot model, proposed by Kaufman, et al., (Mayo model) and the functional model. The Mayo model defines three rigid segments (tibia, hindfoot, and forefoot), aligns the segments using anatomical landmarks, and computes Euler angles between the segments [3]. The second model considered here, the functional model, uses optimization to estimate functional TC and ST axes [4]. The TC and ST axes are used to create a four-segment foot model (tibia, talus, calcaneus, and forefoot). This study consists of an *in-vivo* assessment of the two proposed models in both typical and pathological feet.

### METHODS

Three-dimensional marker trajectories were collected for multiple subjects using a 12 camera Vicon 612 system (Oxford Metrics, Oxford, England). Both physical and virtual markers, as well as functional calibrations were used to define required parameters for all three foot models. Functional calibrations consisted of range-of-motion trials performed to locate the centers and orientations of the subject's TC and ST axes. Each subject then performed five walking trials, which were used to calculate foot kinematics. For both multi-

segment foot models (Mayo and functional), marker trajectory data was low-pass filtered using a Savitzky-Golay smoothing filter, and was rigidly-transformed with respect to each model-defined rigid body segment using Procrustes analysis. The location of the TC and ST joint axes can be described by a position vector in a marker-based coordinate system. The orientation of these axes can be described by 2 rotations in the same coordinate system.

### RESULTS AND DISCUSSION

Initial comparisons between the marker-based bimalleolar axis (Mayo model) and the estimated TC axis (functional model) show good agreement (Figure 1). The transverse plane orientation of the estimated TC axis (Rot 2 TC) relative to the marker-based bi-malleolar axis was the most accurate estimation of the calculated four rotations when compared to the marker-based bi-malleolar axis. The measure of coronal plane orientation of the estimated TC axis (Rot 1 TC) had the most precise results. The functional method allows objective location of the TC axis without the need for subjectively placed skin-mounted markers to identify the bimalleolar axis. Furthermore, the bimalleolar axis is based on anatomical landmarks, and is different than the TC orientation described by Inman [5]. This difference may be especially important in clinical gait analysis of pathological feet.

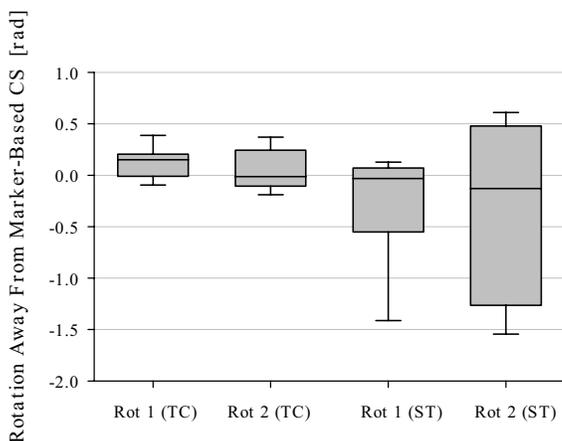

Initial results also show that the ST axis is not as precisely located as the TC axis. Since there is no gold-standard to compare the ST axis, the accuracy was not quantified. Current efforts are focused on using anatomical landmarks to assist in consistently describing the ST axes [5]. Using anatomical landmarks as initial estimations of both the ST and TC joint axes is meant to decrease computation time, provide indirect assessment of accuracy, and increase the precision.

### CONCLUSIONS

The functional model provides precise and objective location of the TC axis. However, current studies suggest that the location of the ST axis is not as consistent or reliable as has been reported [4]. Current efforts are focused on improving the estimation of the ST and TC axes using the functional method in combination with the Mayo foot model.

## THE INFLUENCE OF SEAT HEIGHT ON SIT TO STAND IN THE ELDERLY: A SIMULATION STUDY

<sup>1</sup>Zachary J. Domire, and <sup>2</sup>John H. Challis

<sup>1</sup>Division of Kinesiology and Health, The University of Wyoming, Laramie, WY, USA

<sup>2</sup>Biomechanics Laboratory, The Pennsylvania State University, University Park, PA, USA

email: [zdomire@uwyo.edu](mailto:zdomire@uwyo.edu), [jhc10@psu.edu](mailto:jhc10@psu.edu)

### INTRODUCTION

Lowering seat height has been shown to increase the difficulty of rising from a chair [1]. The impact of this increasing difficulty is particularly important for elderly individuals, because rising from a chair can be a near maximal strength task [5]. Two strategies while in contact with the seat have been proposed for dealing with decreases in seat height: moving the trunk farther forward or increasing the forward momentum of the trunk [9, 7]. The purpose of this study was to examine performance of the sit to stand from progressively lower seat heights, using a validated model of the elderly.

### METHODS

The model consisted of three links (shank, thigh, and head arms and trunk). The inertial parameters for the links were the same as those for a typical experimental subject (mean age 71.8 years) from the study of Burgess [2]. The model was actuated by eight muscle models representing the major muscle groups of the lower extremity. Each muscle model had force-length and force-velocity properties as well as activation dynamics [4]. The original parameters values for the muscle model were based on the data in the literature [3, 8], and adjusted to make them reflective of an older subject.

The neural excitations required for the model to perform the sit to stand were determined by solving an optimal control problem. The objective function found the muscle neural excitations required to perform the sit to stand while minimizing the muscle stresses and the rate of change of the muscle forces [6].

The sit to stand was simulated from three different seat heights of 38, 42, and 50 cm. The shank and the trunk were vertical at the start of each of the simulations. Changing seat height was accommodated by rotation of the thigh segment.

### RESULTS AND DISCUSSION

The simulation produced a similar kinematics and kinetics as the elderly subjects in Burgess [2]. Trunk movement prior to seat off, as seat height decreased, did not support either of the proposed strategies. The hip angle at seat off increased as seat height decreased. However, because of the higher initial hip angle, the resulting anterior trunk rotation decreased as seat

height decreased. Maximum hip flexion velocity also decreased as seat height decreased.

The peak moments required to stand did not necessarily increase as seat height decreased (Table 1). However, if these moments are expressed as a percentage of the moment the muscles are capable of given their current length and velocity then the moments increased as seat height decreased. The maximum knee moment (98 %), and the knee moment at seat off (93 %) for the lowest seat height were close to maximal.

To accommodate the lower seat heights initial hip flexion had to increase. This moved the hip extensors to a less favorable region of the force-length curve. This is complicated by the knee extensors being near maximally stressed at this time, therefore activation of the hamstrings is undesirable. In the simulation from the lowest seat height the gluteal muscles are 90 % activated to reverse the direction of the hip movement, thus not allowing increased forward trunk rotation.

### CONCLUSIONS

Two strategies for motion prior to losing contact with seat have been proposed for dealing with decreases in seat height: rotating the trunk farther forward, or increasing the forward momentum of the trunk. Evidence from this study does not support adoption of either of these strategies, because higher initial hip angles during seat contact places great demands on the hip extensors. Clearly decreasing seat height presents a significant challenge to the elderly, with no obvious strategy for meeting this challenge.

<sup>2</sup>University of Pittsburgh, VA Pittsburgh Healthcare System, USA

### INTRODUCTION

Whole-body vibration can result in low-back pain, disc degeneration and other harmful effects to the body [1]. Researchers are investigating optimal solutions for reducing vibration and seat pressure exposure of electric power wheelchair users [2, 3, 4]. The purpose of this study was to investigate the effectiveness of the newly designed water-filled cushion (NDWF), based on vibration amplitude transmissibility from the wheelchair seat to the head, and pressure mapping while driving an electric-powered wheelchair, as compared to other typical wheelchair cushions (Air-filled (AF), Viscoelastic fluid (VF), Water-filled (WF)).

### METHODS

A triaxial accelerometer (ARJ-A-T ±10g) was mounted on a seat frame to measure the vibration on the seat frame. Another accelerometer was mounted on a Bite-Bar that was held between the teeth of subjects in order to measure the whole-body vibration experienced by subjects. Signals from the accelerometers were amplified and sampled at 200Hz via a battery-powered acquisition system, and pressure distribution mapping was recorded simultaneously. The subjects sat on the different cushions placed on a sensor seat (BIG-MAT) in order to measure two values: the peak pressure and the contact area. Subjects drove the electric-powered wheelchair (JW1-22B) over four different surfaces: pavers, asphalt, brick and gravel, while sitting on four different cushions: AF, VF, WF, and NDWF. The electric-powered wheelchair was driven at one meter per second over these four surfaces. Ten subjects participated in this experiment. Their average age, weight and height were 22.2 ± 1.03 years old, 62.2 ± 9.39 kg, and 171.7 ± 8.32 cm tall respectively. Each driving trial was repeated three times, resulting in each subject driving the wheelchair for 36 trials (3 surfaces x 4 cushions x 3 times). From the collected signals, the Vibration Dose Value (VDV) was calculated for each direction (XYZ) respectively, then determined the resultant vibration dose value (VDV<sub>total</sub>). The Vibration Dose Value Ratio (VDVR) which represented the effective amplitude transmissibility of a cushion was also calculated. From the peak pressure and contact area data, the decreasing rate of the peak pressure (DP) and the increasing rate of the contact area (IC) were calculated based on those normative data when cushions were not used. To evaluate the effect of different cushion designs on a user's whole-body vibration, the variables VDVR, DP and IC were compared for significant differences between cushions using a mixed-model ANOVA, with an alpha of p=0.05.

### RESULTS AND DISCUSSION

The average and standard deviation of VDVR on each surface, peak pressure (DP) and increasing rate of the contact area (IC) are shown in Fig. 1, 2 respectively. Results showed that the

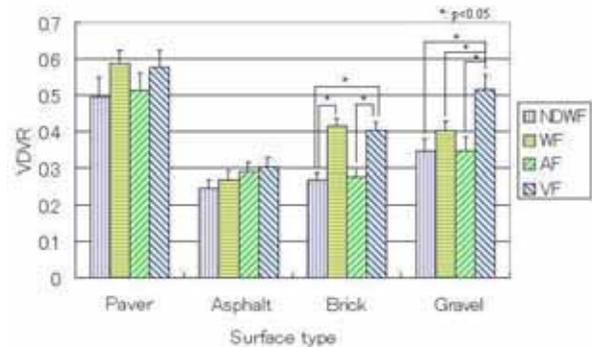

Fig.1 The VDVR on each surface

VDVR on the paver and asphalt surfaces did not have significant differences between cushions. The VDVR of the NDWF and AF cushion showed significantly less than WF, VF cushion on the brick and gravel surfaces (p<0.05). VF cushion showed a significant highest VDVR value compared to other three cushions. (P<0.05)

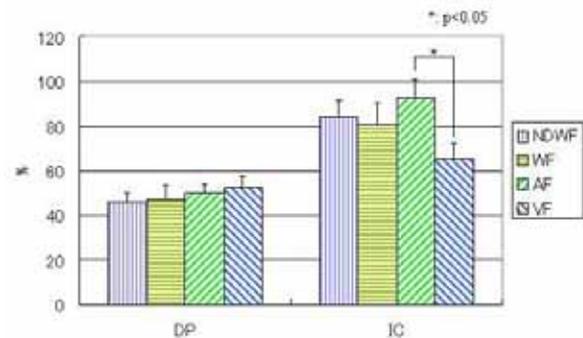

Fig.2 The DP and IC on paver surface

The DP and IC of the NDWF, WF and AF cushion were almost identical while driving wheelchair on the paver surface (Figure 2). From present results, whole-body vibration of NDWF cushion users was significantly reduced and did not change the pressure distribution compared to others three cushions. Based on present limited data, the NDWF cushion was comparable to commercial cushions and might be able to provide a comfortable ride and had a comparable effect in the prevention of pressure sores for power wheelchair users.

## A MODEL FOR ASSESSING THE CONTRIBUTIONS OF HAND FORCES AND TORQUES TO THE SPEED OF A SWINGING IMPLEMENT: APPLICATION TO THE FIELD HOCKEY HIT

Alexander Willmott and Jesús Dapena  
Department of Kinesiology, Indiana University, Bloomington, IN, USA  
Email: awillmot@indiana.edu

### INTRODUCTION

The motions of any striking implement are determined by the force and torque exerted by the hands on it and by the force of gravity [1]. However, the contributions of these factors to an implement's final speed have never been quantified.

The goal of this study was to develop a theoretical model for the analysis of the roles of hand force, hand torque and weight in the generation of the speed of any selected point on a swinging implement, and to apply it to the field hockey hit.

### METHODS

The velocity of any point P on the implement other than its center of mass, G, can be broken down into the absolute velocity of G ( $v_G$ ), and the velocity of P relative to G ( $v_{P/G}$ ). The velocity of G is generated by the forces acting on the implement: force **F**, applied by the hands at the mid-grip position, and the weight of the implement, **W**. (See Figure 1.) The relative velocity  $v_{P/G}$  is linked to the angular motion of the implement, and therefore ultimately results from the torques acting about G: the mid-grip couple **T** exerted by the hands, and the torque produced by force **F** about G.

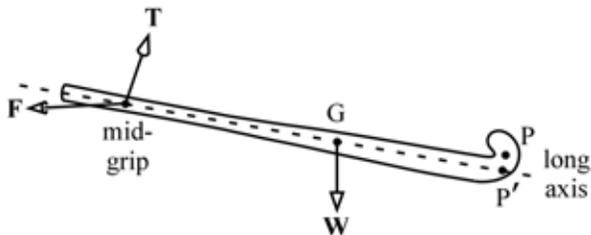

Figure 1: Free-body diagram of a field hockey stick, including the locations of all points used in the model.

In the model, **F** is separated into  $F_N$  and  $F_L$ , its components normal and parallel to the longitudinal axis of the implement. **T** is similarly broken down into  $T_N$  and  $T_L$ . The roles of these factors and of **W** during any given period are calculated as follows. To assess contributions to the linear acceleration of G, each force is divided at every instant by the mass of the implement, and the resulting acceleration vector is projected onto the current  $v_G$  vector. The acceleration is considered positive or negative, depending on whether the projected vector points in the same direction as  $v_G$  or opposite to it. These projected accelerations are integrated over the period to compute cumulative contributions to the change in the magnitude of  $v_G$ . The contribution of each force to the final  $v_P$  is obtained by multiplying its contribution to  $v_G$  by the cosine of the final angle between  $v_G$  and  $v_P$ .

To calculate contributions to  $v_{P/G}$ , each contributing torque is integrated over the period to calculate an angular impulse. The

latter is separated into components normal and parallel to the implement's longitudinal axis at the end of the period. This yields contributions to changes in "somersaulting" and "twisting" angular momentum, respectively. Each is divided by the corresponding moment of inertia to calculate contributions to somersaulting and twisting angular velocity. A linear velocity contribution is calculated for each angular velocity as the cross-product of the angular velocity with the position vector pointing from G to P at the end of the period. The projection of this linear velocity onto the final  $v_P$  gives the contribution of the corresponding torque to  $v_P$ .

This model was applied to the downswing of hits by eight female collegiate field hockey players. The DLT method was used to determine the 3D motion of the stick. Inverse dynamics was used to calculate the mid-grip force and torque.

The point selected for analysis in the field hockey application was P', the point on the stick's longitudinal axis closest to P, the center of the hitting surface. (See Figure 1.) The reason for this decision was that accurate estimates of the moment of inertia of each stick about its longitudinal axis were not available. This made it impossible to measure the effects of the twist rotation of the stick. The latter, however, plays only a minor role in a field hockey hit: the impact speeds of P and P' differed by  $0.7 \pm 0.7$  m/s.

### RESULTS AND DISCUSSION

The speed of point P' at impact was  $28.7 \pm 3.4$  m/s. The contributions from the forces and torques applied to the stick during the downswing accounted for  $27.1 \pm 2.9$  m/s of this amount. The main positive contributions during this period came from the longitudinal force ( $54 \pm 9\%$ ) and from the normal torque ( $62 \pm 18\%$ ). Weight made a very small positive contribution ( $4 \pm 1\%$ ), and the normal force made a rather small negative contribution ( $-19 \pm 9\%$ ). The negative contribution of the normal force was due largely to its effect on the stick's rotation: when this force is in the direction of the hit, the associated torque about G causes a backward linear acceleration of P' relative to G that more than outweighs the beneficial linear acceleration of G.

### CONCLUSIONS

The impact speed of a point near the distal end of the field hockey stick is produced in approximately equal proportions by the pull along the length of the stick and by the couple applied at the mid-grip. The effects of weight and of the force component perpendicular to the stick are much smaller.

## QUANTIFYING LEG ELASTICITY IN MALE VETERAN RUNNERS

<sup>1</sup> Ceri Diss and <sup>2</sup> David Kerwin

<sup>1</sup> University of Roehampton UK,

<sup>2</sup> University of Bath UK; email: [c.diss@roehampton.ac.uk](mailto:c.diss@roehampton.ac.uk)

### INTRODUCTION

Biological changes during aging that are related to running form six categories. They are cartilage, ligament and tendon, muscle, the nervous system, bone and the cardiovascular system. Within these categories one may see a reduction in elasticity, muscle mass, reaction time to stimuli, bone mass and the efficiency of the cardiovascular system. A reduction in elasticity is a result of muscle lengthening, loss of contractile properties, tendon and ligaments' lengthening and stiffening [1]. To quantify leg elasticity a linear spring model has been applied effectively to symmetrical rebound jumping and hopping [2].

The purpose of this study was to determine whether a linear spring model can be applied to a modified asymmetrical rebound jump for the quantification of leg elasticity in veteran runners.

### METHODS

A seven camera infra red system (Vicon 512) operating at 120Hz was synchronised with a force platform (Kistler 9281B11) operating at 1080Hz to obtain kinematic and kinetic data. A static calibration procedure for the identification of the position of the force platform and a dynamic (wand) calibration for 3-D reconstruction of body markers throughout the measurement volume. 36 reflective markers were used to create a full body model for each subject. Davis, R.B. et al (1990) developed the model with normal subjects and based on marker placements and static anthropometric measurements. Quintic spline filtering based on Woltring's method was applied to the real marker trajectory data prior to the modelling of upper and lower body kinematics and kinetics. The kinematic model allowed for point displacement and angles of and between segments to be determined. The kinetic models used mass and moment of inertia of the segments to facilitate the calculation of segmental 'reactions'.

Six veteran (V60) runners (mean mass = 74.66 kg, height = 1.74 m) performed two sets of five modified vertical jumps from which six were selected for analysis for each subject. The approach to the jump was from a step-in, to a two-footed

landing on the force platform followed by a maximal vertical rebound, termed a Step in Jump (SIJ). All subjects signed a consent form and were given a familiarisation period prior to data collection.

### RESULTS AND DISCUSSION

The linear least square values were greater than 0.9 for all subjects indicating that a linear spring model can be used when evaluating leg elasticity of the veteran runner when performing a modified asymmetrical SIJ. This is because the horizontal displacement during the step-in phase is small. If this were to increase the asymmetry would increase hence making the linear spring model unsuitable for such a movement.

Leg elasticity (Kleg) values are quite high for the veteran runner. This is mainly due to the small amount of leg compression (ie leg flexion) during the ground contact phase of the SIJ, since the force values at minimum leg compression (F peak) are similar to those previously reported. The reduced leg compression in turn influences a veteran athlete's ability to jump. This is shown by the reduced rise in the centre of mass (CM Rise) compared to the literature [3].

### CONCLUSIONS

A linear spring model can be used to evaluate leg elasticity of the veteran runner. Their leg stiffness effects their ability to jump mainly because there is in reduction leg flexion during the ground contact phase of the jump.

### INTRODUCTION

Osteoarthritis (OA) is the most common joint disease in humans and results in a severe degradation of joint structures that ultimately leads to joint degradation and failure [1]. The onset of OA is joint dependent and its probability increases with age or joint injury [2]. An anterior cruciate ligament transection (ACLX) is a well established animal model for post-traumatic OA, and changes in the periarticular bone in experimental OA occur as early as 3 weeks after injury [3].

This project is aimed at investigating whether antiresorptive bisphosphate (BP) drug therapy conserves long term joint function and retards OA progression. The effectiveness of BP therapy was assessed in conserving bone mineral at the MCL enthesis, periarticular cancellous bone architecture and the apparent mechanical properties of the periarticular bone in the distal femur and at the MCL insertion in an ACLX joint.

### METHODS

Skeletally mature, female New Zealand White rabbits were used as an experimental OA model and were randomly assigned to three groups (N=10/group). ACLX was performed in two groups; the first group was dosed with BP (risedronate, 0.1 mg/kg s.c. daily for 6 wk), the second group was untreated. The third group was comprised unoperated normal controls. After 6 wk, all animals were sacrificed, and the femur-MCL-tibia complex was dissected free. The medial and lateral femoral condyles were separated with a band saw to reduce the size of the specimen to facilitate scanning of the entire condyle.

Micro computed tomography ( $\mu$ CT) scans of the medial condyle of each cohort group were obtained (Skyscan 1072, Skyscan, Aartselaar, Belgium) at 100 kV through 180° with a rotation step of 0.9°, at an x12 magnification that produced serial cross sectional images of isotropic 19.4  $\mu\text{m}^3$  voxels. All data were filtered ( $\sigma = 1.2$ , support = 2) and a global threshold was applied to extract the mineral phase. The  $\mu$ CT data were input for large-scale finite element (FE) models to determine differences between groups in their apparent mechanical properties using a direct mechanics approach [4]. The approach accounted for the variation in bone micro architectural geometry, but not variation in tissue modulus.

A morphological analysis for each group was also completed and provided a quantification of periarticular cancellous bone architecture by determining trabecular thickness (Tb.Th),

trabecular number (Tb.N), trabecular separation (Tb.S), bone surface to volume ratio (BS/BV), structural model index (SMI) and anisotropy (by mean intercept length, MIL).

### RESULTS AND DISCUSSION

The experimental results revealed that BP therapy conserved medial collateral ligament (MCL) bone complex laxity and bone mineral at the MCL enthesis [5]. It was previously shown by our group (Doschak et al. 2004) that BP therapy conserved periarticular cancellous bone mineral density, elastic modulus, and maximal energy to failure [6]. A qualitative assessment of the  $\mu$ CT scans indicated that periarticular cancellous bone architecture was conserved. Full morphological and finite element results are proceeding.

Conservation of bone mineral density, bone mineral at the MCL enthesis, elastic modulus and energy to failure in the cancellous bone indicated that primary and secondary joint structures were being maintained through BP therapy. A reduction in joint laxity may also have reduced the effect of an ACL injury on joint loading conditions. Those improvements in joint structure and function may have a long term effect on retarding the pathogenesis of OA.

### CONCLUSIONS

Based on a qualitative assessment of the data and on the experimental results obtained, BP therapy appeared to have a positive effect on joint structure and function in the post-traumatic ACLX joint that may retard long term OA progression.

**The Effect of Hindfoot and Forefoot Positions on Posterior Tibialis Muscle Length**

<sup>1</sup> Christopher G. Neville, <sup>1</sup> Adolf Flemister, <sup>1</sup> Josh Tome, <sup>1,2</sup> Jeff Houck

<sup>1</sup>University of Rochester, Rochester, NY

**INTRODUCTION**

Posterior Tibial Tendon Dysfunction (PTTD) is a primary cause of flat foot deformity. The flat foot deformity seen in PTTD is expected to produce increased strain on the posterior tibial (PT) tendon causing eventual rupture. A recent in-vivo study suggests subjects with PTTD show hindfoot (HF) eversion as well as significant forefoot (FF) abduction compared to controls [1]. However, current management of PTTD focuses on relieving strain with orthotics by supporting the HF and medial longitudinal arch, without directly influencing forefoot position. [2]. The differential effects of HF eversion and FF abduction on PT muscle length remain unclear, making it difficult to judge the relative importance of forefoot abduction. The purpose of this study was to describe differential changes in PT muscle length due to non-weight bearing foot positions of FF abduction and HF eversion at three different angles of ankle motion.

**METHODS**

Four fresh frozen human cadaver limbs were potted and mounted on a platform. The PT tendon was dissected proximal to the medial malleolus and a 5 kg weight was sutured to the tendon via a string. Bone pins were inserted into the tibia, calcaneus, navicular, and first metatarsal to track motion of each bone. A 6 camera Optotrak Motion Analysis System (Northern Digital Inc, CAN) was used to track 3 infrared emitting diodes (IREDS) mounted to each bone pin. The platform was arranged so vertical displacement of an IRED on the 5 kg weight tracked PT muscle length. Using Motion Monitor Software (Innsport Training Inc, USA) online feedback of 3D angles (Z-X'-Y'' sequence) were used to achieve reproducible 3D FF and HF positions. After neutral foot position was determined, the foot was moved into 9 specified testing positions designed to stretch and shorten the PT muscle (listed in Table 1). These 9 positions were repeated at 30° of ankle plantarflexion, neutral ankle, and 10° of ankle dorsiflexion, resulting in 27 tested positions. PT muscle length was recorded at each foot position. Data were averaged across limbs for each position to describe differences across positions.

**RESULTS AND DISCUSSION**

Across ankle positions isolated FF abduction and HF eversion produced muscle lengthening while FF adduction and HF inversion produced muscle shortening (Table 1). FF adduction neutralized the effect of HF eversion in the HF EV

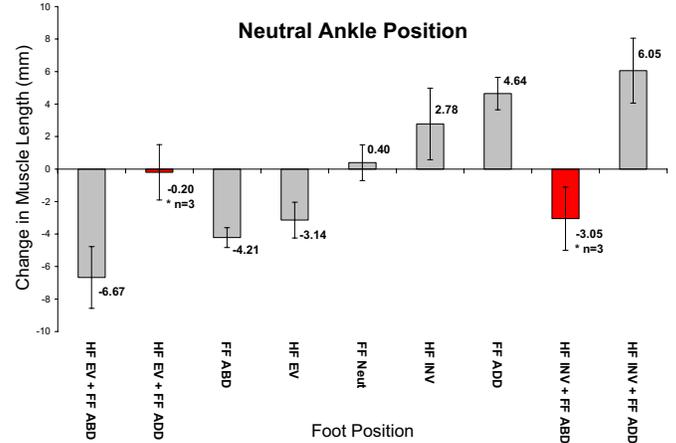

Figure 1: Muscle Length for 9 Neutral Ankle Tests with standard deviation bars.

+ FF ADD position (Figure 1). This effect occurred to an even greater extent in the HF INV + FF ABD position where FF motion surpassed the effect of the HF and produced lengthening. These results demonstrate a trend where the FF produces an equal or greater change in muscle length to that of the HF (Figure 1).

**CONCLUSIONS**

The results from this study suggest FF abduction and HF eversion play an integral role in determining length of the PT muscle. If replicated in weight bearing studies, this would suggest that controlling the FF and HF during gait is necessary to decrease strain on the PT muscle. This may require designing braces to control the FF after heel off, when only the FF is in contact with the ground, in addition to controlling the HF during early stance.

### 3-DIMENSIONAL KINEMATIC MODEL FOR PREDICTING HAND POSTURE DURING CERTAIN GRIPPING TASKS

<sup>1</sup>Jaewon Choi and <sup>2</sup>Thomas J. Armstrong

<sup>1</sup>Mechanical Engineering, University of Michigan; email: [jaewonc@umich.edu](mailto:jaewonc@umich.edu),

#### INTRODUCTION

Hand posture has a pronounced effect on hand grip strength in a given work condition. Even though many studies have addressed hand grip strength capacity, relatively few models have quantitatively explained how hand posture affects grip strength. Buchholz predicted the posture by iteratively increasing joint angles until ellipsoidal finger segment contacts an ellipsoid representing object [1]. Lee suggested a hand posture prediction model using optimization [2]. In the model, he minimized objective function which is summation of distances from center of rotation to the object surface. In this paper, a model for simulating hand posture by use of a contact algorithm has been developed. The distances between object surface and finger segments were calculated as increasing joint angles successively. This model has advantages over the previous models, in that it can estimate hand posture during real grasping scenarios and it considers the effect of finger movement patterns on hand postures. It can also be applied to various types of grips.

#### METHODS

The computational model was developed in a Visual C++ environment and OpenGL graphic functions were used to display the hand and object. The hand was modeled as open chain of rigid body segments, which was described as a truncated cone, the simplest reasonable representation of hand segments. 25 degrees of freedom were used to characterize the joints of the five fingers and wrist. A collision detection algorithm was used to determine when contact occurred between hand and object. Quadratic surface meshes were created for the surfaces of both hand and object. The distance between the meshes on hand and those on object was calculated as the joint angle increased. When the minimum distance between hand and object was smaller than a preset threshold value, it was regarded as a collision occurrence.

Two subjects participated in the experiment. Independent variables considered in this experiment were: 1) object size (cylinder diameter: 26.2mm, 60.0mm, 114.3mm); 2) hand size (hand length/breadth: 192/85.5mm vs. 171/91.0mm). Object location and elbow angles were controlled. Joint angles of each joint were measured for each condition. Each condition was repeated five times for each subject. The markers secured on dorsal side of the hand were tracked by OptoTrak® Certus™ motion tracking system (Northern Digital Inc.).

**Table 1** Mean(SD) values of the model prediction error of difference between observed and predicted joint angle(Middle finger, 2 subjects, 6 trials per subject)

Diameter	MCP	PIP	DIP
26.2mm	-3.9°(2.4°)	9.1°(1.6°)	-24.3°(12.2°)
60.0mm	1.0°(1.6°)	4.5°(2.0°)	5.2°(4.6°)
114.3mm	-5.1°(1.4°)	7.9°(1.4°)	-5.0°(7.1°)

**Figure 1:** Predicted prehensile postures for different object and hand sizes. Left (a): a 95% male hand grasping a 20 mm diameter cylindrical object. Right (b): a 25% female grasping a 40 mm diameter cylindrical object.

#### RESULTS AND DISCUSSION

Table 1 shows the model prediction error between observed and predicted joint angle for varying cylindrical object sizes. The hand model gave reasonable predictions of joint angles for different object sizes ( $R^2=0.79$ ). The errors between observed and predicted joint angle ranged from  $-24.3^\circ$  to  $9.1^\circ$ . The greatest error was found in the small object size. For the larger sized objects, errors ranged from  $-5.1^\circ$  to  $7.9^\circ$ . Joint angles appear to be very sensitive to object location for the small object.

Figure 1 shows different views of grasping objects when 1) a 95% male grasps a 25 mm diameter cylinder; 2) a 25% female grasps a 50 mm diameter cylinder, which were simulated by the computational model.

By applying a simple contact algorithm, prehensile hand postures could be predicted for various object attributes and hand size; however, because this model considered only kinematic relationship, the effects caused by force were not included. The rigid body modeling of the hand without assessing deformation also could also result in errors, probably overestimating angles. The effects of the object location on the hand posture will be studied in the future.

## PERCEPTION OF HAND MOTION DIRECTION USES A GRAVITATIONAL REFERENCE

<sup>1</sup> W.G. Darling, <sup>1</sup> C.R. Peterson, <sup>1</sup> A. Viaene and <sup>2</sup> J.P. Schmiechler

### INTRODUCTION

Kinesthetic sense, or perception of motion, has primarily been studied at the joint level by considering measures such as the time to detect passive motion or the angle through which a limb segment is slowly moved until motion is detected<sup>1</sup>. Such measures may be important in relation to control of joint stability, but the purpose of most limb movements is to place the endpoint (hand or foot) in a specific location. Thus, understanding the frame of reference used in sensing direction of hand motion would provide important information relevant to mechanisms underlying control of upper limb movements. Thus, the purpose of the present research was to determine whether the frame of reference used for kinesthetic perception of hand motion uses intrinsic (i.e., body-fixed) or extrinsic (earth-fixed or visually specified) axes.

### METHODS

Adult human subjects ( $n = 6$ ) were instructed to set unseen motion of the hand (imposed by a motorized linear slide apparatus operating in the frontal plane) parallel to specific axes while in two different body postures: (1) Fixed - normal upright seated posture and (2) Varied - experimenter-imposed tilt (lateral flexion) of the head and trunk to the right or left to different orientations on each trial. Direction of hand motion was controlled by the subject pressing the right and left buttons on a mouse to rotate the hand motion counter-clockwise (ccw) and clockwise (cw), respectively. Hand motion was aligned to visually specified axes presented on a head-mounted display (that also blocked vision of the external environment), to the trunk-fixed longitudinal axis and to the earth-fixed gravitational axis in different conditions. Subjects completed 42 trials when aligning hand motion to visual axes (six trials each for seven visual axes) and 24 trials when aligning the hand to the trunk-fixed longitudinal axis and the earth-fixed vertical axis. Digital encoders in the motorized slide apparatus recorded motion of the hand in the frontal plane. Orientations of the head and trunk were recorded using a 3D electromagnetic system (Ascension Technologies minibrain system).

Errors on individual trials were computed as the signed angular difference between hand motion direction and target axis direction in the frontal plane. Constant errors (CE) were computed as the mean of the signed errors. Variable errors were computed as the standard deviation of the signed single trial errors. In addition, correlation analysis was used to assess whether single trial errors for each axis depended on orientations of the head, neck and visual axis.

### RESULTS AND DISCUSSION

CEs clearly differed ( $p < 0.05$ ) for the different visual axes with axis angled ccw ( $-30^\circ$ ,  $-20^\circ$ ,  $-10^\circ$ ) having positive (cw)

errors and axis angled cw ( $10^\circ$ ,  $20^\circ$ ,  $30^\circ$ ) having negative (ccw) errors (Fig. 1). Constant errors for setting hand motion parallel to the trunk and vertical axes were generally small and cw. VEs were clearly smaller ( $p < 0.05$ ) for setting hand motion parallel to earth-fixed vertical than to visual axes and the trunk-fixed longitudinal axis when head and trunk orientation were varied (Fig. 1). Furthermore, single trial errors depended strongly on neck orientation when setting hand motion to visually specified axes in each subject ( $R = 0.6$  to  $0.9$ ), but not to trunk or vertical ( $R = 0.0$  to  $0.8$ ).

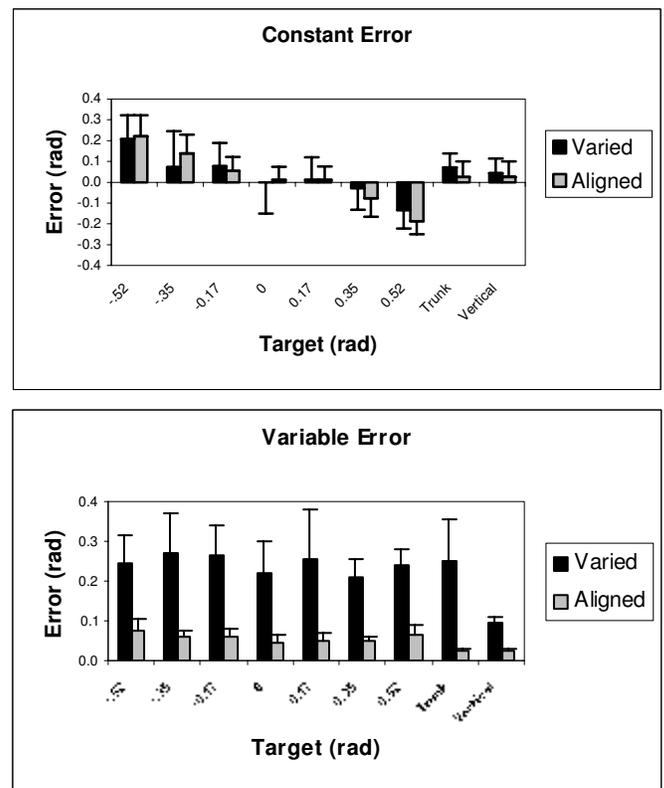

Figure 1: Constant errors (top) and variable errors for aligning hand motion to visual axes ( $-0.52$  to  $+0.52$  rad), trunk-fixed longitudinal axis (Trunk) and earth-fixed vertical (Vertical).

### CONCLUSIONS

The low errors, and lack of dependence of errors on neck angle, when setting hand motion to vertical show that perception of hand motion uses an earth-fixed frame of reference. This is consistent with our previous findings on perception of static forearm orientation perception<sup>2</sup> and motion of an external object<sup>3</sup>.

## PASSIVE KNEE JOINT PROPERTIES IN TIBIAL ROTATION IN MEN AND WOMEN

<sup>1</sup>Hyung-Soon Park, <sup>1</sup>Chulhyun Ahn and <sup>1,2</sup>Li-Qun Zhang

<sup>1</sup>Rehabilitation Institute of Chicago, <sup>2</sup>Northwestern University, Chicago, IL 60611, l-zhang@northwestern.edu

### INTRODUCTION

The anterior cruciate ligament (ACL) is an important structure for controlling knee joint movement and maintaining stability. The incident rate of ACL injury is two to eight times higher in women than in men [1]. ACL impingement against intercondylar notch during excessive tibial external rotation and abduction has been considered as a main mechanism of ACL injury, especially in women [2]. On one hand, the intercondylar notch geometry (“narrower”, loosely speaking) makes it more likely for female knees to have ACL impingement than male knees [2]. On the other hand, women may have larger laxity in tibial rotation and abduction than men, which also makes it more likely for women to have ACL impingement than men under the same knee loading. The purpose of this study was to evaluate passive knee joint properties in tibial rotation in male and female subjects.

### METHODS

The subjects (5 men and 5 women) were seated in a custom designed joint driving device (Fig. 1). The knee and hip flexion angles were 60° and 80°, respectively. The ankle was cast in the neutral position and coupled to one end of an L-shaped aluminum angle located distal and posterior to the foot-ankle cast. The L-shaped attachment was mounted onto the motor shaft through a six-axis force sensor.

To measure tibial rotation, LED markers were attached on the bony and flat anteromedial surface of the tibia, and the 3-D movements of the markers were measured by an Optotrak system at 100 Hz. The femur was fixed by clamping the lateral and medial femoral condyles to the seat (Fig. 1).

The zero tibial rotation was taken with the second toe pointing forward. With the position and torque limits set at the internal and external directions, the motor rotated the tibia at the constant speed of 1.5 deg/sec within the limits.

Joint laxity in tibial rotation is measured in two ways: 1) terminal rotation measured at 7Nm torque, and 2) intermediate rotation measured at the slope of 2 deg/Nm [3]. Joint stiffness and energy loss in tibial rotation were measured at 15 degree rotation (shaded area in Fig. 2).

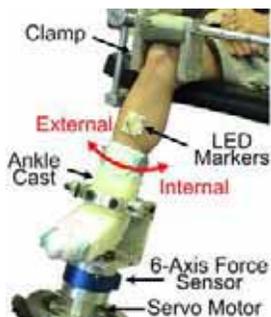

Figure 1: Experimental setup for knee axial rotation. The servo motor rotates the knee about the tibial long axis with the six-axis forces/moments measured by the JR3 force sensor. The ankle was cast for tight coupling. Optotrak markers on the flat tibia surface measure the angle of tibial rotation.

### RESULTS AND DISCUSSION

Under the controlled load, women showed significantly higher laxity in tibial external rotation with larger terminal rotation ( $31.9 \pm 4.2^\circ$  vs  $19.5 \pm 2.2^\circ$ ,  $P=0.001$ ) and larger intermediate

rotation ( $28.1 \pm 4.2^\circ$  in women vs  $15.5 \pm 2.4^\circ$  in men,  $P=0.001$ ). Women also showed lower joint stiffness in external rotation ( $31.9 \pm 13.1 \text{ Nm/rad}$  vs  $47.5 \pm 6.68 \text{ Nm/rad}$  in men,  $P=0.028$ ). In contrast, there was no difference in the passive knee properties in tibial internal rotation between the men and women.

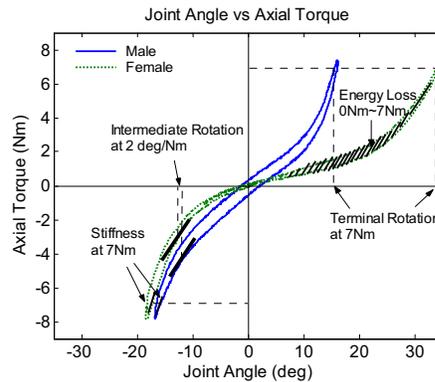

Figure 2. Typical tibial rotation torque-angle relationship in a man (solid blue line) and a woman (dotted green). Intermediate rotation at 2deg/Nm, terminal rotation at 7Nm, stiffness and energy loss at 7Nm are shown.

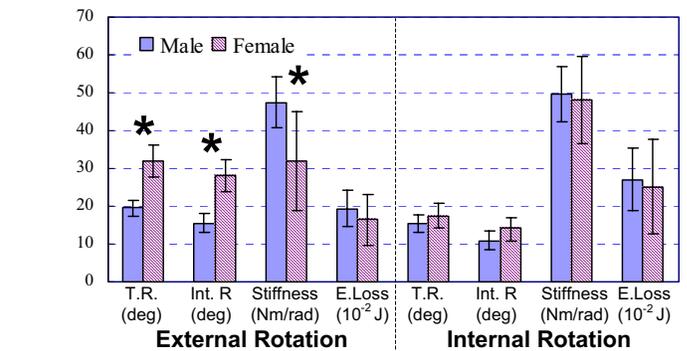

Figure 3. Passive knee joint properties in tibial rotation in men and women.

### CONCLUSIONS

With the narrower notch and larger laxity in tibial external rotation, female knees are more prone to having ACL impingement and thus ACL injury. This study presents an in vivo and accurate characterization of knee biomechanical properties in tibial rotation in men and women, which may help us understand the mechanisms underlying the several fold higher ACL injury rate in women than in men. Clinically, rehabilitation protocols may be developed accordingly to strengthen muscles crossing the knee and modify joint properties in tibial external rotation, especially in women, to reduce ACL injuries.

## GENDER-BASED POSTURAL RESPONSES TO SEATED EXPOSURES

Nadine M. Dunk and Jack P. Callaghan

Faculty of Applied Health Sciences, Department of Kinesiology, University of Waterloo

E-mail: [nmdunk@uwaterloo.ca](mailto:nmdunk@uwaterloo.ca)

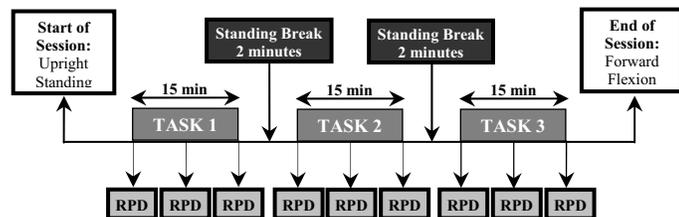

Webpage: [www.ahs.uwaterloo.ca/kin/people/faculty/callaghan.htm](http://www.ahs.uwaterloo.ca/kin/people/faculty/callaghan.htm)

### INTRODUCTION

Extensive research has attempted to determine the “optimal” seating position for the human spine to reduce the risk of low back pain. Thus, different chair designs have emerged to allow individualized optimal seated postures while maintaining comfort and functionality of the chair. However, individuals may respond differently to different chair designs and the factors that influence these sitting behaviours are not well understood. In particular, anecdotal observations of potential gender-specific sitting behaviours led to the primary purpose of this project which was to test the influence of gender on the responses to different seated postural conditions. A secondary purpose included determining if and/or how males and females respond to different seated computer-based tasks.

### METHODS

Sixteen healthy university students (8 males and 8 females) were tested on 4 different chair configurations, each on a separate day. The four chairs included: 1) a fixed chair with no back rest, 2) a pivoting chair with no back rest, 3) a pivoting chair with a back rest and 4) a freely pivoting spring-post stool. Participants performed three 15-minute intervals of simulated office work (mousing, typing and a combination of the two; Figure 1). Kinematics were recorded using OPTOTRAK; spinal angles and upper body centre of mass (CoM) were calculated. The seat pressure profile was collected using a pressure mapping device (XSensor) and was used to obtain the location of the centre of pressure (CoP), peak pressure over time and the average peak pressure for each 15-minute interval. Ratings of perceived discomfort (RPD) were taken 9 times at 7.5 minute intervals.

**Figure 1:** Study Design – For each testing session, participants completed three tasks (mousing, typing, or combination). Ratings of perceived discomfort (RPD) were taken at the beginning, middle and end of each of the three tasks.

### RESULTS & DISCUSSION

Regardless of the chair used or the task performed, average lumbar and trunk angles were significantly more flexed for males than for females (Table 1). The pelvis was posteriorly rotated for males and anteriorly rotated for females (Table 1). The task performed had an effect on the average lumbar angle of all subjects ( $p = 0.0029$ ); the lumbar spine was the least flexed during the typing task ( $52.5^\circ \pm 20.8^\circ$ ), followed by the combination task ( $57.9^\circ \pm 22.1^\circ$ ) and the mousing task ( $62.1^\circ \pm 20.7^\circ$ ). Significant gender\*chair interactions of the location of the individual on the chair seat were most marked for the pivoting chair with a back rest. Females positioned their CoM

and hip joints anterior to the chair pivot point while males' CoM and hip joints were located posterior to the pivot point. Females also sat with their CoM closer to the seat pan CoP than males when a back rest was present. Average ratings of perceived discomfort for each chair were analysed, revealing a significant chair effect for the upper back and overall discomfort. Both male and female participants had significantly less upper back discomfort ( $p = 0.018$ ) and overall discomfort ( $p = 0.012$ ) using the pivoting chair with a back rest when compared to all other chairs.

**Table 1:** Thoracic, lumbar, trunk and pelvis angles averaged over chair and task.

Measurement	Male	Female	P-value
Thoracic	8.6 (12.0)	3.1 (8.1)	$p = 0.201$
% max flexion Lumbar	65.4 (16.2)	49.6 (23.1)	$p = 0.047$
Trunk	29.8 (28.3)	-3.3 (20.4)	$p = 0.0026$
Deviation from vertical (degrees) Pelvis	7.6 (8.2)	-5.5 (9.3)	$p = 0.0008$

Taken as a whole, these findings suggest that men tended to slouch against the back rest while females perched closer to the front of the seat pan. It follows that males and females may be exposed to different loading patterns and may experience different injury pathways. Maintaining spine postures near neutral alignment, avoiding excessive spine flexion, and minimizing joint loading by adopting an upright posture are important factors in maintaining back health and preventing low back pain. Accordingly, males may be more susceptible to developing low back pain from prolonged sitting due to the adoption of a more flexed spine posture that increases the risk of disc herniations (1), and the increased probability of exhibiting seated flexion relaxation (2). Females may be more susceptible to back muscle pain since upright sitting postures require higher muscle activation than slumped sitting (2) and prolonged low level activation has been linked to muscle pain (3).

The identification and exploration of gender differences in seated work has implications for the differential prevention and treatment of injuries as well as the alteration of chair designs to accommodate both genders and knowledge of safe levels of exposure to prolonged sitting in occupational settings.

## MECHANICAL CONSTRAINTS DO NOT CHANGE THE STRENGTH OF LOCOMOTOR-RESPIRATORY COORDINATION DURING RUNNING

<sup>1</sup> William McDermott, <sup>1</sup>Richard E.A. Van Emmerik and <sup>2</sup>Joseph Hamill

<sup>1</sup>Motor Control and <sup>2</sup>Biomechanics Laboratories, University of Massachusetts, Amherst. Email: wm@excsci.umass.edu

### INTRODUCTION

Coupling between movement and breathing rhythms is thought to be a consequence of mechanical constraints placed on these systems. During locomotion, proposed mechanical constraints have taken the form of a visceral piston resulting from the visceral mass moving relative to the trunk cavity [1], the sagittal plane orientation of the trunk [4], and/or the demands placed on the respiratory musculature in controlling the trunk against perturbations [2]. Currently, little is known about the extent to which these constraints influence locomotor-respiratory coordination (LRC) due to limitations in many methods used to evaluate LRC [3] and because these constraints have previously not been measured.

The purpose of this study was to examine the influence of mechanical constraints that are induced by different uphill and downhill slopes on LRC during running. It was expected that greater constraints in terms of trunk flexion and accelerations of the trunk would result in greater strength of LRC.

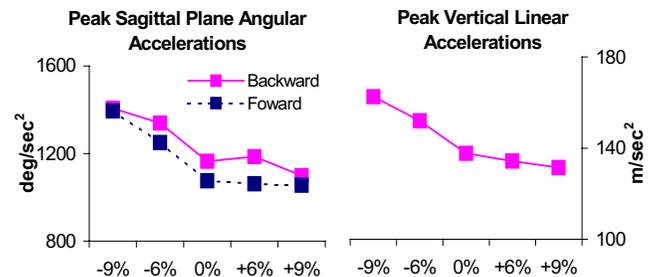

### METHODS

Thirteen male runners whose mean age was 27.4 ( $\pm 11$ ) years and ran 49.9 ( $\pm 15.9$ ) km/week participated in this study. The experimental conditions consisted of running at the preferred speed at level (0%) grade, followed by -9%, -6%, +6%, +9% grades in a random order. During the last 2.5 minutes of each condition, 3D motions of the thoracic trunk and pelvis were recorded (Qualisys, Inc.) along with the timing of right heel strike (tibial accelerometer, Entran Devices) and respiratory volume (respiratory airflow integrated with respect to time, Teem 100, Medical Graphics Corp.).

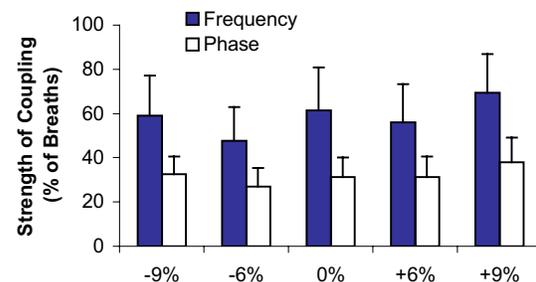

Mechanical constraints were evaluated at the trunk over 20 randomly selected strides by: 1) sagittal plane orientation, 2) magnitude of peak vertical linear accelerations and 3) magnitude of peak sagittal plane angular accelerations. LRC was obtained by first calculating the relative phase between each heel strike and end-inspiration [3]. The strength of LRC frequency coupling was quantified through return maps and time lags, and was defined as the extent to which the dominant frequency coupling occurred. The strength of phase coupling was quantified by the regularity of consecutively occurring phase relations [3].

### RESULTS

Increases in slope resulted in systematic increases in overall trunk flexion from 5.3° during the -9% to 15.1° during the +9% condition ( $p$ 's < 0.0002). Accelerations of the trunk were primarily influenced by the downhill conditions (Figure 1). The peak forward and backward directed angular accelerations (left panel) as well as the peak vertical linear accelerations (right panel) were greater during the downhill grades than during the level and uphill grades ( $p$ 's < 0.05). Despite these

**Figure 1:** Peak angular and linear accelerations of the thoracic trunk.

**Figure 2:** Strength of frequency and phase coupling between the locomotory and respiratory rhythms.

changes there were no consistent changes in the strength of locomotor-respiratory frequency and phase coupling (Figure 2) in response to the imposed uphill and downhill running slopes ( $p$ 's > 0.05). Correlation analyses showed that the timing of peak angular trunk acceleration was associated with the intra-subject variability of LRC ( $r=0.32$ ,  $p=0.01$ ).

### CONCLUSIONS

The results of this study indicate that proposed mechanical constraints do not act to couple locomotory and breathing rhythms in a way that increases the strength of coupling. Results from coupling analyses also suggest that increases in the *variability*, not strength, of LRC may be associated with changes in mechanical constraints. Increases in mechanical constraints imposed may therefore not result in greater coupling between locomotion and respiration, but in enhanced variability in their coordination and decoupling.

## HUMAN MANDIBLE RESPONSE TO IMPACT LOADING OF CHIN

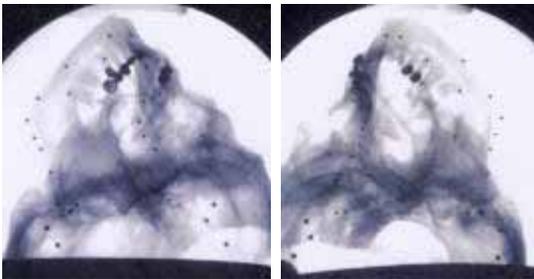

<sup>1</sup> Matthew Craig, <sup>1</sup> Cynthia Bir, <sup>1</sup> David Viano and <sup>2</sup> Scott Tashman  
<sup>1</sup> Wayne State University – Detroit, Michigan, [matthew.craig@wayne.edu](mailto:matthew.craig@wayne.edu)  
<sup>2</sup> Henry Ford Hospital - Bone and Joint Center - Detroit, Michigan

### INTRODUCTION

Load versus deflection response of the human mandible has been evaluated in the testing of cadaveric specimens in three general impact orientations. The output of the study provides a comprehensive look at the mandible, temporomandibular joint (TMJ) and basilar skull response to impact loading at the chin. Three-dimensional tracking of the mandible coupled with measured loading from an impacting drop mass was used to define response corridors of the human mandible. These corridors are to be used in the development of a surrogate mandible for use in automotive and sports equipment testing.

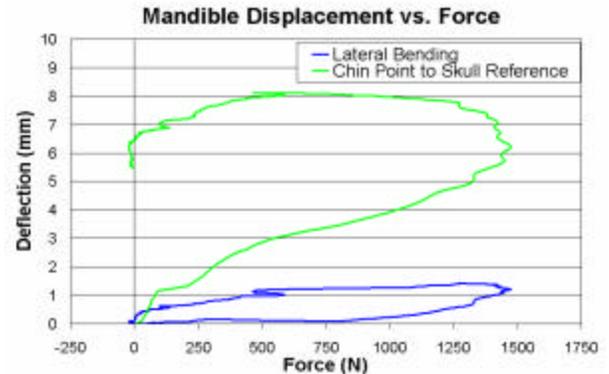

### METHODS

A 5.2 kg drop mass is dropped from various heights onto the chin point of cadaveric specimens. The specimens are potted in an adjustable stand that allows for testing in three pre-determined orientations. The drop stand, previously used by Walilko, et al [1] and refined for use in this study, supports a PVC tube that is used as the drop mass guide. The mass is secured using an electromagnet. Drop mass acceleration is measured with a pair of accelerometers whose data is collected using TDAS PRO™ (DTS, Inc.).

**Figure 1:** Images of bi-planar x-ray coverage of specimen prepared with markers

A high-speed bi-planar x-ray system was used for tracking displacements within the mandible and TMJ. The x-ray system emits an x-ray beam that is digitally recorded at a rate of 1000 frames per second by cameras at the rear of an image intensifier. The motion of lead markers (2-and 4-mm in diameter) placed on the surface of the mandible and skull are recorded and post-processed to produce x, y and z coordinates of the markers versus time (See Figure 1 for images of prepared specimen pre-test). The resulting three-dimensional motion of the markers is then used to evaluate motion between segments within the mandible and between the mandible and skull. That resulting motion is then plotted against drop mass impact force to develop force versus deflection response of the mandible.

**Figure 2:** Load versus deflection for single test on cadaveric specimen.

### RESULTS AND DISCUSSION

Load versus deflection was evaluated for a number of segments within the mandible and between the mandible and skull. Four key segments of deflection were evaluated: (1) chin point (point of drop mass impact) to a subcondylar marker just inferior to the condyle, (2) lateral deflection at 2<sup>nd</sup> molar, (3) sub-condyle to skull fixed reference, and (4) chin point to skull fixed reference. A sample output for the 1<sup>st</sup> and 2<sup>nd</sup> type of measurement listed above plotted versus the drop mass load can be seen in Figure 2. The output from the study is a set of load versus deflection corridors, one for each segment described.

### CONCLUSIONS

The load versus deflection corridors produced in this study provide a complete picture of the response of the human mandible and TMJ joint to direct loading at the chin point under various loads and impact orientations. The corridors will form the basis for a work in process by the author to develop a human mandible surrogate that will be added to existing surrogate headforms for future use in sports equipment (mouthguard, helmet, chinstrap, etc.) testing and possible application in the anthropomorphic test devices used by the automotive industry.

## Foot pronation in vivo – combined midfoot and hindfoot kinematics

<sup>1</sup> Michael Voigt, <sup>2</sup> Marianne Christensen and <sup>2</sup> Ole Simonsen

<sup>1</sup> Dept of Health Science and Technology, Aalborg University, [mv@hst.aau.dk](mailto:mv@hst.aau.dk)

<sup>2</sup> Department of Therapy, Aalborg Hospital, <sup>3</sup> Northern Orthopedic Division, Aalborg Hospital, Denmark

### INTRODUCTION

Tibiocalcaneal (hindfoot) mobility has previously been described in vivo as a measure of foot pronation (e.g. [1]). However, this measure does not include the possible contribution of midfoot motion to foot pronation. The aim of the present study was to describe the combined mobility of the hindfoot and the midfoot in vivo in relation to the level of foot pronation.

### METHODS

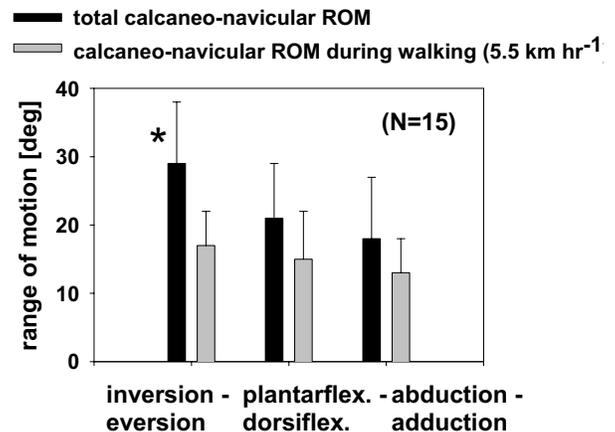

Fifteen volunteers participated in the study (4 females and 11 males). Age 43, SD 13 years, height 1.75, SD 0.1 m, weight 78, SD 13 kg, shoe size 42 SD 3 European.

The level of foot pronation was determined as the height of the medial arch of the foot during static loading ('reference navicular height') and the dynamic variation in this height ('dynamic navicular drop') during barefooted treadmill walking at 5.5 km hr<sup>-1</sup> was measured using a combination digital photography and electrogoniometry [2].

Three-dimensional hindfoot and midfoot motion was determined using a motion analysis system (Qualisys, ProReflex, 4 cameras, 240 frs s<sup>-1</sup>) and derived from bone mounted clusters of reflective markers during barefooted treadmill walking at 5.5 km hr<sup>-1</sup> and a series of full range voluntary ankle-foot movements. Hindfoot motion was determined as the relative tibio-calcaneal rotations and midfoot motion was determined as the relative calcaneo-navicular rotations. During local anaesthesia small pins made of Kirschner wire (K-wire, 50 mm long, 2 mm thick) were inserted about 25 mm in depth into: 1. the lateral epicondyle of tibia, 2. the upper part of the lateral wall of calcaneus and 3. the dorsomedial wall of the navicular bone of the right leg. On each of these pins clusters consisting of three reflective markers (marker diameter 19 mm and distance between markers 60 mm) were mounted. The K-wire in the navicular bone was inserted guided by X-ray to ensure a proper positioning and due to the dorso-medial direction of the inserted pin (fig. 1) the marker cluster on this pin was mounted via a small mechanical joint and thereby directed towards the dorso-lateral side of the foot. The bone orientations were referenced to the orientations during upright standing with full body weight on the foot.

**Figure 1.** K-wires inserted guided by X-ray in calcaneus (upper dark line) and navicula (lower dark line)

**Figure 2.** In vivo midfoot full range of motion (ROM) and ROM during walking (mean & SD). \* = total inversion-

### RESULTS AND DISCUSSION

The preliminary analyses have demonstrated that the reference navicular height ranged between 30 and 60 mm (mean 44, SD 8 mm) representing a wide range medial arch architectures. The dynamic navicular drop ranged between 14 and 61% (mean 30, SD 14%) of the reference navicular height during walking. The total calcaneo-navicular range of motion (ROM) (Fig 2, black bars) was similar to the talo-navicular ROM previously described in vitro [3]. The largest total calcaneo-navicular range of motion was observed in inversion-eversion. During walking the calcaneo-navicular ROM was between 60 and 70 % of the total ROM (Fig. 2, grey bars) with no significant differences between the movement directions. It was expected that tibio-calcaneal eversion and calcaneo-navicular eversion and dorsi-flexion would be correlated to flattening of the medial arch of the foot. However, no significant correlations were found between the level pronation (dynamic navicular drop) and the ROM in any direction of tibio-calcaneal or calcaneo-navicular movement.

### CONCLUSIONS

Due to inter-individual variation in: joint geometry, ligament architecture and mechanical properties, architecture of muscle-tendon attachments, muscle strength and coordination it seems that foot pronation is achieved inter-individually through a wide range of combinations of mid- and hindfoot rotations.

## THE ACCURACY OF USING POSTURAL ASSESSMENT TO DETERMINE CUMULATIVE EXPOSURE

<sup>1</sup>Chad A. Sutherland, <sup>1</sup>Wayne J. Albert, <sup>2</sup>Jack P. Callaghan, and <sup>1</sup>Allan T. Wrigley

<sup>1</sup>Department of Kinesiology, University of New Brunswick, Fredericton, NB, Canada

### INTRODUCTION

Cumulative loading, a known risk factor for low back pain [1] that is separate from peak loading [2] must be investigated to aid in workplace safety. Video-based task analysis in the workplace is often limited by equipment location and production line arrangement, therefore making it difficult to capture the motion in the sagittal plane. The purpose of this paper was to investigate the amount of error in calculating cumulative loading variables (compression, joint anterior shear, joint posterior shear, reaction anterior shear and extension moment) using a posture matching approach (3DMatch; [3]) compared to a 3D coordinate modeling approach (FASTRAK™ electromagnetic tracking system).

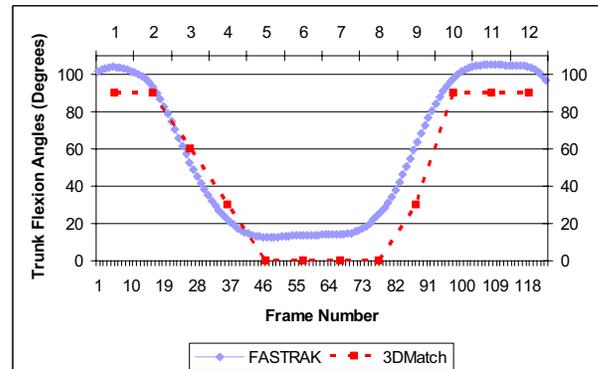

### METHODS

Six participants (3 males & 3 females) performed five repeats of two symmetrical and two asymmetrical stoop lifts while being simultaneously recorded from different camera views. The lifts were videotaped at 0°, 45°, 60° and 90° from the frontal plane. For modeling purposes, participants were suited with eight FASTRAK™ sensors located on the occipital protuberance, posterior surface of the second metacarpal-phalangeal joints, center of mass of the posterior surface of the trunk, upper arms and lower arms.

Four hundred and eighty lifting trials (6 subject \* 20 lifts \* 4 camera views) were analyzed using 3DMatch. 3DMatch uses postures of the trunk and upper extremities that are selected on a frame-by-frame basis from a set of predetermined posture categories (bins), which are used along with the subjects' anthropometric measures and hand forces to calculate the peak and cumulative variables. Relative error scores were calculated between the cumulative values derived from posture matching for each camera view (3DMatch) and those derived from the coordinate data (FASTRAK™). Both approaches used the same biomechanical model.

### RESULTS AND DISCUSSION

No significant difference ( $p < .05$ ) in the relative error for any of the cumulative loading variables across the four different camera views were found. Furthermore the relative error for compression, joint anterior shear, reaction anterior shear and

**Figure 1:** A trunk flexion angle graph representing a large difference between the data from the two model inputs.

extension moment were all below 11% (Table 1). The high relative error for joint posterior shear was due to the different techniques used to determine the segment angle. The posture bin for the trunk was a 30° range with the neutral bin postures ranging from -15° to +15°. The midpoint bin value (0 in this example) is used as input to the 3DMatch model, whereas FASTRAK™ uses the recorded segment angle. Figure 1 illustrates this problem. During frames 5 through 8 the neutral posture category was correctly chosen as the angle was ~14° and therefore a segment angle of 0 was used. However, comparison with FASTRAK™ where the actual 14° angle was used, the simplification of choosing the midpoint of a category inflates the error.

### CONCLUSIONS

These results suggest that 3DMatch is a promising tool for calculating cumulative low back loads as the relative error for all variables was below 11% when compared to a 3D biomechanical model.

## ELECTROGONIOMETRIC EVALUATION OF FOOT KINEMATICS DURING WALKING AT DIFFERENT VELOCITIES

<sup>1</sup>Michael Voigt, <sup>2</sup>Marianne Christensen <sup>2</sup>Ole Simonsen

<sup>1</sup>Dept. of Health Science and Technology, Aalborg University; email: [mv@hst.aau.dk](mailto:mv@hst.aau.dk)

<sup>2</sup>Department of Therapy, Aalborg Hospital, <sup>3</sup>Northern Orthopedic Division, Aalborg Hospital, Denmark

### INTRODUCTION

Exaggerated pronation of the foot (hyperpronation) is a factor that induces painful conditions in the foot and eventually musculo-skeletal problems in the more proximal parts of the lower extremities e.g. shin pain, medial knee pain. However, evaluation of the relationship between the degree of foot pronation and musculo-skeletal disorders in the lower extremities is difficult because the quantification of foot pronation is either based on simple static measurements with a rather low repeatability (Weiner-Ogilvie and Rome, 1998, Vinicombe *et al.*, 2001) or rather complicated 3-dimensional movement analysis of the structure and foot kinematics which are costly and time consuming in daily clinical practice. Consequently, the purpose of this study was to develop and test a clinically applicable method which with good accuracy quantifies the degree of foot pronation both the statically and dynamically (Leardini *et al.*, 1999).

### METHODS

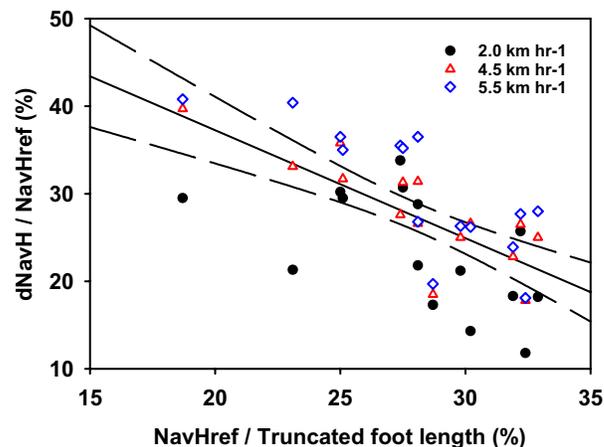

Fifteen persons participated in the study (8 females and 7 males), age 40 yrs (S.D., 8 yrs), height 1.76 m (S.D., 0.10 m), and body weight 72 kg (S.D., 16 kg) and shoe size 41 European sizes, (S.D., 3 European sizes).

The quantification of foot pronation was based on a combination of static photographs of the foot and electrogoniometric measurements of the calcaneal angle and the height of the medial arch of the foot respectively: 1) Calibrated digital photographs were taken of the loaded foot during upright standing in the frontal plane from the dorsal side and in the sagittal plane from the medial side. 2) Two flexible wire goniometers (Biometrics®) were skin mounted one measuring the angle of calcaneus in relation to the shank in the frontal plane and one measuring the angle between the calcaneus and the first metatarsal bone in the sagittal plane. Additionally, two foot switches were placed under the heel and the forefoot respectively to measure temporal gait parameters.

The participants were asked to walk barefooted on a treadmill at three different velocities: 2.0, 4.5 and 5.5 km/hr while data were collected. All signals were sampled at 1000 Hz with a PC-based data acquisition system and processed in Matlab®. All procedures were repeated two times to evaluate the re-test reliability of the method. Two static measures were extracted from the digital photographs: the calcaneal angle in the frontal plane and the vertical height of the navicular bone and from the goniometer signals the dynamic changes in same parameters over the full step cycle were obtained.

### RESULTS AND DISCUSSION

The comparison of selected parameters between the two tests did not reveal any statistical test-retest differences related to the test procedures.

**Figure 1:** The relationship between the normalized static navicular height and the normalized dynamic navicular drop during walking at different velocities.

The static navicular height had a range of 36 – 62 mm between participants in the examined group (group mean 51, S.D., 7 mm), and the amplitude of the navicular movement during a full step cycle walking at 4.5 km hr<sup>-1</sup> ranged between 9 – 17 mm (group mean 14, S.D. 2 mm). The static calcaneal angle in the frontal plane ranged between -2 – 10 deg (group mean 6, S.D., 4 deg) and the corresponding amplitude of calcaneal rotation during the step cycle walking at 4.5 km hr<sup>-1</sup> ranged between 8 and 33 deg (group mean 20, S.D., 5 deg). The magnitude of both calcaneal and navicular movement increased with increasing velocity. An inverse relationship between the normalized static navicular height and the normalized changes in navicular height during walking could be demonstrated (Fig.1).

### CONCLUSIONS

We believe that we have developed a clinically applicable method to evaluate the degree of static and dynamic foot pronation with good accuracy. The method represents a tool for evaluation of the quality/efficiency of a wide variety of operative procedures and/or rehabilitation/training procedures that aim to correct for hyperpronation of the foot.

## THE EFFECTS OF AN OVER-THE-COUNTER ORTHOTIC ON LOWER EXTREMITY KINEMATICS IN MALE AND FEMALE RECREATIONAL RUNNERS

Samuel Brethauer, Aric Warren and Robert Gregory  
Biomechanics Laboratory, University of Kansas, Lawrence, KS, USA;  
email: [rwg@ku.edu](mailto:rwg@ku.edu), web: [www.soe.ku.edu/hses/](http://www.soe.ku.edu/hses/)

### INTRODUCTION

Abnormal foot mechanics during the stance phase of running may affect the kinematics of the lower extremities and predispose an individual to injuries of the foot, ankle, and knee. Custom-made foot orthotics are often prescribed to correct abnormal mechanics during running by restoring dynamic stability to the closed chain of the lower extremity. However, there has been no research done to examine the efficacy of using an over-the-counter orthotic to correct abnormal gait mechanics. In addition, females are reported to demonstrate different lower extremity mechanics during running as compared to males [1]. The goals of this study were: (1) to examine the effects of an over-the-counter orthotic on ankle and knee joint kinematics during running in individuals identified as excessive pronators, and (2) to determine if there are any gender-specific effects of orthotics on ankle and knee joint kinematics during running.

### METHODS

Thirty college-age recreational runners (15 males, 15 females) identified as being excessive pronators participated in this study. Excessive pronators were defined as those individuals with a navicular drop of greater than or equal to 9 mm.

Subjects were required to perform two testing sessions in which they ran with and without orthotics. All subjects used the same model of soft, over-the-counter orthotic (Flat Foot Products, Marathon Shoe Co.) and the same model running shoe (Air Max Moto II, Nike Inc.) during testing. During both testing sessions, the subjects ran on a treadmill at a velocity of  $3.35 \text{ m}\cdot\text{s}^{-1}$  for 15 min. A three-dimensional motion capture system (Visualeyez VZ3000, PhoeniX Technologies, Inc.) was used to record the position of light emitting diodes placed on the foot, shank, and thigh segments at 100 Hz for 50 complete gait cycles during the last 5 min of each testing session.

Range of motion, peak angular velocity, and peak angular acceleration of the ankle and knee joints were calculated for the frontal, sagittal, and transverse planes of motion according to the methods outlined by Eng and Pierrynowski [2]. A two-way analysis of variance was used to assess the effects of orthotic and gender on all kinematic variables.

### RESULTS AND DISCUSSION

No differences between the orthotic and non-orthotic conditions across gender were found for ankle joint kinematics (range of motion, peak angular velocity, and peak angular acceleration) in the frontal, sagittal, and transverse planes of motion. One finding of note is that there was no difference in

the amount of pronation between the orthotic ( $4.1\pm 2.7^\circ$ ) and non-orthotic ( $3.5\pm 2.8^\circ$ ) conditions. This contradicts previous findings that soft orthotics reduce pronation [2,3].

In addition, no differences between the orthotic and non-orthotic conditions were found for knee joint kinematics (range of motion, peak angular velocity, and peak angular acceleration) in the frontal and sagittal planes of motion. However, there was significantly greater ( $p<0.05$ ) transverse plane motion in the orthotic ( $4.6\pm 2.9^\circ$ ) versus the non-orthotic ( $1.7\pm 1.2^\circ$ ) condition. Increased knee joint range of motion in the transverse plane when using soft orthotics has been documented previously [2].

Finally, it should be noted that there were no significant interaction effects between gender and orthotics on ankle and knee joint kinematics. While there was significantly greater ( $p<0.05$ ) pronation in the female ( $7.2\pm 1.5^\circ$ ) versus male ( $4.0\pm 1.4^\circ$ ) runners across orthotic condition, the use of orthotics did not reduce pronation to a greater extent in female as compared to male runners.

### CONCLUSIONS

The results demonstrate that the over-the-counter orthotic used in this study was not effective in altering lower extremity kinematics in male and female runners identified as excessive pronators. It can be concluded that over-the-counter orthotics provide mostly cushioning and little, if any, functional control. For individuals with gait pathomechanics, the use of a custom-made rigid or semi-rigid orthotic may be necessary.

Also, while there were differences in lower extremity kinematics between male and female runners, there were no gender-specific effects of orthotics on ankle and knee joint kinematics during running. Therefore, the over-the-counter orthotic used in this study was no more effective in reducing abnormal gait mechanics in female versus male recreational runners.

### INTRODUCTION

Modeling natural diarthrodial contact requires material constitutive properties that accurately describe the dynamic deformation patterns of articular cartilage. To fill the knowledge gap between whole joint loading experiments and measurements of chondrocyte and cell substructure material properties, we adapted a SMITH+NEPHEW Dyonics arthroscopy system 4-mm 0° arthroscope (Figure 1A) to record real-time streaming video of cyclic cartilage loading in a purpose-designed triaxial compression vessel [1].

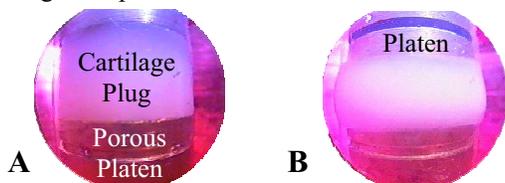

### METHODS

Endoscope optics produce a ‘fisheye’ view (Figure 1B), which is deconvoluted by a transform that was generated by placing the arthroscope tip 4 mm from a geometrically homogenous pattern and unwarping the digital image to known fiducial [2].

**Figure 1** (A) Arthroscope configured for image calibration. The ‘fisheye’ view of an arthroscopic image (B) is deconvoluted (C) to the known grid geometry.

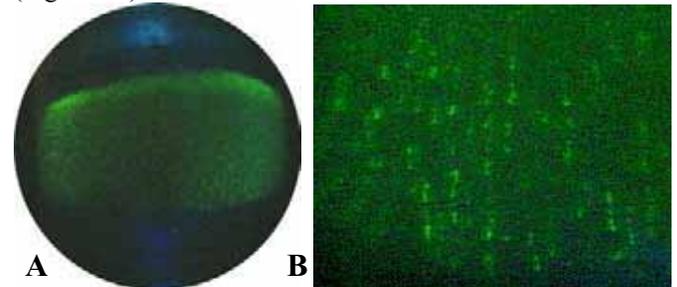

A 4-mm right-circular cylinder (plug) of human tibial plateau articular cartilage, 1.9 mm thick, was cyclically compressed with 0.1–2.0 MPa between porous platens in the nutrient-filled triaxial chamber (Figure 2). The 4 mm-wide platen (400 pixels, 10µm resolution) provided an in-image scale. Vertical movement of the upper platen was measured directly within each cine-frame (30/second) via pixel separation of fiducial grooves on the upper and lower platens. Motion of the upper platen was also recorded by a DVRT monitoring movement of the driving axial piston.

**Figure 2** (A) The cartilage plug as seen before loading and (B) after 0.6 mm of axial compression.

Cartilage was stained with calcein-AM to fluorescently label live chondrocytes. An excitation filter (488 nm) was inserted between the xenon light source and the arthroscope and a yellow dichroic barrier ( $\geq 515$  nm transmission) was inserted at

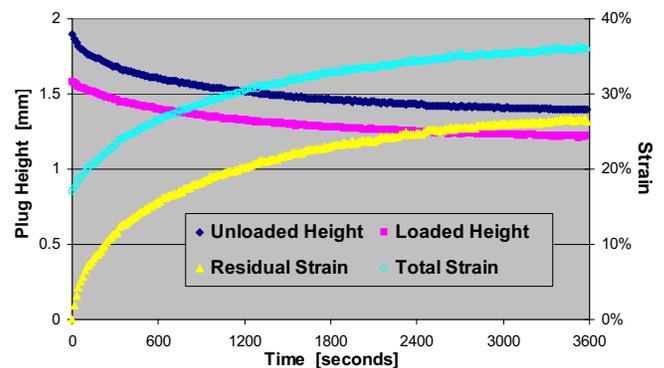

the eyepiece to allow visualization of live cell distribution in the matrix (Figure 3A). Optical resolution is sufficient to distinguish local chondrocyte columns in the deep zone (Figure 3B).

**Figure 3** Chondrocyte morphometry in arthroscopic images; (A) Whole plug with highly fluoresced superficial zone. (B) Chondrocyte columns fluoresce in the deep zone.

### RESULTS AND DISCUSSION

During unconfined axial compression between porous platens, an articular cartilage plug will bulge radially (Figure 2). The tissue will gradually lose height as water is forced from matrix voids under 1 Hz cyclic compression (Figure 4).

**Figure 4** Plug heights and axial strains over 1 hour of loading

Articular cartilage consists of fluid and solid components. The changing shape of the cartilage plug’s silhouette is indicative of the underlying biphasic material behavior. Finite element poroelastic model values of void ratio-dependent hydraulic permeability and depth-dependent modulus can be varied to match dynamic deformation patterns [3].

We present a method of real-time visualization and measurement of tissue deformation in living cartilage. Fluorescence labeling of chondrocytes provides internal fiducial markers that can be used to analyze intra-tissue strains and cell viability during dynamic loading.

## FINITE ELEMENT ANALYSIS OF SHOCKWAVE PROPAGATION IN CORTICAL BONE

<sup>1</sup> Andrea E Tami, <sup>2</sup>Ulf Knothe and <sup>1</sup>Dwight T Davy

<sup>1</sup>Department of Mechanical and Aerospace Engineering, Case Western Reserve University, Cleveland, OH,

<sup>2</sup>Orthopaedic Research Center, The Cleveland Clinic Foundation, Cleveland OH;

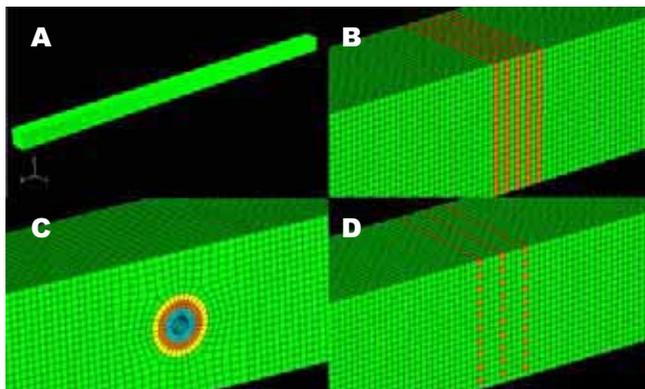

email: [dwight.davy@case.edu](mailto:dwight.davy@case.edu), web: [mael.cwru.edu/mae/Pages/Facilities/mmm/pages/mmm-main.html](http://mael.cwru.edu/mae/Pages/Facilities/mmm/pages/mmm-main.html)

### INTRODUCTION

Osteoporosis on Earth and disuse osteopenia associated with prolonged exposure to microgravity show parallels including loss of bone mass and changes in cellular remodeling activity. Knothe and colleagues [1] have proposed the use of extracorporeal shock waves (ESW) as a means to combat bone loss. Results from in vitro pilot experiments have demonstrated the feasibility of creating microcracks in cortical bone similar to those occurring during physiological loading [1]. Based on the global hypothesis that microdamage acts as a trigger for the onset of remodeling by altering fluid flow and cell signaling, we propose that controlled application of ESW to bone tissue stimulates bone turnover. In order to better understand the therapeutic effect of ESW and to effectively develop this as a potential clinical application, the actual mechanics of the wave propagation and its interaction with local microstructure were analyzed using finite element models.

### METHODS

The finite element analysis was run on the implicit solver of Abaqus 6.4 (HKS Inc., Pawtucket, RI). The basic shape for the model was a prismatic beam with isotropic, homogeneous material properties (Fig. 1A). Structural characteristics corresponding to the micro-architectural features of cortical bone tissue, i.e. lamellae, osteons with Haversian canal, and lacunar spaces, were subsequently included in distinct models (Fig. 1C-D). Comparable to the technical specifications of the lithotripter, the shockwave pulse was implemented as a haversine wave with high compressive amplitude (50-100Mpa), quick build-up time and short pulse width (1microsec). Parametric studies were carried out for different material and wave properties [2,3]. The effect on wave propagation along the beam due to changes in stiffness, density, pulse width and amplitude, as well as due to lamellar thickness and the presence of cavities was evaluated.

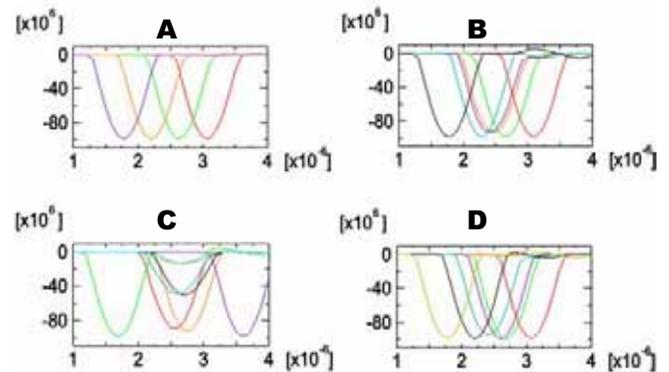

**Figure 1:** Basic model (A) and three modeled scenarios: lamellae (B), osteon (C) and lacunae (D).

### RESULTS AND DISCUSSION

Noticeable changes in stress distribution of the propagating shockwave occurred when interfaces were modeled with very low stiffness (e.g. lacunae and Haversian canals) (Fig.2C-D). In these cases, the stress transmitted through the interface rapidly decreased with increasing interface thickness. Furthermore, in front of those inhomogeneities stress quickly changed from maximal compression to maximal tension due to reflection. When the change in stiffness was less than an order of magnitude, the interface had little effect on the traveling wave and, thus, the stress was not altered considerably.

### CONCLUSIONS

In this study a model was designed that had the necessary spatial resolution for the characterization of bone properties like osteons, lamellae and lacunae, and at the same time could adequately represent the temporal resolution of a real shock wave pulse. More insight into the propagation pattern and stress distribution of a shock wave traveling in an isotropic, though inhomogeneous material was obtained. The possible effects of various interfaces were assessed. The next step will be the implementation of non-linear material behavior and algorithms incorporating the effect of damage.

**Figure 2:** Stress distribution at different locations along the beam, corresponding to the modeled scenarios of Fig.1 (x-axis: time in sec, y-axis: stress in Pa).

## Velocity Sense in the Lumbar Spine is Modulated by the Vestibular and Proprioceptive Systems

<sup>1</sup> Joseph S. Soltys and <sup>2</sup> Sara E. Wilson

<sup>1</sup>Mechanical Engineering, University of Kansas, email: sewilson@ku.edu

### INTRODUCTION

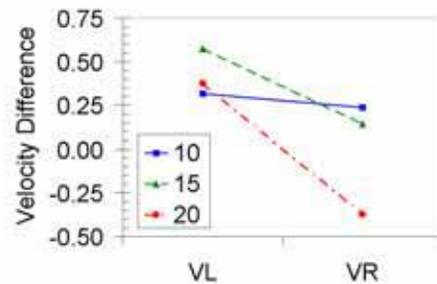

To maintain stability and normal motion of the spinal column, sensory information is necessary[1]. While studies have investigated position sense of the low back, few studies have examined velocity sense. A number of sensory systems may contribute to the perception of velocity of trunk motion. Muscle spindle organs have been shown to sense both joint position and velocity in the extremities[2]. The vestibular system could also contribute to the sense of trunk motion. In this study, the vestibular and proprioceptive contributions to the sense of low back movement were examined. It was hypothesized that altering vestibular and proprioceptive inputs would alter the sense of lateral trunk motion.

### METHODS

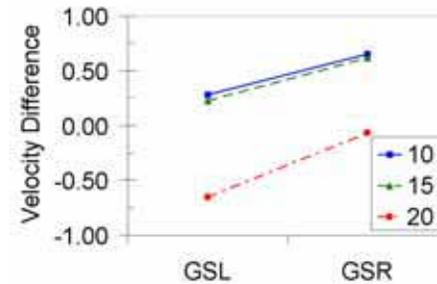

Eight healthy subjects were recruited for the study, which was approved by the Human Subjects Committee, University of Kansas. Galvanic vestibular stimulation was applied via electrodes placed on the mastoid process behind each ear. The stimulation was set below the cutaneous threshold[3]. A vibratory stimulus device was fitted on the subject's back at L3 and adjusted to provide a 30 Hz stimulus to the underlying paraspinal muscle groups on either side of the spine independently. Subjects lay prone on a platform with their pelvis fixed, allowing only lateral trunk movement. Rotation from an optical encoder was used to provide a single audible tone for every 7° of angular displacement. Subjects were blindfolded and asked to flex laterally so that the platform generated audible tones to match a digital metronome. Target paces were 10, 15, and 20 degrees/sec. The protocol consisted of alternate training (w/ audible pace and feedback) and assessment (no audible pace or feedback) trials for each of six conditions, block randomized, for each target speed. The stimulus conditions were defined as follows: NS – no stimulation, GSL/GSR – galvanic cathode at left/right ear, VL/VR – vibration left/right sides. Each trial consisted of two consecutive right to left movements across the maximum comfortable range of lateral trunk motion.

### RESULTS AND DISCUSSION

The differences between consecutive right and left movement velocities for mid-range movement were assessed. Movements were found to be faster to the right with vibration of the left paraspinal muscles than with vibration of the right paraspinal muscles. Cordo et al. found that perception of velocity of movement in the elbow could be altered for frequencies between 20 and 40 Hz with slower frequencies being perceived as slower motion[2]. The muscle vibration used here was found to be interpreted as a slower lengthening, leading to a faster movement in the non-stimulus direction to compensate for the perceived slow-down. This was particularly pronounced at the higher speed where the difference between perceived and actual speed would be greater.

**Figure 1:** Right-Left velocity differences were found to be higher with vibration of the left paraspinal muscles (VL) than with vibration of the right paraspinal muscles (VR). This difference was found to increase with speed (10, 15, 20 deg/sec).

**Figure 2:** Right-Left velocity differences were found to be lower with galvanic vestibular stimulation with a left cathode (GSL) compared to with a right cathode (GSR). This change was found to be independent of speed (10, 15, 20 deg/sec).

With galvanic vestibular stimulation (GVS), movement towards the cathode was found to be faster for both left and right stimuli at all speeds of movement. GVS has previously been shown to induce a perceived motion towards the cathode in studies of dynamic sway[3]. This suggests that the vestibular system also plays a role in perception of velocity.

### CONCLUSION

Both the proprioceptive and vestibular systems have been shown to play a role in the sense of lateral, low-back velocity. Vibration-induced changes in kinesthesia have been found to be a function of the speed of motion. Future research should examine the frequency dependence of these changes.

## MODELING AND SIMULATION OF REACTION FORCES IN A REDUCED GRAVITY EXERCISE SYSTEM

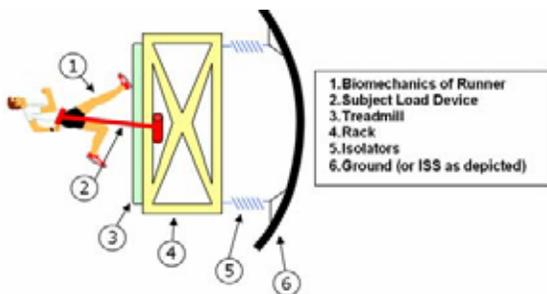

<sup>1</sup>Marcus L. Just, <sup>1</sup>Carlos Grodsinsky, <sup>2</sup>Gail Perusek, <sup>3</sup>Brian Davis, <sup>3</sup>Peter Cavanagh  
<sup>1</sup>Zin Technologies, Inc., Brookpark, OH; email: [marcus.just@zin-tech.com](mailto:marcus.just@zin-tech.com); web: [www.zin-tech.com](http://www.zin-tech.com)  
<sup>2</sup>NASA, Glenn Research Center, Cleveland, OH  
<sup>3</sup>Cleveland Clinic Foundation, Cleveland, OH

### INTRODUCTION

NASA Glenn Research Center (GRC) and the Cleveland Clinic Foundation (CCF) are collaborating to study aspects of exercise as a mitigating countermeasure to the phenomenon of bone density loss experienced by astronauts in extended space missions, despite implementing a rigorous exercise regimen. It is suspected that the reduction of reactive forces introduced by necessary vibration isolation systems make the workout less effective, thus contributing to the persistence of the phenomenon. Isolators are needed at the exercise system interface to attenuate forces that are transmitted into the space vehicle. A 1-Degree of Freedom (1-DOF) ground-based treadmill test bed known as the Enhanced Zero-g Locomotion Simulator (eZLS) has been designed which will allow researchers the ability to simulate an on-orbit reduced gravity environment in one axis. A dynamic model of the eZLS has been built to understand system dynamics and their affect on foot-treadmill reaction forces. One of the goals of the project is to experiment with isolators of different properties and determine their effect on foot reaction forces.

### METHODS

The exercise system has six distinct elements that were included in the simulation (see Fig. 1).

**Figure 1:** Zero-g Exercise Schematic

The model aimed to simulate rigid body dynamics of the treadmill and rack (items 3 and 4 in Fig. 1) as the runner foot forces (1) excited the dynamics of the isolator elements (5). The isolators were assumed to be grounded at (6). Foot forces were approximated as a sinusoidal, displacement driven body load into the runner's legs. Leg stiffness and damping values were chosen to obtain foot force input loads of 2.5 BW peak force [Ref. 1] into solid ground. The cadence was set to a frequency of 3 Hz. The input signal was half-wave rectified since the foot force could only be directed into the treadmill surface. The treadmill and rack were modeled as a rigid body, the position of which was subtracted from the displacement driven runner load. Isolator stiffness and damping properties were calculated so that certain desired resonances could be studied. Since the position of the treadmill was driven by the

runner, depending on isolator stiffness and damping, the treadmill surface tended to dynamically yield against the foot. Output from the model was treadmill deflection, foot reaction forces, and ground reaction forces.

### RESULTS AND DISCUSSION

The model was used to gage the potential effect that various isolator designs may have on foot reaction forces. Four simulated isolators were set to resonances of 1 Hz, 3 Hz, 10 Hz, and 25 Hz. Model output is presented in Table 1. The 1 Hz isolator set naturally produced the best attenuation of forces transmitted into the ground, however at the expense of 8.7% less total foot reaction forces compared to the baseline 25 Hz case, which is nearly hard-mounted. While the 1 Hz case peak forces only dropped by about 4.7%, the sum of the forces, which is a way of measuring total workout, increased in a non-linear fashion. Also, the model showed that a 3 Hz isolator resonance will of course couple with the cadence frequency and cause many undesirable effects such as amplified ground interface forces and treadmill oscillations, and a 43.5% reduction in summed foot reaction forces.

### CONCLUSIONS

The initial rigid body model provides a good illustration of the effects that the eZLS project is setting out to study and serves as a starting point for building more sophisticated models of exercise systems for use in long duration manned spaceflight. Adding more detail regarding bio-mechanical simulation of the runner, higher-order treadmill and rack dynamics, and an active subject loading device will greatly enhance the model. The model can then be validated against tests performed on the eZLS in normal earth gravity and modified for use in 6-DOF in order to simulate performance of astronaut exercise aboard the International Space Station, or Long Duration Lunar and Mars Exploration Missions.

### INTRODUCTION

The elbow is critical to activities of daily living, for gross tasks such as lifting heavy objects and finer tasks such as grooming. Some treatments of elbow injury, including replacement and/or reconstruction, do not restore stability or complete function. Tools are lacking to evaluate kinematics and stability of surgical treatments *in vitro*. An elbow simulator described in the literature has actuated its muscles with open-loop force control [1] and lacked antagonist muscle control making accurate positioning difficult at best. A wrist simulator's success using force and position control illustrates that proportional-integral-derivative control can replicate physiologic motion in an upper extremity joint [2].

The purpose of the current work was to construct an apparatus to replicate realistic, accurate motion and neuromuscular control of a cadaver elbow while maintaining moment arms similar to the broad range of those reported in the literature. Fulfillment of these design requirements will permit the study of force and motion control strategies.

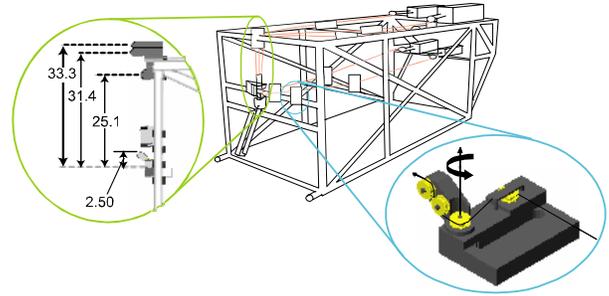

### METHODS

The apparatus controls the dominant movements (flexion-extension (f/e) and pronation-supination (p/s)) via the *brachialis*, *biceps brachii*, *triceps*, *pronator teres*, and *brachioradialis*. A custom frame (Figure 1) supports five servoelectric cylinders (Exonic Systems, Pittsburgh, PA) coupled with Gemini servo drives (Parker Hannifin Corp., Cleveland, OH) to actuate the muscles. Each muscle is connected to its actuator via a cable that passes through a muscle-specific custom pulley system which maintains physiologic alignment (and thus accurate moment arms) throughout the motion. The cables to extend the *biceps brachii*, *brachialis*, and *triceps* do not undergo large alignment changes during elbow motion and require only stationary pulleys. However, the *brachioradialis* and *pronator teres* undergo marked alignment changes with elbow flexion and thus a more advanced pulley system is required to allow multiple rotations (Figure 1, inset) and to prevent cable dislocation with elbow motion.

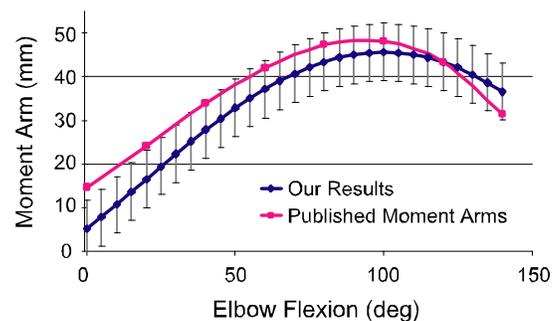

To evaluate the apparatus, a mock elbow with realistic size and mass properties that could move in both f/e and p/s was constructed. The muscle origins were adjustable to encompass the range of values previously reported [3]. The moment arms of the mock elbow's five muscles in our apparatus during 140° of elbow f/e were calculated.

### RESULTS AND DISCUSSION

A realistic elbow simulator has been constructed. The versatile design can accommodate both right and left arm specimens and can test elbows in both varus and valgus

**Figure 1:** Schematic of frame and custom pulleys (insets), dimensions in cm.

**Figure 2:** Moment arm results for *biceps brachii*. Error bars indicate the moment arms within the range of those reported in the literature.

orientations. Custom pulleys (Figure 1) allow the muscles to maintain their physiologic lines of action and moment arms throughout the elbow's range of motion. Calculated moment arms agree closely with previously-published results [4] (Figure 2 shows one of the five outcomes).

As a validation, the apparatus successfully moved the mock elbow through complete f/e and p/s cycles. This design can flex and extend a cadaver elbow at 300°/s (a realistic movement speed) and lift a 7 kg weight in the hand.

## EVALUATE THE POTENTIAL CONTRIBUTIONS OF SWING LEG TO THE STABILITY OF BODY DURING SINGLE FOOT SUPPORT PHASE OF WALKING

<sup>1,2</sup> Ming Wu, <sup>3</sup> Dewen Jin, <sup>3</sup> Linhong Ji, <sup>1,2,4</sup> Brian D. Schmit

<sup>1</sup>Sensory Motor Performance Program, Rehabilitation Institute of Chicago, Chicago, IL, USA

<sup>2</sup>Northwestern University Medical School, Chicago, USA

<sup>3</sup>Department of Precision Instrument, Tsinghua University, PR China

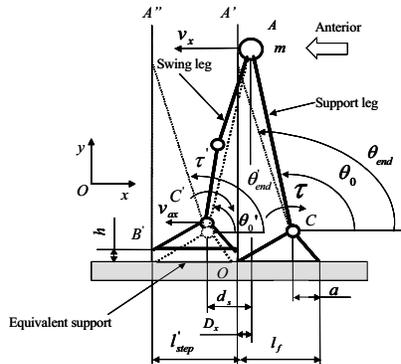

<sup>4</sup>Department of Biomedical Engineering, Marquette University, Milwaukee, WI, USA

### INTRODUCTION

Evaluation of the stability of the body during walking is critical to understanding the mechanisms of balance control. However, the current evaluation index, which is used in biped robot control [1], is not applicable to measurements of the stability of the human body. A critical limitation of this index is that it uses the stability index of the support leg to represent the stability of the whole body while neglecting the contribution of the swing leg. The purpose of this study, therefore, was to evaluate the contribution of the swing leg to the stability of whole body during the single-foot support phase of walking using an energy-work approach.

### METHODS

A simplified five-segmental sagittal model of human body during single-foot support phase of walking is shown in Fig. 1.

**Fig. 1:** A 5 links model of human body during single foot support phase of walking.

Although the swing leg does not provide support to the body during swing, the foot of the swing leg can move downward/forward to touch the ground and form a new support, if a forward perturbation is imposed to the body. After foot touchdown, plantarflexion torque can be generated by the ankle joint to prevent forward rotation of the body. Consequently, the swing leg holds the potential to support the body and this could contribute to the stability of whole body.

We used an equivalent support to estimate the contribution of the swing leg to the stability of human body. The equivalent support consisted of a foot and a leg (without knee flexion) and could provide the same functional contributions to the stability of the body as the actual swing leg would after it touched down, as Fig. 1 shows.

After perturbations, the kinetic energy of the mass of the body transforms into two parts: one of them is the increment in potential energy of the mass when the human moves from its

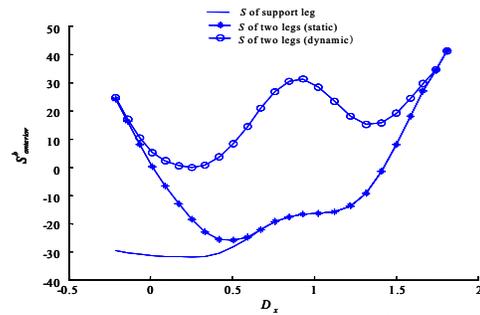

initial position A to the final position A''; the other one is the energy absorbed by the ankle joints, including the ankles of the supporting leg and the swing leg after it touches the ground. This corresponds to when they generate plantarflexion torques to prevent forward rotation of the body. Thus, we define the stability reserve of the human body during a single foot support phase as

$$S_{anterior}^b = W - (E - (P_{end} - P_0)) \quad (1)$$

where  $E$  is the kinetic energy of the human body at the initial position or after perturbations.  $P_0$  and  $P_{end}$  are potential energies of the mass at initial and final positions.  $W$  is the energy absorbed by the ankle joints of the supporting and swing leg after touchdown.

### RESULTS AND DISCUSSION

The stability reserve of the human body during the single support phase is shown in Fig. 2. The center of mass moved from  $D_x = 1.8$  (after the toe off the ground) to  $-0.3$  (before the heel touches with the ground). The stability reserve of the whole body was large before the foot of the swing leg touched the ground. This is consistent with the actual stability of the human body during walking.

**Fig. 2:** The stability reserve of human body during single foot support phase. The  $D_x$  has been normalized by the length of foot.

### CONCLUSIONS

The swing leg potentially contributes to the stability of the body and should be involved in the evaluation of the stability during walking.

### INTRODUCTION

The anterior cervical discectomy and fusion procedure is a well established technique with a fusion rate of approximately 95 % in non-smoking patients<sup>1,2</sup>. However, approximately 25 % of these patients will suffer from degenerative disc disease at levels adjacent to the fusion within 10 years of the initial surgery<sup>3</sup>. It has been shown that there is a significant increase in intra-discal pressure and segmental motion at levels adjacent to a fusion during normal range of motion<sup>4</sup>. Graft size affects the lordotic posture of the spine which in turn affects adjacent level segmental motion. Theoretically reduction of adjacent level segmental motion should lead to a reduction of adjacent level degenerative disease. This study was designed to investigate the affect of varying configurations of cervical spine alignment on adjacent level segmental motion following a simulated cervical fusion.

### METHODS

Eight human cadaveric cervical spine specimens (aged 45 to 57 years, 4 male and 4 female) were X-rayed to ensure that no major structural abnormalities were present. C2 and C7 of each specimen were potted in customized gripping fixtures and sagittal angle markers were carefully inserted into the anterior aspects of each of the vertebral bodies C3-C6. After determination of the centers of rotation of the segments, they were tested to 0.5 Nm in extension and 0.7 Nm in flexion measuring range of motion (ROM) by image analysis using Scion Image (Beta 4.0.2, Scion Image, Frederic, MD, USA). Simulated fusion was performed by a discectomy at C4-C5 and insertion of a 6 mm interbody graft followed by a plate and screws (Orion system, Medtronic Sofamor Danek, Memphis, TN, USA) ventrally. The biomechanical tests were repeated measuring ROM as before. A second simulated fusion was then performed using a 9 mm interbody graft followed similarly by a plate and screws, achieving greater lordotic alignment. The biomechanical tests were repeated measuring ROM as before. The ROM at each level was analyzed using an ANOVA with repeated measures to

determine the difference among the values for the intact state, 6 mm interbody graft fusion and the 9 mm interbody graft fusions, with the significance level at the 0.05 level.

### RESULTS AND DISCUSSION

Two of the spines were inadvertently fractured during testing and were excluded from analysis. The mean values for the sagittal lordotic angle at C4-C5 were as follows: intact =  $6.4 \pm 1.3^\circ$ , 6 mm spacer =  $8.8 \pm 1.4^\circ$  (intact/6 mm graft,  $p = 0.08$ ) and 9 mm spacer =  $12.4 \pm 0.9^\circ$  (intact/9 mm graft,  $p = 0.01$ ). Table 1 shows the measured ROM, compared to the intact there was no significant difference in adjacent segmental motion at C3-C4 with either the 6 or 9 mm interbody graft. Greater amount of adjacent segmental motion was seen at C5-C6 following the 6 mm interbody graft ( $p \leq 0.02$ ), but not with the 9 mm graft. There was a significant increase in inferior adjacent ROM with the 6 mm interbody graft.

### CONCLUSION

The attainment of cervical lordosis at the time of fusion reduces the subsequent adjacent level range of motion particularly at the inferior adjacent level.

### INTRODUCTION

Child neck injury is a devastating trauma outcome with fatal or life-long debilitating consequences. Although spinal injuries to the pediatric populace account for less than 15% of all spine injuries, their subsequent fatality and spinal cord injury rates eclipse those of the adult population. Despite the devastating socioeconomic sequelae from pediatric neck injuries, the biomechanical characterization of neck properties and injury thresholds remains incomplete, hindering progress on advanced child neck injury prevention strategies.

Therefore, over the past five years our research team has been committed to measuring and documenting mechanical properties and injury tolerance of the cervical spine as a function of developmental age. Due to limited pediatric human tissues, this research has been performed using a baboon model (*Papio anubis*). A few biomechanical studies have demonstrated a correlation between baboon and human tissues with a scaling ratio of 0.70 : 1.0.[1-3] The current study was designed to understand the compressive properties of human pediatric tissues and relate them to data collected for the baboon model. Thus, we aimed to validate our baboon model and understand the compressive mechanics of the human spine throughout maturation.

### METHODS

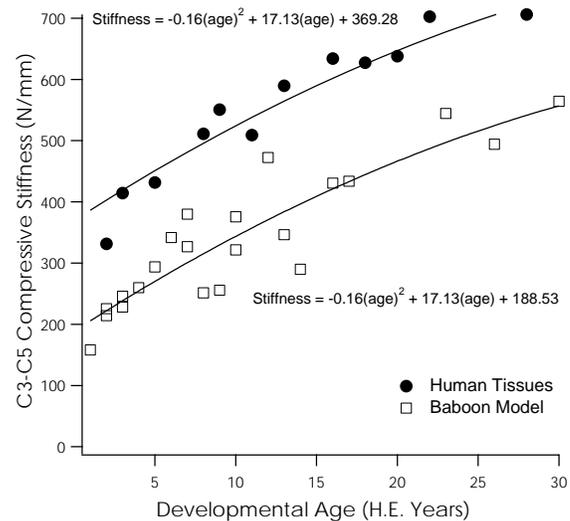

This research effort involved the biomechanical testing of eleven (11) human cadaver cervical spines across the developmental spectrum (2-to-28 years old). These specimens were dissected into 2-FSU constructs (C3-C5), wired, and embedded in PMMA for compression experimentation (Fig.1). The constructs were preconditioned and tested non-destructively up to 75% body weight in compression using a servohydraulic loading frame (MTS, Eden Prairie, MN). Three loading rates were investigated: 0.1, 1.0, and 10-mm/sec and the load-displacement data were collected at 200-Hz. The stiffness was measured as the slope of the linear portion of the load-displacement curve. This protocol mimics the algorithm previously used to test our baboon specimens.[4]

**Figure 1:** Human Cervical Spine C3-C5 Segments Prepared for Testing. A 5-year old (left) and 18-year old (right) are shown wired on top and embedded in PMMA for testing (bottom).

### RESULTS AND DISCUSSION

The human cervical spine compressive stiffness increased with spinal maturation and consistently exhibited greater values throughout development compared to baboon constructs (Fig.2). The baboon data were fit with a 2<sup>nd</sup> order polynomial growth curve which was then shifted upwards to examine its ability to model the human response. The optimal y-intercept was found using a least-squares iteration method. The human cervical spine stiffness data were found to closely match the shifted baboon growth trajectory ( $r^2=0.925$ ).

**Figure 2:** Compressive Stiffness of Human and Baboon C3-C5. Baboon data was fit with a 2<sup>nd</sup> order polynomial. The human data fits this shifted baboon curve ( $r^2=0.925$ ).

These human cervical spine biomechanical stiffness data, the first of their kind, demonstrate an increase over baboon spinal stiffness similar to that previously reported in the literature. This relationship provides strong confidence in our baboon model and our ability to scale its spinal mechanics to humans.

### CONCLUSIONS

Neck compressive stiffness significantly increased with child development and was found to follow a similar growth trajectory as baboon data. Together, these data facilitate our use of the baboon model for the establishment of child neck safety criteria and the development and analysis of advanced safety systems on playgrounds, for sports, and in automobiles.

## KNEE STABILITY: MECHANICAL CONTRIBUTIONS OF INDIVIDUAL MUSCLES

Aaron Derouin, Jim Potvin

Department of Kinesiology, University of Windsor, Windsor, Ont, Canada, email: [derouin@uwindsor.ca](mailto:derouin@uwindsor.ca)

### INTRODUCTION

The knee joint is an inherently complex structure that relies less on the shape of its articulating surfaces for stability than any other joint in the lower extremity [1]. The anatomical structure of the knee, and its location between the body's two longest weight-bearing bones, make it particularly susceptible to injury and subsequent instability. Non-operative treatment options, such as functional training and functional knee brace use, have qualitatively been shown to restore knee joint stability by improving muscular recruitment of key stabilizers. However, little is known about the potential contributions of individual muscles to the rotational stability of the knee. Mechanical stability is defined as the "the ability of a loaded structure to maintain static equilibrium even at small fluctuations around the equilibrium position" [2]. Recently, a new approach to calculate stability about any joint has been proposed by Potvin & Brown [3]. The objective of this paper is to use this method to determine the individual contributions, of the 13 knee muscles, to rotational stability about the valgus-varus and the flexion-extension axes of the knee.

### METHODS

A seven segment biomechanical model of the lower extremity was developed based on the work of Delp *et al* [4] and was used to describe the relative joint rotational and translational characteristics of each segment. The inputs to the stability model were: 1) muscle force (assumed to be 100% of maximum), 2) three-dimensional muscle length, 3) functional moment arm and 4) local muscular coordinates with respect to the knee joint, defining either the origin and insertion or, when applicable, nodes on either side of the joint. These data were determined for rotations about the knee's flexion-extension (z) and the valgus-varus (x) axes for two different functional positions (a neutral and a squat position with the hip and knee both flexed to 90°). Fifth order polynomial equations were fit to Nisell's data [5] to determine the exact x and y translations of the femoral-tibial joint and the patella that occur simultaneously with knee flexion-extension. Additionally, seventh and third order polynomial equations were used to predict the active and passive muscle force length effects, respectively, for both postures.

### RESULTS AND DISCUSSION

Overall, the average summed stability in the squat position was approximately 1.3 times higher than in the neutral posture for both the flexion-extension and the varus-valgus axes. Table 1 provides a brief summary of the dominant muscles that provide the greatest stabilizing potential when activated to 100%.

Muscles with greater cross-sectional areas and high geometric stability (related to having large functional moment arms and short fibre lengths) proved to be the greatest contributors to knee stability. The semimembranosus (SM), for example, has a physiological cross-sectional area that is an average of 3 times greater than that of semitendinosus (ST), biceps femoris long head (BFL) and short head (BFS) [6]. Interestingly, the stability provided by the BFS ranked third as a flexing stabilizer in the squat position. Its geometric stability in this posture is slightly greater than that of SM and is 2.75 times greater than the ST. The maximum force potential of the BFS is about 1.2 times higher than the ST, while its stabilizing potential is about double. The BFS, it seems, almost qualifies as the ideal stabilizer, as it has a relatively short length and a long flexor moment arm [3].

Identification of the key knee stabilizers may prove to be useful during rehabilitation following ligamentous injury, and in setting surgical decision-making criteria. For example, the SM has great potential to stabilize the ACL deficient knee about the flexion-extension axis, particularly beyond 20° of knee flexion. Unfortunately, injury to medial or lateral structures leaves the knee rather vulnerable to valgus or varus instability. In the squat posture, the tensor fascia latae offers the second greatest stability potential. Results of a dissection study revealed that the tensor fasciae latae (TFL) has a greater role in stabilizing the knee than the fibular collateral ligament, as the knee is less resistant to varus angulation when the TFL is sectioned [1]. However, its potential to stabilize the knee is only 20% of that from SM. Rationale for surgery or functional knee bracing would seem to be indicated in severe LCL injuries, as the lateral knee stabilizers offer less support in either posture compared to muscles acting in the flexion-extension axis.

### CONCLUSIONS

The stability model used in this study offers great insight into the stabilizing potential of the individual knee muscles. In a future project, this methodology will be used to determine the potential stabilizing benefits that functional knee braces may provide to ACL deficient patients.

## DISCOORDINATION IN STROKE MEASURED DYNAMICALLY USING THE ACT-3D ROBOT

<sup>1,2</sup> Theresa M Sukal, <sup>2</sup> Michael Ellis and <sup>1,2,3</sup> Julius PA Dewald

Northwestern University Depts of <sup>1</sup>Biomedical Engineering, <sup>2</sup>Physical Therapy and Human Movement Science, and <sup>3</sup>Physical Medicine and Rehabilitation; email: [t-sukal@northwestern.edu](mailto:t-sukal@northwestern.edu).

### INTRODUCTION

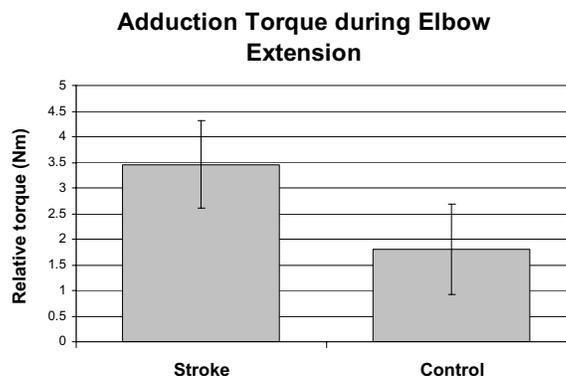

Abnormal synergy patterns, or pathological coupling of joint torques, have been shown to constrain functional reaching in patients beyond that which can be explained by simple muscle weakness [1]. These synergies have also been explored dynamically using an air bearing device. It was found that when a subject's limb was fully supported, they were able to reach targets that were well outside of their active range of motion, which was measured when they were required to lift their arm against gravity [2]. But this leaves to question how stroke subjects are able to do so well under the supported condition. The hypothesis for the current work is that they were simply working into the extension synergy and coupling elbow extension with a great deal of shoulder adduction (i.e. pushing into the table) in order to reach the target. For the first time, we measure the amount of adduction used to reach targets within the workspace under dynamic conditions.

### METHODS

In the current study, we use a modified HapticMASTER robot (FCS Control Systems, The Netherlands) which has been integrated with a Biodex experimental chair (Biodex Medical Systems, Shirley, NY) to form the first generation Arm Coordination Training 3-D (ACT<sup>3D</sup>) device. The advantage of this system is that it incorporates the ability to measure 6 degrees of force and torque measurements while allowing the subject to move in 3-D workspace, features unavailable in the previous protocols. Here, the ACT<sup>3D</sup> is used to explore how shoulder adduction is coupled with reaching and retrieval motions when the arm is fully supported on a haptic table. A series of 5 targets were presented to each subject such that both single joint and multi joint movements in elbow and shoulder flexion and extension were tested, as described previously [3]. Online feedback was given via a 3 dimensional arm on a computer screen, and the subject was instructed to move as quickly as possible to the target without regard to specific endpoint accuracy. By examining only the first 100 ms after movement onset, we focused on the open loop control portion of the movement. Force and torque information in 3 dimensions (JR3 load cell, Woodland, CA) as well as angles recorded by the instrumented gimbal on the ACT<sup>3D</sup> were recorded during trials and saved for later analysis.

### RESULTS AND DISCUSSION

For each trial, HM position arm angles were used to calculate the torques at the shoulder and elbow using inverse dynamics and a Jacobian matrix. Here, we compare a severely impaired stroke subject (Fugl-Meyer upper extremity score 30 out of 66; Chedoke-McMaster arm score 3 out of 7) and a healthy

**Figure 1:** Relative adduction torque (that beyond limb weight) measured during elbow extension task.

control subject whose speeds of movement to the target were similar. For the elbow extension target (target placement required 30° of elbow extension in order to reach it), the stroke subject coupled the elbow extension movement with a significantly greater amount of shoulder adduction ( $p = .002$ ), compared to the healthy control subject. These results are shown in Figure 1.

### CONCLUSIONS

Results indicate that subjects need to use much larger amounts of adduction torque in order to produce the same amount of elbow extension torque when compared to healthy subjects. This information supports the hypothesis that they are simply working within their extension synergies in order to accomplish the elbow extension task when supported by the haptic table. With the current setup, we can also vary the amount of limb support that is given to the subject during arm movements, so a greater resolution can be achieved between supported and unsupported conditions. This will allow us to gain a better understanding of the dynamic expression of synergies and their effect on the reduction of workspace as a function of limb support, and is the subject of ongoing investigation in the lab.

## MOTOR CONTROL STRATEGY TO MANAGE CENTRAL FATIGUE

<sup>1</sup>Jing Z. Liu, <sup>2</sup>Vinod Sahgal and <sup>1,2</sup>Guang H. Yue  
 Departments of <sup>1</sup>Biomedical Engineering and <sup>2</sup>Physical Medicine & Rehabilitation,

### INTRODUCTION

Muscle fatigue is a common phenomenon that causes loss of force generation ability. Mechanisms underlying peripheral fatigue are well understood [1]. However, how the brain manipulates the fatiguing muscle is little tackled due to technical limitations and the difficult nature of the issue itself. More specifically, whether the brain suffers a central fatigue or it has other “smart” strategies to manage the situation is mostly unclear. Here we present our recent studies on this important issue of motor control using advanced functional neuroimaging methods.

### METHODS

**Fatigue Tasks:** Intermittent handgrips of the right (dominant) hand were performed by a group of normal subjects at maximal voluntary contraction (MVC) level.

**Force and EMG Recording and Analysis:** Handgrip force and electromyogram (EMG) from involved muscles were recorded using a custom-built data recording system compatible with fMRI and EEG lab environments [2].

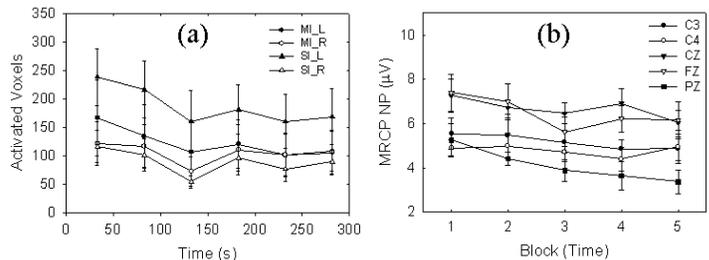

**fMRI Data Recording and Analysis:** Functional magnetic resonance imaging (fMRI) data were collected using EPI sequence on a 1.5 T Siemens scanner during rest and task-performance periods. Data of the two periods were statistically compared using *t*-test combined with other noise reduction procedures to determine which voxels of the brain were activated [3]. The number of activated voxels was calculated in each motor-related cortical region of interest (ROI) including both the primary sensorimotor cortices (SMI) and the higher order ones.

**EEG Data Recording and Analysis:** EEG data were recorded using a NeuroScan 64-channel system. Movement-related cortical potentials (MRCPs) were measured at motor-related locations. Sources that generated the signals were determined in the frame of current dipole model and effects of fatigue on their strengths and locations were analyzed.

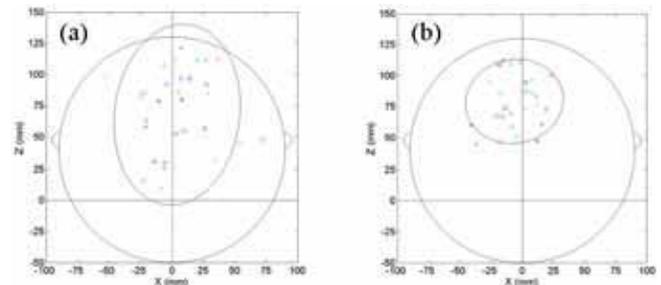

### RESULTS

1. Force and EMG decreased substantially to about 40% of initial MVC levels.
2. fMRI and MRCP-represented cortical activation levels stayed relatively unchanged while showing slight decreases (Figs. 1,2).
3. The strength of the current dipole source was little changed by fatigue, however, the source location showed substantial

**Figure 2:** cortical activation level along fatigue (time). (a) fMRI results; (b) EEG (MRCP) results.

**Figure 3:** Distribution of source location. (a) fatigue condition; (b) non-fatigue control condition.

rotation in comparison to the result of the non-fatigue control condition (Fig. 3).

### CONCLUSIONS AND DISCUSSION

The results suggest that there is a ceiling level for the cortical activation. The slight decreases indicate that central fatigue had factored in; however, the brain had successfully managed to maintain the task by recruiting additional cortical parts as indicated by the rotation of source location. These data support the concept that the neurons are activated in an alternate way so that the brain’s power of motor control can be optimized/maximized, especially during severe situations such as fatigue.

## HOW DOES BONE TISSUE MICROSTRUCTURE RELATE TO *IN VIVO* BONE STRAINS IN THE GOAT RADIUS THROUGH ONTOGENY?

Russell P. Main and Andrew A. Biewener  
 Concord Field Station, Harvard University; email: rmain@oeb.harvard.edu

### INTRODUCTION

Past hypotheses concerning a link between form and function in vertebrate limb bones have generally sought to explain how the architecture of both trabecular and cortical bone reflect habitual loading within the limb skeleton. The goal of this study is to examine how ontogenetic changes in limb bone geometry and certain microstructural features within the cortex of the limb bone diaphysis in the goat radius relate to ontogenetic changes in the measured strain environment in the radius.

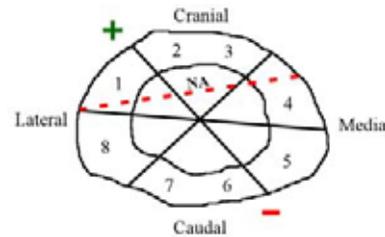

### METHODS

*In vivo* bone strain data were collected from the cranial, caudal, and medial midshaft surfaces of the goat radius in animals of three age/size groups: ‘small’ (<6 kg), ‘intermediate’ (6-11 kg), and ‘adult’ (>15 kg) [1]. In the weeks prior to strain data collection, fluorescent bone labels were given to the animals to be incorporated in to the growing/remodeling bone. After the strain data were collected, cross-sectional histological thin-sections were prepared from each radius at the site of strain gauge attachment. Using a microscope equipped with a digital camera, digital images were taken of the thin-sections from each goat using plain, fluorescent, and circularly polarized light microscopy to quantify bone porosity, secondary osteon density, periosteal growth rates, and the orientation of the collagen fibers, which were classified as either being aligned primarily longitudinally (L), transversely (T), or intermediate between the two (I).

The mean and maximal normal cross-sectional strain distributions were mapped on to each bone’s cross-section. Using the strain distribution and the anatomical bone axes, each cross-section was divided into eight sub-divisions (Figure 1) and the above histological variables measured in each, using custom MATLAB software.

### RESULTS AND DISCUSSION

Measurements from the single ‘small’ goat examined thus far provide interesting preliminary results. The greatest porosity generally occurs in cranial sub-divisions 1, 2, and 3 (Table 1), which are loaded in tension during maximal strain in the radius midshaft (Figure 1). A lower percentage of longitudinally oriented collagen fibers were observed in

**Figure 1:** Goat radius divided into eight sub-sections for histological analysis. The dashed line labeled ‘NA’ represents the position of the neutral axis of bending when longitudinal strains are maximal; loading the cranial and caudal surfaces in tension and compression, respectively.

caudal sub-divisions 6 and 7, where maximal compression occurs (Table 1). However, there was also a caudal sub-division loaded in compression (6) with a high pore density and a cranial sub-division loaded in tension (3) with a similar collagen fiber profile as sub-division 6. At least in the midshaft of this goat’s radius, there are no distinguishing microstructural differences between regions of the bone loaded in tension or compression. Because measurements were made from a young goat, no secondary osteons were observed. However, preliminary observations from older, larger goats show a greater frequency of remodeling in the radius with a greater number of secondary osteons in the caudal regions of the radius. High periosteal growth rates laterally and low growth rates cranially (Table 1) do not correspond to differences in the underlying strain environments in these regions, but are consistent with the growing radius maintaining a higher second moment of area in the medio-lateral, than in the cranio-caudal direction, which has been argued to increase load and bending predictability in the goat radius [1].

Further inclusion of more samples from goats over a wider range of ages/sizes would allow for stronger conclusions and possible identification of a link between bone architecture and the mechanical environments in which bone growth and remodeling occur.

## HIP STABILITY: MECHANICAL CONTRIBUTIONS OF INDIVIDUAL MUSCLES

Jim Potvin, Aaron Derouin

Dept of Kinesiology, University of Windsor, Windsor, Ont, Canada, email: jpotvin@uwindsor.ca

### INTRODUCTION

The hip is a joint that is subjected to high forces during both dynamic and static activities. In the physiological range, translational hip stability is provided by: 1) muscle, 2) the acetabular cup, 3) ligaments. However, in this range, muscles are almost exclusively responsible for rotational stability. Little is known about the potential contributions of individual muscles to the rotational stability of the hip. Recently, a method has been developed to allow for such a calculation with knowledge of the muscle line of action and force generating potential [3]. The purpose of this study was to determine the individual hip muscle contributions to rotational stability about the flexion/extension and abduction/adduction axes in a neutral and flexed posture.

### METHODS

The biomechanical model of Delp et al [2] was used to characterize the joint rotational and translational characteristics and the muscle lines of action of 19 muscles crossing the hip (with a total of 27 separate fascicles). Stability analyses were performed about the: 1) flexion/extension and 2) abduction/adduction axes in the: 1) neutral standing posture and 2) with the knee and hip both flexed to 90 degrees.

The model of Potvin and Brown [3] was used to calculate individual muscle contributions to joint stability for each of the four axis/posture combinations. The minimum potential energy (V) approach was used to calculate stability. This method assumes that a system is stable if its total V is at a minimum. In other words, the second derivative of the system V must be positive definite [1]. For a particular muscle, V was calculated as the elastic energy stored in the muscle plus the work done by the muscle for small rotations:

$$U(m) = F \Delta \ell + \frac{1}{2} k \Delta \ell^2 \quad (1)$$

where:  $U(m)$  = potential energy stored in the muscle,  $F$  = muscle force (N),  $k$  = muscle stiffness (N/m),  $r$  = muscle moment arm (m),  $\ell$  = muscle length (m) defined from the origin (A) to insertion (B). A and B can also be used to define nodes on either side of a joint and are expressed relative to the hip coordinates. The change in length was a function of the rotation ( $\theta$ ). For the hip joint, the anatomical axes were: abduction/adduction (x), internal/external rotation (y) and flexion/extension (z).

The stability contribution of a muscle about the z axis ( $S_z$ ), is calculated as the second derivative of  $U(m)$  with respect to a small rotation angle ( $d\theta$ ) using a Taylor Series expansion, differentiating twice with respect to  $\theta$ , and simplifying. A further substitution of  $k=qF/\ell$  [1] was made yielding equation (2). For muscles without nodes,  $L = \ell$ . Otherwise  $\ell$  is the distance between nodes and  $L$  is the total muscle length. All analyses were run with maximal muscle forces, after correcting for the active and passive force length effects.

$$S(m)_z = F \left[ \frac{A_x B_x + A_y B_y - r_z^2}{\ell} + \frac{q r_z^2}{L} \right] \quad (2)$$

### RESULTS AND DISCUSSION

Flexion/Extension axis: In the neutral posture, the semimembranosus (SM) was found to be the dominant hip stabilizer about the flexion/extension axis, with values 68% and 132% higher than the next highest muscles; biceps femoris long head and rectus femoris (RF), respectively. These muscles have the highest force potential in this posture and each are oriented in such a way as to optimize their geometric potential to contribute to joint stiffness (termed "geometric stability" or  $S_G$  and related to having large moment arms and/or short lengths). The stability values were found to be much lower when the knee and hip were both flexed to 90°, with the largest contributors being: RF and SM (due to high force potential) and adductor magnus 3 (due to its moderate force and high  $S_G$ ). It should be noted that the SM was observed to have values in the flexed posture that were only 33% of that in the neutral posture. In addition, all three hip adductor muscles were found to have greatly enhanced flexion/extension stabilizing potential in the flexed, compared to the neutral, posture. While somewhat unrealistic (because the resulting net moment is not zero), the total maximum stability potential was approximated by setting each muscle force to 100% of maximum and summing across muscles. For the flexion/extension axis, the total stability in the neutral posture was 2.6 times higher than that in the flexed posture.

Abd/Adduction axis: In the neutral posture, the dominant stabilizers were gluteus medius 1 (due to high force and  $S_G$ ) adductor magnus 1 (due to very high  $S_G$ ) and adductor longus (due to moderate force and high  $S_G$ ). However, in the flexed posture, the gluteus medius 1 and adductor magnus 1 dropped to 8% and 22% of their neutral values and the adductor longus increased somewhat to be the dominant stabilizer (due to a very high  $S_G$ ), followed by the adductor magnus 3 and the psoas. Overall, the neutral posture was found to have a maximum abd/adduction stabilizing potential 4.4 times higher than the flexed posture.

### CONCLUSIONS

This study demonstrates the utility of a simple stability equation for accurately dissecting the individual muscle contributions to hip stability. It is anticipated that this work will lead to a better understanding of the factors that lead to hip instability and injury.

## CONTROL OF REACH-TO-GRASP REACTIONS DURING PERTURBED LOCOMOTION IN FAMILIAR AND UNFAMILIAR ENVIRONMENTS: WHEN DOES VISUAL FIXATION OF THE HANDRAIL OCCUR?

<sup>1,2</sup>Charles Cejka, <sup>1</sup>Tracy A. Lee, <sup>1,3</sup>William E. McIlroy and <sup>1,2</sup>Brian E. Maki

<sup>1</sup>Centre for Studies in Aging, Sunnybrook and Women's College Health Sciences Centre, Toronto, Ontario, Canada

<sup>3</sup>Department of Rehabilitation Science, University of Toronto, Ontario, Canada

### INTRODUCTION

In many situations, successful execution of a balance-recovery reaction requires visual information about the environment. In particular, reactions that involve rapid limb movement, such as stepping or reaching, must be controlled to accommodate environmental constraints, i.e. objects or architectural features that can obstruct stepping or serve as handholds to grasp for support [1]. The location of these constraints, in relation to the body, continually changes as we move about in our daily lives.

In this study, we examined the mechanisms by which the central nervous system acquires the critical visuospatial information needed to execute rapid reach-to-grasp reactions in response to sudden, unexpected loss of balance. We hypothesized that: 1) the initial arm motion toward a handrail would rely on spatial information acquired via the visual scanning that automatically occurs when ambulating in an unfamiliar environment; and 2) the later phases of the arm movement and the prehension of the handrail would be guided by visual fixation of the rail occurring after initiation of the arm reaction.

### METHODS

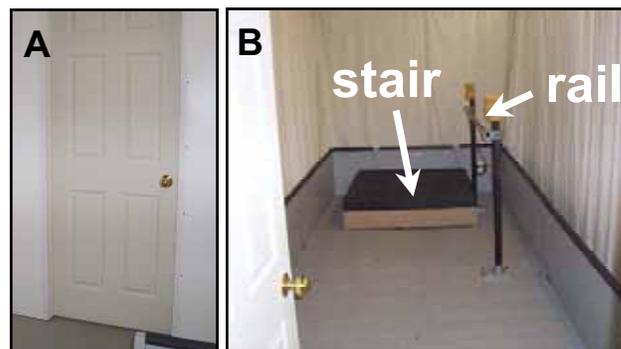

Testing involved a moveable 6.4m walkway, which was surrounded by curtains; a door at the entrance prevented any viewing of the walkway prior to the start of each trial. Eight healthy young adults (ages 24-35) were randomly assigned to either a *handrail* group (handrail located by a stair mounted near the end of the walkway; see Figure 1) or a *control* group (no objects on the walkway). In the first trial, subjects opened the door to view the walkway for the very first time, and then walked to the opposite end at a self-selected cadence. The walkway was controlled to unexpectedly translate forward during right single-support phase when the subject was in the vicinity of the handrail and stair (*handrail* group) or in a similar location (*control* group). A deception was used to ensure that the first perturbation was truly unexpected. In the remaining 59 trials, subjects knew that the walkway might move; however, walkway translations (forward or backward) occurred in only 30% of trials. During each trial, we monitored gaze behavior and arm motion.

### RESULTS AND DISCUSSION

In the very first trial, *control* subjects tended to fixate on the travel path, with few eye movements directed toward the periphery. In contrast, *handrail* subjects fixated on the rail immediately after opening the door (mean dwell time: 483ms). During the subsequent ambulation, gaze was primarily directed at the travel path but typically did return to the handrail one or more times. When the perturbation occurred, all four *handrail* subjects initiated

rapid lateral arm movement toward the rail. In all cases, gaze was not directed at the rail at perturbation onset, but was redirected toward the rail after the initiation of the reaching movement. It is clear that the initial arm motion was not simply a stereotyped response, since the predominant direction of the motion in the *control* group was distinctly different (forward rather than lateral).

With repeated trials, reaching movements occurred less frequently (11% of perturbation trials) and the gaze behavior more closely resembled that of the *control* group (i.e. gaze directed primarily along the travel path). In 3 of the 8 trials where reaching occurred, there was no visual fixation of the rail at any point prior to perturbation onset.

**Figure 1:** View of moveable walkway (*handrail* subjects) from the entrance, with door closed (A) and open (B).

### CONCLUSIONS

These findings suggest that a pre-formed visuospatial map of the surroundings is used to initiate rapid reach-to-grasp reactions. This map is formed automatically (even when there is no expectation that a perturbation may occur) via visual scanning when ambulating in an unfamiliar environment. The capacity to utilize spatial information 'remembered' from previous trials may reduce the need for visual scanning, i.e. when the environment is familiar. Online visual feedback may be used later in the trajectory to guide the arm to its endpoint and/or assist in prehension of the rail. Use of a pre-formed map presumably serves to facilitate more effective balance recovery by allowing an appropriately-directed arm movement to be initiated as rapidly as possible, thereby avoiding delays that would occur if instead the visual scanning of the environment had to be performed after perturbation onset [1].

## WORK TIME AND REST PERCENTAGE DURING PICK-AND-PLACE TASK

Reuben Escorpizo and Anne Moore

School of Kinesiology and Health Science, York University, Toronto, ON

E-mail: [reuben@yorku.ca](mailto:reuben@yorku.ca), Web: [www.yorku.ca/kaahs](http://www.yorku.ca/kaahs)

### INTRODUCTION

In the context of machine-paced tasks, it is of interest to know how production rate affects the physical demands imposed on the worker. The time available to perform a cycle (CT) is a critical factor in determining both the resulting speed the work is performed at, and the rest time available to the worker. Pick and place tasks are a common machine paced task. They have been studied from the perspective of loads<sup>1, 2</sup>, but the relationship between time based measures is unclear. The objective of this study was to measure the effects of shortening cycle time on work time (WT) and the overall available rest (%rest) during a cyclical pick-and-place task.

### METHODS

Six right-handed participants (3m, 3f) with a mean age of 28 yrs (SD=6.9), and mean height of 176.3 cm (SD=14.2) were recruited. The participants performed a cyclical task transferring a 0.7 kg object 0.5 m from one bin to another based on an auditory metronome. Measurements of muscle activation (EMG), hand grip force, wrist posture and error rate were made. WT was defined as the time the hand was in contact with the object (force>0), and task rest was defined as  $(CT-WT)/CT * 100$ . Surface RMS EMG was collected from flexor digitorum superficialis (FDS) and extensor carpi radialis (ECR) using a commercial system (ME3000P8, MEGA, Finland). It was analyzed using a gaps analysis<sup>3</sup> which provides a measure of the actual rest taken by the muscles. A (4 x 2) repeated measures design was used, with two independent variables: CT (1, 2, 5, and 10s) and grip type (power, chuck).

### RESULTS AND DISCUSSION

WT significantly decreases as a function of CT and grip type (Figure 1) as does %Rest (Figure 2). The chuck grip task had a significantly longer WT and associated shorter rest time at all CTs. These indicate that as the cycle time is reduced, the task is sped up; however, more time is taken out of the rest portion of a task. The relationships between the cycle time and both work time and %Rest are non-linear. Although at a one second CT, the nominal rest in the activity was at least 10% of the time, the electromyographic data found that by 2-second CT the muscle activity already occupied 100% of the time (Figure 2). To achieve even 10% muscle recovery, a CT of >3s is required. This data coupled with the EMG will allow us to model optimal CT.

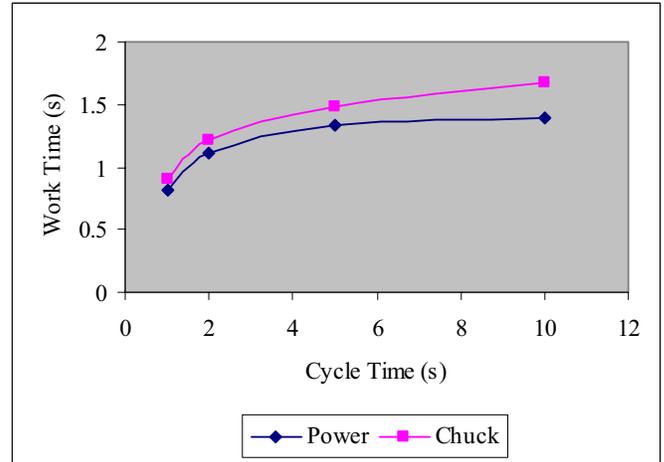

Figure 1: WT decreases as CT decreases (CT p<0.01, grip p<0.001)

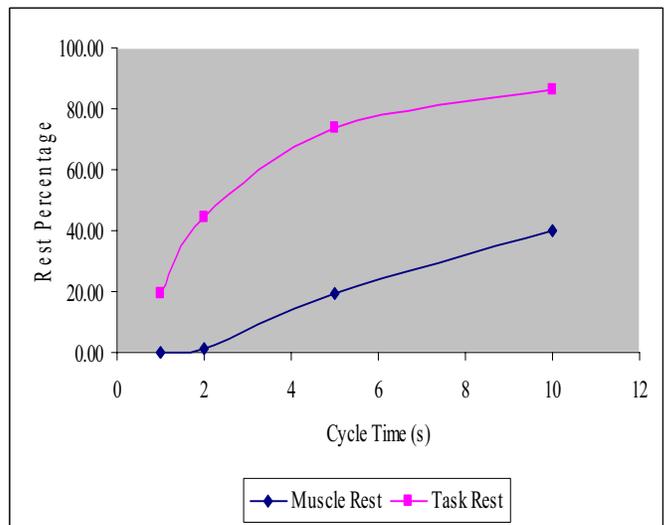

Figure 2: Calculated rest percentage based on grip force (task) and gaps (ECR muscle) during power grip

## TOE OUT GAIT AND REDUCTION OF KNEE OSTEOARTHRITIS PAIN

<sup>1</sup>Thomas R. Jenkyn, <sup>1</sup>Michael A. Hunt, <sup>1</sup>Trevor B. Birmingham

<sup>1</sup>Wolf Orthopaedic Biomechanics Laboratory, University of Western Ontario, London, Ontario, Canada  
 Email: tjenkyn@eng.uwo.ca

### INTRODUCTION

Osteoarthritis (OA) commonly affects the knee joint. The medial compartment is affected 2.5 times more than the lateral [1,2]. During stance phase, an adduction moment acts on the knee that is thought to increase compression in the medial compartment. Individuals with knee OA often walk with a toe-out gait, which seems to reduce pain during weight-bearing. In toe-out gait, the leg is externally rotated with the toe angled laterally to line of progression.

The common explanation for this pain reduction reasons that toeing out moves centre of pressure laterally, orienting the ground reaction force (GRF) so that it passes through the knee joint. This would reduce the moment arm of GRF in the frontal plane, reducing knee adduction moment and medial compartment compression. However, this mechanism would not produce a reduction of adduction moment in early stance when the centre of pressure is under the heel.

This study suggests another mechanism. Toeing-out rotates the anatomy of the knee and transforms a portion of the adduction moment into a knee flexion moment, thus reducing the compression on the medial compartment.

### METHODS

Prior to corrective surgery (high tibial osteotomy), gait analysis was performed on 125 patients (98 males; mean age=46.8 yrs) with knee joint OA primarily affecting the medial compartment. Patients walked at a self-selected speed while three-dimensional kinetic and kinematic data were collected bilaterally. The inverse dynamic method calculated resultant knee moments in both laboratory-fixed and the tibia-fixed frames of reference. Patient progression coincided with the lab x-axis. The perpendicular distance from GRF line of action to knee joint centre (moment arm) was also calculated in each frame.

### RESULTS

The moment arms and moments experienced in the lab-fixed and tibia-fixed frames of references are shown in Figure 1. With no toe-out angle, these frames would be coincident. Figure 1 shows that by toeing out an average of 10.6° on the affected limb, the flexion-extension moment arm and moment are increased in the tibia-fixed frame and the adduction-abduction moment arm and moments are reduced.

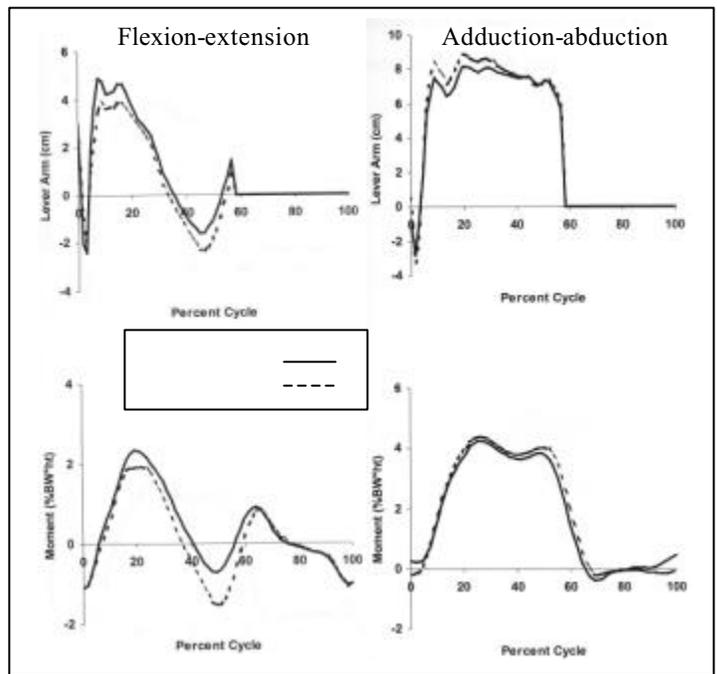

Table 1 shows a comparison of the peaks values of adduction and flexion moment arms and moments for the affected and unaffected limbs.

### CONCLUSIONS

Toeing-out has been shown to rotate the anatomy of the knee such that a portion of the knee adduction moment is transformed into a flexion moment. Flexion moments are carried by the musculature of the knee, thereby reducing the compressive loading in the medial compartment. Such a reduction of medial compartment loading could be responsible for the reported pain relief experienced by patients with OA of the knee during walking gait.

## PREDICTION OF FOREARM MUSCLE ACTIVITY DURING GRIPPING

Peter J. Keir, PhD and Jeremy P.M. Mogk, MSc  
 School of Kinesiology & Health Science, York University, Toronto, Ontario, Canada  
 email: pjkeir@yorku.ca

### INTRODUCTION

There is a strong association between upper extremity musculoskeletal disorders and jobs involving forceful grip exertions and deviated wrist postures [1]. The inherent difficulty in measuring hand and finger forces in the workplace, without interfering with a worker's normal movement patterns, has led to the use of EMG-based mathematical relationships to predict grip force [2-4]. Prediction of grip force is valuable, however, EMG collection in the workplace is an expensive and tenuous task. In addition, predicting grip force itself does not necessarily provide information on which muscles may be at risk of injury or fatigue. Accurate prediction of muscle activity without an elaborate biomechanical model would improve our understanding of muscular loading in the workplace. The purpose of this study was to predict muscle activity of six forearm muscles from grip force and posture using an existing dataset [5].

### METHODS

The dataset [5] was comprised of surface EMG of 6 forearm muscles (FCR, FCU, FDS, ECR, ECU and EDC) collected during 10s static grip force contractions on each of two days. All combinations of 3 forearm postures (pronation, neutral and supination) and 3 wrist postures (45° extension, neutral, 45° flexion) were used. Grip force and EMG were collected at 4 relative effort levels (5, 50, 70 and 100% Grip<sub>max</sub>) and an absolute force of 50 N. EMG and grip force were normalized to maximum. AEMG was calculated from the 3 Hz linear envelope EMG over a 3 s plateau at the target force and during baseline prior to each exertion.

Forward stepwise regression analyses were performed to develop equations to predict AEMG for each of the 6 forearm muscles from grip force and posture using Day 1 data, using STATISTICA (version 6.0, StatSoft Inc., Tulsa, OK). Analyses included linear, factorial and polynomial regressions. All models included the AEMG and measured grip force data from each of the five exertion levels, in each combination of wrist and forearm posture. The predictive ability of each model was judged based on the adjusted r<sup>2</sup> and RMSE<sub>model</sub> (in % MVE). The validation process used Day 2 data as input into the equations developed from Day 1 data, and were evaluated using r<sup>2</sup> and RMSE<sub>valid</sub>.

### RESULTS AND DISCUSSION

Second order regression models improved the prediction of extensor muscle activity over linear regression with r<sup>2</sup> and

RMSE<sub>model</sub> improving by as much as 4% and 0.7%, respectively. The generic form of each equation is:

$$AEMG_i = (a_1 \cdot G) + (b_1 \cdot G^2) + (a_2 \cdot W) + (b_2 \cdot W^2) + (a_3 \cdot F) + (b_3 \cdot F^2) + c$$

where, AEMG<sub>i</sub> is percent muscle activation (i=1-6), G is relative grip force, W is wrist posture (extension = 1, neutral = 2 and flexion = 3), F is forearm posture (pronation = 1, neutral = 2 and supination = 3), and c is a constant. Coefficients were included in each model if they were significant at p < 0.05; most were significant at p < 0.001.

Posture explained less than 2% of the variance. However, when combined with grip force, inclusion of both wrist and forearm posture reduced RMSE<sub>model</sub> to less than 9% MVE for all equations (Table 1). Using the measured wrist angle (in degrees) resulted in weaker models than using nominal wrist posture. Forearm posture had little effect on the prediction of average finger muscle and wrist flexor activations, but improved r<sup>2</sup> and RMSE<sub>model</sub> of the wrist extensors by as much as 4.7% and 0.9% MVE, respectively.

Day 2 AEMG was predicted very well using the equations developed from Day 1 data and was often lower than the development data (RMSE<sub>valid</sub> vs RMSE<sub>model</sub>, Table 1). Each target force level was also evaluated in isolation to determine the ability of each equation to predict muscle activation across the full range of grip forces. The error in predicting muscle activation was greater with increasing grip force. The RMSE for forces = 50% Grip<sub>max</sub> was 0.9-2.3% lower than the overall RMSE<sub>valid</sub> which ranged from 6.6-9.8%. The RMSE values of predicted muscle activity for grip forces above 50% were 3.7-7.3% MVE higher than RMSE<sub>valid</sub>. Preliminary tests using verbal estimates of grip force indicate that the equations are robust, as the predictive capacity was the same as with measured grip force.

These equations provide a simple and accurate tool to predict forearm muscle loading in the workplace, and may be used to complement existing workplace screening tools.

## REGIONAL FOOT PRESSURE DURING RUNNING, CUTTING, JUMPING AND LANDING

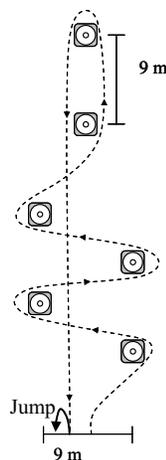

Michael Orendurff<sup>1</sup>, Eric Rohr<sup>1</sup>, Ava Segal<sup>1</sup>, Chris Kweon<sup>2</sup>, Jon Medley<sup>1</sup>, John Green III<sup>2</sup>, Nancy Kadel<sup>2</sup>  
<sup>1</sup>Motion Analysis Lab, Rehab R & D, VA Hospital, <sup>2</sup>Department of Orthopaedics and Sports Medicine, University of Washington, Seattle, WA, USA. email: [michael.orendurff@med.va.gov](mailto:michael.orendurff@med.va.gov) web: [www.seattlerehabresearch.org](http://www.seattlerehabresearch.org)

### INTRODUCTION

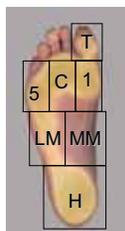

Foot pressure studies have generally focused on walking [1,2] and running [3,4] in a straight line to determine shoe-foot interactions at specific regions of the foot. However, it is likely that for several regions of the foot, straight line running and walking do not adequately quantify the complete range of plantar pressures. Ellis et al [5] has shown that during cutting movements peak pressures at the hallux increase by 40%, while the lateral forefoot undergoes a 54% decrease compared to running straight. The purpose of this study was to compare the peak pressures at seven regions of the foot during straight running, cutting, jump take-off and jump landing with two different shoe types.

### METHODS

Subjects were ten healthy college athletes. All subjects signed an IRB-approved consent form. (Ht.  $186.8 \pm 5.3$  cm; Wt.  $102.3 \pm 18.9$  kg; Age.  $20.5 \pm 1.0$  years). Each subject was asked to run at 75% maximum speed through a course of cones (figure 1), once wearing a wide turf shoe (Air Pro Turf Low; Nike, Beaverton, OR, USA) and once wearing a narrow cleat (Nike Speed TD) in random order. The surface was Fieldturf® (Montreal, Canada). Plantar pressures were measured using insoles (PEDAR Mobile; Novel GmbH, Munich, Germany). Only right insoles were sampled at 99 Hz. Each trial was filmed with a digital video camera (30 Hz); first and second trial times were within 5%. Each step from the foot pressure files processed from Emedlink (Novel) was matched to the corresponding step in the video to determine what maneuver was being performed. Two-way repeated measures ANOVAs were used to compare peak plantar pressure across seven regions (figure 2): great toe (T), medial forefoot (1), central forefoot (C), lateral forefoot (5), medial midfoot (MM), lateral midfoot (LM) and heel (H).

**Figure 1:**  
Running course

**Figure 2:**  
Mask regions

lateral forefoot (5), medial midfoot (MM), lateral midfoot (LM) and heel (H) during running straight, cutting right, cutting left, jump take-off and jump landing (2 shoe types by 5 maneuvers). Scheffe's tests were used for individual comparisons *post hoc*.

### RESULTS AND DISCUSSION

The Speed TD had significantly higher peak pressures than the Pro Turf Low for all regions ( $p < 0.0001$  to  $0.03$ ) except the LM ( $p = 0.19$ ), meaning that the turf shoe had better overall cushioning. For the heel, straight running pressures were  $\frac{1}{3}$  that of cutting, jumping or landing activities ( $p > 0.0001$ ). This suggests that hindfoot cushioning characteristics of sport shoes might be more robustly assessed by evaluating activities other than straight line running. For the great toe (T) similar high pressures were observed running straight, cutting left and jump landing, which were significantly lower than during cutting right and jump landing ( $p < 0.03$ ). Comparing left and right cutting, the left cut produced higher pressures at the medial foot regions (T, 1 and MM;  $p < 0.02$ ) whereas the right cut showed higher pressure at the lateral regions of the foot (5, LM) ( $p < 0.0001$ ). The data suggest we run like we ski: by cutting our inside edges into the surface to carve the turn. All regions of the foot appears to have similar peak pressures for jump take-off and jump landing ( $p > 0.12$ ), except T where jump take-off pressures were significantly higher than landing ( $p < 0.0008$ ).

### CONCLUSIONS

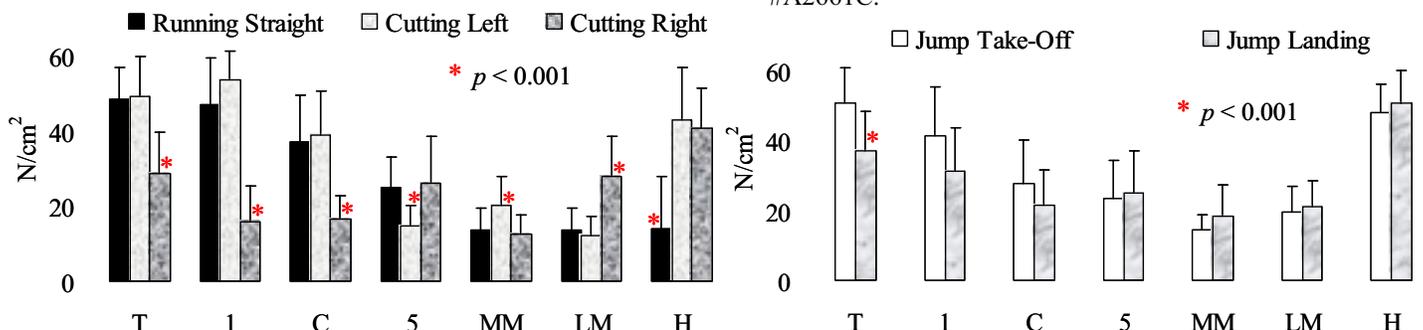

Assessing regional foot pressure over a range of movements may provide a more appropriate and sensitive evaluation of sport shoe performance.

## INVESTIGATION OF SIT-TO-STAND PERFORMANCE FOR INDIVIDUALS AFTER TOTAL KNEE ARTHROPLASTY

Catherine A. Stevermer, Shashank Raina, and Jason C. Gillette

Department of Health and Human Performance, Iowa State University, Ames, Iowa, USA; email: [ktsteve@iastate.edu](mailto:ktsteve@iastate.edu)

### INTRODUCTION

Moving from a seated position to standing is an essential transition for basic activities of daily living and is a prerequisite for ambulation. Many older adults find sit-to-stand to be challenging without additional support [1] due to lower extremity limitations associated with pathology and/or reduced dynamic stability. In contrast to healthy elderly, Cheng, et al. [2] indicated weight-bearing asymmetry and increased postural sway during sit-to-stand may increase the risk of falls in a neurologically impaired population. Before and after total knee arthroplasty, osteoarthritic adults may also have difficulty with this task due to limited range of motion and/or strength deficits [3]. Therefore, sit-to-stand technique may differentiate between standing independently, standing with assistance, or an inability to perform the task.

Janssen, et al. [4] indicated variations in lower extremity positioning, upper extremity assistance, seat height, and movement pattern may affect sit-to-stand performance. Previous research has focused on an assumption of bilaterally equivalent anthropometrics, joint timing and weight-bearing during sit-to-stand. These assumptions may be inappropriate for individuals with weakness and/or mobility limitations due to potential movement asymmetry. The goal of the present study is to determine therapeutic recommendations for foot placement during sit-to-stand in an orthopedic population.

### METHODS

Two individuals with total knee arthroplasty (TKA  $2 \pm 0.5$  yr post-surgery) participated in this experiment (2 males, age  $72 \pm 5$  yr, mass  $88 \pm 12$  kg). Two individuals (1 male/1 female, age  $70 \pm 3$  yr, mass  $84 \pm 15$  kg) without any musculoskeletal disorder participated as healthy control subjects. An eight-camera video system (Peak Performance, Englewood, CO) was used to track 10 reflective markers placed bilaterally on each subject. The subjects sat on a bench (height 45 cm) with their feet on separate force platforms (AMTI, Watertown, MA). Two triaxial force sensors (Kistler, Amherst, NY) measured hand forces applied to the bench. Individual knee range of motion and anthropometrics were measured.

The subjects placed their feet at a comfortable width. Initial foot placements included: feet placed bilaterally at  $90^\circ$  of knee flexion (Foot-neutral), the feet more posterior relative to the knees (Foot-back) at an angle of  $100^\circ$  degrees of knee flexion, and a self-selected position with the dominant foot posterior (Staggered). Lower extremity positions were combined with and without upper extremity assistance. Hand support forces were measured and joint torques were calculated for sit-to-stand movements in each condition. Each subject completed three repetitions of the six sit-to-stand conditions for a total of 18 trials.

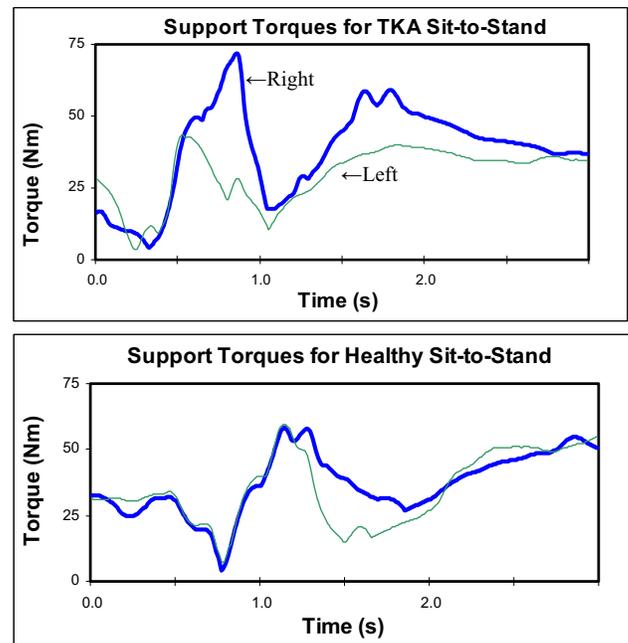

Figure 1: Left/right asymmetry is noted in maximal combined torque during the sit-to-stand ascension phase for an individual after total knee arthroplasty compared to a healthy older adult.

### RESULTS AND DISCUSSION

Relative to healthy older adults, TKA subjects demonstrated greater right/left asymmetry (62%/38% in Foot-neutral) in torque production and larger variation in bilateral joint timing across sit-to-stand conditions (Figure 1). TKA subjects also exhibited increased hip flexion torques (38 Nm vs. 14 Nm), indicating they may rely on upper body momentum generation to compensate for lower extremity deficits.

TKA subjects demonstrated greater symmetry in support torques in the Staggered foot position. Healthy older adults demonstrated greater support torque symmetry and improved joint timing in the Foot-back condition relative to the Foot-neutral condition, likely due to increased ankle contributions and reduced hip strength associated with aging. These results indicate appropriate foot placement may compensate for physical limitations in older adults. In addition, alternative foot placements during the sit-to-stand movement may be used for therapeutic goals of improving dynamic stability, enhancing lower extremity strength and maximizing functional independence for individuals following total knee arthroplasty.

## CAN PASSIVE DYNAMIC ANKLE FOOT ORTHOSES REPLICATE NATURAL ANKLE STIFFNESS?

Alexander R. Razzook, Kelly M. Nelson, Karen Lohmann Siegel, and Steven J. Stanhope  
 Physical Disabilities Branch, National Institutes of Health, Department of Health and Human Services, Bethesda, MD  
 email: [arazzook@cc.nih.gov](mailto:arazzook@cc.nih.gov), web: <http://pdb.cc.nih.gov>

### INTRODUCTION

A Passive Dynamic Ankle-foot Orthosis (PD-AFO) is a type of ankle brace that acts like a torsional spring [1]. PD-AFOs are prescribed to patients with weakened plantar flexors. PD-AFOs are designed to be effective by supporting the natural forward progression of the shank over the stance foot [2] (Figure 1). Natural Ankle Stiffness (NAS) has been defined as the instantaneous slope of ankle moment plotted as a function of ankle angle [3]. The purpose of this study is to characterize NAS using an implied torsional spring PD-AFO model (PD-AFOm) as a basis.

### METHODS

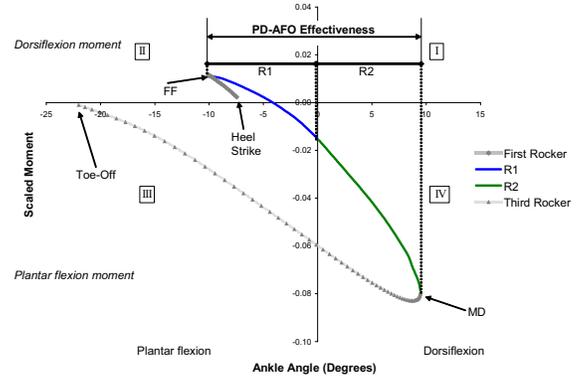

A video-based motion capture system (Oxford Metrics Inc., Oxford, UK) was used to capture the 3D lower extremity gait kinematics and barefoot stance phase kinetics (AMTI, Watertown, MA) of seven normal volunteers (age 26±5yr, body weight (BW) 608.2±78.5N, standing height (H) 1.77±.07m). Gait data were obtained from targeted walking velocity (Wvel) trials at 25%, 50%, 75%, 100%, 125% of normal walking velocity (.785 H/s) [4]. Net plantar/dorsiflexion ankle moments and corresponding ankle angles for three trials at each Wvel were calculated over the stance phase using Visual3D (C-Motion, Inc., Rockville, MD). The period of ankle dorsiflexion from foot flat (FF) to maximum ankle dorsiflexion (MD) was isolated and subdivided into regions R1 and R2 based on the ankle joint neutral reference position (NRP) (Figure 1). Visual inspections of existing PD-AFOs implied the resting position of the PD-AFOm should be aligned to NRP (0.0°) of the ankle obtained from a quiet standing trial. Ankle moment data were scaled by subject BW and H, and combined with angle data in R1 and R2, interpolated to 101 values and averaged for each of the five Wvels. A NAS value for each region was obtained from linear regression.

### RESULTS AND DISCUSSION

Linear regression indicated that the PD-AFOm depicted NAS when evaluated in R1 and R2 ( $r^2 > .940$ ). R1 and R2 NAS each increased with Wvel, 12.3% and 19% respectively (Table 1). R2 averaged 58.4% stiffer than R1 over the range of Wvels. At 100% Wvel, the difference in NAS between R1 and R2 is 61%, and the difference in NAS in R2 between 100% Wvel and 25% Wvel is 47%. As R1 NAS increased, the x intercept angles decreased. The non-zero y intercepts of R2 indicated

**Table 1:** NAS across five walking velocities with corresponding x intercepts (x=degrees) and y intercepts (y=scaled moment)

NAS (1/BW*H)	Walking Velocity (% of 0.785 H/s)				
	25%	50%	75%	100%	125%
<b>R1</b>	-0.00201 x=-7.34	-0.00247 x=-6.06	-0.00270 x=-4.98	-0.00318 x=-3.23	-0.00340 x=-2.2
<b>R2</b>	-0.00433 y=-.0207	-0.00542 y=-.0248	-0.00627 y=-.023	-0.00818 y=-.0164	-0.00999 y=-.0212

**Figure 1:** Mean NAS for 75% normal walking velocity

that the ankle was loaded in the NRP contradicting the assumption in the PD-AFOm. Unloading the PD-AFOm would require moving the NRP of the model by the suggested plantar flexion offsets derived from the Wvel dependent x intercept data changing the origin (NRP) of the model. Despite the origin aligned at the x intercept, patients with sufficiently impaired plantar flexors might never reach FF from heel strike (Figure 1). This data appears to isolate R2 as the dominant region for PD-AFOm fitting and potential enhancement of PD-AFOs by using suggested x intercept angles from R1 to optimize for a targeted Wvel (Table 1).

### CONCLUSIONS

We have developed a novel method to characterize NAS using a PD-AFOm. Although the model indicated two regions for potential application, R1 does not seem feasible in supporting the natural forward progression of the shank over the stance foot (Figure 1). R2 NAS might be modified but supplementary study is needed to identify what adaptive movement control strategies may be necessary to overcome increased stiffness at the higher Wvels. Understanding normal and patient NAS along with robust PD-AFO modeling will be necessary to systematically enhance discrete regions of gait function where a PD-AFO could optimize human mobility.

**PREDICTING CHANGES IN KNEE ADDUCTION MOMENT DUE TO LOAD-ALTERING INTERVENTIONS FOR MEDIAL COMPARTMENT KNEE OA FROM PRESSURE DISTRIBUTION**

**INTRODUCTION**

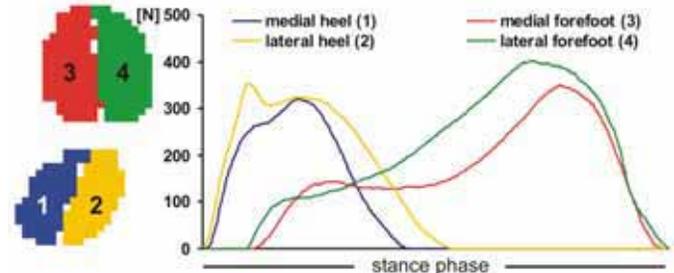

Current interventions for the treatment of medial compartment knee OA aim to reduce the knee adduction moment to decrease the load transferred through the medial compartment of the knee when walking. The most frequently used non-invasive load-altering interventions are footwear modifications [1,2] and bracing [3,4]. Thus, it seems logical that changes in the adduction moment could be predicted by changes in foot contact patterns. The purpose of this study was to test the hypothesis that changes in knee adduction moment due to load-altering interventions for medial compartment knee OA can be predicted from pressure distribution during walking.

**METHODS**

Fifteen physically active adults (6 male, 9 female; age: 31.9 ± 5.9 yrs; height: 1.74 ± 0.10 m; mass: 70.7 ± 15.9 kg) without pain or previous injury in their lower extremity participated in this study after giving written consent in accordance with the Institutional Review Board. Subjects performed 3 walking trials at self-selected slow, normal, and fast speeds in each of 3 shoes with identical uppers: 0° valgus (control); 4° valgus; and 8° valgus. Kinematic and kinetic data were collected using an 8-camera optoelectronic system and reflective markers [5]. Pressure distribution data were collected synchronously using a pressure mat placed on the force plate level with the walkway. First and second peak knee adduction moments were calculated for each trial. The pressure region was divided into four zones, medial and lateral heel and forefoot, respectively (Figure 1). The ratio between the medial and lateral maximum force values were calculated for the heel and the forefoot regions. Average values for each shoe, speed, and subject were calculated. Non-parametric statistics were used to determine the success rate in predicting changes in knee adduction moments compared to the control shoe from pressure distribution.

**RESULTS AND DISCUSSION**

In general, interventions designed to reduce the knee adduction moment during walking were successful. The 4° valgus shoe reduced the 1<sup>st</sup> and 2<sup>nd</sup> peak knee adduction moment for 35 and 42 of 45 total subject × speed cases (77.8

**Figure 1:** Force curves for one representative trial for the four zones of the foot taken from the pressure mat.

and 93.3%), respectively. The 8° valgus shoe reduced the 1<sup>st</sup> and 2<sup>nd</sup> peak knee adduction moment for 43 and 42 subject × speed cases (95.6 and 93.3%), respectively.

These results suggest that there are multiple ways to respond to the intervention. The ratio between the medial and lateral maximum force values successfully predicted changes in the 1<sup>st</sup> peak knee adduction moment at a greater rate for the 8° valgus shoe than for the 4° valgus shoe (Table 1). The strong prediction of changes in the knee adduction moment from the force ratio indicates that the more severe intervention (8° valgus shoe) dominated the mechanism of altering the load for most subjects, whereas with the 4° valgus shoe the mechanism of altering load was influenced by other factors such as limb alignment or upper body movement. Thus, interventions that alter load only slightly could have substantial variations in their load-modifying capacity since other factors may play an important role in the way subjects adjust their gait. A validation of these observations is required for patients with medial compartment knee OA.

## DURABILITY OF ICE HOCKEY HELMETS TO REPEATED IMPACTS

David J. Pearsall, Roghieh Hakim-Zadeh  
 Department of Kinesiology & Physical Education, McGill University, Montréal, Québec, CANADA  
 email: [david.pearsall@mcgill.ca](mailto:david.pearsall@mcgill.ca)

### INTRODUCTION

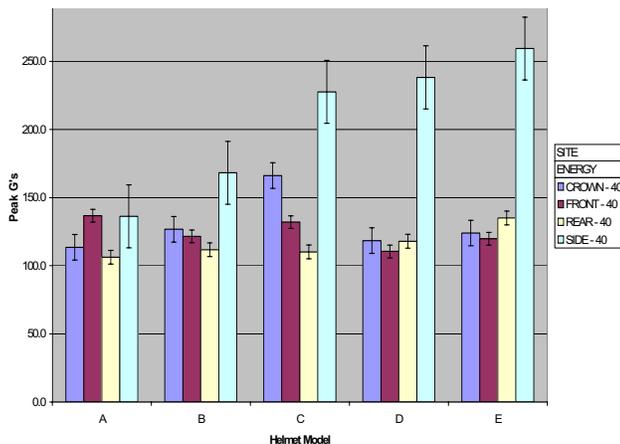

Various sports activities that involve protective head gear have different safety testing criteria (Hodgson, 1991). In ice hockey, helmets need to fulfill their function after multiple impacts. Current standards typically involve three repeated impacts at specified helmet sites at a specific energy (Newman, 1993). Since helmets may be used for several competitive seasons, the mechanical durability of these helmets is unknown (i.e. do helmets sustain their impact attenuation properties after numerous repeated impacts?)

### METHODS

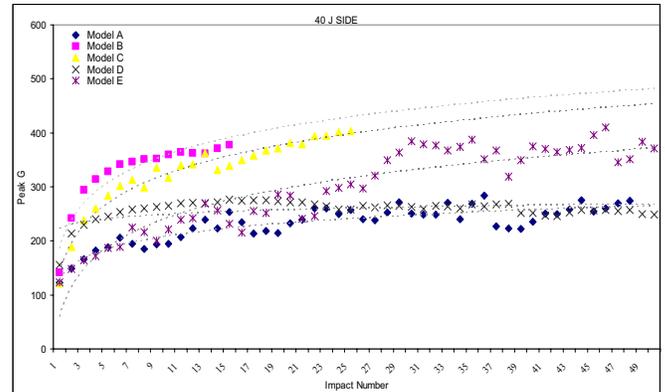

A monorail drop apparatus was used to conduct controlled impact tests according to standard CSA-Z262.1-M95. A uniaxial linear piezoelectric  $\pm 500$  g accelerometer (353B04, Dalimar) was located at a headform's center (ISO, large size, M) to measure peak linear deceleration at impact (sampling rate 10 KHz; filtered at 1000 Hz) in g's (9.81 m/s/s). The helmet/headforms impact energy was set at 40 J. Three samples of five different models of helmet (size large) were used and four impact sites were evaluated: front, rear, side, and crown. Each site was impacted 50 times. Each helmet received a total of 200 impacts.

### RESULTS AND DISCUSSION

Each helmet tested satisfied the safety test criteria at 40 J for the first three impacts (i.e. <275g). The side site showed higher g's than the other sites ( $p < 0.001$ , Fig 1). After several impacts the degradation in impact attenuation properties would plateau and, in some model sites, peak g's would eventually exceed 275g's. The rate of attenuation properties varied with site and helmet model ( $p < 0.05$ , Fig 2).

**Figure 1:** Comparison of peak G between the sites and helmet models at the third repeated impact.

**Figure 2:** Comparison of side impact site peak G measures by helmet models for up to 50 repeated impacts.

The gradual decrease in impact attenuations properties (i.e. increased peak G with repeated impacts) varied with helmet model due to various liner padding materials, shapes, thickness, and outer shell geometry.

### CONCLUSIONS

The above results help to predict the behaviour of helmets under an extreme number of multiple impacts. It also showed the heterogeneous impact response by helmet site; notably different for side impacts. This information may assist in establishing the expected lifetime usage for helmets. Safety standard committees, manufacturers, and national ice hockey associations need to consider this information carefully. Further study is needed to determine the typical mechanical stability of helmets over a normal season-to-season use.

## A PARADIGM TO ASSESS ELECTROMYOGRAPHIC AND KINEMATIC RESPONSES DURING ANTEROPOSTERIOR SURFACE TRANSLATIONS IN SITTING FOLLOWING WHIPLASH INJURIES

<sup>1,2</sup>Isabelle Patenaude, <sup>1,2</sup>Julie Côté, <sup>2,3</sup>Nancy St-Onge and <sup>2,3</sup>Joyce Fung

### INTRODUCTION

Support surface perturbations are used in research to study the postural control system in humans. In standing healthy subjects, appropriate movement patterns and muscle actions are generated by the central nervous system to restore the projection of the body's center of mass (COM) within the base of support following multidirectional surface translations [1]. Similar studies have been done in sitting [2]. Persons with whiplash associated disorders (WAD) display clinical manifestations resulting from neck trauma. A protocol using low-intensity support surface translations could also be used to evaluate the integrity of the postural control system of WAD individuals [3]. The goal of this study was to identify a low-intensity surface translation characterized by stereotypical postural responses in healthy sitting subjects, with a long-term goal of administering this protocol to WAD individuals.

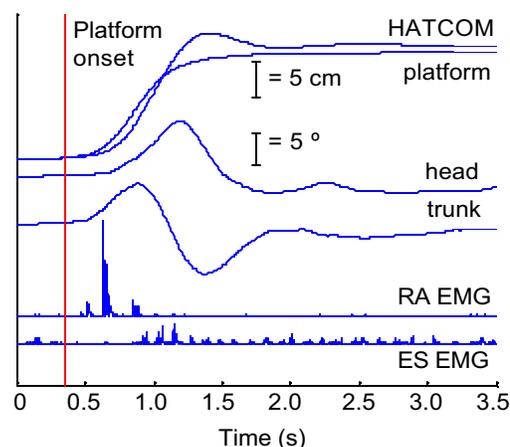

### METHODS

Healthy subjects (N = 3) sat on a chair fixed on a moveable support surface which was servo-controlled by electro-hydraulic actuators. Pilot tests were initially performed to identify the weakest translational perturbation that provoked stereotypical postural responses. Subjects were then submitted to a randomized sequence of 15 perturbation trials at the identified threshold intensity, with 5 forward translations, 5 backward translations and 5 unperturbed trials. Electromyography (EMG) of eight trunk and neck muscles was recorded bilaterally using a system of bipolar surface electrodes (Noraxon©). Reflective markers were fixed on the subject's head, trunk and arms and their position was recorded using a 6-camera high-resolution passive motion capture system (VICON©). EMG onset was identified when the signal surpassed two standard deviations above the mean of the baseline signal. EMG amplitude was determined by calculating the root mean square (RMS) values over 50 ms intervals. The position of the head, arms and trunk center of mass (HATCOM) was determined using marker coordinates and anthropometric data. The onsets of platform, head and trunk, and HATCOM displacements were identified when their velocities surpassed 5 % of maximum value.

### RESULTS AND DISCUSSION

The weakest perturbation that elicited stereotypical muscle and kinematic responses was a support surface translation of 15 cm in 500 ms. For forward perturbations, neck and trunk flexors were activated first (150-250 ms after platform onset), followed by the extensors (600-650 ms). For backward perturbations, extensors were activated first (100-250 ms after platform onset), followed by flexors (450-600 ms). In both directions, flexors were activated for a shorter period as

compared to extensors. Trunk and head segment onsets occurred 0-220 ms and 100-500 ms after platform onset, respectively. Trunk and head angular displacements ranged from 2 to 12 degrees, with head movement about 3 degrees smaller than trunk movement. HATCOM began moving 0-100 ms after platform onset. HATCOM stabilised within 2 seconds after overshooting its final position.

**Figure 1:** Kinematic and muscle responses to a forward support surface perturbation in a typical subject. RA EMG: left rectus abdominis; ES EMG: left erector spinae.

Our results show that in healthy subjects, the selected translations elicited stereotypical muscular and kinematic responses. At this threshold perturbation, the muscular response pattern is such that muscles stretched due to segmental displacement are activated first, as was shown in other studies using higher intensity perturbations [1-2]. We predict that when submitted to this protocol, WAD individuals will display a variety of inappropriate postural responses which may be caused by deficits at the musculoskeletal or proprioceptive receptor levels associated with their WAD [3].

### CONCLUSIONS

Pilot studies were done to identify a low-intensity perturbation that provoked stereotypical postural responses in healthy subjects. This protocol could be used to assess the integrity of the postural control system in WAD individuals.

## ICE HOCKEY STICK RECOIL MECHANICS

Alejandro Villaseñor, David J. Pearsall, and René Turcotte  
 Department of Kinesiology & Physical Education, McGill University, Montréal, Québec, CANADA  
 email: [david.pearsall@mcgill.ca](mailto:david.pearsall@mcgill.ca)

### INTRODUCTION

Several studies have been conducted with respect to the performance of shooting (1,2). From these studies, the authors suggested that movement patterns of elite players were predominant factors in determining critical outcomes such as puck velocity despite the variation of stick stiffness. However, the effect of the different mechanical factors (e.g. stick bend, puck velocity, puck contact time) on shooting performance is not completely understood. For instance, how do these parameters affect the catapult or recoil effect of the stick during a shot? Hence, the purpose of this study was to identify the recoil effect of the ice hockey stick shaft during a stationary slap shot as observe for elite and recreational players.

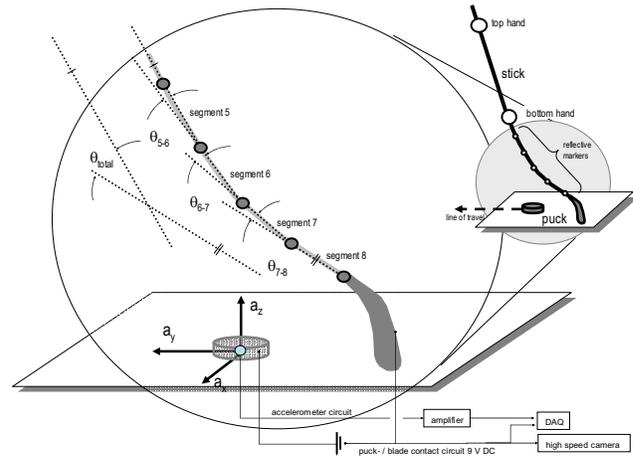

### METHODS

Nine male Hockey players were selected as subjects for this study (four 'elite', five 'recreational'). The subjects wore ice hockey gloves and stood on a 3 m square piece of 0.004 m thick polyethylene (artificial ice) and were asked to complete eight to ten stationary slap shots for one model stick. Performance measures included: puck acceleration, stick shaft bending and kinetic energy. Data collection consisted of the simultaneous use of a high speed video recording at 1000 Hz (HSC Motion Scope RedLake Imaging, Model PCI 1000), and a piezoelectric triaxial accelerometer (Kistler Inst. Co., model 8792A500) linked to a coupler (Charge Amplifier Type 513m4, Kistler Instrumentation Corp., Amherst, NY, USA) then to a data acquisition card (AT-MIO-16X PC DAQ board, National Instruments). Blade-puck contact time was recorded (LabView 4.1® software) using the same DAQ by means of wrapping the blade of the hockey stick and the puck with a metal foil, thereby creating a  $\pm 5V$  contact circuit which allowed the synchronization of both systems (Figure 1). The shaft kinematics was processed using APAS Software (Ariel Dynamics Inc.).

### RESULTS AND DISCUSSION

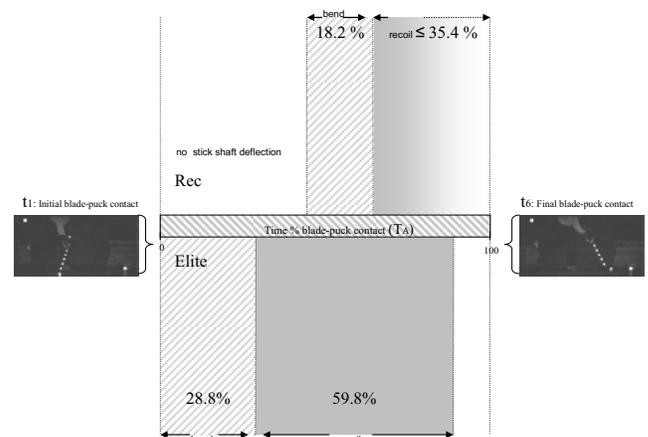

As Figure 2 shows, differences in both the magnitude and sequence of the two main phases identified (i.e. stick shaft bend and recoil) were observed between groups. For instance, a consistent bend-recoil sequence of the three stick shaft segments examined for the 'elite' group was observed in contrast to the 'rec' group, where a 'recoil' phase was relatively non-existent. For the 'elite' group, the bending occurred shortly before or at the instant of first contact ( $t_1$ ) until 28.8 % of blade-puck contact window, followed by the recoil-phase, which lasted until 59.8 % after bend phase or 88.6 % after first touch. Conversely, the "rec" group showed a different sequence, such that the bend phase began only after half way through the contact window (i.e. 44.4 %), and then lasting for only 18.2 % of  $T_A$  before initiating the stick recoil (up to 35.4 % of contact time remaining).

On average, the 'elite' group achieved higher puck velocities than the 'rec' group within a range of  $120.8 \pm 18$  km/h and  $80.3 \pm 11.6$  km/h, respectively. In addition, significant

**Figure 1** Set up of the experiment. Stick angle deflections ( $\theta_{5-6}$ ,  $\theta_{6-7}$ ,  $\theta_{7-8}$ ,  $\theta_{total}$ ) and system synchronization.

differences were observed in the stick elastic (bend) energy, whereby the 'elite' and 'rec' groups showed  $16.49 \pm 13.29$  joules versus  $2.10 \pm 2.10$  joules, respectively. Furthermore, strong relationships were found between puck velocity and stick bending energy and between puck velocity and blade-puck contact times.

**Figure 2** Percentage bend-recoil during puck-blade contact time in the slap shot.

### CONCLUSIONS

Stick elastic bend energy (i.e.  $E_d$ ) and blade puck contact times (i.e.  $T_A$ ,  $T_B$ ) were identified as the two main factors highly related to final puck velocity. From these results, a better understanding of the impact blade-puck event during a stationary slap shot was obtained.

## NON-LINEAR ELASTIC BEHAVIOR OF SMALL INTESTINAL SUBMUCOSA

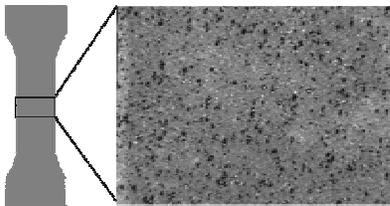

<sup>1</sup>Brent S. Mitchell, <sup>2</sup>Lori Sahakian, <sup>2</sup>Prasanna Malaviya, and <sup>1</sup>Glen L. Niebur  
<sup>1</sup>Tissue Mechanics Laboratory, University of Notre Dame, Notre Dame, IN,  
<sup>2</sup>DePuy Orthopaedics, a Johnson & Johnson Company, Warsaw, IN

### INTRODUCTION

Small intestinal submucosa (SIS) has been used as a bioactive scaffold for repair of soft tissue injuries. For load bearing and tissue engineering applications, knowledge of the material properties of the implanted scaffold is essential. The properties of SIS have been characterized by linear elastic constant[1]. However, most soft tissues exhibit non-linear elastic behavior. The goal of this study was to characterize the non-linear elastic behavior of SIS laminates.

### METHODS

Five 20-layer SIS samples were cut into a dog bone shape with the gage length of 60 mm, cross sectional width of 25 mm, and 40 mm tabs. While dry, a speckle pattern was painted on the samples using an airbrush to facilitate the strain measurement using a digital speckle displacement measurement technique (Fig. 1).

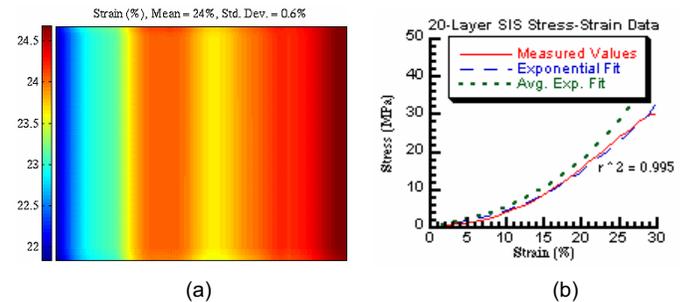

**Figure 1.** Dog-bone specimen shown with location of strain correlation.

The dry mass of each specimens was measured after which they were soaked in deionized water for two hours for full hydration prior to testing. The hydrated samples were weighed and the new dimensions were measured. They were then placed into cryogenic tissue grips on a material testing machine (Instron 8821, Instron, Canton, MA). A uniaxial tensile test was performed at a strain rate of 100%/s to specimen failure. During the test, video images were taken using a black and white CCD video camera (Sony XCD-X710, Sony Corporation, Tokyo, Japan) at 30 frames per second. A two-dimensional strain field was computed from the images using Vic-2D (Correlated Solutions, West Columbia, SC) optical displacement measurement software. Due to the strains uniformity in each (Fig. 2a) image the average strain values were used to generate stress-strain curves. The out-of-plane strain was calculated by assuming incompressible behavior. The force, stress, and strain at failure were also recorded.

A nonlinear constitutive model was constructed using an exponential strain energy function of the form:

$$W = C(e^{b_1(I_1-3)} + e^{b_2(I_2-3)} - 1) \quad (1)$$

where  $W$  is the strain energy,  $C$ ,  $b_1$ , and  $b_2$  are constants, and  $I_1$  and  $I_2$  are the invariants of the right Cauchy Green deformation tensor.

**Figure 2.** (a) A typical strain field demonstrating uniformity with a size of 25 mm by 10 mm. (b) Stress-strain behavior of laminated SIS. The dashed line is the fit of the data shown by the solid line. The dotted line is the model prediction using the mean coefficients from five specimens.

### RESULTS AND DISCUSSION

The hydrated samples had an 80% change in cross-sectional area and an increase of mass of over 100%. Based on the hydrated cross-sectional area the average ultimate tensile strength was  $30.5 \pm 2$  MPa. The constants  $C$ ,  $b_1$ , and  $b_2$  in the nonlinear material model (Eqn. 1) had values of  $3.268 \pm 1.4$  MPa,  $0.076 \pm 0.84$ , and  $1.045 \pm 0.25$  (mean  $\pm$  std. dev.), respectively (Fig. 2b).

Variations of this model have been used to characterize the biaxial mechanical data of SIS [2], pressure properties in a rabbit aorta [3], and blastula wall stiffness[4]. Although this non-linear neo-Hookean exponential constitutive model agreed with the experimental data, other models can also be applied to this data to assess which model best describes the material behavior.

### CONCLUSIONS

An exponential neo-Hookean constitutive model was found to correlate well with the measured stress-strain behavior of layered laminated SIS. This constitutive model can be applied to further research of SIS soft-tissue composites to predict the strength of the construct as a load bearing scaffold.

## EVALUATION AND QUANTIFICATION OF BRUISING

<sup>1</sup> Don Sherman, <sup>1</sup> Cynthia Bir, <sup>1</sup> David Viano and <sup>1</sup> E. Mark Haacke  
<sup>1</sup> Wayne State University - Detroit, Michigan email: [dsherman@wayne.edu](mailto:dsherman@wayne.edu)

### INTRODUCTION

In the United States there were 903,000 estimated cases of child abuse or neglect in the year 2001 [1]. Despite this high number, many cases go unreported each year due to an inability to positively identify a case of abuse. In fact, a child will be seen several times in the acute care setting before an exact diagnosis and proper intervention can occur. This delay is partly due to subjectivity that results when dealing with cases of bruises with unknown etiology and the lack of proper documentation. The accuracy of a physician's assessment in terms of timing of a bruise based on physical examination has been previously reported to be less than 48% [2]. Therefore, there is an urgent need to objectively quantify bruises in order to document the occurrences early in the treatment process.

The purpose of this research is to develop a model for bruising to evaluate methodologies to assist in the quantification of bruises with known impact conditions.

### METHODS

The gastrocnemius muscle complex of the adult Wistar rat was selected for impact based on the relative size of the complex and the ease of access. 30 adult female Wistar rats weighing between 300 to 375 grams were tested. Prior to testing, approval from the Animal Care Committee at Wayne State University was granted.

As part of this effort, a pneumatic impactor was developed to achieve a wide range of impact conditions. The pneumatic system consists of a pressure accumulator which is attached to a tube or barrel by way of an electric solenoid. A projectile is placed into the barrel and when triggered the solenoid opens and the pressure accelerates the projectile which is allowed to drive into the specimen. Three impactors ranging in mass from 50 to 100 grams were used. Each impactor surface has a diameter of 1.27 cm and a cross-sectional area of 1.27 cm<sup>2</sup>. The impactor surfaces are a flat circle with 1 mm radius around the entire circumference to reduce the edge loading effects.

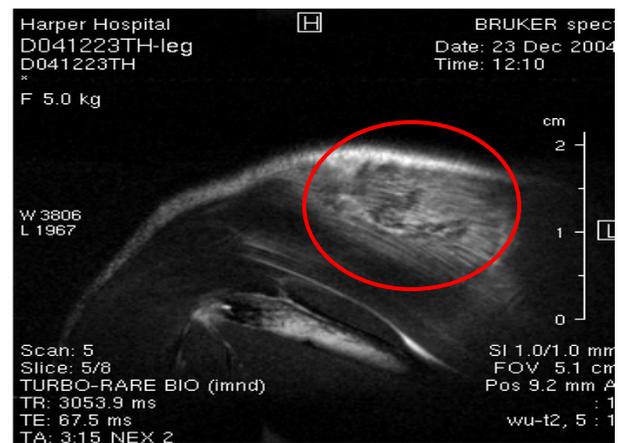

After anesthetization, the hind limbs of each specimen were shaved to expose the gastrocnemius muscle complex which includes the gastrocnemius, soleus, and plantaris muscles. Both hind limbs of the specimen were then scanned in a 4.7 T MRI to establish a baseline image. Next, one hind limb from each animal was randomly selected for impact with the other limb serving as a control. The specimen was placed in sternal recumbency with the selected hind limb extended and 90° of dorsiflexion in the ankle. The gastrocnemius complex was impacted with one of the six impact conditions list in table 1. After impact the hind limbs of the specimen were scanned again to determine the volume of the contusion that was created.

**Table 1:** Impact Conditions for the Six Impact Groups

Impactor Mass (g)	Impactor Velocity (m/s)	Impact Energy (J)
50	14.14	5.00
75	11.55	5.00
100	10.00	5.00
50	16.73	7.00
75	13.66	7.00
100	11.83	7.00

### RESULTS AND DISCUSSION

The impact conditions were selected based on preliminary pilot studies. Multiple masses were selected to assess the effect of varying mass and velocity while maintaining impact energy. Two impact energies were selected to assess the effect of increasing velocity while maintaining the mass. Impact energies were selected based on preliminary studies and published data [3]. Figure 1 is an MRI scan of the contusion created at the 4.92 J energy level.

**Figure 1 :** A T2 weighted MRI scan of an impacted gastrocnemius (Impact energy was 4.92 J)

### CONCLUSIONS

This model is capable of producing bruises on the adult Wistar rat. The 4.7 T MRI provides a viable method for visualizing and quantifying a bruise in vivo.

## HIP ABDUCTOR STRENGTH MAY BE CRITICAL FOR SUCCESSFUL GAIT COMPENSATION IN PATIENTS WITH MEDIAL COMPARTMENT KNEE OSTEOARTHRITIS

<sup>1</sup>Anne Mündermann, <sup>1</sup>Chris O. Dyrby, and <sup>1,2</sup>Thomas P. Andriacchi

### INTRODUCTION

The external adduction moment at the knee during walking has been shown to be a strong predictor for medial compartmental knee osteoarthritis (OA) severity (1) and rate of progression (2). A recent study (3) showed that the knee adduction moment is only elevated compared to matched control subjects for patients with more severe knee OA. The reasons for differences in the adduction moments based on severity are not well understood. It has been suggested (4) that hip musculature could be an important factor in a patient's ability to reduce the knee adduction. However, this study did not segregate patients of different disease severity. The purpose of this study was to test the hypothesis that a reduction in the knee adduction moment is related to the hip adduction moment during walking and that this relationship is dependent on the severity of the disease.

### METHODS

Forty-two patients (22 female, 65.1 ± 10.2 yrs, 169.1 ± 10.1 cm, 79.2 ± 13.3kg) with OA in the medial compartment of the knee participated in this study after giving written consent in accordance with the Institutional Review Board. Inclusion criteria have been defined previously (3). Patients were classified as less or more severe based on the K-L grades of both knees (less severe: K-L grade ≤ 2; more severe: K-L grade ≥ 3). For each patient, an asymptomatic control subject matched for gender, age, height and weight (62.8 ± 10.6 yrs, 169.3 ± 8.5 cm, 76.6 ± 12.9 kg) was selected after giving written consent in accordance with the Institutional Review Board. All control subjects had no clinical diagnosis of OA or rheumatoid arthritis or a history of knee trauma or pain.

All patients and control subjects performed walking trials walking at their self-selected normal speed. Kinematics and kinetics were collected using a previously described method (5). A MANOVA was used to detect an overall significant difference in gait pattern between groups. Upon a significant result of the MANOVA, separated repeated measures ANOVAs were used to detect significant differences in discrete variables describing the intersegmental angles, moments and forces between groups ( $\alpha \leq 0.05$ ).

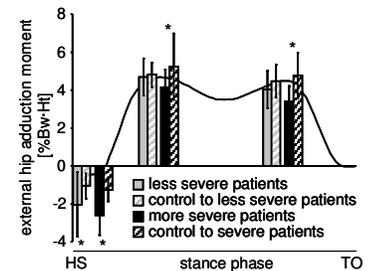

### RESULTS

Patients with less severe knee OA had normal hip adduction moments while patients with more severe knee OA had substantially lower hip adduction moments compared to their control subjects (-29.0%;  $P < 0.001$ ; Figure 1). In contrast, patients with more severe knee OA had greater knee adduction moments (+11.4%;  $P = 0.039$ ). Irrespective of severity, all patients had a more rapid increase in the ground reaction force (+50.1%;  $P < 0.001$ ), greater medial ground reaction forces (+54.0 %;  $P < 0.001$ ) and greater hip adduction moments

immediately following heel-strike (+100.7%;  $P < 0.001$ ; Figures 1 and 2) combined with the knee in a more extended position at landing (+5.3°;  $P = 0.003$ ) suggesting a tendency for a rapid shift of the body's load to the contralateral limb.

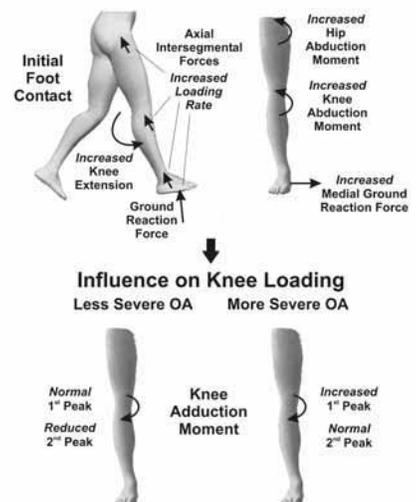

### DISCUSSION

The results support the conclusion that the hip adduction moment could influence the patient's ability to reduce the knee adduction moment, suggesting that patients with less severe knee OA have sufficiently strong hip abductor muscles to maintain a position of the trunk associated with a lower adduction moment whereas more severe patients may lack sufficient hip abductor strength (Figure 2).

**Figure 1:** Hip adduction moments for patients with less and more severe knee OA and matched asymptomatic control subjects (\*  $P < 0.05$ ).

### Gait Changes Secondary to Knee OA

**Figure 2:** Similar compensation mechanisms lead to different knee adduction moments in patients with less and more severe knee OA.

## THE EFFECT OF SPEED ON GROUND REACTION FORCES DURING LOCOMOTION IN WEIGHTLESSNESS

<sup>1</sup>John DeWitt, <sup>2</sup>Grant Schaffner, <sup>2</sup>Jason Bentley and <sup>3</sup>R. Donald Hagan

<sup>1</sup> Bergaila Engineering Services, Houston, TX, USA; <sup>2</sup> Wyle Life Sciences, Houston, TX, USA;

<sup>3</sup> NASA Johnson Space Center, Houston, TX, USA; email: john.k.dewitt1@jsc.nasa.gov

### INTRODUCTION

During long-term space missions, astronauts perform treadmill locomotion as an exercise countermeasure. One of the goals of the exercise is to apply force to the musculoskeletal system via the ground reaction force (GRF). Keller et al. [1] have shown that vertical GRF increases with increasing speed during locomotion at various speeds in normal gravity (1G). The purpose of this investigation was to determine how gait speed affects GRF during locomotion in weightlessness (0G). It was hypothesized that the interaction of speed and peak GRF will be affected by gravitational condition.

### METHODS

Four subjects (2M/2F; 172.75 ± 11.14 cm; 73.18 ± 14.03 kg) performed locomotion at 1.34 (walk), 2.23 (jog) and 3.13 (run) m/s on the ground (1G) and during 0G onboard NASA's KC-135 airplane. Vertical GRF data were collected at 250 Hz for 25 sec during multiple trials with a GRF-measuring treadmill (Kistler Gaitway, Amherst, NY).

During 0G trials, the subjects wore a harness that attached at the hip to an external load (EL) set at 1.0 bodyweight (BW) during quiet standing. Bilateral dynamic loading forces were measured at 120 Hz with load cells (ELPS-T3E-500L, Entran Devices, Inc, Fairfield, NJ) placed inline with the EL configuration. The mean dynamic EL for each trial was calculated throughout the entire trial. During 1G trials, subjects ran without the harness.

Peak impact force (PIF) and peak propulsive force (PPF) were determined for eight consecutive footfalls (4 left and 4 right) from each trial. Trial means for all eight footfalls were computed for each GRF variable. All variables were normalized to subject body weight (BW).

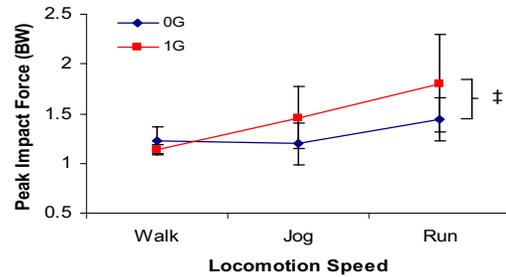

A 2-way (gravitational condition × speed) ANOVA was performed on each outcome variable to identify any significant interactions. Bonferroni (all-pairwise) multiple comparison tests were used to determine differences at each speed. Results were considered significant at p<.05.

### RESULTS AND DISCUSSION

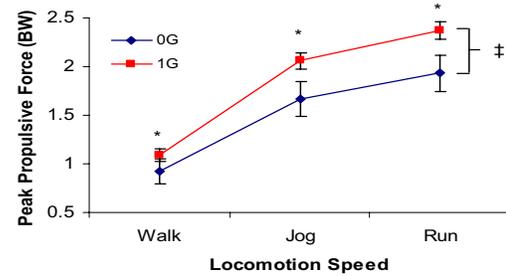

Dynamic mean EL was determined to be 0.91 BW during the 0G trials. Mean PIF and PPF were between 1.0 and 2.4 BW depending on the speed and gravitational condition (see Table 1). The ANOVA analysis revealed significant effects for speed, and a significant interaction between speed and

**Table 1:** Mean ± SD of Peak Impact Force and Peak Propulsive Force during locomotion in 0G and 1G; \*p<.05.

Gravitation Condition	Peak Impact Force (BW)			Peak Propulsive Force (BW)		
	Walk	Jog	Run	Walk	Jog	Run
0G	1.23 ± .13	1.20 ± .21	1.44 ± .22	0.92 ± .13*	1.67 ± .18*	1.93 ± .18*
1G	1.14 ± .05	1.46 ± .31	1.80 ± .49	1.09 ± .07	2.06 ± .08	2.37 ± .09

**Figure 1:** Mean peak impact force at varying speeds during locomotion in 0G and 1G. ‡ Significant speed × gravitational condition interaction, p<.05.

**Figure 2:** Mean peak propulsive force at varying speeds during locomotion in 0G and 1G. ‡ Significant speed × gravitational condition interaction, p<.05.\*Significant speed effect, p<.05.

gravitational condition for both PIF and PPF. This suggests that each of these variables is affected by speed and that the speed effect is different between 0G and 1G (see Figures 1-2). The PIF were similar during 0G and 1G locomotion at each speed, but the PPF were different.

### CONCLUSIONS

In both 0G and 1G, increases in locomotion speed affect the GRF. However, the affect is different between gravitational conditions. While locomotion in 0G may create similar PIF at varying speeds, PPF are less than those occurring at similar speeds in 1G. It is possible that the decreased PPF in 0G may be related to the harness-EL system that is necessary to allow locomotion during 0G exercise. The decreased PPF may result in different training effects during 0G locomotive exercise than that occurring during 1G exercise.

## The Talocrural and Subtalar Helical Axes are not fixed during Plantarflexion

<sup>1,2</sup>Frances T. Sheehan, <sup>1</sup> Andrea J. Rebmann, and <sup>1,3</sup>Jeanine M. Graham

<sup>1</sup>National Institutes of Health, Physical Disabilities Branch, University of Maryland School of Medicine, Physical Therapy & Rehabilitation Sciences Department., <sup>3</sup>The Catholic University of America; email: [fsheehan@cc.nih.gov](mailto:fsheehan@cc.nih.gov)

### INTRODUCTION

In an attempt to understand the etiology of ankle joint injury and degeneration, numerous models of this joint have been created as a means to estimate ankle joint forces. Due to a lack of non-invasive *in vivo* measurement techniques, the kinematics required to drive these models have typically been acquired in cadavers or using external markers to infer internal bone motion. This has left some uncertainty as to the validity of the two most common model simplifications (assuming that the talocrural joint is a locked joint or that both joints are simple hinge joints). Thus, the purpose of this study was to quantify the 3D finite helical axis of the subtalar and talocrural joints non-invasively *in vivo* during plantarflexion, in order to test if the above assumptions were true.

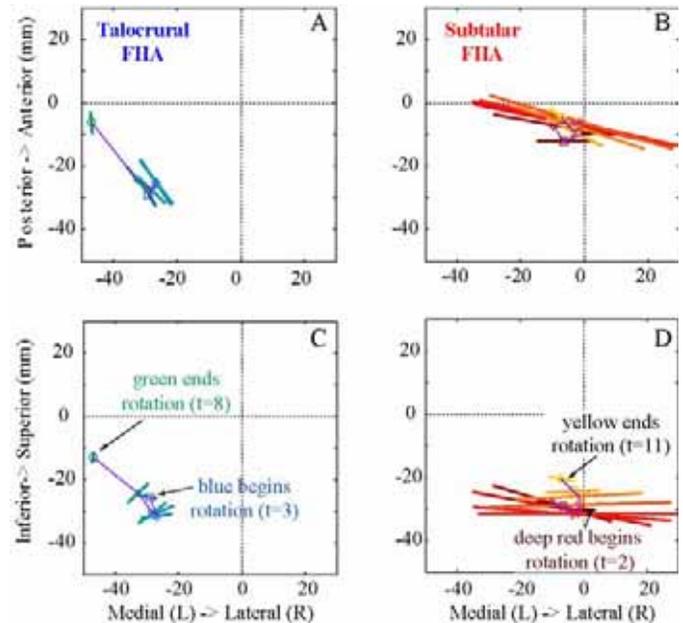

### METHODS

Four healthy male subjects participated in this IRB approved study. In total data for 6 ankles were collected (age=26.2±5.0 years, mass=79.5±11.6 kg, height=173.6±1.3cm). Subjects were placed supine in a 1.5T MR imager (LX; GE Medical Systems, Milwaukee, WI, USA) after obtaining informed consent.

A specialized ankle loading device, which allowed 3 degrees of rotational freedom at the ball of the foot, was used to apply load during plantarflexion. Time permitting, both ankles were studied. Plantarflexion (PF) was defined as the rotation of the calcaneus about the tibial medial-lateral (M-L) axis. Zero degrees PF was defined as when the long axis of the tibia was perpendicular to the plantar surface of the foot. While subjects cyclically plantarflexed and dorsiflexed their ankle at 35 cycles/min, aided by an auditory metronome, fast-PC MR images (anatomic and x, y, and z velocity images, temporal resolution=72 ms, imaging time=2:48) were collected. The imaging parameters were consistent with prior studies [1]. The sagittal-oblique imaging plane contained the soleus musculotendon junction, tibia, calcaneus, and talus. The 3D time dependent attitude of the tibia, talus and calcaneus was derived through integration of the velocity data [2]. From these data the FHA was determined. Since it is undefined as the angular velocity goes to zero, the FHA was not reported for angular velocities less than 0.25 rad/s. For clarity, on PF is being reported.

### RESULTS AND DISCUSSION

The subtalar joint rotation for all subjects occurred primarily about the medial-lateral axis (Fig 1B&C) during plantarflexion. Yet the FHA was not oriented solely in the M-L direction and rotation of subtalar FHA with minimal displacement during plantarflexion was seen across all subjects. The lateral side of the FHA began PF angled towards the anterior and inferior direction and as the ankle plantarflexed it rotated posteriorly and superiorly. One

**Figure 1: 3D Talocrural (A&C) and Subtalar (B&D) FHAs During Plantarflexion for subject 9821R.** All FHA's are plotted relative to the tibial coordinate system. The talocrural joint changes from blue to green and the subtalar FHA changes from deep red to yellow as the ankle plantarflexes. **A&B.** a view from above the ankle (AP vs. ML) **C&D.** a frontal view (IS vs. ML). The length of the FHA indicates the magnitude of the angular velocity. The center of the FHA is the closest point to the talar origin (A&C) or the tibial origin (B&D). PF angle for this subject ranged from 1.9° to 39.4°.

exception was seen in one subject, where lateral side of the FHA pointed posteriorly and inferiorly at the beginning of PF and rotated further posteriorly and superiorly. The talocrural FHA was directed primarily in the anterior-posterior direction (Fig 1A&C). The amount of angulation in the M-L and superior-inferior directions did change during PF, but was variable across subjects. The angular velocity of the talocrural joint was smaller than that of the subtalar joint.

The data from this study clearly indicate that neither joint is a simple hinge joint, nor is the talocrural joint a locked joint. One interesting kinematic result of the latter is that inversion occurs about the talocrural joint, while eversion occurs about the subtalar joint during plantarflexion. Thus, the eversion that is seen externally is much smaller than that which is occurring at the subtalar joint. The tendency of the subtalar and talocrural joints to rotate and translate will impact the calculation of tendon and ligament moment arms and, thus, alter the moment producing capabilities of the force generating structures at the ankle joint. Therefore, future modeling studies should investigate the sensitivity of the model outputs to variations in the FHA direction and location.

**In Vivo Patellar Tendon Moment Arm and Tibial-Femoral Helical Axis**

<sup>1,2</sup>Frances T. Sheehan, <sup>1</sup> Andrea J. Rebmann, and <sup>1,3</sup>Jeanine M. Graham

<sup>1</sup>National Institutes of Health, Physical Disabilities Branch, University of Maryland School of Medicine, Physical Therapy & Rehabilitation Sciences Department., <sup>3</sup>The Catholic University of America; email: [fsheehan@cc.nih.gov](mailto:fsheehan@cc.nih.gov)

**INTRODUCTION**

To further improve and validate knee joint models and to develop better surgical and rehabilitative protocols for knee joint injury, a complete understanding of *in vivo* knee joint kinematics and kinetics is critical. Specifically, patellar tendon (PT) moment arm length relative to the tibial-femoral finite helical axis (FHA) plays a crucial role in joint tissue loading and thus, by extension, in the etiology of knee joint pathology. Yet a clear quantitative *in vivo* measurement of this important factor is lacking, due to the fact that the majority of previous studies have been 2D, static and cadaver based. A recent study [1] did investigate 3D PT moment arm, but it was limited to a cadaver model. Thus, the purpose of this study was to experimentally quantify the PT moment arm non-invasively and *in vivo* during a volitional leg extension task in healthy volunteers. A secondary goal was to quantify the tibial-femoral FHA in these subjects in order to determine if the tibia primarily rotates or rotates with translation relative to the femur during extension. The final goal was to determine if the rotation and translation of the FHA was consistent across healthy subjects, thus indicating the applicability of a general model.

**METHODS**

Twenty knees [9M/11F, age=24.5±6.0years, height=172.8±7.7 cm, mass= 65.6± 12.8kg] from fifteen healthy subjects with no prior history of knee problems or pain participated in this IRB approved study. After obtaining informed consent, subjects were placed supine in a 1.5-T MR imager (LX; GE Medical Systems, Milwaukee, WI, USA).

Subjects cyclically extended and flexed their knee in a supine position at 35 cycles/min, aided by an auditory metronome. Using a sagittal imaging plane, which was perpendicular to the femoral epicondyles and bisected the patella, a full fast-PC data set was collected (anatomic and x, y, and z velocity images, temporal resolution=72 ms, imaging time=2:48). The imaging parameters were consistent with prior studies [2]. If time permitted, both legs were studied. Using rigid body mechanics, the 3D attitude of the patella, femur and tibia were quantified through integration of the 3D velocity data [3]. The insertions of the PT were defined in a single time frame and

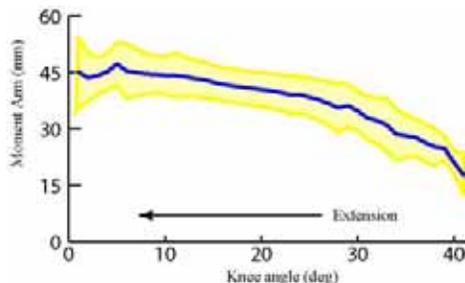

Figure 1: Average Patellar Tendon Moment Arm (blue) ± 1 SD (yellow)

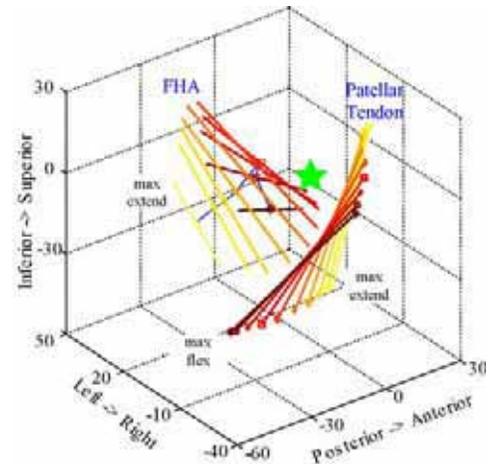

Figure 2: FHA and PT Moment arm for Subject 6468R: The transition from deep red to yellow indicates extension. Deep red line w/ star = full flex ... yellow line w/diamond = full ext. Green star indicates the origin of the femoral coordinate system (0mm,0mm,0mm). The length of the FHA indicates the magnitude of the angular velocity. All axes are in mm.

tracked throughout the cycle based on the 3D patellar and tibial attitude. The FHA was defined by the direction of the angular velocity vector of the tibia relative to femur and the perpendicular vector connecting the tibial origin to the FHA.

**RESULTS AND DISCUSSION**

All 20 subjects had very similar profiles for the PT moment arm, FHA translation and FHA rotation.. The moment arm increased from max flexion to max extension by 28.4mm (Fig 1). On average, the FHA shifted posteriorly (19.0mm) and superiorly (12.1 mm) and rotated externally (28°) relative to the femoral coordinate system (Fig 2).

This study is the first to measure both the 3D PT moment arm and FHA attitude *in vivo* during a volitional, weighted task using a completely non-invasive measurement system. One interesting point of note is that the moment arm increased as the knee extended, contrary to that which was reported in a recent 3D cadaver study (1). This increase is consistent with the kinematic data collected in that the FHA tended to shift posteriorly while the PT rotated laterally. The discrepancy between these two studies is likely due to the differences in experimental set-up. In addition, the remarkable similarity in kinematic profiles indicates that a general kinematic model may be appropriate for the general population. The next steps in this project will be to determine if these profiles are consistent across an older population and across populations with specific impairments.

## THE INFLUENCE OF INCLINED SUPPORT SURFACE ON THE BIOMECHANICS OF ECCENTRIC OVERLOAD IN SQUATS

<sup>1</sup>Kjartan Halvorsen, <sup>2</sup>Anna Frohm and <sup>1</sup>Alf Thorstensson

<sup>1</sup>University College of Physical Education and Sports, Stockholm, Sweden, email: kjartanh@ihs.se

<sup>2</sup>Elite Sports Centre, Swedish Sports Confederation, Bosön, Sweden

### INTRODUCTION

Eccentric overload training, i.e. resisting a moving force that exceeds what the body is able to move concentrically or hold statically, is widely used both for high performance training and for rehabilitation training. At the Elite Sports Center in Bosön, Sweden, a device has been developed to offer eccentric squat training under safe and controlled conditions (Frohm et al. 2005). It consists of a barbell suspended from two steel wires, which is raised and lowered by a hydraulic machine.

Recently, a pilot study on squat training as rehabilitation of patellar tendinopathy has suggested that performing the squat on an inclination board is more efficient (Purdam et al. 2004). The reason indicated is that the inclination board facilitates a technique that gives more load on the knee extensors. This is the hypothesis we have set out to test.

### METHODS

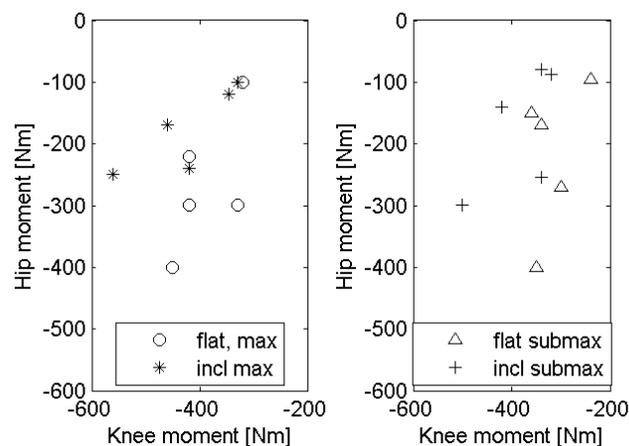

The barbell was loaded with 320kg, and the velocity during descent was set to 0.11m/s (unresisted velocity). The subjects stood on two force platforms (60cm × 40cm, 50cm distance center-center; Kistler AG, Switzerland). The movement was measured using a seven-camera motion capture system (ProReflex, Qualisys Medical AB, Sweden) with four reflective markers on the pelvis (ASIS and PSIS), three markers on each of four clusters taped to the thighs and shanks, and markers at the lateral malleolii, the heels and the base of the second phalanxes. Force and motion was recorded on a single PC; data sampled at 2kHz and 200Hz, respectively. Bilateral measurements of the activity of the *biceps femoris*, *vastus lateralis* and *gastrocnemius* was performed using surface EMG electrodes and recorded on a separate PC with a sampling frequency of 1kHz (Powerlab, ADInstruments Pty Ltd, UK). A single channel of raw force data from the Kistler amplifier was split and fed to both computers to serve as synchronization signal.

Five well trained individuals (18-23years, 60-95kg, 1.70-1.80m) have so far been tested, performing squats in the machine. Starting from the upright position, the subjects were instructed to let the barbell descend about 10cm, and then resist the movement all the way to the bottom position, which corresponded to about 90° knee flexion. During the upward movement, the subjects did not assist nor resist the movement. Four different conditions were tested: Subjects standing either on a horizontal plane or on an inclination board (25° plantar flexion at the ankle), and performing either maximal resistance, or submaximal resistance. The submaximal resistance was instructed to be 80% of the maximal resistance produced isometrically in a squatting position of 90° knee

flexion. The submaximal resistance was controlled by providing a visual feedback of the ground reaction force to the subject. A recording was done with the subject in a neutral standing position with extra markers laterally from the knee centers. The centers of the knee and ankle joints were determined with the knowledge of the width of the knees and ankles. The locations of the hip joint centers were estimated from motion capture data (Halvorsen, 2003), taken when the subjects moved their legs using as much of the range of motion of the hip as possible.

In the post-processing step, the data series (3D marker data, force data and EMG data), were aligned in time, saved in C3D files, and analyzed using Visual3D (C-Motion, Rockville, USA). Moments at the ankle, knee and hip joints were calculated using inverse dynamics.

### RESULTS AND DISCUSSION

**Figure 1** Peak joint moments. Negative values means that an extending muscle force is required.

The most obvious effect that the inclination board has is to remove the limitation that a poor range of motion in the ankle sets on the squatting technique. If the subject cannot dorsiflex the ankle enough, more flexion at the hip is needed to stay in balance, thus leading to larger moment about the hip and less about the knee. This pattern is indicated in figure 1, with peaks for the inclined squats lying on a higher diagonal line than for flat squats. Two subjects did not exhibit limitation of ankle range of motion, and performed the two types of squats with only small differences in kinematics and joint moments.

## HIP CONTROL IN LOCOMOTION

Andre Seyfarth, Susanne Lipfert and Jürgen Rummel  
 Locomotion Laboratory, University of Jena  
 email: [oas@uni-jena.de](mailto:oas@uni-jena.de), web: [www.lauflabor.de](http://www.lauflabor.de)

### INTRODUCTION

In walking and running the leg retracts during stance phase and protracts during flight phase. Proper timing of retraction and protraction seems to be crucial to obtain stable locomotion [1]. Therefore, we ask whether the difference in duty factor (ratio between stance and cycle time) between walking and running requires gait-specific timing of protraction and retraction in running and walking. Furthermore, we investigate to what extent passive joint mechanisms could help to simplify hip control.

### METHODS

1) *Hopping Robot*. A two-segmented leg is constructed with an elastic joint between the two leg segments and a kinematically driven upper joint (servo motor with sinusoidal control function). For the given joint stiffness, stable hopping patterns exist for certain combinations of hip frequency  $f$  and offset angle  $\phi$  of the servo motor control function.

2) *Human Locomotion*. In an experimental study on treadmill locomotion, subjects were asked to switch between walking and running every 9 seconds at a given speed. Leg kinematics (QUALISYS) and ground reaction forces (instrumented ADAL3D treadmill) are recorded for later analysis.

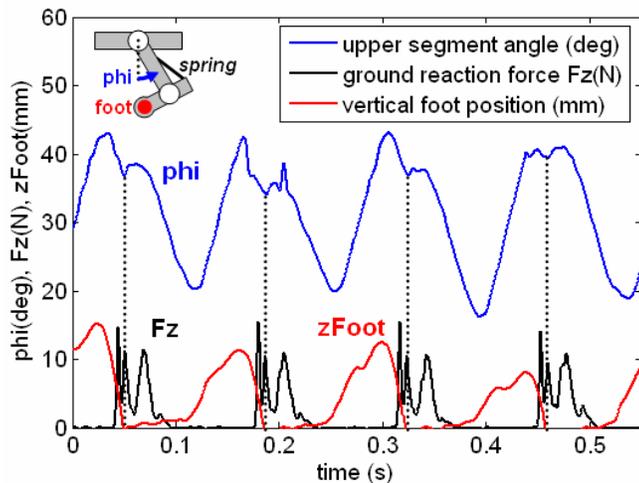

Figure 1: Kinetics and kinematics of the hopping robot.

### RESULTS AND DISCUSSION

1) *Robot Locomotion*. Stable hopping exists in different regions in the control space ( $f, \phi$ ) of the servo motor (details in: Rummel et al., this conference). During the fastest configuration, stable hopping is observed with the leg joint pointing to the forward direction. Although the motor is controlled using a perfect sine function, the upper segment kinematics showed a reset (re-initiation of the sine wave) at touch-down during the retraction phase (dotted lines).

2) *Human Walking and Running*. The thigh kinematics during walking and running are similar to the robot kinematics. In both gaits, the thigh protracts during about 35% of the gait cycle. Leg retraction is briefly interrupted at touch-down.

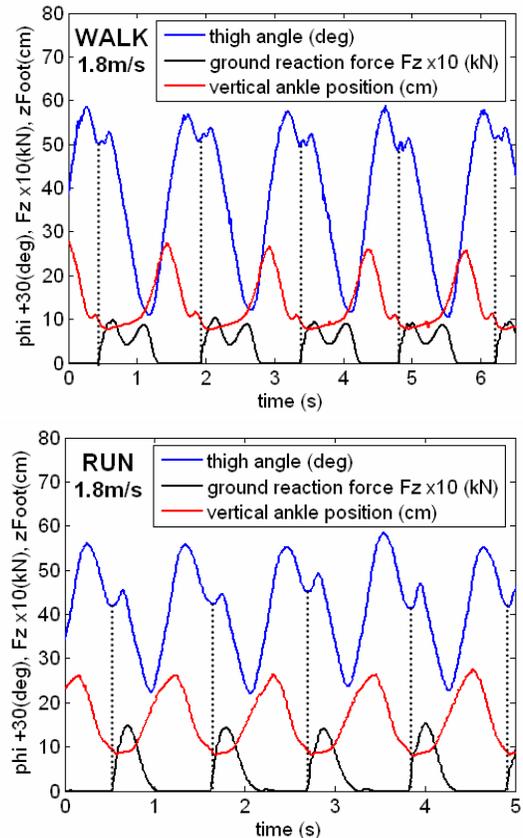

Figure 2: Kinetics and kinematics in human walking and running at 1.8m/s.

### CONCLUSIONS

The results indicate that hip control during locomotion could be very similar during walking and running. The duration of the stance phase with respect to the gait cycle could be modulated by the knee function depending on the gait. The asymmetry in protraction and retraction does not imply that the biological hip controller (e.g. CPG) needs to work asymmetrically. The simple hopping robot demonstrates that joint play and compliant actuator properties could result in the experimentally observed acceleration of the protraction phase.

## WALKING AND RUNNING ON PLACE

Andre Seyfarth and Susanne Lipfert  
Locomotion Laboratory, University of Jena  
email: [oas@uni-jena.de](mailto:oas@uni-jena.de), web: [www.lauflabor.de](http://www.lauflabor.de)

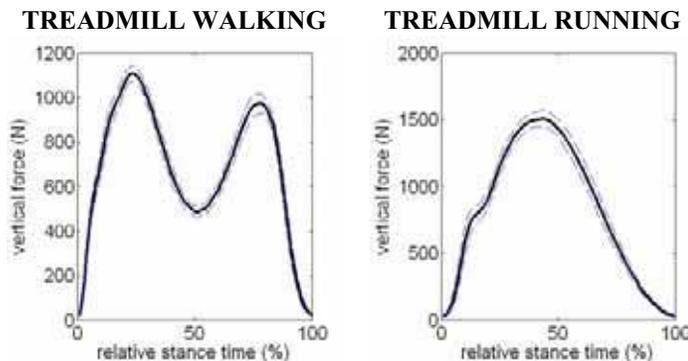

### INTRODUCTION

A central question in locomotion research is to understand how leg movements are generated. In the last decade a number of experimental and analytical approaches were undertaken to reveal basic mechanisms for stable leg operation in running and hopping. As a result of this research we do believe that the leg function can be compared to a mechanical spring [1]. This means that leg forces during contact increase with the amount of leg shortening. A similar description of the leg operation in walking will be presented at this conference (Geyer et al.).

To improve our understanding of leg operation, we ask whether the well-known shape of the force patterns (Fig. 1) could be a result of the gait-specific longitudinal leg shortening and extension rather than an effect of the leg rotation (retraction during stance).

To approach this issue we investigate the leg behavior during walking and running on place. Here, the backward rotation of the stance leg (retraction) can not contribute to the leg force generation.

Our hypothesis is that the leg force patterns are primarily dependent on gait-specific leg compression dynamics and therefore similar to forward locomotion when walking and running on place.

**Figure 1:** Vertical ground reaction forces (mean  $\pm$  S.D.) in treadmill walking and running at preferred walk-run transition speed (1.9 m/s).

### METHODS

Three subjects (body mass  $m=54, 73, 67$ kg; body height  $h=167, 182, 182$  cm) were asked to walk and run on two adjacent KISTLER force plates. The kinematics of the right toe, ankle, knee, hip and shoulder were recorded using a high-speed camera system (QUALISYS).

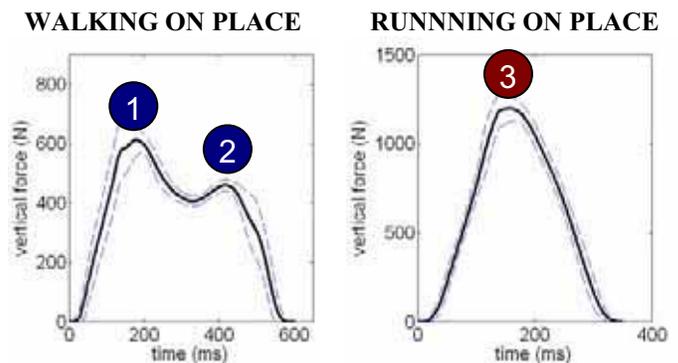

First, subjects were asked to select their preferred gait at frequencies between 1 and 4 Hz. Then, they were required to change gait every 10 contacts at their preferred gait transition frequency. Using the marker data the inner leg joint angles (ankle and knee) were calculated.

### RESULTS

The analysis of walking and running on place shows a high similarity in the ground reaction force patterns (Fig. 2) compared to forward locomotion (Fig. 1). In *running*, a single force peak (circle 3) is observed. For *walking* on place, a double humped (circles 1 and 2) force pattern - similar to forward walking - is present. In comparison with forward walking, however, the second hump (circle 2) is slightly reduced in magnitude.

*Walking kinematics:* During stance, large extension-flexion cycle of the knee (ca. 135-175 deg) and two ankle flexion-extension cycles (ca. 105-115 deg) are observed.

*Running kinematics:* Leg shortening during stance is mainly achieved by the ankle joint (125-100 deg).

**Figure 2:** Vertical ground reaction forces (mean  $\pm$  S.D.) during walking and running on place at preferred transition frequency (2.8 Hz).

### DISCUSSION

Both, walking and running on place keep general features of forward locomotion, such as *maximum leg force* at midstance in running and *two local force maxima* and *one local minimum at midstance* in walking. On the joint level, a clear distinction of knee and ankle operation between walking and running can be found.

In conclusion, we suggest that the organization of the leg behavior during stance does primarily rely on the longitudinal dynamics of leg compression and extension. Further research needs to be done to evaluate the effects of forward movement on the leg function during locomotion.

## INTERSEGMENTAL DYNAMICS OF THE SWING PHASE OF WALKING IN TRANS-TIBIAL AMPUTEES

<sup>1</sup>Jeremy D. Smith, <sup>1</sup>Philip E. Martin and <sup>2</sup>Sarah J. Mattes

<sup>1</sup>Department of Kinesiology, Penn State University, University Park, PA 16802,

<sup>2</sup>Department of Kinesiology, Arizona State University, Tempe, AZ 85287; email: [jds431@psu.edu](mailto:jds431@psu.edu)

### INTRODUCTION

Unilateral, trans-tibial amputees reflect significant inertial asymmetries between the intact and prosthetic limbs [1] and also exhibit temporal, kinematic, and kinetic gait asymmetries during walking [2]. Early modeling research [3] suggested lower extremity inertial symmetry may lead to more symmetrical gait patterns in unilateral amputees. Mattes et al. [1], however, found that matching inertial properties exacerbated existing temporal asymmetries. In an effort to better understand the influence of inertial manipulation on swing phase dynamics for unilateral, trans-tibial amputees, we examined the effect of matching the inertial properties of prosthetic and intact legs on intersegmental dynamics at the knee and hip during walking.

### METHODS

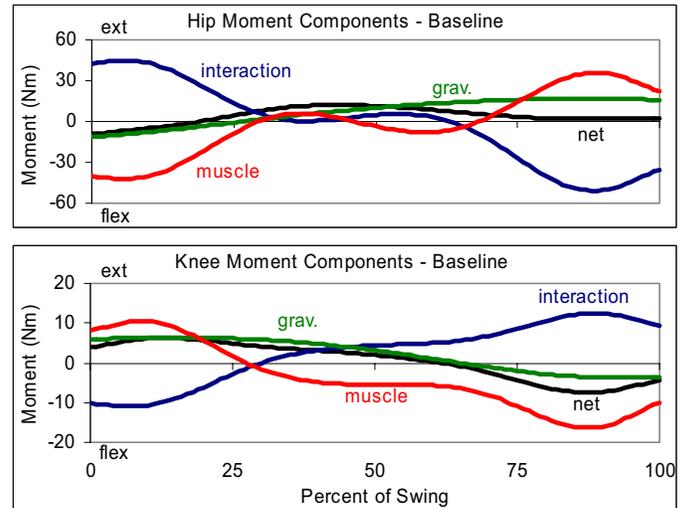

Six males with unilateral, trans-tibial amputations (age: 32±12 yrs, body mass: 85±6 kg, body height: 179±6 cm, time since amputation: 3-15 yr), using energy storing prosthetic limbs, were first acclimated to treadmill walking and prosthesis load conditions. Inertial properties of the intact and prosthetic limbs were measured or estimated [4]. In a separate session, subjects completed overground walking at 1.34 m/s as sagittal plane motion and ground reaction force data were sampled (60 Hz and 480 Hz, respectively) under three prosthetic limb inertial conditions: 1) a baseline condition in which no load was added to the prosthetic limb, 2) a 100% mass condition in which prosthetic limb mass and moment of inertia about a transverse axis through the knee were matched to those of the intact limb, and 3) a 50% mass condition in which the added load was half that added to the limb for the 100% condition.

An intersegmental dynamics approach was used to partition net moments about the knee and hip into interaction, gravitational, and muscle components [5]. Absolute angular impulses for each moment component were computed and used to express each as a percentage of the total of the three components.

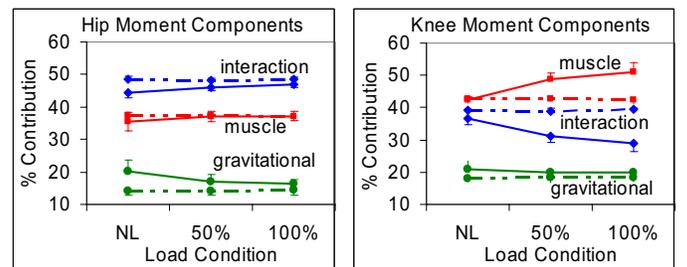

### RESULTS AND DISCUSSION

Net moments and moment components attributed to muscle, gravitational, and interaction during the swing phase (Figure 1) of walking were consistent in amplitude and pattern with published data for able-bodied walking [5]. Intersegmental dynamics at the knee and hip of the intact limb were not affected by inertial increases of the prosthetic limb. In contrast, the magnitude of moment components at both the hip and knee of the prosthetic leg increased systematically as prosthesis inertia was increased. In addition, the relative contributions of the individual moment components were altered, particularly at the knee where the relative contribution of muscle increased and interaction contribution decreased (Figure 2). Increased muscle moments at the hip and knee as

prosthesis inertia increased paralleled higher metabolic costs of walking observed by Mattes et al. [1] for the same load conditions.

**Figure 1.** Net joint moment and partitioned components for the hip and knee joints of the prosthetic leg (unloaded condition; swing phase only). Note the counterbalancing effects of the muscle and interaction components at both joints. The intact leg showed similar patterns.

**Figure 2.** Relative contributions of the muscle, gravitational, and interaction components for prosthetic leg (solid lines) hip and knee were altered as prosthetic limb inertia increased. There were no changes for the intact leg (dashed lines).

### CONCLUSION

The increased relative contributions of the muscle moments to the net moments at the hip and knee suggest that the prosthetic limb requires more active control by the musculature as prosthesis inertia increases.

### INTRODUCTION

As the trend of longer life span continues, more and more people receive bilateral total knee replacements (TKR) in their lifetime. It is common that many patients have two different TKR systems implanted, one on each side. The functional performance of bilateral TKR patients with two different systems during daily activities is not well understood. Although it was reported that a single-radius TKR (SR) compared to a multi-radius TKR (MR) could facilitate unilateral TKR patients' sit-to-stand (STS) movement [1], it is not known if bilateral TKR patients with an SR and an MR on each side rely on their SR limbs to perform a STS movement.

The purpose of this study is to investigate the influence of an SR and an MR TKA on functional performance during a STS performed by bilateral TKR patients.

### METHODS

Eight healthy participants (age =  $71 \pm 9$  yr.) with an SR (Scorpio™ PS, Stryker Orthopaedics Inc.) and an MR (S-7000™ PS, Stryker Orthopaedics, Inc. and P.F.C.™ PS, Johnson & Johnson, Inc.) on each side took part in this study. Three high-speed video cameras (120Hz) were used to track participants' motion. An EMG system (1080 Hz) and a force platform (1080 Hz) were used to monitor leg muscles' activation and ground reaction force (GRF), respectively. Participants performed four STS trials for each leg.

An inverse dynamic method [2] was used to calculate joint reaction forces (JRF), moments, and powers of ankle, knee, and hip joints. Horizontal and vertical impulses were calculated for the forward-thrust phase and extension phase of the STS. Normalized root-mean squared (RMS) EMG was used to quantify the contractions of quadriceps and hamstrings. Paired Student t-tests were used to determine the kinematic, kinetic, and EMG differences between the SR and the MR limbs ( $\alpha = 0.05$ ).

### RESULTS AND DISCUSSION

Compared to the MR limb, the SR limb exhibited greater: peak antero-posterior (AP) GRF; peak AP JRFs of the ankle and knee joints; and AP impulse during the forward-thrust phase (Table 1). However, the vastus lateralis (VL) RMS

EMG of the SR limb ( $1.185 \pm 0.508$ ) was less than the MR limb ( $1.354 \pm 0.031$ ).

Due to the greater peak AP GRF, the SR limb had greater peak AP JRFs in the ankle and knee joints compared to the MR limb. Greater AP GRF accounted for the greater AP impulse during the forward-thrust phase. During this phase, the trunk segment rotates around the hip joint so that the upper body mass can be shifted from the seat to the feet. The increased AP impulse associated with the SR limb might help produce trunk rotation by producing extra rotational momentum.

As the moment arm length for the quadriceps force acting on the tibia via the patella tendon is longer for the SR design than the MR designs used in this study [3, 4], we anticipated that the MR limb would produce more quadriceps activation during the STS. However, we only found a weak support for this notion. The increased VL activation seen in the MR limb might be due to the TKR design differences but could also be related to knee stability.

Surprisingly, we did not detect the significant differences between the limbs for the lower extremity joint moments. Likely it was due to small sample size and high inter-individual variability.

### CONCLUSIONS

Bilateral TKR patients with an SR and an MR on each side showed unique GRF differences and different VL muscle activation between the two limbs.

## AXIAL CYCLIC AND FAILURE LOADING OF PEDICLE SCREWS

Mike Ehlert, Serkan Inceoglu and Robert McLain  
Spine Research Laboratory, Spine Institute, The Cleveland Clinic Foundation  
e-mail: [inceogs@ccf.org](mailto:inceogs@ccf.org)

### INTRODUCTION

Screw loosening and pullout are common ways of fixation failure in clinic preventing fusion and causing pain. Standard pullout test is used to assess the mechanical behavior of the bone-screw interface. In the pullout test, the screws are placed in either synthetic or bone specimens and are withdrawn by applying an axial load at a constant rate. Although bone is known to be a viscoelastic material and thus produce a mechanical response to the loading depending on the application rate, it is still not clear if the bone-screw interface behaves similarly. Therefore, we designed this study to test the effects of loading rate on the mechanical performance of the pedicle screw in pullout.

### METHODS

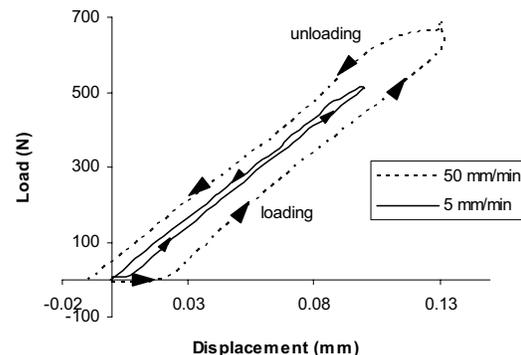

For this purpose, 20 conical pedicle screws (Xia, Stryker Spine, Allendale, NJ) with a size of 6.5x40mm were inserted into a foam material (Sawbones, Pacific Research Laboratories, Vashon, WA) with a density of 0.32 g/cc and axially cycled at four different rates, i.e., 0.1, 1, 5, 50 mm/min -and 1 mm/min again for diagnosis-, up to a pre-yield load (500 N) and pulled out. Then, another 40 of the same screws were inserted in foam blocks and immediately pulled out. The aforementioned loading rates were used for pullout tests, i.e., yielding 15 screws for each rate. Additionally, a lumbar bovine spine was cleaned of soft tissue and separated into vertebral levels (L1-5). Ten pedicle screws were inserted in 5 calf lumbar vertebrae according to the standard surgical technique. After instrumentation, the vertebral specimens were cut in half sagittally isolating each pedicle for testing. After embedding, one of each pair of screws in each calf specimen was pulled at a rate of either 0.1 or 50 mm/min after cycled axially at the rates of 0.1, 1, 5, 50 mm/min, sequentially, around a pre-yield load (500 N). All the testing was conducted using an MTS testing machine and custom adapters. The gripping fixtures were carefully adjusted so that there was no laxity in the system to allow cycling without losing the contact. Stiffness was calculated as the slope of the load-displacement curve in the interval of 50-450 N. The peak load was the highest load encountered during destructive testing.

### RESULTS AND DISCUSSION

The results showed that the strength and stiffness were significantly affected by the loading rate. The stiffness at 1 mm/min was higher than that at 0.1 mm/min ( $p<0.001$ ) and lower than that at 5 mm/min loading rate ( $p<0.001$ ). The stiffness significantly dropped at the 50 mm/min ( $p<0.05$ ) compared to the 5 mm/min in the foam group but it was still significantly higher than that at 0.1 mm/min ( $p<0.001$ ). In bone group, the stiffness at the 5 mm/min rate was higher than those at the 0.1 mm/min ( $p<0.05$ ) and 50 mm/min ( $p<0.05$ ) but not 1 mm/min ( $p>0.05$ ). The difference between the 0.1

mm/min and 50 mm/min loading rates was not significant ( $p>0.05$ ). The peak load at the 50 mm/min rate was significantly higher than other loading rates ( $p<0.01$ ) in the foam group except for the 1.0 mm/min ( $p>0.05$ ). The peak load at 50 mm/min was significantly higher than that at 0.1 mm/min in the bovine group ( $p<0.05$ ). The effects of loading rate on the hysteresis curves are shown in Figure 1.

The bone-screw interface usually exhibits completely different mechanical and viscoelastic behavior than bone alone. However, our results showed that the mechanics of the interface was significantly affected by the loading rate, as similarly to bone alone. The results also showed that the mechanical behavior of the foam-screw interface was similar to that of the bone-screw interface. However, the hysteresis behavior of the interface in the elastic region was surprisingly different from those of bone and foam and totally new to the current literature. The authors speculated that the data collected during the unloading phase of cycling could source from loading of different sites of the foam or bone threads and cause the load-displacement data to draw this unexpected curve. Further analysis needs to be conducted.

**Figure 1:** High loading rate caused increased hysteresis. The hysteresis behavior of the interface in pre-yield region was different than those seen in foam or bone. This unexpected trend of unloading curve might source from loading of other sites of the bone or foam threads.

### CONCLUSIONS

This study investigated the axial cyclic behavior of a bone-screw interface in pre-yield load level at different rates for the first time in the literature. The results showed that the loading rate significantly affected the strength and stiffness of the interface. This suggests that for a fair comparison between screw pullout tests in the literature, the pullout rate needs to be matched. In the future, these results should be confirmed for other screw designs. The stress-strain behavior of a bone thread also needs to be investigated in a greater detail.

## SHOULDER KINEMATICS DURING CLINICAL GLENOHUMERAL TESTS. DIFFERENCES BETWEEN NO-PLAYERS AND WATER POLO PLAYERS

<sup>1</sup> Catarina Tainha and <sup>2</sup> Augusto Gil Pascoal

<sup>1</sup>Health Superior School of Alcoitão, Estoril, PORTUGAL,

<sup>2</sup>Faculty of Human Kinetics, Lisbon, PORTUGAL; email: [catarina.tainha@netcabo.pt](mailto:catarina.tainha@netcabo.pt)

### INTRODUCTION

Water polo combines the skills of swimming and throwing. On both the shoulder movement is according a pattern that combines adduction and internal arm rotation, in an elevated arm position. This pattern cause retraction on the anterior glenohumeral structures (capsule-ligamentous and/or muscular) and is assumed to be one of the most important aetiology factor involve in water polo players shoulder injuries, as glenohumeral instability and shoulder impingement [1,2]. The identification of this anterior glenohumeral retraction is made by clinical tests that put the arm (passively or actively) on a maximal available external arm rotation or arm abduction position. The advantage of the active tests is that mostly the passive structures are stretching given that the anterior shoulder muscles are inhibit. The active test is a global arm movement that involves the glenohumeral joint and the shoulder girdle. However, diagnose is over a predisposed factor for shoulder injury on the glenohumeral joint, assuming the shoulder girdle as a stable platform. Thus, the purpose of this study was to identify the anterior glenohumeral retraction in water polo players and additionally to describe the shoulder girdle involvement during two glenohumeral active clinical tests: external rotation test and horizontal abduction test.

### METHODS

The dominant shoulders of a group of five female elite water polo players (age =  $20 \pm 2.1$ ) and a group of five no-players female subjects (age =  $21 \pm 2.3$ ) were tested during two glenohumeral active clinical tests: external rotation test and horizontal abduction test. The subjects were asking to move slowly the arm to a maximal position (external rotation or horizontal abduction), while the arm was artificially supported in an elevated position. Each subject performs three repetitions of each test. Shoulder rotations were recorded by mean of a six-degree-of-freedom electromagnetic tracking device (Flock of Bird System) and described as Euler angles with respect to the thorax local coordinate system, according to a standardization protocol [3]. A “scapulalocator” device, similar to Pascoal et al. [4], was used for recording scapular 3D position.

Differences between both group in humeral (arm elevation, axial rotation and horizontal abduction) and scapular rotations (protraction, latero-rotation and spinal tilt) were analyzed by mean of a *t*-test approach.

All statistical analysis was performed with SPSS (version 10) and the alpha-level set as 0.05.

### RESULTS AND DISCUSSION

The non-player group showed greater values of external rotation and horizontal abduction than the water polo players group. However, scapular rotations are greater in the water polo players group on both tests. All these differences are statistically significant with exception for scapular latero-rotation's angles. These results are in contradiction with those reported by other studies that showed larges active ranges of humeral lateral rotation in overhead sports players [5]. A possible explanation is that on the water polo the arm movement must be done without leg ground fixation. Thorax and scapula are not used as fixed points but as essential elements inside a kinetics chain that connects the hand to the trunk. On these conditions, humeral rotations are reduced and scapular rotations augmented. According with Ludewig & Cook [6] the excessive contribution of scapula during arm movement is a sign of shoulder impingement pathology, caused by the decreases in serratus anterior muscle activity and increases in upper trapezius muscle activity or to an imbalance of forces between the upper and lower parts of the trapezius muscle.

### CONCLUSIONS

During clinical active shoulder tests, water polo players showed reduced values of external and horizontal abduction rotations, when compared with no-players subjects. Inversely, scapular protraction and spinal tilt rotations are greater in water polo players. These results seem to be related with specific shoulder demand in water polo where the throwing arm is moving again a less fixed trunk. The increased scapular rotations during maximal active arm external and horizontal abduction rotations, observed in water polo players, could be a predispose factor for some shoulder pathologies as shoulder impingement.

## CAN THE PATELLAR TENDON MOMENT ARM LENGTH BE PREDICTED FROM ANTHROPOMETRIC CHARACTERISTICS?

Dimitrios Tsaopoulos, Constantinos N. Maganaris and Vasilios Baltzopoulos

Institute for Biophysical & Clinical Research into Human Movement, Manchester Metropolitan University, Alsager, U.K.

### INTRODUCTION

It has been suggested that muscle moment arms are related to anatomical differences and could be predicted from anthropometric characteristics [e.g. 1-2]. If moment arms can be predicted from easily measured anthropometric variables then analysis of muscle and joint forces could become significantly easier without the need for complicated imaging techniques. More recently, Krevolin et al. [3] reported that when the patellar tendon moment arm was normalized to femoral condyle width, it remained roughly constant across individuals, suggesting that prediction of patellar tendon moment arm length from relevant anatomical or anthropometric measurements would be possible.

The purpose of this study was to examine the relationship between patella tendon moment arm and relevant anthropometric characteristics.

### METHODS

Twenty-two males (age: 25.7±5.7 years) without any musculoskeletal injuries in the lower limbs volunteered to participate after the study was approved by the local Ethics Committee. The patella tendon moment arm was measured at rest with a 0.2 T MRI system (Esaote Medical, Italy) with the knee in full extension. The 3D MRI images (52 slices 1.7 mm apart) were analysed as follows to determine the patellar tendon moment arm. The contact points of the lateral and medial condyles were first determined as the midpoint of the shortest distance between the condyles and the tibial plateau. The specific sagittal plane slices in the medial and lateral side were chosen by examining the condyle-tibial plateau distances in the frontal plane slices. The knee contact point was calculated as the midpoint of the line connecting the medial and lateral condyle contact points. The sagittal slice corresponding to that point was used to measure the moment arm as the length of the perpendicular (shortest) line between the patella tendon and the knee contact point in the sagittal plane. In addition the following anthropometric measurements were taken: Height, mass, knee circumference, mediolateral (M-L) knee width, anteroposterior (A-P) knee width, femur (greater trochanter-tibial plateau) length, tibia (tibial plateau-malleolus) length and leg length (greater trochanter-malleolus) length. Pearson correlation coefficients and multiple regression were used to examine the relationships between the anthropometric measurements and the patellar tendon moment arm.

### RESULTS AND DISCUSSION

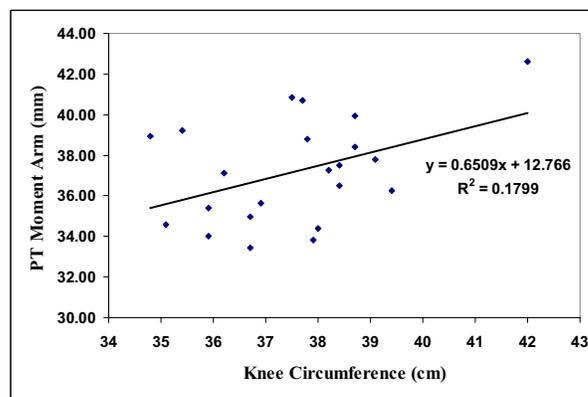

The Pearson correlation coefficients obtained ranged from -0.04 to 0.42 (Table 1). None of the correlations examined was statistically significant ( $P > 0.01$ ). The variable with the best correlation with the moment arm was knee circumference

( $r=0.49$ ,  $P < 0.05$ ) but the coefficient of determination  $R^2$  was only 0.179 (Figure 1) indicating that only about 18 % of the variance in PT moment arm can be explained by knee circumference.

**Table 1.** Descriptive statistics of the anthropometric parameters examined and correlation coefficients with patella tendon moment arm.

	Mean±sd	r	P
Height (cm)	181.90±7.98	0.31	0.076
Mass (kg)	79.19±7.56	0.40	0.036
Knee Circumference (cm)	37.52±1.66	0.42	0.024
Knee Width (M-L) (cm)	11.04±0.47	0.25	0.133
Knee Width (A-P) (cm)	12.66±0.54	0.21	0.166
Leg length (cm)	86.91±4.30	0.18	0.201
Femur Length (cm)	43.12±3.09	-0.04	0.419
Tibia Length (cm)	42.24±2.99	0.30	0.086

Multiple regression entering all the above anthropometric variables generated a slightly higher multiple correlation coefficient ( $R=0.52$ ) with the overall coefficient of determination  $R^2=0.27$ . These results indicate that the

**Figure 1:** Scatter plot and linear regression between Patellar Tendon (PT) moment arm and knee circumference.

anthropometric variables examined in this study cannot be used for accurate prediction of the patellar tendon moment arm.

## EFFECTS OF ISOMETRIC AND ISOKINETIC CONTRACTIONS ON THE PATELLAR TENDON MOMENT ARM

<sup>1</sup>Dimitrios Tsaopoulos, <sup>1</sup>Vasilios Baltzopoulos, <sup>1</sup>Costis Maganaris and <sup>2</sup>Paula Richards

<sup>1</sup>Institute for Biophysical & Clinical Research into Human Movement, Manchester Metropolitan University, Alsager, U.K.,

<sup>2</sup>North Staffordshire University Hospital & Keele University, U.K.; email: d.tsaopoulos@mmu.ac.uk

### INTRODUCTION

The purpose of this study was to examine the effects of contraction on knee joint mechanics and more specifically the effects of isometric and isokinetic contractions on the patellar tendon moment arm.

### METHODS

Three males (age  $27 \pm 6.93$  years, mass  $77 \pm 4.36$  kg, height  $1.76 \pm 0.05$  m) without any musculoskeletal injuries of the lower limbs volunteered to participate after signing informed consent and radiation risk information forms. The study was approved by the local Ethics Committee. The movements were performed on a CYBEX Norm fitted with an extended input arm, to allow an adequate gap (45 cm) between the chair and the main unit to accommodate the image intensifier of a GE FlexiView 8800 C-arm X-Ray system (Figure 1). The participants were positioned on the chair and were stabilised with the standard belts and thigh straps. The most prominent point of the femoral epicondyle on the lateral surface of the knee joint and a metal disc on a strip of Perspex glass that was rigidly attached to the chair were aligned with the dynamometer axis of rotation using a special laser pointing device.

Figure 1: Photograph of the experimental set-up.

The participants performed a passive and an isokinetic knee extension at 30 deg/s and an isometric knee extension at 20 deg of knee flexion. Moment and angular displacement data from the CYBEX were captured at 200 Hz and the movements were also recorded using a pulsed mode X-ray video at 25 frames/s. The patellar tendon (PT) moment arm was measured from the X-ray video based on the methods described before [1]. Distortion correction of the images was based on a thin-plate splines method [2].

### RESULTS AND DISCUSSION

There was an almost linear increase in the PT moment arm with intensity up to 75% MVC (Figure 2). The difference between moment arm values at rest and a given isometric contraction intensity was up to almost three times greater than

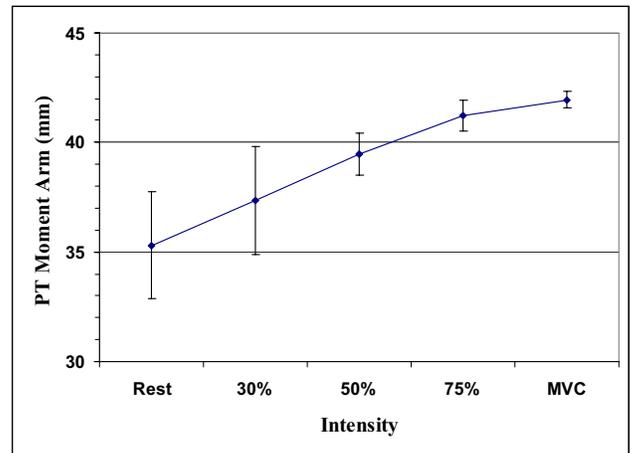

Figure 2: Patellar tendon moment arm (mean $\pm$ sd) at rest and at different intensities of isometric contraction.

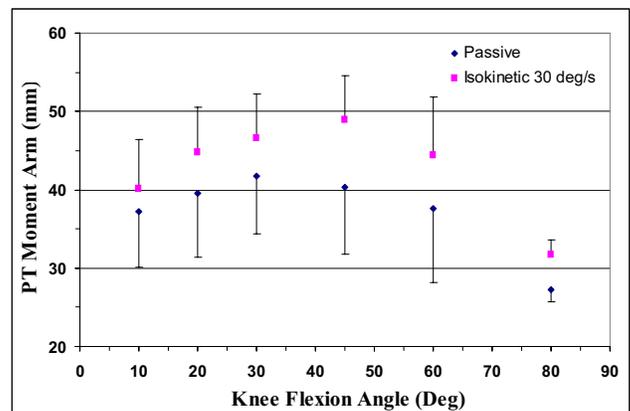

Figure 3: Patellar tendon moment arm (mean $\pm$ sd) in different knee flexion angles in passive conditions (relaxed) and during isokinetic 30 deg/s knee extension.

that shown in Figure 2 when accounting for changes in tibio-femoral joint angle induced by contraction. There was also an increase in the PT moment arm between the passive movement and the isokinetic knee extension (Figure 3). The maximum average difference was recorded at 45 deg of knee flexion (8.7 mm). These results show that there are significant changes in the knee joint dynamics with contraction. Estimation of PT and knee joint reaction forces, for example, from the joint moment using PT moment arm data at passive conditions from the literature will significantly overestimate muscle and knee joint forces.

## QUANTIFICATION OF ENERGY ABSORBED BY THE LOWER EXTREMITY DEPENDS ON ENDPOINT OF THE IMPACT PHASE

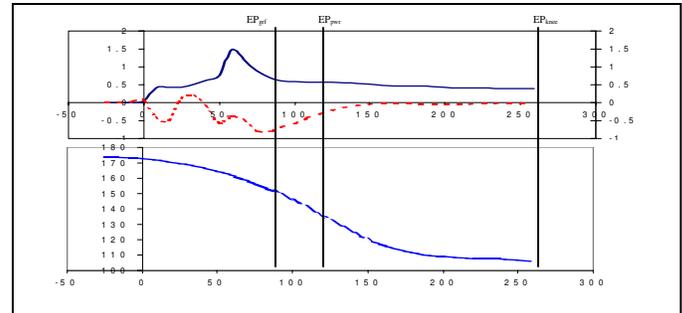

Saori Hanaki and Steven T. McCaw  
 Illinois State University, Normal, IL;  
 email: [shanaki@ilstu.edu](mailto:shanaki@ilstu.edu); web [www.cast.ilstu.edu/mccaw](http://www.cast.ilstu.edu/mccaw)

### INTRODUCTION

Landing is a complex task essential in physical activity. The lower extremity initially absorbs kinetic energy present at contact using eccentrically controlled hip and knee flexion and ankle dorsiflexion, momentarily stabilizes the body in a knee flexed position, and finally generates energy to extend the body into upright posture or a subsequent movement. The work performed by the eccentrically active muscles is estimated as the integral of the negative phase of the ankle, knee and hip joints mechanical power-time curves [1]. Several researchers have investigated the relative contribution of the leg joints to energy absorption during different landing techniques [2,3], and reported differences in relative joint contributions. However, the use of different end points to define the impact phase confounds comparison of the results. The purpose of this study was to compare the absolute and relative amounts of negative work performed at each joint using different methods to define the impact absorption phase.

### METHODS

Eighteen college age females, free of lower extremity trauma, volunteered as participants. In one session, 10 trials of landing from a 38 cm stool were performed; instructions were to “land comfortably.” Joint kinetics (JMF) were calculated [1] using inverse dynamics from synchronized video (120 Hz) and force platform (960 Hz) data beginning before contact to beyond maximum knee joint flexion; joint mechanical power (JMP) was calculated as  $JMF \cdot \omega$ . The JMP-time curves were integrated to calculate negative mechanical work beginning with first ground contact; three end points were used: 1) when the vertical GRF leveled out or reached a minimum [3] ( $EP_{grf}$ ), 2) when the lowest C of G was reached, or max knee flexion [2] ( $EP_{knee}$ ), and 3) when the negative power at the knee was equal to 20% of the maximum negative knee power ( $EP_{pwr}$ ), based on the observation that subsequent kinetics are more related to stabilization than energy absorption. Total work was calculated as the sum of the ankle, knee and hip works. Impact phase duration, absolute negative work and relative % work ( $Work_{joint} / Work_{total}$ ) was calculated for each of the three defined impact phases. The 10-trial mean values were entered into a repeated measure ANOVA ( $\alpha=.05$ ), with Bonferroni adjustment to the *post hoc*s.

**Figure 1.** Typical vertical GRF (top), knee power (middle), and knee position (bottom) curves.

### RESULTS AND DISCUSSION

Impact phase duration was significantly different among the techniques, shortest when defined by the GRF and longest when defined by max knee flexion (table 1). The total work and individual joint works also increased, but not significantly at the hip joint. Basically, the longer the impact phase, the greater the energy absorbed. However, for % total work, differences  $EP_{grf}$  differed from the other methods at the ankle and the knee, but not at the hip joint.  $EP_{pwr}$  and  $EP_{knee}$  did not differ for % total work at any joint. For  $EP_{grf}$ , the ankle and knee joints absorbed similar % total energy, but for both  $EP_{pwr}$  and  $EP_{knee}$  the knee absorbed significantly more energy than the ankle.

### CONCLUSIONS

The method of identifying the end of the impact absorption phase affects the total and joint work calculated. The hip joint is least affected by the definition used. Most importantly, since the % contribution of joints to total energy absorption is used as a reflection of neuromuscular strategies [2,3], the comparison of the conclusions on neuromuscular adaptations must consider the different definition used in the studies.

### INTRODUCTION

Prolonged high compressive sitting stress in the buttock soft tissue of wheelchair users increases the risk of pressure ulcer (PU). However, interface pressure is currently the only available clinical tool to assess sitting load. The objective of this study was to develop a 3D finite element (FE) model to investigate how the buttock-thigh soft tissue responds to external sitting load. It was expected that this FE model would be a powerful tool for better understanding of the biomechanical response of buttock tissue to sitting load.

### METHODS

A healthy subject was posed and loaded in a customer-designed apparatus at a simulated sitting posture. MRI scan was performed with two loading conditions: “No Load” and “Sitting Load”. Volumetric sagittal MR images of the right buttock-thigh were acquired in the two loading conditions.

The “No Load” image sequence was segmented to reconstruct the geometry for femur, pelvis, muscles, fat and skin. Based on the geometry, the FE mesh of the buttock-thigh was created with tetrahedral elements (Fig. 1). Neo-Hookean material was employed to model each soft tissue with published data.

**Figure 1:** FE model of the buttock-thigh.

The bones were assumed as fixed boundary. Since the simulation was focused on the sitting area, the upper plane was assumed to be fixed while the longitudinal ends of muscles and skin that connect the rests of thigh or buttock structures were constrained from longitudinal motion. The medial buttock plane was assumed to be constrained from the medial-lateral motion due to the symmetry of the buttocks. The measured interface pressure (157-160mmHg) was applied on the skin in the sitting area. The static FE analysis was performed using ABAQUS. The results were examined for three regions of the tissues in the sitting area that represented the soft tissues under IT, under femur, and with no bone above, respectively.

### RESULTS AND DISCUSSION

The results of the simulations showed that the internal compressive and shear stress distributions were substantially different among muscles, fat, and skin. The maximum

compressive stress occurred in the muscle under IT (Table 1), which is consistent with the experimental observation from other researchers [1]. The compressive stress in fat layer was distributed relatively uniform, while in muscle and skin layers, the soft tissue under bony prominences bore substantially higher internal compressive stress (Table 1). The maximum shear stress occurred within muscle under IT and skin under femur. The shear stress within muscle and skin were significantly higher than that in fat. This supports the conclusion that the shear stress may be one of factors to form PU’s in the skin by other researchers [2]. The study also showed that the soft tissues were deformed significantly and the deformation was not uniform among the soft-tissue layers of the sitting area: The maximum deformation involved the deep layer, i.e. muscular layer, which was consistent to the observation from the unloaded and loaded MRI images.

**Table 1: Comparison of the compressive and shear stress levels in deep soft tissues.**

Region	Layer	Compressive Stress (mmHg)		Shear Stress (mmHg)	
		Mean ± SD	Max	Mean ± SD	Max
Under IT	Muscle	316.9 ± 99.1	568.6	144.4 ± 28.2	205.3
	Fat	182.5 ± 7.1	200.8	20.7 ± 1.3	25.3
	Skin	280.4 ± 81.8	527.9	41.3 ± 13.5	67.3
Under Femur	Muscle	245.6 ± 81.8	458.7	96.7 ± 13.6	136.4
	Fat	189.1 ± 20.1	233.2	42.5 ± 7.5	56.5
	Skin	325.2 ± 91.8	486.9	159.4 ± 26.9	234.8
No Bone Above	Muscle	206.3 ± 22.5	262.9	96.9 ± 7.9	117.5
	Fat	183.3 ± 21.7	252.3	24.8 ± 4.3	38.6
	Skin	271.2 ± 58.9	419.4	75.8 ± 15.2	133.9

The study indicates that tissue necrosis may first occur in the deep buttock-thigh soft tissue of wheelchair users because the higher internal pressure would clog the vascular system and thus reduce or terminate the supply of blood. The high shear stress within the skin and muscle may contribute to the formation of PU’s in skin and muscle. The FE model will be further improved to predict the normal biomechanical response, the outcomes from potential interventions, and the interaction between the buttock-thigh and cushion.

## EFFECTS OF REPETITIVE WORK ON DISCOMFORT AND PERFORMANCE DURING COMPOSITE TASKS

Kathleen Shyhalla

Department of Industrial Engineering, University at Buffalo, email: [shyhalla@eng.buffalo.edu](mailto:shyhalla@eng.buffalo.edu)

### INTRODUCTION

Precision work has been associated with certain musculoskeletal disorders that develop when some muscle fibers do not rest. The level of task precision might impact the development of such disorders. During short tasks people moved a probe repetitively between a Home and precision target. The activation of the descending trapezius increased and the kinematics of the forearm and wrist changed with increased task precision (1).

Additional information about the impact of precision work on the extremities required understanding how and why movement patterns change during longer duration work. During a recent experiment participants performed repetitive tapping tasks for seven minutes. These tasks were preceded and followed by Composite Tasks where work was at three levels of precision. It was hypothesized that movement patterns would change after seven minutes of repetitive work and affect performance on subsequent tasks. People's performance on the Composite Tasks and their responses to discomfort surveys are described below.

### METHODS

During Main Tasks participants, who had been trained in all work administered, repetitively tapped with a probe, between a Home and a precision target for seven minutes. Main Tasks were in two layouts to elicit movements in either the scapular or sagittal planes. Targets of 48 mm, 19 mm, 10 mm, and 3.2 mm diameter created no, low, medium, and high precision conditions. Composite Tasks elicited movements in the same place as the intervening Main Task, and were performed before and after each Main Task. Composite Tasks required tapping between the Home and a ray of disks in a predefined sequence for 45 seconds. Two high precision, two medium precision, and two low precision disks were on the ray. Discomfort surveys were administered before the Main Task and after the later Composite Task. Breaks were provided after later Composite Tasks. Nine participants worked in the sagittal plane only, eleven worked in the scapular planes, and nine worked in both the scapular and sagittal planes.

### RESULTS AND DISCUSSION

Discomfort increased significantly during work on the Main Tasks ( $P = 0.027$ ). The level of precision during the Main Task significantly impacted discomfort ( $P < 0.001$ ), with high precision work leading to greater discomfort than other work. A statistically significant interaction between precision and Task Unit Number ( $P < 0.001$ ) occurred since discomfort ratings increased greatly with Task Unit Number after high precision work, whereas discomfort ratings after work at

lower levels of precision were not sensitive to Task Unit Number. The significant interaction reveals that high precision work exacerbated residual discomfort even after breaks. Errors, or the number of deviations from the predefined sequence, increased after work ( $P = 0.043$ ). Errors did not depend on precision ( $P = 0.712$ ) or Task Unit Number ( $P = .960$ ). The time to make Home to target movements declined significantly after repetitive work ( $P < 0.001$ ). The change in timing impacted Phase II ( $P < 0.001$ ), with these movements requiring 0.478 seconds after work whereas they required 0.517 seconds before work. The timing of Phase I movements were not significantly affected after work ( $P = 0.131$ ). Declines in the times to reach each disk in the Composite ray were similar ( $P = 0.973$ ). The Main Task's precision barely impacted the time necessary for Phase II movements ( $P = 0.103$ ). Post-hoc analysis revealed that Phase II movements were faster after low precision work than after high precision work, with times required after medium and no precision tasks were intermediate between those two.

Results show that changes to movement patterns occurred after repetitive work. The Phase II movement iteratively corrected for differences in the position of the probe and the target, and practice on this movement might have affected its timing. Practice on the proprioceptive Phase I might also have affected Phase II. If the spatial endpoint from the Phase I movement was repeatedly optimally located to reduce the need for corrective actions, the average Phase II time would have been shortened. Since Phase II movements were shortened by approximately 0.04 seconds for all target precision levels a common learning effect, not one sensitive to the target's precision, was impacting Phase II. Additional data, already collected, will provide more information about the development of Phase I and Phase II trajectories.

## THE ANALYSIS OF PRESSURE RESPONSE IN HEAD INJURY: A VALIDATION STUDY

<sup>1</sup>Johnson, E. A. C. and <sup>1,2</sup>Young, P. G.

<sup>1</sup>School of Engineering and Computer Science, University of Exeter, Exeter, UK Email: [e.a.c.johnson@ex.ac.uk](mailto:e.a.c.johnson@ex.ac.uk)

<sup>2</sup>Simpleware Ltd, Innovation Centre, Rennes Drive, Exeter, UK. Email: [p.young@simpleware.com](mailto:p.young@simpleware.com)

Web: [www.simpleware.com](http://www.simpleware.com)

### INTRODUCTION

The study of head injuries is of obvious importance with approximately 1 million head injury cases reported in the UK each year. 60% of all such injuries are caused by motor vehicle accidents but even a simple fall or blow to the head can result in serious damage. In the present study a new approach to generating physical and numerical models of the human head is presented. We aim to investigate whether it is possible to predict the response of the head for a particular impact scenario using these modelling techniques. Firstly, by predicting the global response characteristics of the head such as the duration of impact ( $T_p$ ) and secondly, by studying the pressure response of the intra-cranial tissues. An approximate analytical model based on full 3D elasticity equations was developed by one of the authors and implicit analytical expressions proposed to predict the response to blunt impact [1]. The model is based on significant geometric and material simplifications and so in order to test the validity of the assumptions on which the analytical model is based, experimental and numerical models were developed for comparison. The predictions from this model were validated using finite element (FE) and rapid prototyped (RP) models generated from MRI scans obtained *in vivo*. Both the numerical and physical models were generated from the conversion of 3D image data using an in-house software package, Scan FE/IP™.

### METHODS

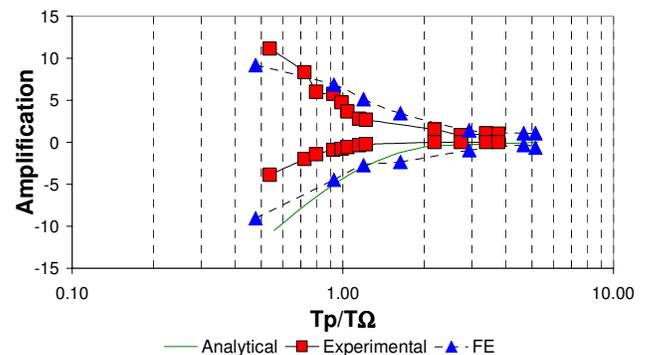

The analytical model, presents a blunt direct impact with a solid, elastic spherical shell of isotropic homogeneous linear elastic material properties and filled with an inviscid compressible fluid. Even for this simplified case the response is dependent on a number of material and geometric parameters including the shell thickness ( $h$ ), radius of curvature ( $R$ ), Young's Modulus ( $E$ ) and Poisson's Ratio ( $\nu$ ).

MRI scan data of an adult male was obtained and an STL file was created using an in-house software package, Scan IP™ [2]. The STL file was used to manufacture a 3D, patient specific, rapid prototyped (RP) model of the human skull using Duraform™ Polyamide, a material used typically for strong, functional applications. A 3D FE mesh of the skull and intra-cranial contents was also generated from the same MRI dataset, using the in-house software package ScanFE™. The FE model consisted of over 200,000 hexahedral and tetrahedral elements and a sliding contact surface was assumed at the brain-skull interface. The material properties for the RP material and a steel impactor were incorporated

into the model and LS-DYNA3D was used to perform the numerical solutions.

### RESULTS AND DISCUSSION

The authors have previously reported [3] on the excellent agreement between the three modelling modalities for the measurement of global response characteristics such as impact duration, acceleration and peak force. The emphasis of this current paper is, therefore, on the pressure response of the intracranial fluid. Impacts of low duration, for example, have often been associated with increasingly large pressure transients as illustrated in Figure 1 and carry significant implications for the occurrence of brain tissue damage.

**Figure 1.** Peak positive and negative pressure values as obtained using the three modelling methods

The remarkable conformity between the three modelling techniques is clear and corroborates the prediction of increasing pressure amplification at the site of impact, for impacts of low duration.

### CONCLUSIONS

In addition to the obvious significance in the area of head injury biomechanics, the study demonstrates how numerical and biofidelic physical models, can be generated from 3D medical imaging modalities and used effectively to simulate physical processes.

### INTRODUCTION

Most plantar foot ulcers in diabetic patients are caused by a combination of neuropathy and elevated plantar pressure and develop in the regions of forefoot and toes. Casting devices (i.e. Total Contact Cast or Mabal shoe) are commonly used for offloading these ulcers. Alternatively, in many diabetic foot centers where casting technicians are absent, prefabricated forefoot offloading shoes (FOS) are used for ulcer treatment. However, little is known about the biomechanical effectiveness of the FOS. Therefore, the purpose of this study was to assess the effectiveness of FOS in offloading the forefoot in diabetic patients with peripheral neuropathy.

### METHODS

Twenty-four diabetic patients (20 men, 4 women) with peripheral neuropathy participated. Mean (SD) age, height, and weight was 60.0 (7.0) years, 1.72 (0.07) m, and 92.0 (15.2) kg, respectively. Loss of protective sensation due to neuropathy was confirmed using a 10-grams monofilament. Four FOS were tested: the Thanner Cabrio ([www.thanner-gmbh.com](http://www.thanner-gmbh.com)), Rattenhuber Talus ([www.rattenhuber.de](http://www.rattenhuber.de)), Fior&Gentz Hannover, and Fior&Gentz Luneburg ([www.fior-gentz.de](http://www.fior-gentz.de)), together with a Pulman shoe ([www.fld.fr](http://www.fld.fr)) used as control condition. The Mabal fiberglass cast shoe was also added for comparison [1].

Patients walked at their own preferred speed across a 18-m walkway wearing the test shoe on the right foot and their own shoe on the left foot. Shoes were randomly assigned to each patient. In-shoe plantar pressure was measured using the Pedar system (Novel, Germany). A minimum of 20 steps in 3 trials were collected. Walking speed was measured using a stopwatch. Peak pressure, pressure-time integral (PTI), and force-time integral (FTI) were calculated for 6 different anatomical foot regions: heel, midfoot, MTH1, MTH2-5, hallux, and lesser toes. Comfort of walking was assessed on a scale from 0 (very uneasy) to 10 (very easy). ANOVA was used for statistical comparisons between the shoes ( $P < 0.05$ ).

### RESULTS

Walking speed varied from 1.99 m/s in the F&G Luneburg to 2.07 m/s in the control shoe and was not significantly different between shoe conditions. At the MTH regions, peak pressure and PTI were significantly reduced (by 38-58%) in all FOS and the Mabal cast shoe when compared with the control shoe (Table 1) ( $P < 0.001$ ). Loading (FTI) of the heel was similar between shoe conditions, but midfoot FTI was substantially increased in the FOS when compared with the control shoe (up to 162% in the F&G Luneburg). Walking comfort varied substantially between conditions with the control shoe being the most comfortable and the F&G Luneburg the least comfortable shoe (Table 1).

### DISCUSSION

All four FOS were equally effective in offloading the forefoot of the neuropathic diabetic patients, with only minor differences between the shoes. The action of the FOS to transfer pressure from the forefoot to proximal regions was clearly illustrated by the substantially increased midfoot loads when compared with the control shoe. Compared with the Mabal cast shoe, which has been shown to be effective in healing relatively small neuropathic plantar ulcers [1], the FOS reduced MTH peak pressure to a greater extent. Although we do not know how much offloading is required to heal ulcers, these data suggest that the FOS may be effective for this purpose. We are currently studying the efficacy in healing neuropathic plantar forefoot ulcers using the FOS. Due to its low perceived comfort of walking, the Fior&Gentz Luneburg should not be used as therapeutic shoe for diabetic patients.

## POWERING THE KNEED PASSIVE WALKER WITH BIARTICULAR SPRINGS

<sup>1</sup> Jesse C. Dean and <sup>2</sup> Arthur D. Kuo

University of Michigan, Ann Arbor, MI. E-mail: jcdean@umich.edu

### INTRODUCTION

Passive dynamic walking can be powered by push-off impulses applied along the trailing leg. This form of powering is possible in both straight-legged models [3, 4] and following the addition of knees [1]. In the kneed model, the addition of torsional springs at the hip and knee—as an analogue for muscular torque generation—allows for a wider range of stable gaits. These springs also can reduce energetic losses associated with redirecting the body center of mass during step-to-step transitions [3]. The hip spring helps to generate human-like step frequencies, and the knee spring facilitates proper knee lock timing. Here we show that similar effects can be achieved with a single biarticular spring crossing the hip and knee joints of the swing leg. The spring produces forces similar in phase to those expected from the biarticular muscle activity seen in humans. It appears to be theoretically advantageous to produce higher torques about the hip than the knee, because a human-like gait can be achieved with the lowest spring forces.

### METHODS

While torsional springs can be used to model the torques produced about the joints, the human leg also has biarticular muscles which cross both the hip and knee joints. Of particular interest in gait are the rectus femoris, which can produce hip flexion and knee extension, and the long head of the biceps femoris, which generates hip extension and knee flexion. Biarticular springs with attachments above the hip and below the knee can model the action of these two muscles. We used dynamical simulations to determine the effect of a biarticular spring on the kinematics, energetic costs, and stability of the kneed walking model.

**Figure 1.** Side view of the walking model. The stance leg is actuated by an impulsive push applied along the leg prior to heel strike, and the joints are actuated by biarticular springs on the anterior and posterior sides of the swing leg. Stance, swing thigh, and swing shank angles are measured counter-clockwise with respect to vertical.

Our planar kneed walking model was similar to McGeer's [4], consisting of four segments with anthropometrically distributed mass, and curved feet offset forward from the legs (Fig 1). Hyperextension of each knee was prevented by a passive mechanical stop. We added a push-off impulse applied at the ground contact point of the stance leg and directed toward the hip, and a variable stiffness spring with one attachment point directly above the hip, and the other on the shank below the knee. The moment arms about the hip and the knee, as controlled by the attachment points, were variable. The model was made non-dimensional by normalizing by body mass ( $M$ ), leg length ( $L$ ), and gravity ( $g$ ).

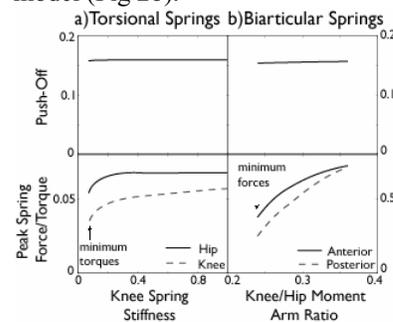

The periodic gait was powered solely by push-off. During a gait cycle, knee lock and heel strike, modeled as impulsive inelastic collisions, produced instantaneous changes in segment speeds with accompanying energy losses.

### RESULTS AND DISCUSSION

As found in the model with torsional springs, step length was predominantly governed by push-off impulse. Step frequency was controlled by the biarticular spring stiffness and the moment arm about the hip. At higher speeds, a minimum spring stiffness is required for stability, and to generate high step frequencies. For a given spring stiffness and hip moment arm, there is a minimum knee moment arm required to ensure that knee lock occurs before foot touchdown.

The configuration of the biarticular spring on the swing leg causes hip flexion and knee extension torques early in the swing phase, and hip extension and knee flexion torques late. This pattern is similar to the torques expected from rectus femoris and biceps femoris muscle activity [2].

Stable gaits at the preferred human speed and step frequency (1.2 m/s, 1.8 Hz) can be generated by appropriate choice of parameters. Push-off is approximately constant across the possible range, but the peak forces or torques produced by the springs, representing muscular forces, can be minimized by producing more torque about the hip than the knee. This may be accomplished by choosing a weak spring about the knee in the torsional spring model (Fig 2a), or springs with a smaller moment arm about the knee than the hip in the biarticular model (Fig 2b).

**Figure 2.** Human-like gaits can be generated using (a) torsional or (b) biarticular springs. In both models, spring forces or torques are minimized by generating less torque across the knee than the hip.

## LOCATING FATIGUE MICROCRACKS OCCURRING IN CEMENTED TOTAL HIP ARTHROPLASTY

Jihui Li<sup>1</sup> and Gang Qi<sup>1,2</sup>

<sup>1</sup>Dept. of Biomedical Engineering, <sup>2</sup>Dept. of Mechanical Engineering, The University of Memphis, Memphis, TN 38152  
E-mail: [jihui@memphis.edu](mailto:jihui@memphis.edu) Web: [http://www.me.memphis.edu/mar\\_lab/mar\\_lab/home.htm](http://www.me.memphis.edu/mar_lab/mar_lab/home.htm)

### INTRODUCTION

Accumulation of fatigue microcracks (MCs) has been reported as a major cause of the loosening of cemented total hip arthroplasty (THA). Although experimental models were developed to locate MCs in the cement layer [1-2], they were often limited to certain cross-sections and loading cycles. Acoustic emission (AE) is a non-destructive technique that is capable of locating a MC when its signals are received by four or more AE sensors, but the traditional AE algorithm using an iterative approach worked poorly when applied to THA specimen that had multiple layers of materials [3]. The purposes of this work were to: 1) investigate the drawbacks of the traditional algorithm and improve it accordingly; and 2) examine the error level of calculated locations of fatigue MCs.

### METHODS

A cemented THA specimen was prepared for this study using Spectron stem, Palacos R cement and Sawbone femurs. 8 AE sensors were attached on the specimen's surface to monitor the MCs. Theoretically, parameters involved in MC location calculation included: receiving time and velocity of the AE signals, and the sensors spatial coordinates. There were three layers of materials in THA specimen, AE signals reflected and/or refracted a number of times at the interfaces before being received by sensors. Inhomogeneity and anisotropy of cement and bone complicated the signal propagation as well. As a result, the velocity was frequently delayed (receiving time was linear correlated to velocity and ignored in analysis). The delay induced significant errors in MC locations when using the traditional algorithm, in which velocity was an estimated constant assigned to all signals. In the improved algorithm, velocity was set as a variable that could be adjusted based on the magnitude of the residual of the signal's receiving time. The improved algorithm was first verified using artificial MCs (pencil lead break, PLB) generated on the THA surface. Then it was used to locate fatigue MCs. The area that the most MCs cumulated was sectioned and inspected using SEM. Location error was evaluated by overlaying the calculated MCs to the observed MCs.

### RESULTS AND DISCUSSION

The improved algorithm reduced location errors of artificial MCs from 7.1 mm (using the traditional algorithm) to 4.2 mm. Most calculated fatigue MCs located in the proximal THA, whereas many of them were out of THA when computed by the traditional algorithm (Fig. 1). Six short discontinuities were observed along the stem-cement interface on Section A, adjacent to most calculated MCs (Fig. 2). When comparing the locations of these two sets of MCs overlaid on the same section image, the average error in X direction was 3.3 mm and 1.7 mm in Y direction. Considering the overlay could induce an average error of 3 mm (generally less than this), the total absolute error in X-Y plane was 4.77 mm. Error in Z

direction was unavailable because the information was limited to only one section.

It was found that the range of adjustment on velocity was different among sensors. Generally the range was small for sensors that were close to the MC, and large for sensors far away from the MC. The range was small in artificial MCs (high strength) and large in fatigue MCs. This indicated that the delay of velocity was influenced by material distribution, signal strength and travel path (related to signal attenuation).

### CONCLUSIONS

This study found that, in the traditional AE location algorithm, the major reason for inaccurate MC locations was the delay of signal velocity. The algorithm was improved by adjusting the value of velocity in computation. The new algorithm improved the accuracy of MC location significantly and achieved an average error of 4.77 mm in the X-Y plane.

## OPTIMAL CONTROL SIMULATIONS DEMONSTRATE HOW USING HALTERES (HAND-HELD WEIGHTS) CAN INCREASE STANDING LONG JUMP PERFORMANCE

Blake M. Ashby

Department of Mechanical Engineering, The University of Texas at Austin

email: [blake.ashby@stanfordalumni.org](mailto:blake.ashby@stanfordalumni.org)

### INTRODUCTION

Swinging the arms during the standing long jump has been shown to increase distance performance [1,2]. Studies have also suggested that using halteres (hand-held weights) as the ancient Greek Olympians did can further improve jump distance by at least 17 cm [3]. Since the combined body and halteres system must follow a parabolic trajectory during flight, throwing the halteres backwards just before landing could further enhance performance by thrusting the body forwards [3].

The present study used optimal control simulations of the standing long jump to assess if performance is improved by using halteres, and if so, how the performance increase is achieved. In addition, simulations were performed to determine how the size of the halteres influences jump distance and if further performance gains can be achieved by releasing the halteres before landing.

### METHODS

The take-off and flight phases of the standing long jump were simulated using a 2-D seven segment (foot, shank, thigh, head-neck-trunk, upper arm, forearm, halteres) link model of the human body [2] (Figure 1). The ankle, knee, hip, shoulder, and elbow joints were modeled as revolute joints and were actuated by individual joint torques. The magnitude of torque generated by the joint actuators was governed by the activation, joint angle, and joint angular velocity [2].

The optimal activations that would maximize jump distance were found using a simulated annealing algorithm. Optimal solutions were determined for three types of jumps: i) jumping without halteres, ii) jumping with halteres (different total masses of 4, 6, 8, 10, and 12 kg) without releasing them during the flight, and iii) jumping with halteres with the option of releasing them during flight to improve jump distance.

### RESULTS AND DISCUSSION

Using halteres during the standing long jump improved performance by much more than the 17 cm suggested by Minetti and Ardigó [3]. The jump distance for the nominal simulation (no halteres used) was 2.35 m (Table 1). Performance improved for all the different masses, but was greatest for the simulations using the 8 kg halteres. For the case in which releasing the halteres before landing was not allowed, the simulated jump distance was 2.74 m, an improvement of 39 cm.

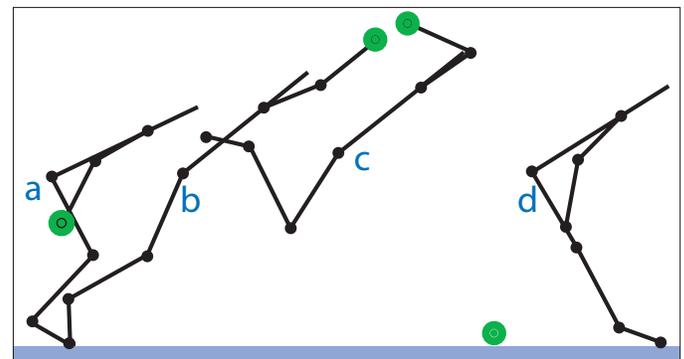

Analysis of the simulation mechanics showed that 12 cm of this 39 cm improvement was due to the greater horizontal position of the center of gravity at take-off due to extending

the halteres ahead of the body. The remaining 27 cm of improvement was due to the 22% greater velocity of the center of gravity at take-off. This greater velocity was primarily due to the increased kinetic energy (292 J) (obtained by swinging the arms back and forth before take-off [3]) and potential energy (45 J) of the halteres at the beginning of the simulation. However, some of the improvement in the take-off velocity for the jump with halteres can be explained by the additional 45 J of work performed by the joint actuators during the propulsive phase.

**Table 1:** Jump distances for the three types of jumps.

Type of jump	Jump distance
i) jump without halteres	2.35 m
ii) jump with 8 kg halteres without release	2.74 m
iii) jump with 8 kg halteres with release	2.89 m

Releasing the halteres during flight increased the jump performance an additional 15 cm, for a total jump distance of 2.89 m. However, optimal performance was not obtained by releasing the halteres just before landing as previously suggested [3]. The optimal time to release the halteres was about 0.18 s after take-off when the arms were extended above the head near the top of the jump (Figure 1). Releasing the halteres just before landing only resulted in an improvement of about 1 cm relative to not releasing them.

**Figure 1:** Body configurations at the starting point (a), take-off (b), the point where the halteres are released (c), and landing (d) for the simulated jump with 8 kg halteres.

### INTRODUCTION

Aggressive inline skating, or trick skating, is a relatively new sport. Previous studies of aggressive skating have only examined epidemiological data of skate park injuries [1]. This novel biomechanical study of aggressive skating focused on the “stall”, a basic balance training activity where the skater repeatedly jumps on an elevated surface (concrete bench edge, metal hand rail, or specially designed skate park “grind” rail). We were interested in understanding how skaters are able to successfully land and maintain balance over such a narrow base of support. Specifically, we examined sagittal-plane biomechanics of the lower extremities to see how impact force, skater experience, and joint behaviors (maximum flexion, net eccentric/concentric contraction and work) were related. We hypothesized that, to smoothly decelerate the body and minimize impact forces, this exercise emphasizes development of muscle control through eccentric contractions of the lower extremity joints. We also hypothesized that more experienced skaters would minimize impact force.

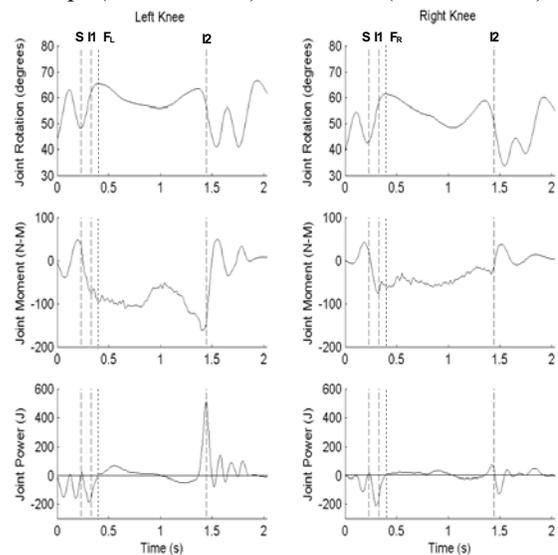

### METHODS

Ten male skaters ( $21.8 \pm 8.5$  years,  $179.0 \pm 6.5$  cm,  $78.3 \pm 8.0$  kg) performed 10 stalls each. Each subject was instructed to jump onto a grind rail, maintain balance (1-3 s), and jump down. No constraints were placed on landing and balancing techniques, allowing the skater to maintain his unique style of performance. A simply-supported, steel grind rail (5 cm diameter pipe, 178 cm length x 26 cm height) was constructed to sustain no moments at the supporting ends. Load cell data (MTS Systems, Minneapolis, MN; 1000Hz sampling rate) from each end were used to compute vertical impact force (% body weight). Joint flexion at the ankles, knees and hips were determined from kinematic data collected with a 6-camera motion capture system (VICON 460, Oxford, UK; 100 Hz sampling rate). The landing phase was defined as the period between initial contact with the rail (S) and point of greatest flexion of the joint ( $F_i$ , where  $i = L$  or  $R$ ) (e.g., Figure 1 for knee). For each joint, maximum flexion during the landing phase was defined as the magnitude difference in flexion between S and  $F_i$ ; similarly, eccentric work during the landing phase was defined as the area under the negative power curve between S and  $F_i$ . Finally, the parameters, maximum joint flexion and eccentric work, were computed from the average of the right and left values. To test our hypotheses, correlation analyses assessed whether peak impact force associated with skater experience or maximum joint flexion.

### RESULTS AND DISCUSSION

Peak impact force was found to significantly decrease as skater experience increased ( $r = -0.842$ ,  $p = 0.002$ ). Less-experienced skaters were not capable of reducing impact force while successfully landing and maintaining balance. Peak

impact force was also found to significantly decrease with increasing knee flexion for six of ten subjects ( $p \leq 0.041$ ). Three of four subjects with no correlation had the least amount of experience. The remaining experienced skater displayed a significant correlation between decreasing peak impact force and increasing ankle flexion. No significant correlation was found between hip flexion and peak impact force for any subject. During the landing phase, skaters utilized eccentric contraction of all lower extremity joints in order to decelerate the body and absorb energy. Of the three lower extremity joints, the knees performed on average the most eccentric work during the landing phase ( $50.6 \pm 12.0\%$  (SD)), followed by the hips ( $30.1 \pm 13.5\%$ ) and ankles ( $20.5 \pm 12.9\%$ ).

**Figure 1:** Typical profiles for left and right knee. Vertical lines identify instants of initial rail contact (S), first peak impact force -- used in correlation analyses (I1), greatest joint flexion (F), and second peak impact force (I2). Flexion angle, flexor moments, and concentric contraction are defined as positive.

### CONCLUSIONS

Increasing knee flexion (or net eccentric contraction of the thigh muscles) immediately after contact with the rail and throughout the landing phase was extremely effective in reducing peak impact forces. Subjects who did possess a joint flexion correlation with peak impact force had significantly more experience than those who did not. Less-experienced skaters may be more concerned about maintaining balance, rather than refining their technique to (subconsciously) minimize impact force.

## MODELING EXTRINSIC FINGER FLEXOR TENDON KINEMATICS

Jeremy P.M. Mogk, MSc and Peter J. Keir, PhD

School of Kinesiology & Health Science, York University, Toronto, Ontario, Canada

email: pjkeir@yorku.ca

### INTRODUCTION

Trauma to the tendons and nerves of the hand and wrist has been attributed to chronic tissue stress experienced during their interactions with surrounding osseous and soft tissues. Biomechanical modelling has become a common non-invasive method to estimate tissue and joint forces. While a number of models of the hand and wrist exist, recent evidence suggests improved joint kinematics are needed to increase the accuracy of predicted force transmission [1]. Tendon excursion for the same finger motion has been shown to vary depending on wrist posture using both an analytical model [2] and in canine limbs *in vivo* [3]. In addition to excursion itself, the effects of tendon motion also require investigation, as movement of the tendons relative to each other, as well as bone surfaces, likely alter tissue loading (tensile, compressive and shearing forces). The purpose of this study was to develop a model of finger flexor tendon motion that incorporates the interactions between the tendons and their surrounding tissues during finger motion.

### METHODS

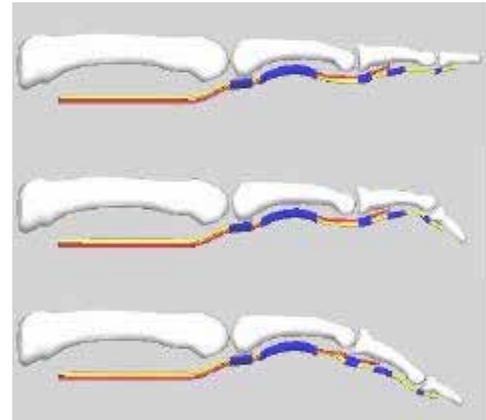

A three-dimensional dynamic model of the hand was developed using Maya™ v5.0 software (Alias®, Toronto, Canada). Each of the fingers was constructed as a series of four rigid body segments, sculpted to represent the metacarpal and phalangeal bone surfaces (Figure 1). A coordinate system positioned at each of the MCP, PIP and DIP joint centres defined locations and orientations of the tendons and bone segments, and defined joint posture. Scalable relationships were used to determine segment lengths, joint centre locations, and tendon centre locations of the flexor digitorum profundus and superficialis muscles proximal and distal to each finger joint space [4,5]. The annular pulley system of each finger was modelled as a series of modified rigid body cylinders attached to the palmar surface of each phalanx, to constrain palmar and mediolateral displacement of the flexor tendons. In order to utilize the mechanics of solid materials inherent in the software, each tendon was defined as a string of rigid body spheres, affixed to one another via pin joints. Tendon excursion and resultant joint motions were dependent on the interactions between the spheres, as well as with the pulleys surfaces. Initial testing focused on tendon excursion and changes in moment arm magnitude during isolated joint movements in the flexion-extension plane, allowing results to be compared to those found in the literature. For this communication, analyses were limited to the deep (FDP) and superficial (FDS) flexors of the index finger.

### RESULTS AND DISCUSSION

While model development and testing are ongoing, this study represents one step in the development of a biomechanical model of the hand and wrist. Flexor tendon excursions for the index finger are in agreement with those in the literature with greater FDS than FDP excursion during MCP flexion [4]. DIP flexion of 90° resulted in 6.7 mm of FDP excursion. In addition, the physical interactions between the tendons

resulted in slight FDS movement when tension was applied to the FDP tendon (1-2 mm depending on condition). And, with tension applied to both FDS and FDP, concurrent flexion of all three finger joints resulted.

While the hand and wrist model is still in its relatively early stages, the benefits are readily visible. This method enables tendon thickness and natural restraints created by the bone, tendon and pulley surfaces to predict tissue interactions and force transmission. In the future, the shape and cross-sectional area of each tendon can be incorporated from existing MRI data to improve the anatomic fidelity. By incorporating tendon excursion and changes in moment arm lengths into our existing model of the carpal tunnel [6], a more realistic and complete understanding of three-dimensional tendon movement through the carpal tunnel will result. This will enable investigation of soft tissue interactions within the carpal tunnel, including median nerve compression. A model that includes differential tendon excursion and interaction, with the potential to add frictional effects, is an important step in understanding injuries at the wrist, such as carpal tunnel syndrome and tenosynovitis.

**Figure 1.** Excursions were measured from the straight finger (top) and included DIP (middle) and PIP (bottom) joint flexion.

## FATIGUE EFFECTS ON BAR KINEMATICS DURING THE BENCH PRESS

<sup>1</sup>Michael J Duffey and <sup>2</sup>John H Challis

<sup>1</sup>Department of Physical Education, The United States Military Academy, West Point, NY

<sup>2</sup>Biomechanics Laboratory, The Pennsylvania State University, USA

email: [mike.duffey@usma.edu](mailto:mike.duffey@usma.edu), [jhc10@psu.edu](mailto:jhc10@psu.edu)

### INTRODUCTION

The kinematic patterns of the bar during a single lift bench press have been reported [1], however, there is no report of how bar movement changes as a subject performs multiple repetitions to failure. Multiple repetitions of an exercise are often used to train for a single exertion for example in powerlifting, or as means of training a particular muscle group. If the kinematics of the task change with increasing number of repetitions the specificity of the training must be questioned, as can its training effect on a particular muscle group. The purpose of this investigation was to examine the effects of fatigue on the movement of the bar during a free weight bench press.

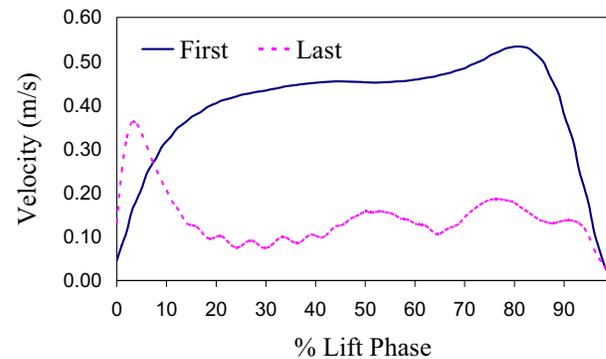

### METHODS

Eighteen male and female subjects were recruited after completion of a college level introductory weight training course. They had a range of maximal bench presses from 52 to 166% of body weight. All subjects were considered experienced recreational lifters. Maximal single repetition bench press load (1-RM) was determined, and then subjects were asked to perform as many repetitions as possible at 75% of 1-RM load. A Pro-Reflex motion analysis system was used to determine bar path during each trial. Subsequent processing of these data provided bar velocity, and the timings of key kinematic events. For each repetition the start of lowering was considered 0% of movement time, and the end of raising the bar 100% of movement time. Repeated measures ANOVA was used to compare across various metrics of bar path and trajectory across repetitions. Alpha was set at  $p \leq 0.05$ .

### RESULTS AND DISCUSSION

Subjects were able to complete between 4 and 16 repetitions with 75% of their 1-RM load. All data are presented as the group mean and standard deviation for the first and last repetitions. The time to lower the bar ( $1.43 \pm 0.54$  s) and the distance the bar traveled in each lift ( $0.33 \pm 0.04$  m) remained nearly constant throughout the trials.

As the subjects progressed from their first to last repetition, several changes were observed. The time to lift the bar increased from  $1.08 \pm 0.26$  s to  $2.38 \pm 0.66$  s ( $p < 0.01$ ), which accompanied a decrease in average vertical velocity from  $0.33 \pm 0.07$  m.s<sup>-1</sup> to  $0.15 \pm 0.04$  m.s<sup>-1</sup> ( $p < 0.01$ ) and a decrease in peak vertical velocity from  $0.46 \pm 0.11$  m.s<sup>-1</sup> to  $0.25 \pm 0.08$  m.s<sup>-1</sup> ( $p < 0.01$ ). Most notably, the timing of the peak vertical velocity changed from occurring late in the lift phase ( $65 \pm 15\%$  of upward lift phase) to very early in the lift phase ( $18 \pm 21\%$  lift phase,  $p < 0.01$ ). This pattern change is illustrated in Figure 1.

**Figure 1:** Bar vertical velocity for the lift phase of the first and last repetitions of a representative subject.

In the horizontal plane, subjects kept the bar more directly over the shoulder as the number of repetitions increased. The mean horizontal distance between the bar and the shoulder decreased from  $0.108 \pm 0.025$  m to  $0.073 \pm 0.039$  m ( $p < 0.01$ ) but change in maximal horizontal deviation of the bar from the shoulder was not found to be significant  $0.142 \pm 0.0027$  m to  $0.131 \pm 0.030$  m ( $p = 0.075$ ).

### CONCLUSIONS

This study has demonstrated differences in bar path and trajectory over a set of free weight bench presses. These results have implications of the training effect of multiple repetitions of this exercise. The pattern of keeping the bar more directly over the shoulder during the later repetitions is believed to be a strategy to reduce the moment produced by the weight of the bar about the shoulder, as suggested by Madsen and McLaughlin [1]. Their study, however, looked at differences in single, maximal lifts between world and national caliber lifters. They found that the strongest lifters kept the bar closer to the shoulder. It is unclear why lifters would not use this strategy throughout all of the repetitions, unless the strategy used by the lifters is in some way distributing fatigue across the available muscles.

### THREE-DIMENSIONAL BONE KINEMATICS IN AN ANTERIOR DRAWER TEST OF THE ANKLE JOINT

<sup>1</sup> Leendert Blankevoort, <sup>1</sup>Gino M.M.J. Kerkhoffs and <sup>2</sup>Idsart Kingma

Institute of Fundamental and Clinical Human Movement Sciences (IFKB);

<sup>1</sup>Orthotrauma Research Center Amsterdam, Academic Medical Center, Amsterdam;

<sup>2</sup>Faculty of Human Movement Science, Free University, Amsterdam; email: [orca@amc.uva.nl](mailto:orca@amc.uva.nl)

#### INTRODUCTION

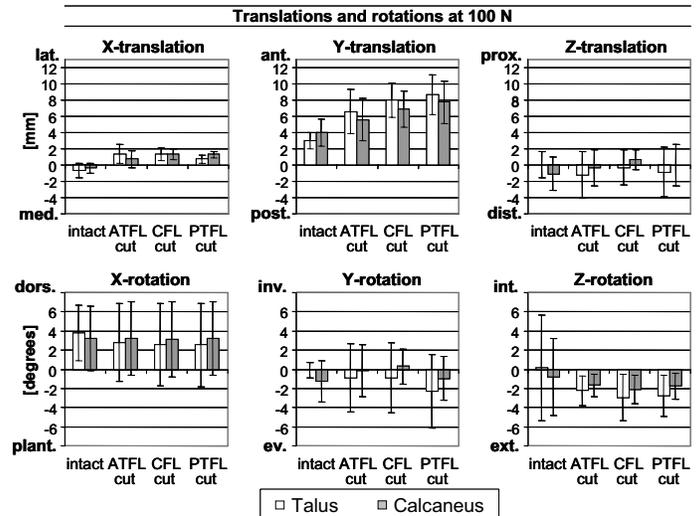

For evaluating the function of the anterolateral ligaments in the ankle joint an anterior drawer test can be performed [1]. The heel is forced forward relative to the shank. The anterior displacement of the calcaneus relative to the tibia is a measure for the anterior laxity of the ankle joint, which actually should represent the displacement between the talus and tibia. The assumption is that the calcaneus moves with the talus for the intact ligaments as well as for the ruptured ligaments [2]. The motions between the talus and calcaneus may affect the measurement in a newly designed instrumented tester. This study addressed the question to what extent the talus and calcaneus move as one in a test that is aimed at quantifying anterior ankle joint laxity.

#### METHODS

Five fresh-frozen cadaveric tibia-foot specimens were used. Simultaneous measurements were made with an instrumented anterior ankle laxity tester and a three-dimensional kinematic analysis system (Optotrak). Tracking LEDs were fixated to tibia, fibula, talus and calcaneus. From the continuous motion data, the three-dimensional translations and rotations of those bones were determined for anterior drawer forces up to maximally 150 N. The translations were calculated for a point at the center of the talocrural joint as marked after finalization of the drawer experiments. This point moved either with the talus or with the calcaneus. The drawer test was repeated after sequential cutting of the anterior talofibular ligament (ATFL), the calcaneofibular ligament (CFL) and the posterior talofibular ligament (PTFL).

#### RESULTS AND DISCUSSION

In one specimen, a luxation of the ankle joint was observed. This specimen was excluded from further analyses. For the remaining four specimens, the major motion was an anterior translation. The other translations and rotations were small and variable as illustrated by the data at 100 N anterior force (Figure 2). The anterior translation of talus and calcaneus showed a significant increase with increasing ligament damage and with increasing loads (ANOVA;  $p < 0.05$ ). On average, the motion differences between the talus and calcaneus were small, i.e. less than 1.5 mm and 2 degrees at 100 N (Figure 2). Surprisingly, the effect of cutting the ATFL was greater for the talus anterior translation than for the calcaneus anterior translation due to the altered kinematics in the subtalar joint after ligament cutting. In all 4 joints the motion coupling was mainly affected after cutting the ATFL.

**Figure 1:** The translations and rotations at 100 N (average +/- s.d.) of the intact specimens (N=4) and after sequential cutting of the ATFL, CFL and PTFL. The translations are calculated for a point in the center of the talocrural joint that moves with the talus and for the same point that is virtually attached to the calcaneus and moves with the calcaneus. The motion data are calculated relative to the translation- or rotation readings at 0 N. Explanation of the abbreviations: lat. = lateral; med. = medial; ant. = anterior; post. = posterior; prox. = proximal; dist. = distal; dors. = dorsal; plant. = plantar; inv. = inversion; ev. = eversion; int. = internal; ext. = external.

#### CONCLUSIONS

If testing the anterior drawer of the ankle joint by evaluating the motions between the calcaneus and the tibia, then the actual translation measurement is affected by the motions between the calcaneus and the talus. This effect is small relative to the measured anterior translation. The motion coupling between the calcaneus and the talus is changed after sectioning the anterior talofibular ligament.

## GAIT PATTERNS OF CHILDREN WITH HYPOTONIA

<sup>1</sup> Victoria Chester, <sup>2</sup>Maureen Tingley and <sup>3</sup>Edmund Biden  
<sup>1</sup>Faculty of Kinesiology, <sup>2</sup>Department of Mathematics and Statistics,  
<sup>3</sup>Department of Mechanical Engineering; email: [vchester@unb.ca](mailto:vchester@unb.ca)

### INTRODUCTION

Hypotonia, or decreased muscle tone, is a common diagnosis in infants and children. The presence of hypotonia is generally indicative of an underlying neuromuscular or genetic disorder, including Down syndrome. In conjunction with decreased muscle tone, children with hypotonia typically exhibit ligamentous laxity and instability of the lower limb joints, which may result in abnormal walking patterns [1]. We currently know very little about hypotonic gait patterns and treatment strategies for this disorder are controversial. The purpose of this study was to identify gait parameters that differentiated between hypotonic and normative gait patterns using statistical classifiers. A greater understanding of hypotonic walking patterns will lead to improved treatment procedures and a reduction in health care demands.

### METHODS

Fifteen children, aged 3-13 years, diagnosed with hypotonia participated in the study with parental consent. Participants were recruited from the Stan Cassidy Centre for Rehabilitation in Fredericton, NB. A six-camera Vicon 512 motion capture system (Oxford Metrics Ltd.) was employed to track the three-dimensional trajectories of twenty reflective markers placed on the participants' skin at a sampling frequency of 60 Hz. Two force plates (Kistler 9281B21, AMTI BP5918) collected the three-dimensional ground reaction forces and moments during each gait cycle at a sampling frequency of 600 Hz.

A comprehensive kinematic and kinetic analysis of each child's gait was performed. The body was modeled as a series of rigid links joined by 3 degree of freedom articulations. The model consisted of the left and right foot, shank, thigh and the pelvis and trunk. Joint center locations were estimated in accordance with Davis et al. [2]. Joint angles were computed from the relative orientations of the embedded coordinate systems using Euler angles. A mathematical model (elliptical cylinder method) of the human body was used to estimate the segment inertial properties of each child [3]. Net joint moments and joint power for the hip, knee, and ankle joints were estimated using the Inverse dynamics approach.

Statistical classifiers were used to determine whether hypotonic data were significantly different from age-matched normative data. The classifier generates eight one-dimensional indices of normality for the hypotonic data [4]. The classifier examines differences in amplitude and pattern of patient gait compared to normative data. The computation of the one-dimensional indices is based on the Hotelling's T-statistic (Equation 1), which uses the normative covariance structure ( $\Sigma_B$ ), and the difference in the means between the normative and hypotonic gait data ( $B^{(i)}$ ).

$$D^{(i)} = \frac{82-11+1}{82 \times 11} (B^{(i)})^T \sum_B^{-1} B^{(i)} \quad (1)$$

The input data for statistical tests were the eight one-dimensional indices of normality (or scores) for the hypotonic and normative groups. Four of these scores were based on kinetic gait parameters, three of these scores were based on kinematic gait parameters, and the eighth score was an overall combination of all seven scores. A series of nonparametric Mann-Whitney tests were used to test for significant differences in the median score results between the two groups of data.

### RESULTS AND DISCUSSION

Significant differences were found for all scores, with the hypotonic group showing higher median (and mean) values across all scores ( $p < 0.05$ ). Therefore, as a group, hypotonic gait patterns were distinguishable from normative gait patterns based on the indices of normality. To further explore the reasons for these differences, we decomposed the indices of normality into their subcomponents and examined differences in standardized means and covariance structures between the two groups.

Differences in standardized means and covariance structures between the hypotonic and normative groups showed that hypotonic abnormalities were most readily identified by specific kinematic indices of normality. These parameters were trunk obliquity and rotation, pelvic angular acceleration, sagittal knee and ankle angles, and shank angular velocity. Kinetic parameters that contributed to the identification of hypotonic gait patterns were sagittal ankle moment, ankle power, frontal hip moment, and hip power.

Numerous differences in correlations between gait parameters were also found for the hypotonic group compared to normative data. This suggests differences in coordination and control in the hypotonic group.

### CONCLUSIONS

This study identified gait parameters that could distinguish between hypotonic and normative gait patterns. A greater awareness of the gait parameters that deviate from normative values will increase our understanding of the disorder and aid in treatment planning and evaluation.

**DO LOWER LIMB MUSCLE ACTIVITY PATTERNS CHANGE WITH PROLONGED LOAD CARRIAGE?**

<sup>1</sup> Katrina M Simpson, <sup>1</sup> Julie R Steele and <sup>1</sup> Bridget J Munro

<sup>1</sup> Biomechanics Research Laboratory, University of Wollongong, Wollongong, Australia, kms99@uow.edu.au

**INTRODUCTION**

In occupational, military and recreational activities, loads are often carried in a backpack. Modern backpacks utilise a hip belt and shoulder straps to redistribute the load from the back to the large muscle groups surrounding the hips and legs in an attempt to protect the lower back from injury. However, by redistributing these loads the lower limbs are subjected to repetitive mechanical stress during prolonged load carriage while wearing heavy backpacks, which may, in turn, lead to lower extremity overuse injuries.

Numerous studies have identified gait and posture adaptations to carrying load, including changes to stride length, stride frequency, double and single support time, knee and trunk flexion, vertical and horizontal ground reaction forces [1,2]. However, little research has investigated changes in muscle activity during load carriage. Increased EMG activity with load has been reported for the gastrocnemius, hamstring, and quadriceps muscles [4]. Other research has found load carriage prolonged the duration of EMG activity for vastus lateralis, although hamstring EMG duration remained unchanged with load [5]. However, most of this previous research has focused only on the effects of short duration load carriage on changes in muscle activity, despite the fact that loads are often carried in a backpack for extended periods of time. Therefore, this study aimed to investigate the effects of prolonged load carriage on lower limb muscle activation patterns during gait.

**METHODS**

Fifteen healthy female recreational hikers (age = 22.3 ± 3.9 years) participated in the study. Each trial involved the subjects walking an 8 km circuit at a self selected speed carrying 30% of their body weight in a backpack. Data were collected at the start of the course and at 2 km intervals during the load carriage trial. During each trial muscle activity was sampled using a Noraxon Telemetry System (1000 Hz; 16 - 500Hz bandwidth) for six superficial lower limb muscles while the ground reaction forces generated at foot-ground contact were collected (1000 Hz) a Kistler force platform. The vertical GRF data were used to determine initial foot-ground contact (IC) and peak braking force (IC-peak). The EMG signals were full-wave rectified, filtered using a zero phase 4th order Butterworth low pass filter to create linear envelopes. Temporal characteristics of each muscle burst (see

Table 1) were then determined using a threshold detector whereas the intensity of muscle activity was calculated by integrating the muscle bursts of interest. To determine whether there were any significant ( $p < 0.05$ ) differences in the muscle activity patterns displayed with increasing hiking distance, a one-way repeated measures ANOVA design was used.

**RESULTS AND DISCUSSION**

Means and standard deviations calculated for the dependent EMG variables are presented in Table 1. No significant differences were noted for the temporal characteristics of tibialis anterior (TA), medial gastrocnemius (GM), rectus femoris (RF) or biceps femoris (BF) with increasing distance during load carriage. However, a significantly shorter semitendinosus (ST) muscle burst duration was evident when comparing the values obtained at the start of the 8 km circuit and all other distances. ST also was found to turn on significantly later between the start and the 8 km distance. The intensity of the vastus lateralis (VL) muscle burst also decreased from the start of the 8 km circuit in comparison to all other distances. Irrespective of any main effects of walking distance, all subjects displayed high variability in their EMG data, as is evident via the high standard deviations in Table 1.

The findings suggest that lower limb muscle activation patterns are relatively unchanged during prolonged carriage when subjects walk at a self selected speed over an 8 km circuit. However, the significantly shorter ST duration and later ST onset at the end of the load carriage trial may indicate that this muscle group is fatiguing and, in turn, may not be able to control deceleration of the limb in preparation for initial foot-ground contact. This lack of control of the leg by the hamstring muscles may predispose the knee to increased loading. However, further investigation of the internal forces acting on the lower limb is required to confirm or refute this notion.

## PREPARATION TO A PREDICTABLE PERTURBATION DURING MULTI-FINGER FORCE PRODUCTION

Sun Wook Kim, Jae Kun Shim, Vladimir Zatsiorsky, and Mark Latash  
Department of Kinesiology, The Pennsylvania State University, University Park, PA 16802  
email: [mll11@psu.edu](mailto:mll11@psu.edu)

### INTRODUCTION

Two recent studies (Shim et al. 2005, Olafsdottir et al. 2005) have described changes in covariation patterns among finger forces involved in a multi-finger force production task in preparation to a change in the total force. This novel phenomenon has been termed anticipatory covariation (ACV). During steady-state total force production, individual finger forces typically show negative covariation both along a trial and across trials. This negative covariation stabilizes the total force, i.e. resists its deviations from the steady-state level. ACV has been assumed to facilitate planned changes in the total force by decreasing the negative covariation.

We investigated patterns of finger force covariation in experiments with force perturbations applied during the task of four-finger total force production at a comfortable constant level. The perturbations were triggered either unexpectedly or by the subject himself/herself. We hypothesized that ACV would be observed prior to the moment of force perturbation in trials with self-triggered perturbations but not in trials with perturbations triggered by the experimenter unexpectedly.

### METHODS

Twelve healthy, right-handed volunteers, six males and six females participated in the experiment. The subjects sat comfortably in a chair and positioned the right forearm on the horizontal board directly in front of the subject. The fingertips of the right hand were placed on unidirectional force sensors spaced to fit the subject's individual anatomy. Changes in the forearm and hand position were prevented by a set of Velcro straps and using a custom-fitted wooden piece placed under the palm. A loop was placed on each finger and positioned under the distal interphalangeal joint. Each loop was connected to a 0.3 N load through a pulley system and an electromagnetic lock. The loads created forces acting on the fingers upwards. The subjects watched a 17" monitor that showed a target force level and the actual total force measured by the four sensors.

The subjects were required to press naturally on the sensors and to match the total force as accurately as possible with the target level. The target force was set at 8 N. There were four series (12 consecutive trials each) presented in a balanced order. Each trial lasted 10 s and involved unloading of one of the fingers disengaging the lock at some time over the second half of the trial. After the unloading, the subjects were required to bring the total force back to the required level as quickly as possible. Two series involved unloading of the index finger (I), either unexpectedly by the experimenter (I-Exp) or by the subject (I-Self); two other series involved unloading of the ring finger (R-Exp and R-Self).

All trials within a series were aligned by the time of unloading ( $t_0$ ). Average time profiles of the total force and individual finger forces were computed for each series and each subject separately. Further, variance of the total force ( $V_{TOT}$ ) and the sum of the variances of individual finger forces ( $\sum V_{Fi}$ ) were computed and used to compute an index of finger force covariation,  $\Delta V = (\sum V_{Fi} - V_{TOT})/\sum V_{Fi}$ . The time of  $\Delta V$  changes associated with the unloading was defined when it deviated from its average level over the steady-state force production by over 2 standard deviations.

### RESULTS

No changes in the total force level were observed prior to the unloading in all series. An unloading was accompanied by an increase in the force produced by the unloaded finger on its sensor followed by corrections of all finger force. During steady-state force production,  $\Delta V$  was about 0.75 in all series corresponding to negative covariation of finger forces. In I-Exp and R-Exp series, a drop in  $\Delta V$  was observed on average about 25 ms after  $t_0$ . In contrast, during I-Self and R-Self series, these changes started, on average more than 100 ms prior to  $t_0$ . Following a perturbation,  $\Delta V$  dropped dramatically and reached, on average -0.20 for I-Exp and R-Exp series and -0.10 for I-Self and R-Self series.

### DISCUSSION AND CONCLUSIONS

Our observations support the hypothesis that humans can change patterns of finger force covariation in anticipation of a planned change in the total force. These observations extend results of the earlier studies (Shim et al. 2005, Olafsdottir et al. 2005) to ACV in preparation to a quick correction of the total force following a self-triggered perturbation. In that sense, the phenomenon of ACV is somewhat similar to the anticipatory postural adjustments. Apparently, ACV allowed subjects to avoid excessive total force destabilization over the period of correction as reflected in less negative  $\Delta V$  values in I-Self and R-Self series.

**MUSCLE FUNCTION LOCALLY MEDIATES BONE HOMEOSTASIS**

Sarah E. Warner, Sundar Srinivasan and Ted S. Gross  
 University of Washington, Seattle, WA  
 tgross@u.washington.edu

**INTRODUCTION**

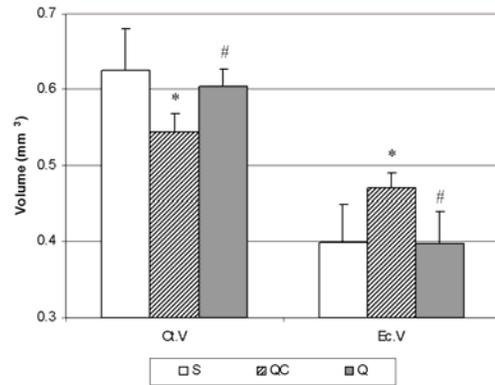

Muscle contractions serve as one of the two major sources of mechanical loading on bones and thereby directly effect bone homeostasis [1]. However, the means by which muscle function serves to maintain bone health is poorly understood. Recently, we observed that acute muscle paralysis induced by Botulinum neurotoxin (Botox) injection rapidly precipitates substantial muscle and bone degradation in mice [2]. As well, preliminary data from the model indicated that individual mice demonstrating the greatest loss of muscle also experienced the greatest bone degradation [3]. Here, we examine the hypothesis that local muscle function is required to maintain local bone homeostasis.

**METHODS**

Twenty female C57B6 mice (16 wk) were randomized into three groups: 1) saline (S; n = 5), 2) quadriceps and calf Botox injections (QC; n = 5), and 3) quadriceps Botox injection (Q; n = 10). At day zero, each IM injection consisted of either 2.0 unit/100 g body weight of Botox or equal volume of saline. This dose of Botox is within the range approved for human use. All mice were allowed free cage activity and food and water ad libitum for 3 weeks. At sacrifice, the quadriceps and calf wet mass were determined. The right femurs and tibiae were imaged via micro-CT at a 10.5 µm voxel resolution (Scanco Viva CT). Bone volume/total volume (BV/TV, %) are reported for the distal femur epiphysis and proximal tibia metaphysis. At the tibia mid-shaft, a 0.1 mm thick transverse cross section was assessed for cortical volume (Ct.V; mm<sup>3</sup>) and endocortical volume (Ec.V; mm<sup>3</sup>). Treatment effects were evaluated using ANOVA (p = 0.05) while linear regression was used to explore relations between muscle mass and site-specific bone alterations.

**RESULTS AND DISCUSSION**

Intramuscular injection of Botox induces temporary muscle paralysis by blocking the release of acetylcholine into the neuromuscular junction [4]. In the murine Botox model, lameness is maximal by 3 days post-Botox injection, with gradual restoration of weight bearing occurring within 2 wk. Weight bearing remains compromised compared to control mice for 4 to 6 wk. Muscle mass was significantly diminished at each Botox injection site when compared to S (range: -52% to -60%). In contrast, calf muscle mass in the Q group was diminished -29% (Table 1). Both Botox groups demonstrated similar degradation of femur and tibia BV/TV when compared to S (QC: -52 and -70%; Q: -46 and -51% respectively, p <

**Figure 1:** Tibia cortical bone volume and endocortical volume. \*QC different from S, #Q different from QC.

0.05; Table 1). However, while QC mice demonstrated a 15% loss of cortical volume due to endocortical expansion, the tibiae of Q mice were not altered compared to S mice (Figure 1). Quadriceps wet mass was strongly predictive of femoral BV/TV for all Botox mice (QC: r = 0.995, p < 0.001 and Q: r = 0.957, p = 0.011), but calf wet mass was related to tibia Ct.V only in the presence of calf paralysis (QC: r = 0.751, p < 0.001 and Q: r = 0.334, p > 0.05).

The only observed functional difference between the Botox injected groups was that the Q mice continued to perform calf contractions during attempted ambulation, while the QC mice were unable to contract the calf muscles. As such, it is likely that the Q mice maintained a physiologic level of small magnitude muscle contractions in the face of minimal large contractions (due to limited weight bearing). Thus, the absence of tibial cortical bone loss in the Q mice supports our initial hypothesis while implicating small muscle contractions as one mechanism by which muscle function may locally mediate bone homeostasis.

## KINETICS AND KINEMATICS OF MALES AND FEMALES DURING TWO STYLES OF DROP LANDING

<sup>1</sup>Rhonda L. Boros and <sup>2</sup>John H. Challis

<sup>1</sup>Biomechanics Laboratory, Texas Tech University, <sup>2</sup>Biomechanics Laboratory, The Pennsylvania State University

### INTRODUCTION

Female athletes are six times more likely than males to suffer a “non-contact” anterior cruciate ligament (ACL) injury [1], and landing from a drop has been identified as a movement stressful to the ACL [2]. The kinematics and kinetics of landing from a drop have been studied extensively. The consensus is that males demonstrate greater body weight normalized vertical ground reaction forces (VGRF) compared with females, while females tend to land on more extended knees with greater trunk lean [3] and exhibit longer landing phase durations [4]. Specific gender comparisons across more than one style of landing are lacking; and many studies selected a single trial for analysis, potentially skewing performance characteristics and statistical comparison.

Previous studies typically assumed a rigid body model and thus ignored skin-mounted marker movement, compromising the accuracy of subsequent kinetic calculations [5]. Efforts to minimize this error have been made previously [6] and similar efforts were adopted in the present study. The purpose of this study was to examine kinetic and kinematic differences between males and females during two styles of landing from a drop (flat-footed and toe) utilizing an externally affixed rigid link device as representative of underlying skeletal motion.

### METHODS

Simultaneous 2D kinematic (240 Hz) and kinetic (1920 Hz) data were collected as 10 subjects (5 male, 5 female) performed 5 trials each of two-footed hanging drop landings onto flat feet and toes. A rigid link device was secured to the right lower extremity of the subjects, and the intersection of the lines representing the two segments of the device served to determine the knee joint center for kinematic analysis. Torso and foot kinematics were obtained from markers placed on the acromion process, greater trochanter, lateral malleolus, calcaneal tuberosity and fifth metatarsal. Two additional markers were placed on the anterior portion of the thigh in an effort to quantify the magnitude of soft tissue motion relative to the rigid link. The instant of impact was considered time zero for all parameters, and kinetic and kinematic data were time-synched to this instant. Peak VGRF, loading rate, joint angles, angular velocities, angular accelerations, resultant joint moments (RJM), and phase durations were calculated and compared across gender. All comparisons were tested utilizing a repeated measures ANOVA ( $P < 0.05$ ).

### RESULTS AND DISCUSSION

No significant differences were observed between the genders across landing conditions in force plate derived temporal variables. Mean landing duration for both styles ranged from 1.5 to 1.7 seconds. Both groups demonstrated significantly greater VGRF during the flat-footed compared with toe landings ( $7.4 \pm 2.1$  and  $4.9 \pm 1.7$  versus  $6.5 \pm 1.4$  and  $4.2 \pm 0.9$  BW

for males and females, respectively). Males also demonstrated slightly greater rates of loading.

Contrary to the literature, males had significantly greater knee extension at impact and at the time of peak VGRF for both landing styles. Toe landings resulted in significantly greater ankle joint angular velocities compared with flat-footed landings, and such velocities were significantly greater for males during toe landings, perhaps indicative of an alternate ankle joint strategy compared with females. Flat-footed landings resulted in more rapid onsets of peak RJM for both genders compared with toe landings. Males exhibited significantly greater RJM at the hip during toe landings and experienced these greater moments later in the landing phase compared with females. Albeit not statistically significant, females demonstrated substantially greater resultant joint moments at the hip during flat landings compared with males. Greater RJM at the hip during impact could lead to an increased risk of knee injury if the heel were to remain firmly planted and a horizontal acceleration were introduced, as occurs during an off-balanced landing. Females also demonstrated significantly greater horizontal and vertical displacement of the soft tissue compared with males across landing styles, possibly affecting true joint kinetics. No other kinematic differences were observed.

### CONCLUSIONS

Methodological differences (e.g. knee joint center kinematics, repeated versus single trial analysis) may account for the discrepancies between the present kinematic results and the literature. Considering the rigid body assumption for kinetic analysis, gender differences in soft tissue motion suggest that females may be experiencing different joint loads compared with males. Quantification of this soft tissue motion and its contribution to knee joint load may provide some insight into the predisposition of females to ACL injury.

## EXPLORING MECHANICAL LOADING INDUCED $Ca^{2+}$ OSCILLATIONS IN OSTEOCYTES

Brandon J. Ausk, Ted S. Gross and Sundar Srinivasan

Orthopaedics and Sports Medicine, University of Washington, Seattle; email: [bjausk@u.washington.edu](mailto:bjausk@u.washington.edu)

### INTRODUCTION

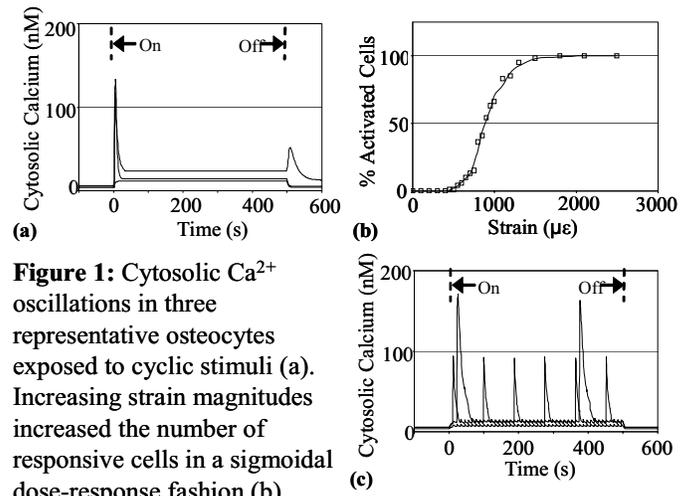

Bone is highly sensitive to alterations in its mechanical environment. In fact, extremely brief loading sessions (e.g., 100 s of exogenous loading) are sufficient to activate mechanosensory osteocytic cells within minutes and presumably drive osteoblastic bone formation days and weeks later[1]. One potential signaling pathway that would satisfy these observations is the  $Ca^{2+}$  ion second messenger system, which permits real-time cell responses to a variety of agonists, including mechanical stimuli[2,3]. However, given the inaccessibility of osteocytes, it is not possible to confirm this mechanism *in vivo*. As a potential solution, we have developed a novel agent based model of real time  $Ca^{2+}$  signaling. We examined the validity of the model by simulating  $Ca^{2+}$  oscillations induced in osteocytic cells challenged by either cyclic or rest-inserted mechanical stimuli.

### METHODS

Cytosolic  $Ca^{2+}$  oscillations induced in osteocytic cells by mechanical stimuli were simulated in an agent based modeling environment (Netlogo 2.1).  $Ca^{2+}$  oscillations were governed by the following cellular functions previously identified *in vitro*[2,4]: 1) at steady state,  $Ca^{2+}$  influx occurs at a low-rate from the extracellular milieu, 2) for homeostasis, the resulting cytosolic  $Ca^{2+}$  build-up is removed via a concentration dependent efflux across the plasma membrane and uptake into the cell mitochondria, 3) mechanical stimuli causes a strain dependent influx of  $Ca^{2+}$  (via stretch activated  $Ca^{2+}$  channels), 4) when cytosolic  $Ca^{2+}$  concentrations exceed thresholds, endoplasmic reticulum (ER)  $Ca^{2+}$  stores are released into the cytosol, 5) the threshold for  $Ca^{2+}$  release from ER is inversely related to ER  $Ca^{2+}$  store concentrations, 6) the rate of  $Ca^{2+}$  release from the ER is strain and concentration dependent, and lastly, 7) when cells are quiescent, ER  $Ca^{2+}$  stores are replenished from the mitochondria in a concentration dependent manner. Using this model,  $Ca^{2+}$  oscillations induced by 500 s of cyclical (1-Hz) and rest-inserted stimuli (10-s rest between load cycles) were contrasted.

### RESULTS AND DISCUSSION

Real-time  $Ca^{2+}$  oscillations induced by cyclic loading followed one of three fundamental responses (Fig 1a). A small subset of cells were non-responsive (~20%), while a majority of cells displayed either a high-magnitude transient  $Ca^{2+}$  oscillation followed by low-level steady state fluctuations (40%), or an additional secondary  $Ca^{2+}$  transient upon cessation of the stimulus (40%). The number of responsive cells was increased when the magnitude of the stimulus was increased, regardless of the waveform (Fig 1b). In contrast to the response to cyclic stimuli, multiple high-magnitude  $Ca^{2+}$  oscillations were induced when cells were subjected to rest-inserted stimuli (Fig 1c).

**Figure 1:** Cytosolic  $Ca^{2+}$  oscillations in three representative osteocytes exposed to cyclic stimuli (a). Increasing strain magnitudes increased the number of responsive cells in a sigmoidal dose-response fashion (b). Rest-inserted stimuli induced multiple high-magnitude  $Ca^{2+}$  transients in osteocytes (c).

In our agent based model of  $Ca^{2+}$  ion balance, distinct  $Ca^{2+}$  ‘fingerprints’ were not explicitly ‘hardwired’ within the model. Instead, they emerge via interactions between real cellular attributes (e.g.,  $Ca^{2+}$  influx via stretch activated channels, ER  $Ca^{2+}$  stores). In our view, such an emergence based approach substantially extends model robustness and utility. Importantly, all  $Ca^{2+}$  response characteristics observed here (heterogeneous cell response, sigmoidal dose-response relations and multiple transients elicited by rest-inserted stimuli) were consistent with previous *in vitro* studies[3,5,6].

More broadly, it is possible to determine adaptation induced by mechanical waveforms at a variety of levels *in vivo* (from protein expression to cell proliferation and differentiation). Our model now provides a framework to functionally relate these adaptive events with unique  $Ca^{2+}$  fingerprints elicited *during* brief bouts of mechanical stimuli[2]. As a result, it may be possible to decipher the mechanisms underlying the distinct adaptive outcomes elicited by specific mechanical stimuli (e.g., why rest-inserted stimuli is dramatically osteogenic, but cyclic stimuli at identical loading magnitudes is not)[7]. Ultimately, the model and its expansions could serve as a powerful tool for optimization of bone tissue adaptation by enabling tailored design of loading waveforms that enhance cellular responses on the order of seconds.

## CELL DEFORMATION IN RESPONSE TO LOCAL MATRIX STRAIN

<sup>1</sup> Rachna Sah, <sup>2,3</sup> Markus Wimmer and <sup>2,3</sup> Amarjit Viridi

<sup>1</sup>Department of Bioengineering, University of Illinois at Chicago, Chicago, IL; <sup>2</sup>Department of Orthopedics, <sup>3</sup> Department of Anatomy and Cell Biology, Rush Medical Center, Chicago, IL; e-mail: markus\_a\_wimmer@rush.edu

### INTRODUCTION

Chondrocyte deformation within compressed extracellular matrix (ECM) and/or agarose composites has been studied extensively during the past years [e.g. 1,2]. Since the elastic modulus of the cells is some magnitudes smaller than that of ECM, a stress concentration exists on the micro-level around the chondrocyte [3]. This needs to be taken into consideration for tissue engineering because the initial elasticity modulus of the cell-seeded artificial matrix is typically lower than that of mature ECM. In order to evaluate stresses and strains at the micron-level numerical models may be used. For the input a precise description of the matrix deformation in the immediate vicinity of the cell is necessary. In this study we employed a technique based on grayscale correlation of microscopy images. We hypothesized that considerable strain perpendicular to the primary loading axis occurs and strains are affected by cell type.

### METHODS

Metacarpalphalangeal joints from 18-months old steers were dissected to obtain samples from articular cartilage. Superficial (~15% uppermost) and deep (rest) zones were separated by slicing manually. Chondrocytes were isolated by digesting the slices with pronase and collagenase. Isolated cells were labeled with calcein dye and cell/agarose constructs were prepared by mixing  $5.7 \times 10^6$  cells  $\text{ml}^{-1}$  of 3% agarose. In addition, fluorescent beads (molecular Probes) were added as extracellular markers. After solidification at 4°C, constructs were cut into ten 10mm cubes each. A loading apparatus (Fig. 1) was used to apply unconfined compression in steps of 500 microns up to 2 mm. The corresponding local agarose deformation was studied using a confocal laser microscope capturing the relative displacement of the fluorescent beads. The sets of images were analyzed using VEDDAC™- an image correlation software which uses grey scale data to give a vectorial representation of displacement. Creating a grid of measurement points with an X & Y pitch of 65µm, the grey scale information from a 4350µm<sup>2</sup> correlation area around each point was used to identify the displacement. The search area was limited to 33000 µm<sup>2</sup>. A strain calculation algorithm based on linear regression was added to determine the local principal strains. The deformation index (Fig.1) and perimeter of cells were quantified for ten cells per cube and load step.

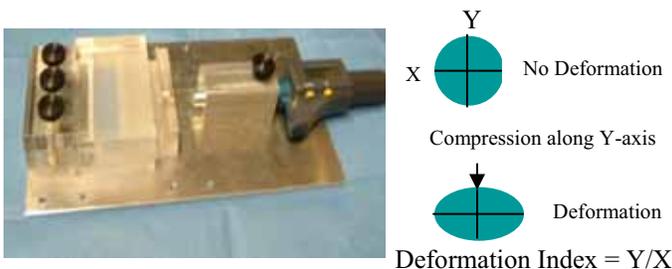

Figure 1: Compression apparatus

### RESULTS AND DISCUSSION

A homogenous gradient of deformation was observed for all samples both in axial and lateral direction (Fig.2). On average, the local axial strain was similar to applied 'global' strain, however, individual values varied greatly among samples as well as between deformation steps. Thus, a nominal 5% step generated local strains from as low as 1.3% to as high as 8.8%. The local lateral strain was dependent on applied load and decreased with increasing axial strain (Fig.2) Thus, the Poisson-like values started from 0.45 and decreased with increasing strain to 0.26 and 0.32 for the superficial and deep cell-agarose composites respectively. Also deformation on the cellular level differed between the two cell populations. The slope of the deformation index was steeper for the deep cells (Fig.3). Interestingly, the cells behaved differently with regard to their perimeter (Fig.3) suggesting a growing cell volume for the deep cells and a shrinking volume for the superficial cells with increasing strain (Fig.3).

### CONCLUSIONS

Locally generated strains were variable among samples and appeared to be affected by cell type and loading. Grayscale correlation is helpful in the precise computation of local strain.

### INTRODUCTION

A generic bone template must be scaled to quantify the shape differences between it and a particular bone. Computational joint models rely on the scaling of a generic model to approximate the bone geometry of an individual subject. Previous modeling studies have used both single [1-3] and multiple scale factors [4] to approximate individual femurs from templates. The objective of this study was to determine whether a single scale factor is sufficient. We examined normal subjects to determine whether consistent relationships exist between designated femur lengths. We hypothesized that multiple scale factors would be necessary: three factors for the superior-inferior direction (corresponding to proximal, mid-shaft, and distal sections of the femur) and one scale factor each for the anterior-posterior and medial-lateral directions.

### METHODS

Landmark coordinates for 52 skeletal femur specimens were obtained from an existing database [3]. Landmark coordinates for ten volunteers were obtained from geometric models generated using Geomagic Studio (Research Triangle Park, NC) based on data segmented from T1-weighted MRI scans. Volunteer and skeletal specimens were all skeletally mature and free from known orthopaedic abnormalities. Relevant lengths were measured as the distances between the following pairs of landmark points: the most lateral points on the greater trochanter and on the femoral epicondyle (LE) (referred to as “palpable length” due to the accessibility of the landmarks); the top of femoral head and the inferior base of lesser trochanter (LT) (“proximal length”); the superior corner of adductor tubercle (AT) and the most inferior point on the femur (“distal length”); LT and AT (“shaft length”); the most medial point on the femoral epicondyle and LE (“width”); and the origin of the VMO fibers (near the anterior-medial corner of the patellar groove) and a line connecting the most posterior points on the medial and lateral distal condyles (“depth”). Kolmogorov-Smirnov (K-S) normality tests were performed to ensure normally distributed measurements and that further statistical testing was appropriate. Correlations were sought between the palpable length, a measurement that could potentially serve as the basis for a uniform scale factor, and each of the other lengths. For each correlation, the lower and upper bounds on the 95% confidence interval were found.

Measurements were normalized by their respective mean values and linear regression analysis (with y intercept=0) performed to determine the rate of change of each length with change in palpable length. The regression coefficients for these normalized data were compared.

### RESULTS AND DISCUSSION

The palpable length for the 62 test subjects was 382 ±25 mm. The standard deviations for the five test measurements, when normalized by their means, ranged from 6% to 13% (Table 1, row 1). The distribution of these data was found to be normal in all cases; the Lilliefors significance level was well above 0.05 for the K-S tests (row 2). Significant (p-values <0.0001) correlation values (R) relating each of the five dependent measures to the palpable length ranged from 0.50 for (depth) to 0.96 (shaft length) (row 3). The 95% confidence intervals were narrow and the lower bounds found for R were never lower than 0.29 (row 4) and the upper bounds were as high as 0.98. The strong correlations for the three length measurements indicate that individual femoral sections change size proportionally to changes in femoral length. The width and depth correlations indicate that the changes in the two orthogonal dimensions are also proportional to the superior-inferior femoral dimension. The linear regression model proved valid as all models demonstrated significance (t-value >>2 and significance <<.01). The most important finding was that the regression coefficients for the normalized data were all the same (row 5), indicating that, not only do all five parameters vary with the palpable length, they vary at the same rate. Thus, we have shown that when scaling a model femur to match an individual femur, a single scale factor is sufficient to match the three sections and three dimensions of the bone.

<sup>2</sup>Bone & Joint Center, VA Palo Alto Health Center; email: scslove@stanford.edu, web: biomotion.stanford.edu

### INTRODUCTION

Video observations of non-contact injuries to the anterior cruciate ligament (ACL) suggest that the injury occurs during the deceleration phase of landing on a single limb with a combination of valgus and internal or external rotation [1]. A cadaveric study supports the conclusion that combined internal torque and valgus moment increase forces in ACL [2]. However, the dynamic effect of combined loading at physiologic levels on ACL strain during landing has not been studied. This study tested the hypothesis that the strain in the ACL is higher under combined valgus and internal rotational moments during landing than with either applied individually. The study was conducted by applying actual *in vivo* loading data to a validated simulation model of the knee to predict ACL strains.

### METHODS

A combination of valgus moments, internal rotation moments, and vertical landing forces were used to drive dynamic simulations of a previously validated knee model constructed from MRI of the distal femur, proximal tibia, patella, and cartilage of a cadaveric knee (Figure 1) [3]. Peak valgus moments for valgus landers and neutral landers were obtained from the results of a previous study on sidestep cutting [4] and normalized to an average-size person (height=1.75m, weight=750N) to choose 4 physiologic levels of valgus moment for the simulations (Table 1). Four physiological levels of peak internal rotational moments were obtained from another single limb landing experiment using 30 subjects (21 female, 9 male) with no history of musculoskeletal injury (Table 1). The vertical impact force used had a peak of 1400N. Other values of valgus and internal rotation moment were also tested to illustrate the shape of the response surface. The valgus and internal rotational moments were applied at the midpoint of the trans-tibial line, while the impact force was applied at the top of femoral axis of the upper limb. The strains in both bundles of ACL were calculated, but only the anteromedial bundle strain is presented since it was the higher of the two.

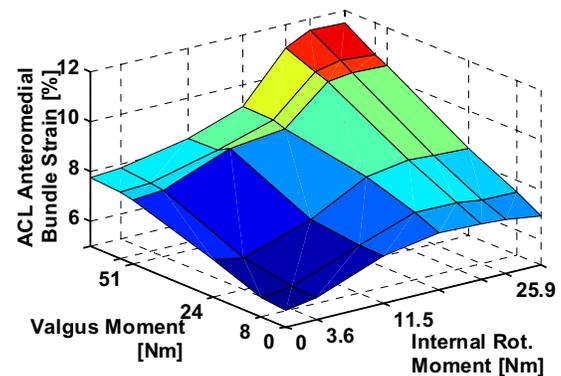

**Figure 1.** Knee model showing ligaments.

### RESULTS AND DISCUSSION

The strain in the ACL due to combined physiological maximum valgus (51 Nm) and internal rotational moment (25.9 Nm) was 10.5%, which is in the reported range for ACL rupture of 9-15% [5,6]. When applied individually, neither of the two rotational moments caused ACL strain higher than 7.7%, and the effect of each moment reached a plateau at or near the maximum level observed *in vivo*. However, when applied in combination the two rotational moments had a much larger effect, and the sensitivity of ACL strain to increases in either quantity was much higher when the other was held at a high level (Fig. 1).

Moreover, subjects whose typical valgus and internal rotation moments are high may be at greater risk because ACL strain is most sensitive to perturbations in the applied moments at those levels, as shown by the steepest slope of the surface when valgus moment is between 24 and 51 Nm, and internal rotation moment is between 11.5 and 25.9 Nm (Figure 1).

This work has shown that the combination of valgus and internal rotation moments that occur *in vivo* during simple cutting and landing maneuvers can cause ACL strains that may be high enough to cause injury, even in the absence of an anterior shear force.

**Figure 1.** Response of ACL anteromedial bundle strain to applied valgus, internal rotation, and combined moments.

## KINETIC LIMITATIONS OF MAXIMAL SPRINTING SPEED REVISITED

<sup>1,2</sup> Stephen C. Swanson and <sup>1</sup>Graham E. Caldwell

<sup>1</sup>Biomechanics Lab, University of Massachusetts, Amherst, MA USA,

<sup>2</sup>The Orthopedic Specialty Hospital, Salt Lake City, UT USA; email: [tosskans@ihc.com](mailto:tosskans@ihc.com)

### INTRODUCTION

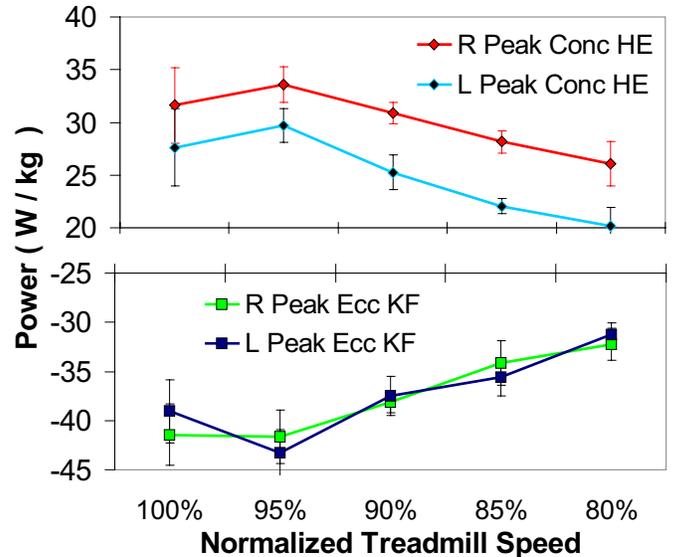

Many studies have examined running biomechanics, but few have addressed the factors that limit maximal sprinting speed. As running speed increases above 9 m/s, the athlete must produce large ground forces in a very short time (< 110 ms; [2]). Skillful coordination of the lower extremity during recovery may be an important aspect of realizing effective ground forces during stance. Chapman and Caldwell [1] identified energy absorption by eccentrically acting knee muscles during recovery as a key variable in limiting sprint speed. However, their analysis was limited to the planar motion of a single elite subject. The goal of the present study is to examine limitations in maximal running speed in multiple subjects with three-dimensional (3D) kinetic analysis; due to space limitations only 2D sagittal kinetics are reported here.

### METHODS

Eight skilled male sprinters ( $19.2 \pm 2.6$  yrs.,  $1.83 \pm .04$  m,  $85.7 \pm 6.2$  kg) ran on a high-speed treadmill at 100%, 95%, 90%, 85% and 80% of their maximal speed ( $9.46 \pm .4$  m/s). The 3D motion of 47 reflective markers on the arms, trunk, pelvis, and lower extremities was recorded with eight Motion Analysis™ digital cameras at 200 Hz. Marker trajectories were smoothed at 12 Hz. 3D kinematics and kinetics were computed with Visual3D™ software. Stance and swing were identified from the kinematics of markers on the 1<sup>st</sup> and 5<sup>th</sup> metatarsal heads, using event identification algorithms validated in a pilot study with a force treadmill. Net joint moment and power data from the hip and knee were selected from five consecutive strides in each speed condition and peak power values were calculated for distinct periods of swing. The effect of speed on peak powers at the hip and knee was tested with a within-subject repeated-measures ANOVA using post-hoc orthogonal contrasts (SPSS™). All differences reported have  $p < 0.05$ .

### RESULTS AND DISCUSSION

Table 1 presents bi-lateral peak power data during periods of concentric hip extension (Conc HE) and eccentric knee flexion (Ecc KF). Peak Conc HE and Ecc KF power values increased in magnitude with treadmill speed from 80-95%. At maximal speed, each power reached a plateau and was similar in magnitude to the 95% condition. The within-subject stride-to-stride variability of the peak power values *increased* at maximal speed (SD values in *italics*) compared to all other

**Figure 1:** Bi-lateral mean peak Conc HE and Ecc KF power values across speeds for one subject. Error bars are  $\pm 1$  SD.

speeds. Further, as illustrated for one subject in Figure 1, significant differences *between limbs* in Conc HE, Ecc KF peak power, or both measures were observed in 5 of the 8 subjects. The bilateral differences were unique to each subject. The data suggest that changes in energy generation at the hip and energy absorption at the knee may be key variables in the limitation of maximal sprint speed. Bi-lateral asymmetry and increased variability in hip and knee kinetics at maximal speed may indicate a failure in lower extremity coordination during swing that hinders effective force application during the subsequent stance phase. To definitively examine this possibility and to gain further insight into the limitations of maximal sprinting speed, additional research on stance phase kinetics of elite sprinters is needed.

## Metabolic Cost of Walking Varies with Foot Roll-Over Radius

<sup>1</sup>Peter Gabriel Adamczyk, Kaitlin A. Schneider, Arthur D. Kuo  
 Department of Mechanical Engineering  
 University of Michigan, Ann Arbor, MI USA  
<sup>1</sup>email: [padamczy@umich.edu](mailto:padamczy@umich.edu)

### INTRODUCTION

Humans perform simultaneous positive and negative work during the double support phase of walking [1]. In order to redirect the body center of mass (COM) velocity between steps, the leading leg performs negative work on the COM as the trailing leg pushes off with positive work. A simple passive dynamics-based model of walking predicts that the mechanical work required at push-off should decrease quadratically as the effective roll-over radius of the feet increases [2]. Because mechanical work requires metabolic energy, we hypothesize that a similar trend should appear in metabolic rate with variation in roll-over radius. We artificially varied the effective shape of subjects' feet by attaching cylindrical arched boots to the lower leg. We measured metabolic rate while subjects walked on arcs of several sizes. We found that metabolic rate decreased substantially with higher radius of curvature, suggesting that simultaneous positive and negative work during double support is a major contributor to the total metabolic cost of walking.

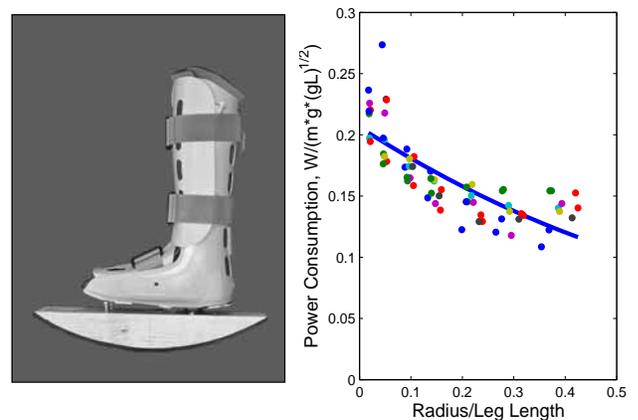

### METHODS

We measured metabolic energy consumption as human subjects walked on different-sized wooden arcs. The experimental setup consisted of a speed-controlled treadmill, a breath gas analyzer, and seven pair of wooden arc shapes used to give the subject a specific foot roll-over radius (arcs' radii of curvature were 2, 5, 10, 15, 22.5, 30, and 40 centimeters). These arcs were attached to the legs of the subject through a pair of Air-cast Pneumatic Walker boots modified to allow the interchange of foot shapes (Figure 1a). The boots immobilized the ankle, causing the subject's leg to function much like that of the passive walking model. When standing upright, the contact point of the arcs with the ground was about 7.6 cm in front of the tibia, near the metatarsal head.

Ten healthy young adults (five male, five female) were recruited to perform this study. Each subject's rate of oxygen consumption was measured during treadmill walking at 1.3 meters per second using each of the wooden arcs in random order. Step frequency was held constant across all trials in order to eliminate possible energetic variation due to swinging of the legs; frequency was set to the subject's preference when walking on the largest (40 cm) arcs. Average metabolic rate was estimated in Watts, and then non-dimensionalized using the subject's mass ( $m$ ) and leg length ( $L$ ) and the gravitational acceleration ( $g$ ). Collision losses experienced by passive walking models decrease with increasing radius of curvature [3], because roll-over arcs greatly affect the change in COM velocity during double support. The theoretical relationship between mechanical work ( $W_{\text{mech}}$ ) per step and radius of curvature  $R$  is given by [1, 3]

$$W_{\text{mech}}/\text{step} = \alpha^2 (1 - (R/L))^2, \quad (1)$$

where  $\alpha$  is the half-angle between the model's legs at heel strike. We hypothesized that this mechanical work would exact a proportional metabolic cost [1]. At constant step fre-

**Figure 1:** (a) One of the experimental boots, with 40 cm radius attachment. Metabolic rate decreased substantially with increasing radius of curvature. (b) Metabolic power vs. radius of curvature, with theoretical curve fit (Eq. 2).

quency, the relationship between mechanical work per step and the hypothesized metabolic rate  $P_{\text{met}}$  has an unknown constant of proportionality [2]. Allowing for different offsets above basal metabolism, data were therefore fit to the curve

$$P_{\text{met}} = C * (1 - (R/L))^2 + D. \quad (2)$$

### RESULTS AND DISCUSSION

Average net metabolic power expenditure decreased significantly with radius of curvature (Fig. 1b). Net metabolic rate was highest at the smallest radius of curvature. Expenditures using the smallest arcs averaged 218% greater than normal walking (511 vs. 203 W above resting); expenditures using the 30 cm arcs averaged only 46% greater (296 W above resting).

The results indicate that metabolic rate roughly followed the trend predicted theoretically. Fig. 1b also shows the best fit of these data to the theoretical curve of Eq. 2:  $C = .134$ ,  $D = 0.072$ ,  $R^2 = 0.79$ . There are several reasons why the results do not agree entirely with the theoretical curve. Visually, it appears that the best quadratic fit to the data is not the theoretical curve, but rather one centered around  $R/L = 0.3$ . This early upturn suggests that phenomena not included in the simple model may cause humans to expend more energy when the radius of curvature causes the effective foot length to be greater than normal. An explanation noted by McGeer [3] is that in the models, bipeds with mass distributed near the feet have lower efficiency than those with mass closer to the hip (as used to derive Eq. 1). Early simulation results suggest that anthropomorphic mass distribution may explain the optimum roll-over radius observed here.

## THE SPRING-MASS MODEL FOR WALKING

<sup>1,2</sup>Hartmut Geyer, <sup>1</sup>Andre Seyfarth and <sup>2</sup>Reinhard Blickhan

<sup>1</sup>Locomotion Laboratory, Jena University, Dornburger Str. 23, D-07743 Jena, Germany

<sup>2</sup>Dept. of Motion Science, Jena University, Seidelstrasse 20, D-07749 Jena, Germany

### INTRODUCTION

In general, two different models are employed when addressing animal and human locomotion on a simple mechanical level: the *inverted pendulum model for walking*, where the body is reduced to a point mass  $m$  at the center of mass (COM) vaulting over a rigid stance leg of length  $l_0$ , and the *spring-mass model for running* or hopping, where the rigid stance leg is substituted by a compressing spring of rest length  $l_0$  and stiffness  $k$ .

The spring-mass model reproduces salient features of the characteristic ground reaction force (GRF) pattern observed in running, which renders it ideal to explain experimental observations, predict functional dependencies, and formulate biological control hypotheses.

By contrast, the inverted pendulum model suffers from GRF patterns inconsistent with experimental observations. Consequently, experiments also demonstrate that instead of vaulting over rigid legs (characterized as ‘compass gait’), the COM experiences much less vertical excursion necessitating significant stance limb compressions, which at high speeds are even comparable to those observed in running [e.g. 1].

Motivated by these experimental findings, we here ask in how far the characteristic GRF patterns of walking can be explained by purely elastic leg behavior.

### MODEL

To address this question we extend the planar spring-mass model for running [2] by a second idealized leg spring and investigate a single walking step characterized by two subsequent apices (Fig. 1).

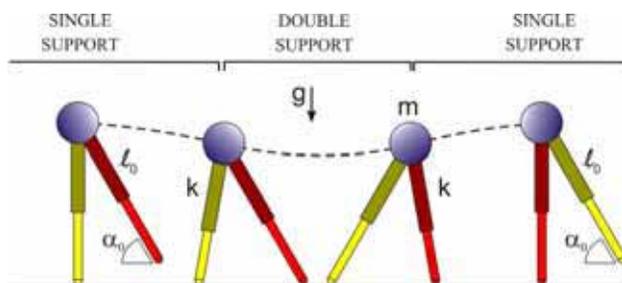

Fig. 1: Two-legged spring-mass walking model.

Starting in single support, the stance leg compresses due to the acting gravitational force (gravitational acceleration:  $g$ ). The swing leg, however, remains in a fixed leg orientation (angle of attack  $\alpha_0$ ) until it touches the ground initiating the double support phase. During this phase, the COM is redirected upwards since both spring forces together exceed the counteracting gravitational force. Maintaining forward progression, the rear leg-spring relaxes and eventually reaches its rest length initiating the subsequent single support phase.

### RESULTS AND DISCUSSION

By scanning the model’s behavior throughout the parameter space (angle of attack, spring stiffness, and system energy), we find that (i), similar to spring-mass running [2], the extended model describes self-stable and robust periodic locomotion if the parameters are properly chosen. (ii) Furthermore, the resulting steady state trajectories yield GRF patterns similar to those observed in animal and human locomotion (Fig. 2) suggesting leg compliance to be an essential feature not only in running but also during walking.

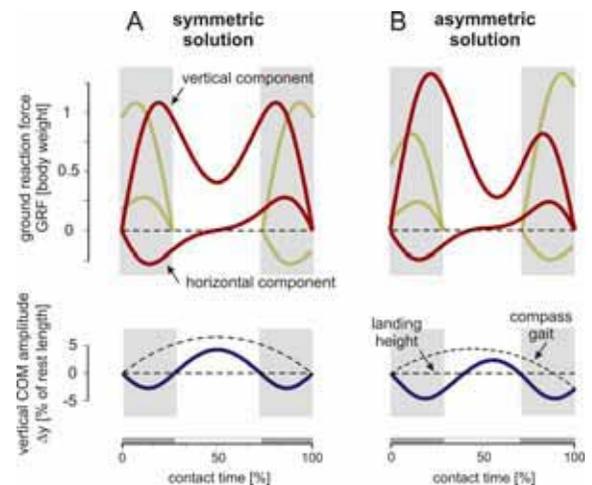

Fig. 2: Steady-state patterns of GRF and vertical COM amplitude in spring-mass walking. Dependent on the actual parameters, (A) symmetric and (B) asymmetric steady-state trajectories can be observed.

### CONCLUSIONS

The bipedal model put forth in this study is probably the simplest mechanical model describing GRF patterns similar to those observed in walking. In comparison to the inverted pendulum model it establishes two new qualities. First, it emphasizes the importance of the double support. Second, it incorporates the experimentally observed motion along the leg axis as an additional degree of freedom. Moreover, as a direct derivative of the spring-mass model for running, the bipedal model allows to describe the two fundamental gait patterns within a single framework unifying the investigation of legged locomotion on the mechanical level from walking to the walk-run transition to running.

## A PARAMETRIC MADYMO ANALYSIS FOR DETERMINING SEAT BELT USAGE IN A FRONTAL COLLISION

David E. Raymond, Jon B. Landerville, Jeffrey B. Wheeler, David A. Dainty  
Vector Scientific, Inc., Los Angeles, California  
[draymond@vectorscientific.com](mailto:draymond@vectorscientific.com)

### INTRODUCTION

Forensic biomechanics is often called upon for the purposes of determining whether a seat belt was utilized in automotive collisions. A parametric analysis utilizing MADYMO was performed to elucidate seat belt usage in a high speed frontal collision based upon the known injury outcome.

### METHODS

Vehicle accident reconstruction was performed utilizing PC-Crash to determine the impact severity. Since PC-Crash does not have the ability to generate a crash pulse, two pulses were assumed: AAMA generic MVSS 208 sled pulse and a NCAP pulse from the NHTSA vehicle crash test database. The AAMA pulse was felt to represent the lower bound of the impact severity and the NCAP the upper bound of the impact severity based upon the vehicle reconstruction analysis.

Medical records were reviewed that revealed a C2 fracture, intimal rupture of the aortic arch and right tibial plateau fracture. Geometric measurements of the vehicle determined from NHTSA's vehicle database were used to generate a MADYMO model of the right front passenger compartment [1]. A generic passenger side airbag model was utilized. The Hybrid III 5<sup>th</sup> percentile female ellipsoid model was chosen as best representing the subject. Additional unknowns were included leading to an overall matrix of two collision pulses, three fore/aft passenger seat positions, and four deployment times of the passenger side airbag for both belted and unbelted conditions. For the belted condition, a generic MADYMO belt was utilized. Injury assessment values were monitored for the neck, chest and lower extremities. Injury indices ( $N_{ij}$ , Chest G, Tibial Index) were calculated and related to MVSS 208 injury criteria.

### RESULTS AND DISCUSSION

The subjects C2 fracture was consistent with biomechanical literature on compression-extension injury mechanisms to the upper cervical spine [2]. Figure 1 demonstrates representative kinematics of both belted and unbelted conditions.  $N_{ce}$  (compression-extension) values were significantly higher for both AAMA and NCAP pulses for unbelted than belted conditions but only exceeded the injury criteria of 1.0 for the unbelted NCAP conditions as seen in Figure 2.  $N_{cf}$  (compression-flexion) values were also found to exceed the injury criteria in the NCAP unbelted condition with airbag deployments of 40-50 milliseconds (ms) for all three seating positions. Upper tibial indexes were also significantly higher for unbelted conditions for both AAMA and NCAP pulses and exceeded the injury criteria in all unbelted conditions but met for belted conditions. Chest acceleration (3 ms clip) was not significantly different

between belted and unbelted AAMA pulse conditions. Chest accelerations did exceed the 60 G criteria in the NCAP, unbelted conditions for all three seat positions for the 40-50 ms airbag deployment times as a result of bottoming out the bag and striking the dummy's chest to the dashboard.

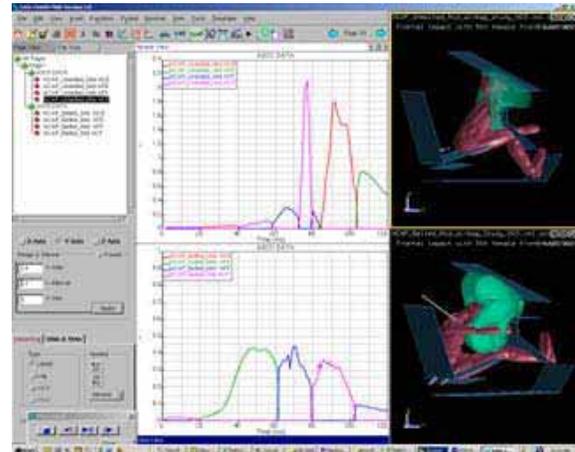

Figure 1

Tibial indexes and  $N_{ce}$  increased as seat fore/aft position increased. Chest accelerations had an increasing trend when in closer proximity to the deploying airbag.

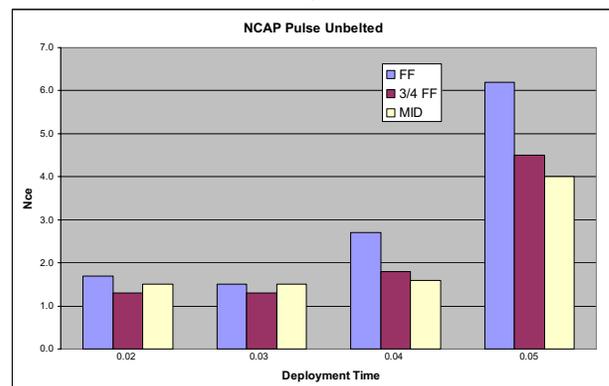

Figure 2

### SUMMARY

A parametric MADYMO study was performed to determine seat belt usage in a frontal collision based upon known injury outcome. Analysis of accepted injury indices and criteria demonstrated a significantly higher probability of injury in the unbelted scenario with the occupant located at the approximate mid fore/aft position at the time of impact.

## OCCUPANT KINEMATIC ANALYSIS OF AN UNBELTED MINIVAN PASSENGER: A FREE BODY APPROACH

David E. Raymond, Edward C. Fatzinger Jr., Thomas J. Connors, Jeffrey B. Wheeler  
Vector Scientific, Inc., Los Angeles, California  
[draymond@vectorscientific.com](mailto:draymond@vectorscientific.com)

### INTRODUCTION

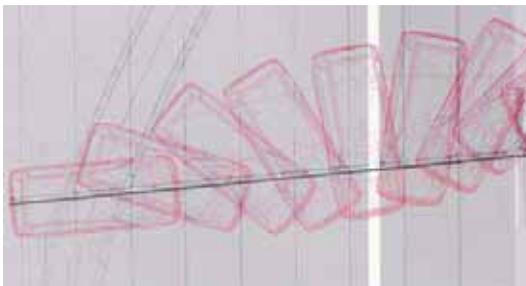

A case analysis is presented where an unbelted second row passenger of a minivan claimed to have been ejected through the second row passenger side window when his vehicle was struck on the passenger side at an intersection. A vehicle dynamics analysis, occupant kinematic analysis, and vehicle interior dimensional analysis, were utilized to develop an understanding of the occupant kinematics.

### METHODS

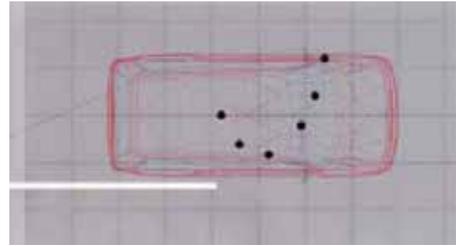

Medical records were reviewed that revealed a minor laceration to the right cheek and minor knee contusions. Examination of an exemplar minivan was also carried out. Geometric measurements of the vehicle were recorded for use in analysis. Occupant kinematics were based on results of vehicle collision dynamics along with pre-impact body position evidence. Vehicle dynamics were determined using accident reconstruction engineering techniques and analysis. Occupant kinematics were determined using methods outline by Bready et al. and interior dimensional analysis [1].

### RESULTS AND DISCUSSION

Vehicle kinematics were used to establish the pre-impact heading of the unbelted second row occupant. Since the occupant was unbelted the assumption was made that the second row occupant would act as an uncoupled body in the crash and continue along his pre-impact heading until acted on by an interior vehicle component. Once the heading was determined, the occupant position at coincidental time intervals as the vehicle dynamics data was determined and plotted. Once this was done the two are merged to give gross occupant kinematics assuming no interior contacts. Offset of the occupant initial position was made based on testimony of the occupant and interior vehicle measurements of the second row bench seat.

Once this was done, the coordinates were transformed into the vehicle coordinates system.

This trajectory was used to then render a 3-D drawing of occupant motion relative to vehicle interior components.

An 11-14 inch offset existed between the top of the bench seat and the bottom of the passenger side second row window. 3-D analysis revealed that the occupant would not have ejected out of the side window but rather contacted the front passenger seat as shown below. This is mostly due to the rotation of the minivan upon impact. The occupant is shown in a position close to the floor of the van which is an effect of both gravity and ramp effect of the seat back. The occupant presented with a facial laceration to the right cheek that coincided with contact of the right front seat inboard armrest as shown below.

### SUMMARY

An occupant kinematics study was undertaken to investigate whether an unbelted second row occupant in the prone position, would eject through the passenger side window during a side impact. Published methods of occupant kinematic analysis, vehicle reconstruction techniques, and 3-D rendering were used to determine that the occupant would not have ejected through the passenger side window.

**WRIST ELECTROMYOGRAPHY AND KINEMATICS WHEN PROPELLING STANDARD, COMPLIANT, AND POWER-ASSISTED PUSHRIM WHEELCHAIRS: A PILOT STUDY**

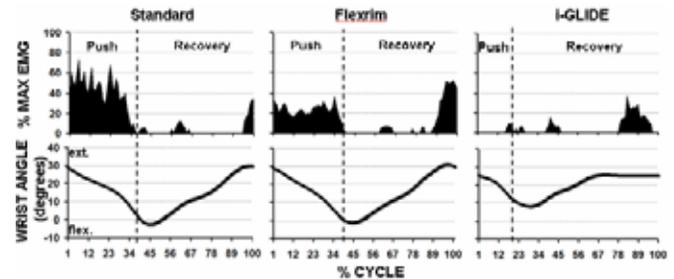

Philip Requejo, Ernest Bontrager, Craig Newsam, Valerie Eberly, Joanne Gronley, and Sara Mulroy  
 Pathokinesiology Laboratory, Rancho Los Amigos National Rehabilitation Center, Downey, CA, USA  
 email: [prequejo@larei.org](mailto:prequejo@larei.org), web: [www.larei.org](http://www.larei.org)

**INTRODUCTION**

Alternative modes of manual wheelchair (WC) propulsion offer a way to reduce demands on the upper extremities [1]. A compliant pushrim can reduce the impact forces on the hands during the push-phase of propulsion [2]. A pushrim-activated power-assisted WC (PAPAW) that applies power to the hub at each push requires less effort [3] than standard unassisted WC. While the demands on the upper extremities when propelling on a standard WC are well documented [4], measurement of muscle activity allows us to determine the muscular demands when propelling with alternative modes of WC propulsion. The purpose of this pilot study was to document the electromyographic activity of the wrist muscles and range of motion of the wrist joint when propelling a standard and two alternative pushrim designs. We hypothesized that these alternative pushrim designs can reduce the demands on the wrist musculature during manual WC propulsion.

**METHODS**

A non-disabled adult male served as a subject for this preliminary study. He read and signed an IRB approved informed consent form before participating. The subject propelled a Standard pushrim, a compliant pushrim design (FlexRim) [1], and a PAPAW (i-GLIDE™) [2] design positioned on a stationary custom wheelchair ergometer [4]. Data were recorded at a self-selected free and fast propulsion speed (level ground simulation) and at a simulated 8% grade. Switches were taped to the right palm to determine the push and recovery phase timing. Wrist muscle activity was documented with bipolar, fine-wire electrodes inserted into the flexor digitorum sublimis (FDS), flexor carpi radialis (FCR), extensor carpi radialis longus (ECRL), extensor digitorum communis (EDC), opponens pollicis (OP), flexor pollicis brevis (FPB), supinator (SUP), and pronator teres (PT) muscles. EMG signals were transmitted via a co-axial cable and digitized (2500Hz) using a data collection computer. The EMG data were full wave rectified and integrated over 0.01sec interval. The EMG values during propulsion were normalized by the highest 1 second of activity obtained in a maximal effort manual muscle test for each muscle (%MAX). The average integrated EMG was determined at each 1% of the propulsion cycle. Three-dimensional motion of the right upper extremity and trunk was recorded (50Hz) during each 10-sec propulsion trial using a Vicon (Oxford Metrix) motion analysis system. Wrist joint kinematics was calculated from the recorded data using an Euler/Cardan rotation sequence.

**Figure 1:** FDS activity during push and recovery phase of graded propulsion with a Standard, Flexrim, and i-GLIDE

**RESULTS AND DISCUSSION**

Five muscles had their primary activity during the push phase while three muscles were primarily active during recovery. Intensities of these muscles increased primarily in the fast and graded propulsion with Standard and FlexRim but remained low with the i-GLIDE (Table 1), particularly in the graded propulsion (Figure 1). All push-phase muscles had an onset late in recovery. Intensities of these muscles were highest primarily in the Standard. Intensities of the grip muscles (OP, FPB, and FDS) were less in the FlexRim than Standard during free and fast propulsions. During graded propulsion, the push-phase time was 52% less (42 vs. 20% cycle) for the i-GLIDE compared to Standard and FlexRim. In the graded propulsion, the push-phase flexion/extension range of motion in the i-GLIDE was 57% less (31 vs. 13degrees) than Standard and 52% less (13 vs. 28degrees) than the FlexRim (Figure 1). The lower EMG, reduced push phase timing and range of motion is indicative of reduced muscular demands. Use of alternative WC pushrim designs has the potential to benefit WC users, particularly when propelling in more demanding terrains. Assessment of wrist demands in everyday WC users remains as future work.

## THREE DIMENSIONAL MULTISCALE RECONSTRUCTION OF EMU FEMORAL HEAD OSTEONECROSIS: FROM CELL TO ORGAN LEVEL

<sup>1</sup>Jessica Goetz, <sup>1</sup>Thomas Baer, <sup>1</sup>Gail Kurriger, <sup>1</sup>Douglas Pedersen, and <sup>1</sup>Thomas Brown  
<sup>1</sup>Department of Orthopaedics and Rehabilitation University of Iowa;  
email: [jessica-goetz@uiowa.edu](mailto:jessica-goetz@uiowa.edu), web: [poppy.obrl.uiowa.edu](http://poppy.obrl.uiowa.edu)

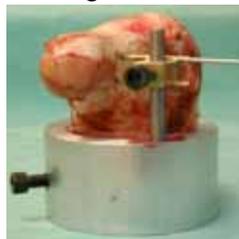

### INTRODUCTION

Osteonecrosis of the femoral head is a disorder whose mechanical pathogenesis (collapse) is significantly affected by the geometric details of the necrotic lesion. The (bipedal) emu model of osteonecrosis, unlike other animal models, mimics human clinical collapse. For lesions induced by liquid nitrogen insult, systematic studies of the resulting structural compromise require delineation of zones of necrosis in three dimensions relative to the global femoral head. Unfortunately, the gold standard for determining osteonecrosis is by time-consuming histologic evaluation, thus requiring novel multiscale analysis.

Automated histologic image analysis [1], which can determine osteocyte viability, requires that global orientation of the femoral head be preserved throughout histologic processing and analysis. Post-analysis, data from multiple slides need to be reassembled into a three-dimensional global map of osteocyte survival.

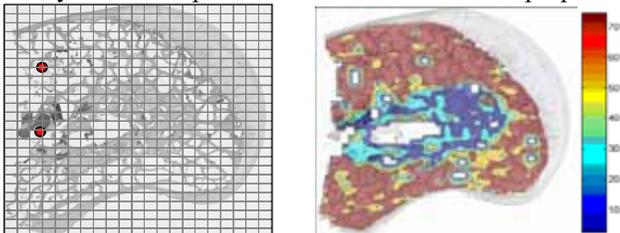

### METHODS

Immediately post-necropsy, the proximal portion of emu femur is fixed in formalin. After fixation, the femur is landmark leveled and potted upright in PMMA. The potted specimen is then transferred to a custom drill guide and two parallel holes, 1.6 mm in diameter and 10 mm apart, are drilled through the femoral neck (Figure 1). Two orthogonal cuts are made 3.8 mm from the holes to remove the femoral head and neck from the remainder of the proximal femur. The femoral head is then decalcified in formic acid.

**Figure 1:** Potted femur in drill guide.

Since there is no practical way to preserve serial section registry after paraffin embedment and conventional microtoming, it was necessary to introduce fiducial markers that had the unique attributes of accurate shape preservation during subsequent histological processing, yet sufficient friability to not damage the delicate microtome blades. After investigating many candidates, we found that ordinary household potato had that combination of properties.

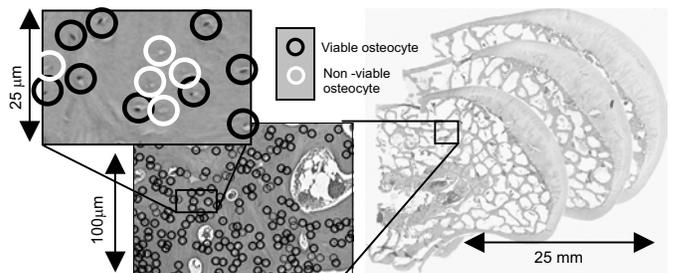

**Figure 2:** (a) Reconstructed slide image with dowel marker (red) and grid lines between every second subimage. (b) Two dimensional contour plot of osteocyte survival.

Upon decalcification, two 1.5 mm diameter dowels of potato, dried for 48 hours in a 42°C oven, are inserted through the two holes in the femoral neck. The femoral head, with fiducial dowels in place, is then dehydrated in ethanol, cleared in xylene, and embedded in paraffin. Serial sections are taken every 0.5 mm through the entire thickness of the head. Each section is mounted and stained in Wiegert's hematoxylin and eosin.

Each slide is scanned on a stepper-motor-driven microscope stage, and saved in the form of approximately 2000 subimage .tif files. Every subimage is analyzed to measure fractional osteocyte survival. These individual subimages are then reconstructed in Matlab into a whole-section image, and osteocyte viability data for each slide are reassembled into a corresponding two-dimensional matrix (Figure 2). Each two-dimensional whole-head section is rotated and translated until the centroids of its two dowel fiducial markers are coincident with those from the other sections (Figure 3). After this affine transformation, these sections are assembled into a three dimensional matrix, and interpolated to output the three-dimensional distribution of osteocyte necrosis.

### RESULTS AND DISCUSSION

The present three-dimensional arrays of fractional osteocyte viability represent the first instance of histology-based osteocyte status being mapped at the whole-bone level. This allows direct registration of the cryo-induced lesion relative to osseous stresses that result from external loading of the joint, toward the goal of understanding the role of lesion pathogenesis in global mechanical collapse.

**Figure 3.** Stacked sections of femoral head with zoomed-in insets of an individual subimage and further zoom in of individual osteocytes.

## IN VITRO VALIDATION OF THERMAL FINITE ELEMENT ANALYSIS OF CRYOINSULT DELIVERY FOR EMU FEMORAL HEAD NECROSIS

<sup>1</sup> Jessica Goetz and <sup>1</sup>Thomas Brown

<sup>1</sup>Department of Orthopaedics and Rehabilitation University of Iowa;  
 email: [jessica-goetz@uiowa.edu](mailto:jessica-goetz@uiowa.edu), web: [poppy.obrl.uiowa.edu](http://poppy.obrl.uiowa.edu)

### INTRODUCTION

In ongoing work with the emu as a bipedal animal model of osteonecrosis, lesions are induced by means of a custom built cryoprobe surgically inserted into the femoral head [1]. In order to study the factors governing the size of these lesions, a thermal finite element model has been developed to quantify freeze and thaw rates, as well as freeze front geometry, as a function of operator-controlled parameters during surgery.

Initial validation of the finite element model had been performed in a geometrically simplified agarose preparation [2]. Because this model needs to accurately model the freeze cycle as it occurs intraoperatively, further benchtop testing has been performed in fresh emu femur specimens.

### METHODS

Six emu femurs were obtained fresh from an abattoir. PMMA molds were made of the lateral side of each femur and used as a drill guide. A 4 mm diameter drill hole and four 0.8 mm diameter drill holes were drilled through the PMMA. The drill guide was attached to the femur and holes drilled approximately 50 mm into the femoral head. Copper-constantan thermocouples embedded in 0.8 mm diameter tubing were inserted into the four small drill holes.

A custom built cryoprobe [2] was inserted into the femoral head through the main drill hole, and the femur was positioned with its head embedded in a reservoir of 1% agarose, to provide thermal inertia (Figure 1a). A seven-minute freeze from room temperature to  $-30^{\circ}\text{C}$  was performed followed by a passive seven-minute thaw. Temperatures were recorded for the four thermocouples in the femoral head, and one each at the tip of the probe, in the probe shaft, and in the agarose 1 mm from the medial side of the femoral head. Post-thaw, the femoral head was cut open and the actual locations of the thermocouples measured for verification.

The finite element model reflected the geometry of probe used for the experimental testing, and was driven from the time-temperature curve recorded at the tip thermocouple during each benchtop test. Both non-homogeneous conductive effects and phase change latent heat nonlinearity were

**Figure 1:** (a) Experimental set-up with femur in agarose and probe and thermocouples inserted into femoral head from lateral side of femur. (b) Close-up of thermocouple insertion.

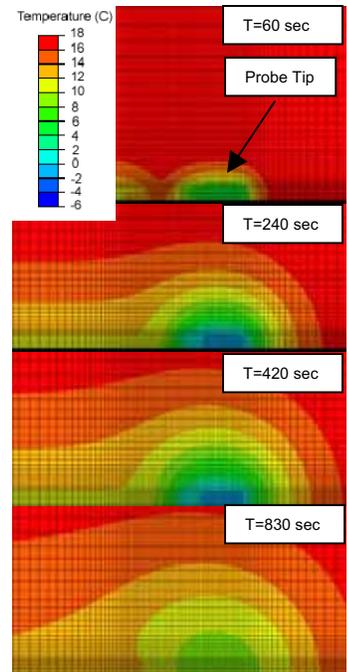

included. Temperature curves for nodes corresponding to the location of the thermocouples were extracted and compared to the experimental temperature curves.

### RESULTS AND DISCUSSION

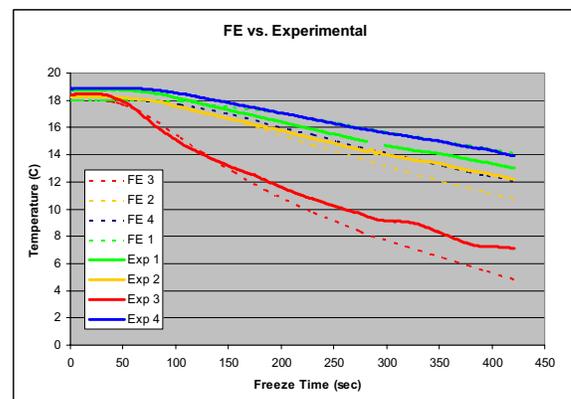

The current FEA parameter set results in a model that is capable of replicating experimentally measured temperatures to within  $3^{\circ}\text{C}$  (Figure 3). Because of the accurate results obtained from the testing in this preparation, the finite element model is suitable to model the freeze cycles occurring intraoperatively, with due accommodation of tissue heating effects.

### CONCLUSIONS

The finite element model of cryoinsults to a cadaver emu femoral head accurately models in vitro thermal behavior.

**Figure 2:** Finite element run of a seven-minute freeze followed by a seven minute thaw.

**Figure 3:** Temperature curves for thermocouples in the femoral head during a 7-minute freeze (thick lines) and the corresponding nodal temperature curves.

## PREDICTORS OF SUCCESS IN THE 3000M STEEPLECHASE WATER JUMP

Bryan K. Lindsay and Iain Hunter

Department of Exercise Sciences, Brigham Young University, Provo, UT, USA

email: [bkl8@email.byu.edu](mailto:bkl8@email.byu.edu), web: [biomech.byu.edu](http://biomech.byu.edu)

### INTRODUCTION

While the steeplechase has been contested for over 150 years, relatively little research has been completed regarding the technique involved in this unique event. In our research, we looked at six different characteristics of the water jump barrier technique: Minimum hip angle of the lead leg at take-off, knee angle of the support leg (pushing off the barrier), take-off distance, center of mass height above the barrier, approach speed, and landing distance (see figure 1). These characteristics were chosen due to past work by coaches and researchers [1,2]. This study determined which characteristics are significant predictors of the ratio of race pace to speed through the water jump.

**Figure 1:** Definitions of some of the measured characteristics.

### METHODS

Seventeen women and 19 men were filmed and digitized to measure two-dimensional characteristics of water-jump technique in the 3000-meter steeplechase using Peak Motus 8.2 (Centennial, CO). Subjects were filmed at three different meets during 2004: The Cardinal Invite (Palo Alto, CA), The Oxy Invite (Eagle Rock, CA), and The Olympic Trials (Sacramento, CA). These meets provided a range of athletes from Division II NCAA athletes to Olympic qualifiers, including one Olympic Finalist.

Multiple linear regression was used to determine which characteristics of technique significantly predict the ratio of race pace to speed through the jump. Speed through the jump was measured between 2.5 m prior to the barrier and 2.5 m past the water. The ratio of speeds was chosen to normalize speed between athletes.

### RESULTS AND DISCUSSION

Approach speed and landing distance were significant predictors of speed divided by race pace for men and women

(Tables 1 and 2). All other variables in the full model were rejected due to non-significance at the 0.05 alpha level. The ratios of race pace to speed through the water jump for women and men respectively were 0.89 and 0.92.

While approach speed and landing distance were significant predictors of the ratio of race pace to speed through the jump, they were very different in how much variance they explained for each model. Approach speed was clearly the most noticeable factor for women. However, for men, landing distance was much more critical. With the event being fairly new for women, race times are dropping rapidly. This should increase their approach speed, which may lead to landing distance explaining more of the variance for women in the future as is seen with the men.

**Table 1:** Prediction for speed divided by race pace for women.

Variable	$\beta$	Partial R <sup>2</sup>	p-value
Approach Speed (m/s)	0.113	0.614	<0.001
Landing Distance (m)	0.067	0.078	<0.001
Intercept	0.013		0.016

**Table 2:** Prediction for speed divided by race pace for men.

Variable	$\beta$	Partial R <sup>2</sup>	p-value
Approach Speed (m/s)	0.013	0.015	0.044
Landing Distance (m)	0.136	0.605	<0.001
Intercept	0.443		<0.001

### CONCLUSIONS

Success in completing the water-jump of the 3000m steeplechase without dropping from race pace dramatically can be accomplished by accelerating during the approach to the barrier and accomplishing a relatively long landing distance. There are obviously limits to how much acceleration and how far of a jump off the barrier should be attempted. However, with the athletes analyzed in this study, the larger the approach speed and the longer the jump into the water, the better the athletes were able to keep their water-jump horizontal velocity close to their race pace.

## COMPARISON OF ARTHROMETER (PASSIVE) AND FUNCTIONAL ACTIVITY (ACTIVE) ANTERIOR TIBIAL DISPLACEMENTS

<sup>1</sup> Robert Deusinger, <sup>1</sup>Dequan Zou, <sup>1</sup>Keith Minor, and <sup>1</sup>Ben Seedorf

<sup>1</sup>Human Biodynamics Lab, Program in Physical Therapy, Washington University School of Medicine,  
4444 Forest Park Blvd., Campus Box 8502, St. Louis, MO Email: [deusingerb@msnotes.wustl.edu](mailto:deusingerb@msnotes.wustl.edu)

### INTRODUCTION

KT-1000 and KT-2000 arthrometers commonly are used as diagnostic aids by clinicians to passively detect excessive amounts of anterior tibial displacement (ATD) associated with disruption of the anterior cruciate ligament (ACL) as well as during reconstructive surgery and subsequent rehabilitation as a means to determine levels of restored and maintained ACL integrity [1]. However, these devices assess only passive ATD during non-weight-bearing. Because many daily functional activities involve active movement on weight-bearing limbs, it is important to know whether the passive ATD measures imply anything about ACL integrity during actively performed non-weight-bearing (NWB) as well as weight-bearing (WB) functional activities. The purposes of this presentation are to examine whether: 1) there is concurrent validity of passive KT-1000 and active movement, functional activity ATD measurements; 2) joint surface kinematics of ATD, % rolling, and % gliding differ between a NWB and WB activity; and 3) tibiofemoral % rolling and % gliding reflect ATD during the active movement functional activities.

### METHODS

Data were collected on 12 subjects (3 males and 9 females, mean age 24.8±2.1 yrs, mean weight 138.4±22.6 lbs.) and a history of no injury to the test knee within the last 5 years.

Passive anterior tibial displacement was measured at maximum manual force using a KT-1000 arthrometer. The measurements were obtained between 25°-30° knee flexion based on patient size and comfort, and according to manufacturer guidelines. Active movement ATD, % rolling, and % gliding measurements were obtained by inputting 3-D videographic motion analysis kinematic data into a computational geometric knee model [2] for a sitting knee extension (NWB) and a sit-to-stand (WB) activity. Based on the model, a slip ratio [3] was computed from which percent rolling and gliding were calculated. Using femoral arc length and tibial contact point displacement components of the slip ratio, active movement ATD measures were obtained. All knee arthrometer and active movement knee model data were averaged over three trials at respective subject-specific, knee arthrometer test angles.

Analysis: A Pearson correlation between knee arthrometer passive and knee model active movement ATD of the NWB and WB activities was used to establish concurrent validity. ANOVA was performed to determine whether meaningful differences occurred between the NWB and WB activities for ATD, % rolling, and % gliding. A multiple regression was used to identify whether tibiofemoral % rolling and/or % gliding reflect active movement ATD during NWB and WB activities.

### RESULTS AND DISCUSSION

The mean passive ATD was 6 times greater than the active movement ATD of the NWB and WB activities whereas ATD for the NWB and WB activities were similar (Table 1). Pearson r-values ( $r = 0.572$ ;  $r = 0.488$ ) strongly support no concurrent validity between the passive and active measures of ATD suggesting they measure different aspects of ATD. High correlation values ( $r = 0.978$  to  $0.993$ ) between active ATD and % rolling and % gliding demonstrate a strong association of ATD to rolling and gliding (Table 2). The lower value of active ATD for NWB likely reflects stabilizing effects of muscle activity while the lower ATD for WB likely reflects the role of both muscle activity and joint compression effects that minimize ATD, while enhancing joint stability. Conversely, the greater passive ATD may indicate tibiofemoral stability without constraints of muscle activity and joint surface compression.

Table 1. Mean Passive and Active ATD Values

Passive ATD (mm)	NWB ATD (mm)	WB ATD (mm)
8.94 ± 1.80	1.56 ± 0.05	1.37 ± 0.07

Table 2. Multiple Correlation of Functional Activity (Passive) ATD with Percent Rolling and Gliding

	NWB ATD	WB ATD
% Rolling	-0.993	-0.978
% Gliding	0.993	0.978

### CONCLUSIONS

We analyzed both passive NWB and active NWB and WB measures of anterior tibial displacement in healthy knees. A similar analysis is planned for ACL deficient knees. We believe our preliminary results provide a foundation for further investigation. Substantiating a combined use of passive and active ATD measures may help differentiate whether impairments of appropriate muscle activity patterns and/or joint surface alignment contribute to abnormal joint surface kinematics with ACL disruption.

## STABILITY OF PLATE FIXATION CONSTRUCTS WITH LOCKED AND NON-LOCKED SCREWS

<sup>1</sup>Larry W. Ehmke, <sup>1</sup>Michael Bruehl, <sup>2</sup>Daniel C. Fitzpatrick, and <sup>1</sup>Michael Bottlang

<sup>1</sup>Biomechanics Laboratory; Legacy Clinical Research & Technology Center, Portland, OR,

<sup>2</sup>Orthopedic Healthcare Northwest, Eugene, OR; email: [mbottlang@biomechresearch.org](mailto:mbottlang@biomechresearch.org)

### INTRODUCTION

The development of locked plate technology represents a changing approach to fracture fixation. Locked plates function as internal fixators and allow secondary bone healing through endochondral ossification [1]. The mechanics of locked plates are fundamentally different from conventional non-locked plates and so require a revised understanding of the plate-bone construct stability.

This study was designed to investigate the stability of unicortical and bicortical locked plate constructs relative to conventional, non-locked constructs in an osteoporotic long bone model. We hypothesized that locked unicortical and bicortical constructs were at least as stiff and strong as conventional non-locked constructs.

### METHODS

To represent osteoporotic bone, 27 cylindrical surrogate specimens were machined from 30pcf foam blocks (G.P., Tacoma, WA) to 30mm outer diameter, 3mm wall (cortex) thickness, and 200mm length. A 10-hole 4.5mm narrow LCP (Synthes, Paoli, PA) was affixed to bone surrogates by either 4.5mm non-locking or 5.0mm locking screws. A 10mm fracture gap was simulated by fixing the LCP to surrogate bone on one side and to a rigid aluminum cylinder on the other (representing stiff diaphyseal bone).

Plate-specimen constructs were loaded into a material test machine (Instron 8874) to be tested in torsion, axial compression, and 4-point bending under progressive dynamic loading. Cyclic amplitude was increased with each loading cycle until construct failure or plate separation. Construct stiffness was assessed at the beginning of cyclic loading, before the onset of implant loosening or construct plastic deformation. Strength was defined as the maximum force, torque, or bending moment required for construct failure (considered as specimen breakage or plate loosening).

Three groups of screw types were tested in a 1,3,5-screw configuration: conventional non-locked (Non-Lock), locked unicortical (Lock-Uni), and locked bicortical (Lock-Bi). A one-way ANOVA was used to detect differences among groups. Subsequently, a Dunnett's test was conducted to determine significance versus Non-Lock constructs ( $\alpha < 0.05$ ).

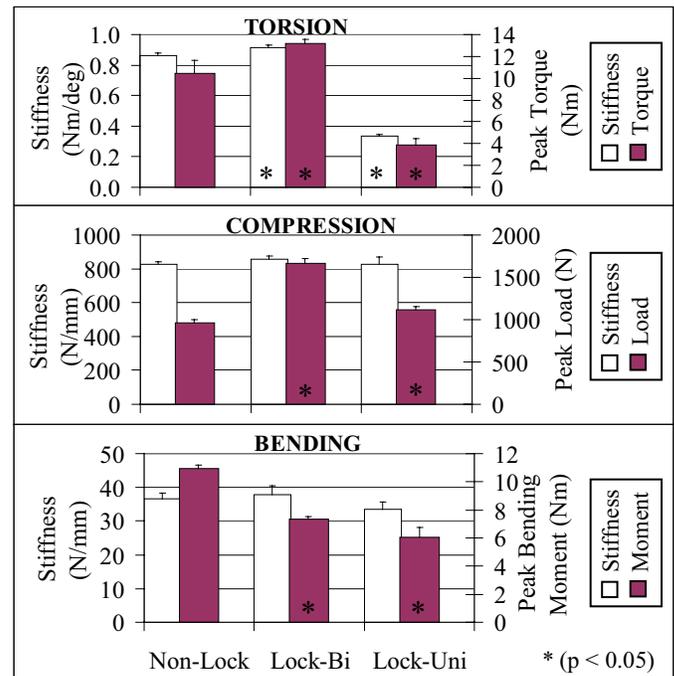

### RESULTS

**Construct Stiffness:** In torsion, Non-Lock constructs were 7% less stiff than Lock-Bi constructs ( $p < 0.05$ ), but were 60% stiffer than Lock-Uni constructs ( $p < 0.05$ ) (Fig. 1). In compression and 4-point bending no significant difference in stiffness was detected among groups.

**Construct Strength:** In torsion, Non-Lock constructs were 27% weaker than Lock-Bi constructs ( $p < 0.05$ ), but were 63% stronger than Lock-Uni constructs ( $p < 0.05$ ) (Fig. 1). In compression, Lock-Bi and Lock-Uni constructs exhibited 72%

( $p < 0.05$ ) and 16% ( $p < 0.05$ ) larger peak loads as compared to Non-Lock constructs, respectively. In 4-point bending, Lock-Bi and Lock-Uni constructs sustained 33% ( $p < 0.05$ ) and 45% ( $p < 0.05$ ) lower peak bending moments as compared to Non-Lock constructs, respectively.

In both torsion and 4-point bending, failure of all constructs was dominated by breakage of foam specimens through the screw hole furthest from the fracture gap. Plate loosening was primarily responsible for construct failure during compression.

**Figure 1:** Stiffness and strength for locked and non-locked screw types in a) torsion, b) compression, and c) 4-point bending (\*= $p < 0.05$ ).

### DISCUSSION

Results of this study provide a better understanding of the role of locked plating in comparison to non-locked techniques. Stiffness represents the initial fixation characteristics of the plate-bone construct. Similar to Pater et al., our results show that bicortical screw constructs provide greater stiffness and strength in torsion than unicortical locked constructs [2]. Under both torsion and compression locked bicortical constructs exhibited the highest load to failure. Interestingly, in bending, conventional non-locked constructs provided the highest resistance to failure, which may be in part due to smaller diameter screw holes.

**UPPER LIMB MOTION DURING SNOW SHOVELING WITH REGULAR AND MODIFIED SHOVEL**

<sup>1</sup>Hitoshi Yanagi, <sup>2</sup>Noriyuki Yamamoto, <sup>1</sup>Xiaohui Gai, <sup>1</sup>Katsumi Miyakoshi and <sup>3</sup>Tadao Isaka  
<sup>1</sup>Satellite Venture Business Laboratory, Kitami Institute of Technology,

**INTRODUCTION**

Snow shoveling is a hard labor routine in a cold northern region in the winter. The task should be considered a physically intensive activity and associated with local muscle pain of the lower back. Freivalds [1] stated in his review that a second handle on a shovel might improve shoveling performance by reducing the amount of stooping. We confirmed that the amount of the thorax forward tilt, the lower limbs flexion and the center-of-gravity distance traveled were significantly smaller when using a shovel with a second handle [2, 3]. However, the effects of the second handle on the upper limbs have never been studied. Thus, this study attempted to determine how different types of shovel affect the motion of the upper limbs during the shoveling of snow.

**METHODS**

Five right-handed male subjects volunteered to participate in the laboratory experiments. The mean values  $\pm$  SD of their heights, weights, and ages were  $1.68 \pm 0.06$  m,  $66.3 \pm 10.6$  kg,  $28.2 \pm 8.7$  yrs., respectively. They received an explanation of the experimental protocol and provided informed consent prior to testing.

Two types of shovel were compared in the study, a regular shovel and a modified shovel with a second handle. The regular shovel is a commonly used one and consists of a 1.5-m main shaft and a plastic blade. The modified shovel resembles the regular shovel in its blade and main shaft but an additional second handle is mounted perpendicularly to the main shaft.

Subjects shoveled simulated snow with the two different shovels in the laboratory. The simulated snow was stuffed bags with shredded paper in three different weights. For each bout, subjects used one of the two shovels, and were required to scoop up one bag placed diagonally left in front of their left foot and throw it onto a 0.7-m-height box 1.75 m away from them.

The measurements of kinematic data during the shoveling were established using the VICON 460 motion analysis system (Vicon Motion Systems, UK) with six cameras at 120 Hz placed on the laboratory ceiling. The flexion angles of the elbow joints were chosen in order to describe the motion of

the upper limbs while shoveling. The shoveling was divided into the three phases; squatting, lifting and throwing according to the previous study [2, 3].

The kinematic data during the shoveling were expressed as mean  $\pm$  SD. A Student's paired *t*-test was used to determine significant differences between the two types of shovel on measured variables. The *p*-value was considered significant when it was found to be less than the usual level of significance 0.05.

**RESULTS AND DISCUSSION**

Table 1 shows the flexion angles of the elbow joints during the shoveling with the regular and modified shovel. The minimum left elbow flexion angle was significantly smaller in the squatting phase when the subjects used the modified shovel than when they used the regular shovel. Although the maximum left elbow flexion angle was slightly larger when using the modified shovel, there was no significant difference between the two shovels. Moreover, the angular displacement of the left elbow joint was significantly larger when shoveling with the modified shovel. The right elbow flexion angles were significantly smaller both in the squatting and the lifting phases when using the modified shovel. Bending the left elbow would be needed to keep the blade horizontal with the ground so as not to let the snow slip off. Consequently, more stresses may be imposed on the left elbow flexor muscles when using the modified shovel. In order to reduce the amount of the left elbow flexion it may be necessary to increase the lift angle between the blade and the main shaft or to lower the second handle height. Further shovel modification would help users shovel snow more comfortably.

### INTRODUCTION

Approximately 170,000 individuals worldwide receive prosthetic heart valves every year; 95% of these are mitral and aortic valve replacements, and more than 60% of those are mechanical heart valves. In general, mechanical heart valves tend to last longer than biological prosthetic valves, but they also carry a greater long-term risk of cardiovascular complications. Such complications are thought to be caused by high blood shear stress, turbulence and the overall complexity of hemodynamics in the mechanical heart valves. So far, important advances have been achieved in the implementation of computational fluid dynamics to study cardiovascular physiology using numerical techniques that require domain discretization, such as finite element methods or finite difference techniques. However, these cannot fully represent the moving and deforming boundaries present in an operating valve, an issue that can be approached using the Boundary Element Method (BEM), a numerical technique that has not yet been applied in cardiovascular modeling.

The main goal of this project is to develop a mathematical and numerical model to simulate blood flow through bileaflet prosthetic valves based on the BEM. This technique will be suitable for modeling the flow in these geometrically complex systems which are dominated by moving and deforming boundaries.

### METHODS

The flow of blood in the cardiovascular system can be considered incompressible and Newtonian. Therefore, the momentum equations are reduced to the Navier-Stokes equations, a system of partial differential equations that basically describe fluid flow; though fundamental and rigorous, they are nonlinear, non-unique, complex and difficult to solve. They do not have a general solution, and so far only a few particular solutions have been found. These exact solutions are important because basic phenomena described by the mathematical model can be analyzed; also they can be used as standard solutions to compare with the approximate numerical solutions. However, in almost every practical situation, it is necessary to use numerical methods in order to obtain a solution of the Navier-Stokes equations.

Through mathematical manipulation, the governing equations were transformed into boundary integrals, requiring a boundary-only discretization for their solution. This solution scheme of the complex equations, which include moving boundaries, is the BEM.

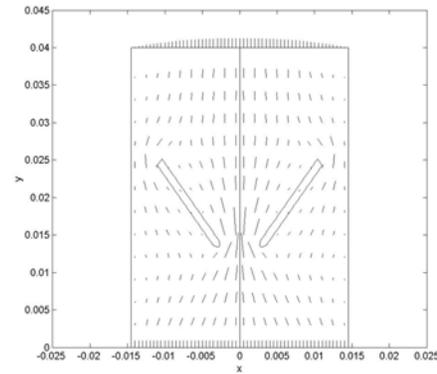

Figure 1: Snapshot of flow through the valve.

A two-dimensional (2D) model of the mechanical bileaflet valve geometry was developed, which consisted of a cylindrical tube containing a bileaflet valve. Due to the symmetry the simulation was performed to half the domain (see Figure 1). The valve diameter and thickness were 29 mm and 1 mm, respectively; the length of the tube was 40mm. The gap between the leaflet and the tube wall in the closed position was fixed to 0.1 mm. The constant values used for density and viscosity were 1,000 kg/m<sup>3</sup> and 0.004 kg/m-s, respectively. The non-slip boundary condition was used on the tube wall.

### RESULTS AND DISCUSSION

Simulations were performed on 10 valve positions between 0° and 70° with respect to the transverse axis of the tube. Figure 1 shows the velocity vectors through an opening valve (55° position). At small opening positions, vortices between the two leaflets were generated due to high flow acceleration in that region. As the valve opens, the flow stabilizes and shows a characteristic parabolic profile downstream.

## QUANTITATIVE PREDICTION OF PROGRESSION OF ARTICULAR CARTILAGE DEGENERATION FOLLOWING INCONGRUOUS INTRA-ARTICULAR FRACTURE REDUCTION

Yang Dai<sup>2</sup>, Thomas D. Brown<sup>1,2</sup>, J. Lawrence Marsh<sup>1</sup>

<sup>1</sup>Department of Orthopaedics and Rehabilitation, <sup>2</sup> Department of Biomedical Engineering  
 University of Iowa, Iowa City, IA; email: [tom-brown@uiowa.edu](mailto:tom-brown@uiowa.edu)

### INTRODUCTION

Intra-articular fracture reduction is a very difficult orthopaedic procedure since it is widely believed that the residual incongruity can induce stress aberration in the articular cartilage and then provoke a mechano-response leading to degeneration of cartilage (secondary osteoarthritis).

The degeneration of cartilage is a chronic procedure. From a mechanical perspective, the neighboring healthy cartilage will endure elevated load since degenerative cartilage becomes more compliant. Therefore, healthy cartilage may degenerate with time, a cascading effect leading to whole joint degeneration.

Here, Discrete Element Analysis (DEA)[2] was used to quantitatively calculate the possible degeneration area in an acetabular fracture, as an example to show the effect of progressive degeneration when the cascade effect is taken into account.

### METHODS

A hip joint model was created from the CT slices and the potential contact area was selected between the femoral head and acetabulum. [3] Treating the femoral head and acetabulum as rigid bodies, the region between them, viz. the cartilage, is represented as an array of linear elastic compressive springs. The springs' stiffnesses in the normal direction (Equation 1) depend on the cartilage modulus (E), Poisson ratio ( $\nu$ ) and thickness (h). Shear can also be addressed in DEA, but due to joint lubrication, the stiffness in shear here is assumed to be negligible.

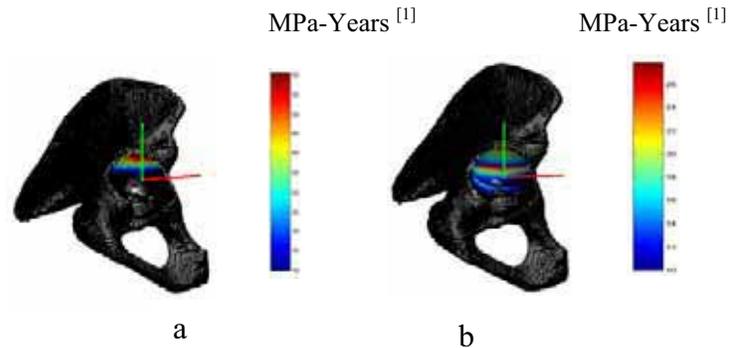

$$k_n = \frac{E(1-\nu)}{(1+\nu)(1-2\nu)h} \quad [1]$$

A trans-tectal displaced fracture model was created. A gait cycle with 16 instances was used to calculate the contact stress distribution. Cumulative pressure exposure ( $P_c$ ) for the cartilage was then calculated [3]. The results were scaled to compare with literature on chronic cartilage pressure tolerance. [1]

The potential degeneration area is defined as any area with  $P_c$  large than 10 MPa-years. Here, a year was used as a time span. The cartilage modulus in any region with degeneration was reduced to only 20% that of normal. The same procedure was used to calculate the potential degeneration area in the next year and so on.

### RESULTS AND DISCUSSION

For different residual step-offs (2.5, 2.0, 1.5, 1.0, 0.5 and 0mm), the cumulative pressure exposures were calculated for a 2-year time span. Also, progressive degeneration was calculated. (Figure 1)

**FIGURE 1** DISTRIBUTION OF CUMULATIVE PRESSURE EXPOSURE AT 2 YEARS, FOR A 2MM STEP-OFF

(a) Without progressive degeneration (b) with progressive degeneration

Step-off (mm)	2-year Overpressure Area (mm <sup>2</sup> ) without cascade effect	2-year Overpressure Area (mm <sup>2</sup> ) with cascade effect
0	0	0
0.5	6.68	845.64
1.0	486.89	1688.50
1.5	576.34	1747.80
2.0	700.60	1798.10
2.5	988.94	1954.00

**Table 1:** Cartilage area experiencing over 10MPa-years of cumulative over-pressure (Total potential contact area = 3402.9mm<sup>2</sup>)

Areas of cartilage degeneration are much larger when cascading progressive degeneration is taken into account. So, mechanical degeneration may substantially accelerate the pathogenesis of whole joint OA.

The percentages of the degeneration area are 24.8%, 49.6%, 51.4%, 52.8% and 57.4% of the available contact area. From this perspective, any fracture reduction with residual step-off greater than 1mm step-off faces high OA risk at a 2-year span.

## RECRUITMENT ORDER HAS LITTLE EFFECT ON THE SHORT-RANGE STIFFNESS OF FELINE MEDIAL GASTROCNEMIUS MUSCLE

<sup>1</sup>Lei Cui, and <sup>2</sup>Thomas Sandercock

Department of <sup>1</sup>Biomedical Engineering and <sup>2</sup>Physiology, Northwestern University  
email: [t-sandercock@northwestern.edu](mailto:t-sandercock@northwestern.edu)

### INTRODUCTION

The ultimate goal of our research is to determine the contributions of both individual muscles and muscle combinations to whole limb endpoint stiffness in 3 dimensional space. A computer muscle model, capable of predicting whole muscle short-range stiffness (SRS) based on anatomical properties, is believed to be necessary for accomplishing this goal. Knowledge of the effect of motor unit composition and muscle architecture on SRS is essential for developing such a muscle model.

Slow motor units have been shown to be 1.3 times stiffer than similar fast motor units [2]. In spite of this difference muscle architecture—fiber length and tendon properties—may be the principle determinants of whole muscle SRS.

The goal of this study is to test the hypothesis that the recruitment order of motor unit types has little effect on the SRS versus force characteristics of a muscle. Preliminary results are reported here.

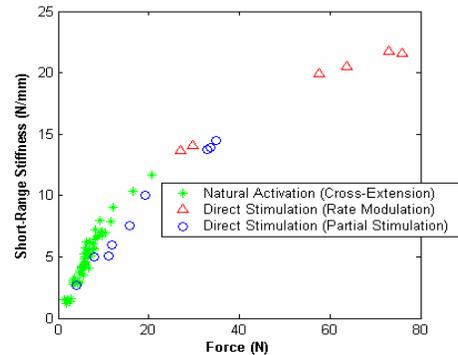

### METHODS

The hypothesis was tested in 5 cat medial gastrocnemius (MG) muscles. The cats were mounted in a rigid frame with all muscles in the left hindlimb denervated except for the MG. The MG was partially freed from surrounding tissue with its nerve and blood supply left intact. The calcaneus was cut and attached to a muscle puller allowing force to be measured during step changes in length (1.2 mm in 7 ms). The cats were decerebrated allowing activation of the MG using normal recruitment via the crossed extension reflex (CXR). A laminectomy exposed the ventral roots, which were cut after the CXR measurements were complete, and stimulated with hook electrodes.

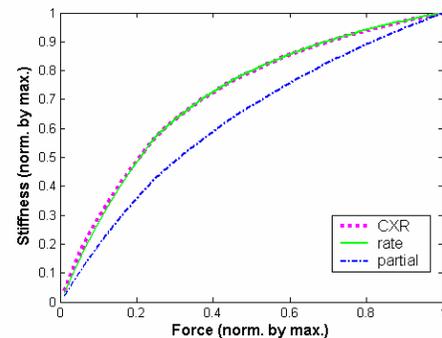

SRS was measured during three types of muscle activation: 1) CXR activation; 2) Rate modulation; and 3) Partial muscle activation. CXR modulation preserves the normal recruitment order and rate modulation of slow and fast motor units. Rate modulation was achieved by dividing the ventral roots into 4 to 6 bundles, and stimulating the bundles asynchronously to keep whole muscle force smooth, even at low frequencies [1]. Thus the whole muscle was active but at a low frequency. Partial muscle activation was achieved by stimulating part of the ventral roots at 100 Hz.

### RESULTS AND DISCUSSION

The most complete results from as single cat are shown in Figure 1. Total force from CXR activation was limited and never exceeds 20% of maximum tetanic force. In contrast, steady low force is difficult to achieve with rate modulation, so these two protocols were not studied over the same force

**Figure 1:** Results from one cat showing SRS plotted against Force (mean value 50 milliseconds before perturbation) using three different types of activation (see text).

**Figure 2:** Normalized SRS plotted against normalized Force based on the common tendon model simulation.

range. Still, rate modulation seems to closely match the CXR data, even though rate modulation does not employ normal recruitment. Similar results were obtained in the other cats.

Figure 2 shows predictions made using a simple common tendon model [3]. Slow units were assumed to comprise 25% of the muscle fibers and were fully recruited by 25% of muscle force. The model provides a reasonable fit to the experimental data.

### CONCLUSIONS

Recruitment order of motor units has little impact on SRS of cat MG muscle. If these preliminary results are supported, it suggests recruitment order can be ignored in the hind limb models of stiffness.

## EFFECTS OF SMOOTH VS "PRICKLY" SURFACE CONDITIONS ON TILTBOARD PERFORMANCE

<sup>1</sup> Peter M. Quesada, <sup>2</sup>Michael P. Durham, <sup>2</sup>Robert V. Topp, <sup>3</sup>Ann M. Swank and <sup>1</sup>Danielle Biton

### INTRODUCTION

The somatosensory system, along with vestibular, visual, and proprioceptive functions, coordinates with neuromuscular systems to maintain postural stability. Investigations of somatosensory influence have often involved comparisons of diminished and normal function [1-3]. These efforts have demonstrated that compromised somatosensory function is associated with reduced postural stability. Such assessments have commonly involved measurements obtained during static standing, or with imposed perturbations. Neither approach, however, evaluates balance capacity or mechanisms associated with passively unstable surfaces.

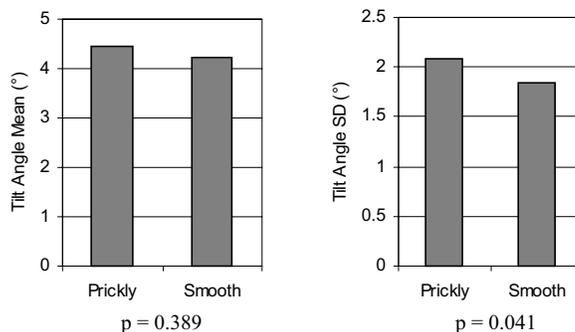

The present study investigated the effects of a "prickly" standing surface versus a smooth surface on the performance of a tiltboard balance task. A basic tiltboard is a flat circular standing platform with a solid hemisphere attached to it. The addition of a prickly texture on the surface of a tiltboard was intended to enhance plantar surface sensation. The use of a tiltboard was intended to provide a passively unstable surface.

### METHODS

Thirteen healthy subjects (8 males, 5 females), with mean height and weight of  $176 \pm 8$  cm and  $71 \pm 10$  kg, participated in this study. Each individual signed an informed consent form that approved by this institution's IRB. Each subject was provided an opportunity to "warm up" with a tiltboard prior to testing. Three reflective markers were placed at  $90^\circ$  intervals at the edges of the tiltboard. These markers represented right, left, and rear edges. Body markers were placed in a Helen Hayes arrangement, and surface EMG electrodes were also placed bilaterally over the gastroc/soleus, tibialis anterior, quadriceps, and hamstring groups.

For each tiltboard balancing trial, feet were positioned, such that the dorsal crease at the tibial/midfoot junction was aligned along the diameter line between the right and left tiltboard markers. For each trial the subject was instructed to maintain the tiltboard as stable as possible for an extended duration, while marker spatial coordinates were obtained at 100 Hz, with a Hawk Motion Tracking System (Motion Analysis Corp.). This duration was intended to be 35 seconds for all subjects; however, three subjects were tested with 20 second durations, and one individual performed 25 second trials. The 20 second trials were also performed without placement of body reflective markers or surface electrodes. A random draw determined whether the first trial would be performed with a "prickly" or smooth surfaced tiltboard. The second trial was then performed with the remaining surface. Another random draw then determined the order of the third and fourth trials.

Data processing has focused, to this point, on results obtained from the tiltboard reflective markers. These marker coordinate

**Figure 1:** Mean & SD of tilt angle magnitude for prickly and smooth tiltboard surfaces

trajectories were used to determine tilt angle magnitude, and tilt direction (relative to an anterior/posterior axis) for each sampling interval. Tilt angle means and standard deviations were determined for each trial, and values from prickly and smooth surface trials were compared, using ANOVAs, to determine effects of tiltboard surface type. Plots of tilt angle magnitude vs. tilt direction were more qualitatively evaluated to assess preferred balancing orientations. EMG evaluation was intended to assess muscle activity durations.

### RESULTS AND DISCUSSION

Tiltboard surface type did not have a statistically significant effect on tilt angle magnitude mean values ( $p = 0.389$ ), while standard deviations of tilt angle magnitudes were found to be significantly larger for the prickly surface ( $p=0.041$ ). This result suggested that balance performance was poorer with the prickly surface, although this surface was intended to intensify plantar surface somatosensory input. This finding seems somewhat contrary to some previous reports that demonstrated improved balance performance with better plantar surface sensation. It was noted, however, that such improved performance was generally associated with more static balance tasks. While Horak [2] reported that healthy vs neuropathic balance differences were mitigated when sway referencing was introduced, neither the effects of an intervention directed towards intensifying somatosensory input, nor the influence of an inherently unstable surface was considered.

Analyses of tilt angle magnitudes vs tilt orientations, and of EMG recordings are more preliminary at this time. Tilt magnitude vs tilt orientation findings, however, suggest that anterior/posterior or medial/lateral tilt orientations are more prevalent during tiltboard balance tasks. EMG results indicate little, if any, periods of inactivity of lower extremity muscles.

## HETEROGENEITY OF CHANGE IN MUSCLE CIRCULATION AMONG SYNERGISTS DURING DYNAMIC MUSCLE ACTION

<sup>1</sup> Yoshiho Muraoka, <sup>2</sup>Atsuko Kagaya

<sup>1</sup>Faculty of General Education, Meisei University,

<sup>2</sup>Research Institute of Physical Fitness, Japan Women's College of Physical Education

### INTRODUCTION

In case of a single muscle, muscle contraction impairs blood inflow to a muscle with an increase of intramuscular pressure. Some studies have reported that muscle circulation of synergists interacted among themselves. For example, the significant decrease in muscle blood volume detected by near-infrared spectroscopy (NIRS) was found in medial gastrocnemius but not in the lateral gastrocnemius during static plantarflexion [1]. However, the result of muscle circulation in static muscle action might not be directly applicable to that in dynamic muscle action.

The purpose of present study was to clarify the heterogeneity of change in muscle circulation among synergists during dynamic muscle action. For this purpose, we investigated muscle blood volume and oxygenation in triceps surae muscle during calf-raise exercise using NIRS.

### METHODS

Subjects were five healthy males. They were asked to sit quietly for more than 3 min as a control period. Then they stood up and performed 4 s calf raise consisted of 2 s heel up phase and 2 s heel down phase. They repeated the calf-raise 20 times led by an electric metronome.

Surface electromyogram (EMG) was recorded from medial and lateral gastrocnemius (MG and LG) and soleus (SOL) using bipolar electrode (SX-230, DKH, Japan).

To estimate the oxygenated hemoglobin and myoglobin ( $O_2Hb/Mb$ ), deoxygenated hemoglobin and myoglobin ( $HHb/Mb$ ), total hemoglobin and myoglobin ( $cHb/Mb$ ) content and tissue oxygenation index (TOI) in target muscles, two channels optical probes NIRS were firmly placed on the skin surface of muscle belly (NIRO-200, Hamamatsu Photonics, Japan). Firstly, MG and LG muscles were measured at once, and MG and SOL muscles were measured using the same protocol.  $O_2Hb/Mb$ ,  $HHb/Mb$  and  $cHb/Mb$  were expressed as changes from rest values, and TOI was expressed as a percentage (%).

The change of ankle joint angle was measured using an electric goniometer (SG110/A, DKH, Japan).

The data of EMG, NIRS and joint angle were stored on a personal computer by using an analog-to-digital converter (PowerLab/16sp, ADInstruments).

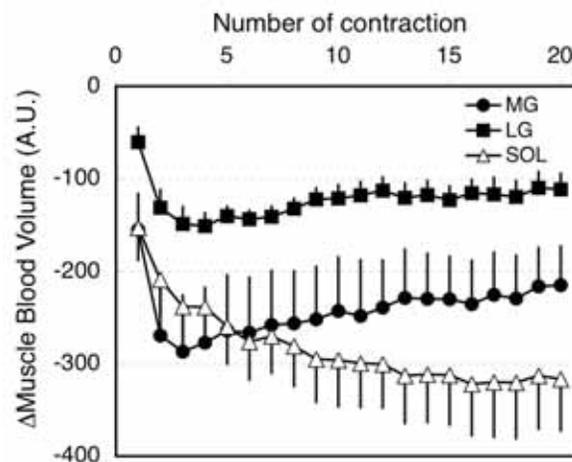

### RESULTS AND DISCUSSION

The mean amplitude of EMG (mEMG) increased greater in MG than in LG, and mEMG of SOL showed almost constant value during exercise.

$O_2Hb/Mb$  of all three muscles decreased during the exercise, and a marked decrease in the value of MG was observed.  $HHb/Mb$  of all three muscles decreased at the onset of exercise, then the great increase was observed in MG. The decline of TOI was greater in MG than LG. The TOI values at the last (20<sup>th</sup>) calf-raise were  $29.4 \pm 3.6\%$ ,  $47.9 \pm 3.8\%$  and  $56.1 \pm 4.0\%$  for MG, LG and SOL, respectively.

Muscle blood volume of all three muscles decreased rapidly at the beginning of exercise. Then the blood volume in MG and LG increased gradually, but that in SOL continued to decrease until the end of exercise (Figure 1).

The present results suggest that muscle circulation among synergists was different from each other during dynamic exercise such as calf-raise exercise.

**Figure 1:** The changes of muscle blood volume during calf-raise exercise in MG, LG and SOL. Values are the mean  $\pm$  SE

## COMPARISON OF METHODS USED TO DETERMINE INDUCED VERTICAL GROUND REACTION FORCE

<sup>1</sup>Zachary J. Domire, and <sup>2</sup>John H. Challis

<sup>1</sup>Division of Kinesiology and Health, The University of Wyoming, Laramie, WY, USA

<sup>2</sup>Biomechanics Laboratory, The Pennsylvania State University, University Park, PA, USA

### INTRODUCTION

Every muscle action contributes to the ground reaction force via joint reaction forces passed through the system. Calculation of these effects is of interest, as it gives insight into a muscles role during a particular movement. Direct dynamic simulations have been used determine the role of individual muscle during gait [1,5], however different methodologies have been used. Neptune et al. [5] determined an individual muscle's contribution to the ground reaction force at each instant in time by taking the difference of the actual ground reaction force and the ground reaction force caused by all forces except the muscle of interest. Anderson and Pandy [1] determined an individual muscle's contribution to the ground reaction force by applying each muscle force in isolation and determining the resulting ground reaction force. The purpose of this study was to determine the induced vertical ground reaction forces during jumping using both methods and compare the summed induced vertical ground reaction forces with the actual vertical ground reaction force.

### METHODS

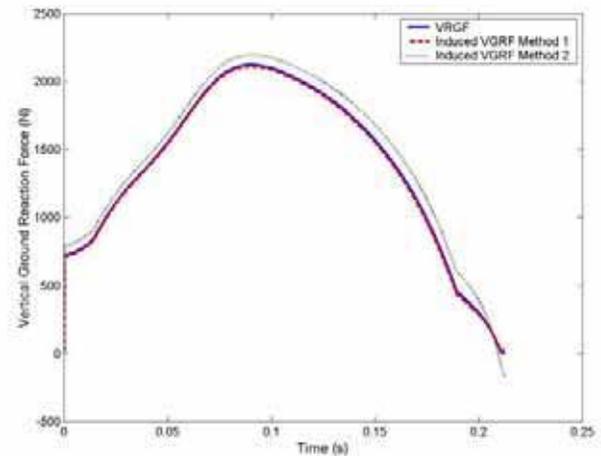

An optimal control, direct dynamics simulation model was used to simulate vertical jumping. The model had four rigid links (foot, shank, thigh, and a combined head, arms, and trunk), connected by frictionless hinge joints. The foot was connected to the ground by a hinge joint at the metatarsal-phalangeal joint. It had a rotational spring-damper at this joint to represent the floor-heel interaction [6]. The equations of motion were formulated as mixed differential-algebraic equations [4]. The model was actuated by six muscle models representing the major muscle groups of the lower extremity. Each muscle was represented by a Hill-type model consisting of a series elastic element and a contractile element [2]. A genetic search algorithm [3] was used to select sequences of muscle model neural excitations for each of the muscles so that the total potential and kinetic energy of the center of mass was maximized at the instant the foot lost contact with the ground.

Induced vertical ground reaction forces were calculated using the methodology of Neptune et al., [5] (Method 1) and Anderson and Pandy [1] (Method 2). The induced ground reactions force for each muscle were summed and compared to the actual ground reaction force.

### RESULTS AND DISCUSSION

The procedures for determining induced vertical ground reaction force produced similar results. When the individual, induced vertical ground reactions forces were summed, the total was similar to the actual vertical ground reaction force for both methods examined (Figure 1).

Method 2 produced a larger total vertical ground reaction force than method 1, with method 1 being closer to the actual values. This difference was fairly consistently spread across all of the muscles. The reasons for this difference are not completely clear, however method 1 allows for the possibility that a muscles contribution to the ground reaction force can change based upon the activity of other muscles.

**Figure 1:** Total induced vertical ground reaction force for each method compared to actual vertical ground reaction force (VGRF).

### CONCLUSIONS

Calculation of induced ground reaction forces can provide insight into a muscles role during a particular movement. Determining a muscles induced ground reaction force by subtracting the ground reaction force caused by all other forces from the total ground reaction force at each instant in time produces results closer to the actual ground reaction force than does applying each muscle force in isolation and determining the resulting ground reaction force.

## MUSCLE OPERATING RANGE INCLUDES OPTIMAL LENGTH AT EXTENDED JOINT POSTURES FOLLOWING BRACHIORADIALIS TENDON TRANSFER

<sup>1</sup>Wendy M. Murray, <sup>1</sup>M. Elise Johanson, <sup>1</sup>Anca Velisar, <sup>1</sup>Niels Smaby, and <sup>1,2</sup>Vincent R. Hentz

email: murray@rrdmail.stanford.edu, web: guide.stanford.edu

### INTRODUCTION

Intraoperative sarcomere length measurements have provided evidence that transferred muscles are often attached longer than optimal length during tendon transfer surgery [1]. These data suggest that outcomes of tendon transfers may be sub-optimal because muscles are too long to generate adequate active force. However, minimal data are available that describe active muscle function following tendon transfer. As a result, the influence of surgical tensioning on clinical outcomes has not been established in patients.

Brachioradialis, an elbow flexor, is commonly transferred to the paralyzed FPL, a thumb flexor, following cervical spinal cord injury. This procedure is intended to restore active lateral pinch and to improve the ability to use the hand. Because brachioradialis (Br) changes length with elbow flexion, we expect pinch force to vary with elbow position following this transfer. The aims of this study are: (i) to quantify changes in pinch force with elbow flexion following Br-FPL transfer and (ii) to estimate the operating range of the transferred muscle on the isometric force-length curve.

### METHODS

Lateral pinch force produced during maximum effort was quantified in 7 subjects (8 limbs) with Br-FPL tendon transfers. Pinch force was measured with the shoulder positioned at 90° flexion and in both an extended (0°-25° flexion) and a flexed (80°-126° flexion) elbow posture. The elbow was externally stabilized; wrist position was not constrained but was recorded during testing. Passive force was also quantified as a function of elbow and wrist position. The component of lateral pinch force due to active muscle contraction was calculated by subtracting the passive force at the appropriate posture from the measured pinch force.

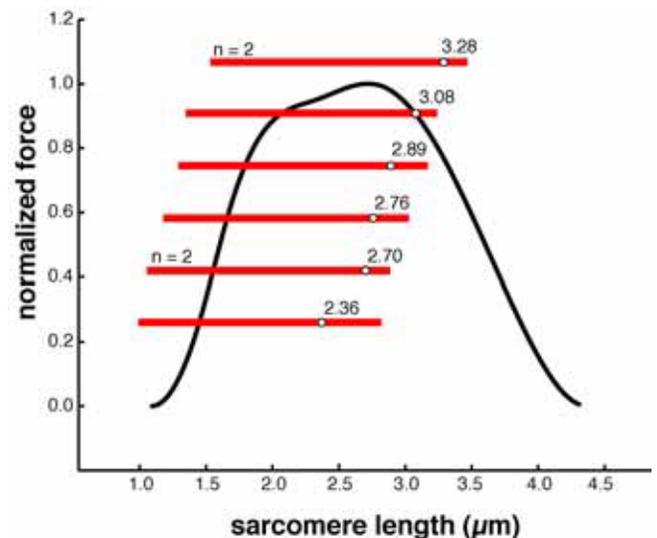

Using a computer model of the upper extremity [2] we estimated the length of the Br-FPL transfer as a function of elbow and wrist position. The muscle-tendon path of Br was altered in the model to simulate transfer to FPL. PCSA, optimal fiber length, and pennation angle for the transfer were defined to be the same as for Br. Tendon slack length was adjusted to simulate 30 different surgical attachment lengths. For each subject, we calculated the attachment length that best matched the observed change in active pinch force given the measured elbow and wrist positions. The simulations assume full activation and that the observed differences in active pinch force result from isometric force-length properties.

### RESULTS AND DISCUSSION

Median lateral pinch force produced by the subjects was 25.2 N with the elbow extended (range = 7.9 N-45.9 N) and 17.5 N with the elbow flexed (5.0 N-36.1 N). Subjects extended their wrists while pinching; median wrist position was 51° extension with the elbow extended and 57° extension with the

elbow flexed. In the wrist postures adopted during maximum effort, median passive force was 1.2 N (0.6 N-2.7 N) with the elbow extended and 1.0 N (0.5-1.5 N) with the elbow flexed.

Differences in active pinch force ranged from a 15% increase to a 39% decrease with elbow flexion. Based on these data, the computer simulations indicate that the transferred brachioradialis operates at lengths that include optimal length when the wrist is extended (Fig. 1). We estimate that median resting sarcomere length (zero activation, 10° elbow flexion, wrist in neutral) is 2.83  $\mu\text{m}$  among these subjects (circles and labels in Fig. 1 indicate range). This length is approximately 20% shorter than the average resting sarcomere length measured in the transferred Br during surgery (different patients). With a resting sarcomere length of 2.83  $\mu\text{m}$  and with the wrist extended between 50° and 60°, optimal length (i.e., peak force) occurs between 34° and 44° elbow flexion.

**Figure 1.** Br-FPL operating ranges as a function of elbow flexion (8 subjects). Wrist position is 55° extension, forearm is neutral, thumb is positioned for lateral pinch. Red bars indicate sarcomere length ranges during full muscle activation from 0° to 130° elbow flexion. Circles indicate resting sarcomere length at 10° elbow flexion, neutral wrist and forearm, and the same thumb posture.

### CONCLUSIONS

The data are consistent with length ranges that maximize force with both the elbow and wrist extended. This work suggests that the surgical attachment length chosen (which was not quantified in these subjects) did not result in post-operative lengths that were too long for active force generation.

## SIGNIFICANCE OF SURGICAL ATTACHMENT LENGTH FOR HAND FUNCTION FOLLOWING BRACHIORADIALIS TENDON TRANSFER

<sup>1</sup>Wendy M. Murray, <sup>2</sup>Vincent R. Hentz, <sup>3</sup>Jan Fridén, and <sup>4</sup>Richard L. Lieber

<sup>1</sup>Bone and Joint Center, VA Palo Alto HCS, <sup>2</sup>Dept. of Surgery, Stanford University, <sup>3</sup>Dept. of Hand Surgery, Sahlgrenska University Hospital, Göteborg, Sweden, <sup>4</sup>Depts. of Orthopaedics and Bioengineering, UCSD and VAMC, San Diego; email: [murray@rtdmail.stanford.edu](mailto:murray@rtdmail.stanford.edu), web: [guide.stanford.edu](http://guide.stanford.edu)

### INTRODUCTION

Intraoperative sarcomere length measurements have provided evidence that transferred muscles are often attached longer than optimal length during tendon transfer surgery [1]. It is possible that surgical outcomes could be compromised if post-operative muscle fibers are too long to generate active force. However, the relationship between surgical attachment length and functional outcome remains unclear.

Brachioradialis (Br), an elbow flexor, is the most commonly utilized donor muscle to restore hand function following tetraplegia. The aims of this study are (i) to quantify the sarcomere length of the brachioradialis chosen by surgeons at the time of tendon transfer and (ii) to evaluate theoretically muscle operating ranges given the current surgical approach.

### METHODS

Sarcomere length was measured *in vivo* using laser diffraction in 13 individuals (14 limbs) with tetraplegia undergoing tendon transfer of brachioradialis to FPL (n = 12), ECRB (n = 1), or FDP (n = 1). All patients provided informed consent. Sarcomere length was measured both *in situ* and following transfer in 11 limbs, and following transfer only in 3 limbs. Measurements were taken with the elbow positioned in extension (approximately 0°-20° elbow flexion), the forearm in neutral rotation, the wrist in neutral, and the thumb in a lateral pinch posture.

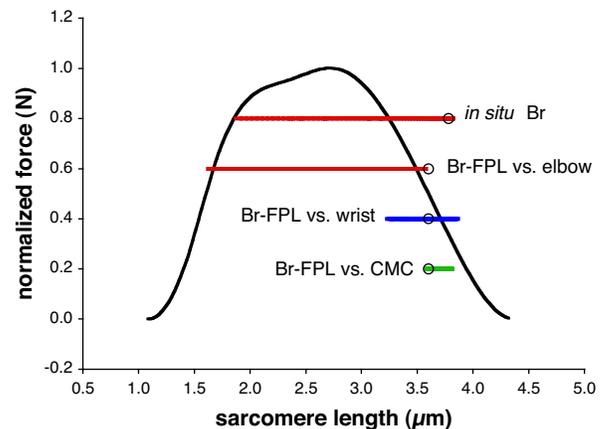

A model of the Br-to-FPL tendon transfer was developed using a computer-graphics-based model of the upper extremity [2]. We assumed the line of action of the transfer was identical to the path of brachioradialis at the elbow joint and to the path of FPL at the wrist and thumb joints. Sarcomere length of the transferred brachioradialis in the model was set at the surgical attachment length measured intraoperatively, assuming the same limb posture and zero muscle activation. We then estimated the length of the transferred Br under full activation as a function of elbow, wrist, and CMC joint positions.

### RESULTS AND DISCUSSION

The average sarcomere length of the brachioradialis following tendon transfer was  $3.59 \pm 0.27 \mu\text{m}$ . Transferred sarcomere lengths ranged from  $3.10 \mu\text{m}$  to  $3.90 \mu\text{m}$  across subjects. For the eleven limbs in which sarcomere length was measured both *in situ* and after tendon transfer, transferred length was significantly correlated to *in situ* length ( $r = 0.76$ ,  $p < 0.01$ ). The paired *in situ* and transferred lengths indicate that chosen surgical attachment lengths were slightly shorter ( $p < 0.01$ ) than *in situ* lengths (mean =  $3.78 \pm 0.27 \mu\text{m}$ ). *In situ* lengths ranged from  $3.39 \mu\text{m}$  to  $4.15 \mu\text{m}$ .

After transfer to the FPL, the Br changes length as a function of elbow, wrist, and thumb position. Based on the intraoperative data, we estimate that, with the wrist in neutral and

the thumb in a lateral pinch posture, Br lengths span the plateau of the isometric force-length curve, and are comparable to lengths of the *in situ* Br (Fig. 1, compare red bars). Individuals with tetraplegia and Br-FPL transfers tend to extend their wrists when using their hands to augment the tenodesis effect; CMC extension is needed to grasp larger objects. Wrist extension and CMC extension both increase the transferred Br's length. With the elbow fully extended, the wrist at 70° extension, and the CMC joint at 45° extension, we estimate the sarcomere length of the transferred Br is approximately 13% longer than the measured surgical attachment length and 8% longer than the *in situ* length.

**Figure 1.** Br operating ranges as function of elbow position (red bars, 0°-130° elbow flexion), wrist position (blue bar, 70° extension to 70° flexion) and CMC position (green bar, 45° extension to 0° flexion). Open circles indicate sarcomere length measured *in situ* and following transfer at 10° elbow flexion, neutral forearm and wrist, and the thumb in a lateral pinch posture (0° CMC flexion).

### CONCLUSIONS

This analysis suggests that the surgical attachment lengths documented intraoperatively could result in muscle lengths that are sub-optimal for force development in extended joint postures, which are functionally important. We expect that the sarcomere lengths observed here could either compromise clinical outcome in extended postures or promote structural adaptations in the transferred muscle [3].

## STRAIN FIELD ACQUISITION ON OVINE FRACTURE CALLUS WITH ELECTRONIC SPECKLE PATTERN INTERFEROMETRY

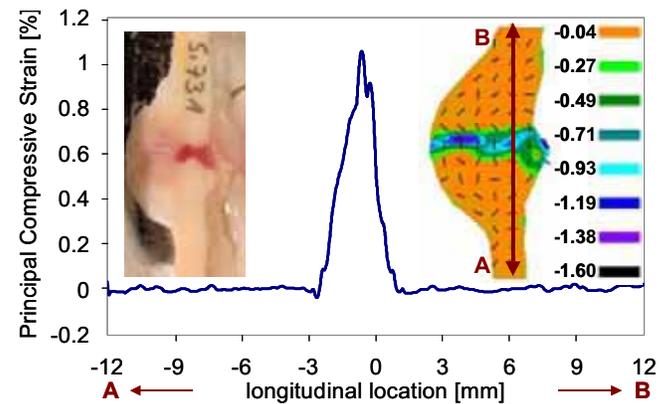

<sup>1</sup>Tanja Augustin, <sup>1</sup>Wangdo Kim, and <sup>2</sup>Lutz Claes, <sup>1</sup>Michael Bottlang,  
<sup>1</sup>Biomechanics Laboratory, Legacy Research & Technology Center, Portland, Oregon, USA  
<sup>2</sup>Institute for Orthopaedic Research and Biomechanics, Ulm, Germany  
email: [mbottlan@lhs.org](mailto:mbottlan@lhs.org)

### INTRODUCTION

Fracture callus exhibits structural and constitutive heterogeneities, which provide biomechanical conditions inductive for fracture healing[1]. Quantifying strain gradients in fracture callus provides a unique opportunity to characterize biomechanical conditions which affect callus differentiation and fracture healing. This study assessed compressive strain distributions in an ovine fracture callus using an optical strain measurement approach based on the Electronic Speckle Pattern Interferometer (ESPI) [2-3].

### METHODS

The fracture callus of an ovine tibia with heterotrophic non-union was harvested and frozen. A 3 mm thick sagittal cross-sectional slice of the callus was extracted with a diamond saw and thawed. First, its gross histology was documented photographically. Subsequently, a contrast powder was applied, ensuring adequate reflective properties of the specimen surface for optical strain measurement. The specimen was mounted in a custom-built compression stage. Specimen ends were rigidly clamped to induce unconfined axial compression over a 50 mm long section under displacement control. Displacement was applied manually with a micrometer screw in combination with a precision linear translation stage. The entire setup was assembled on a rigid base plate, ensuring stable conditions for laser-based strain acquisition with an Electronic Speckle Pattern Interferometer (ESPI, Q100, Etmeyer AG, Nersingen, Germany). This laser-based non-contact measurement system generated speckle images of the specimen surfaces before and after callus compression. Subsequent speckle image subtraction and fringe analysis algorithms enabled quantification of surface strain fields in absence of specific surface markers. The particular ESPI system used in this setup sequentially captured speckle images from three linear independent illumination directions for computation of three-directional surface displacement vectors. It acquired three-directional displacement reports at 512 x 512 individual locations over a 25 x 50 mm region of interest (ROI). Not to exceed the measurement range of the ESPI system, displacement was applied in 50 increments of 1  $\mu\text{m}$ , and the sum of all 50 displacement reports was calculated. Based on this summary displacement report in response to 0.1% specimen compression, the minimal principal strain distribution (i.e., compression) was computed over the callus ROI. Throughout the measurements, the callus specimen remained in a humidified atmosphere.

**Figure 1. Principal compressive strain distribution on fracture callus.**

### RESULTS AND DISCUSSION

ESPI measurements on the cortex and callus delivered continuous strain reports. In callus, a clearly demarcated layer of elevated strain was observed which bisected the fracture callus transversely. This high-strain region correlated closely to the fibrous non-union layer visible on the specimen cross-section. Compressive strain in this fibrous zone exceeded 1% in response to 0.1% overall specimen compression. Corresponding strain vectors were perpendicular to the orientation of the fibrous layer. In the remainder of the callus tissue and on cortical bone, compressive strain remained below 0.1%, and was one order of magnitude smaller than that in the fibrous non-union layer. This small strain magnitude did not allow for consistent calculation of compressive strain vectors. Soft tissue in the intramedullary cavity of the ovine specimen was structurally unstable and had geometric discontinuities, for which reason it was excluded from continuous strain field acquisition with ESPI.

### CONCLUSIONS

ESPI provided the unique ability to measure minute surface deformation and strain over a considerably large ROI, which allowed capturing of continuous strain maps over an entire fracture callus cross-section. Results reflect constitutive heterogeneities of a fracture callus in a quantitative manner. As such this approach provides a unique tool for analysis of mechano-biological factors in fracture healing and for validation of computational models thereof.

### INTRODUCTION

Recently, the occurrence of ankle arthritis has increased due to an increase of injuries and people's life span [1]. Biomechanical studies of the normal ankle joint complex provided knowledge on range of motion, movement coupling between calcaneus and tibia, gait kinematics and kinetics and functional zones of foot and lower leg [2, 3]. Only a few studies addressed the kinematic characteristics of the disabled ankle in vivo [4]. However, no studies addressed the clinically seen muscle atrophy of the lower leg muscles for subjects with ankle arthritis.

Therefore, the aim of the present study was to analyze the electromyogram and the strength of the lower leg muscles during isometric maximal voluntary dorsi- and plantar-flexion contraction of the arthritic ankle. The results were compared to the contralateral healthy side and a normal population, as well as to clinical orthopaedic and radiological variables.

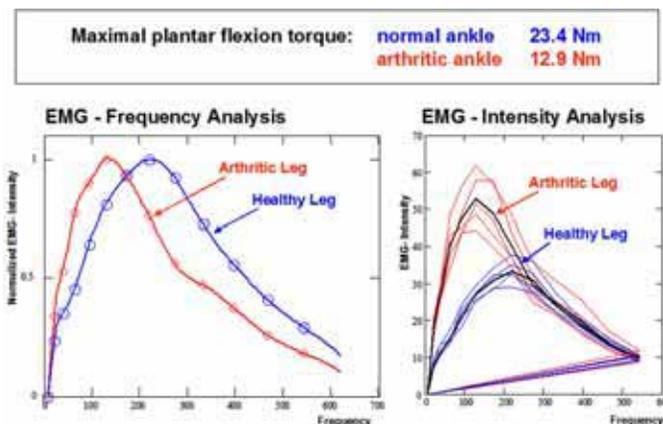

### METHODS

Seven patients and 7 healthy control subjects participated in the study. The patients (3 males and 4 females with an average age of 49 years (range between 43-57 years)) suffered from unilateral posttraumatic end-stage ankle arthritis. The control subjects were age matched with no muscular-skeletal pathologies of the lower extremity.

The clinical variables assessed through an orthopaedic examination included subjective pain score (visual analogue scale 0-10), functional American Orthopaedic Foot and Ankle Society (AOFAS) hindfoot score (0-100 points), hindfoot alignment (valgus, varus degree), muscle mass (shank circumference), ankle range of motion, latency time between injury and symptomatic ankle arthritis, and ankle arthritis degree (X-rays). The biomechanical variables included electromyography (EMG; frequency, intensity) and muscle force (ankle joint torque). Muscle activity was quantified using surface EMG during maximal voluntary dorsi- and plantar flexion for the tibialis anterior, gastrocnemius medialis, soleus, and peroneus longus. Electromyograms were analyzed using a wavelet analysis by decomposition the EMG for specified wavelets into an intensity pattern resolving the power of the signal in time and frequency) [5].

### RESULTS AND DISCUSSION

The results showed a significant pathology of all clinical variables of patients suffering from ankle arthritis compared to the healthy population. There was a significant decrease of the torque produced by the arthritic joint compared to the torque produced at the contralateral side and the normal population for maximal voluntary dorsi- and plantar flexion. Compared to

**Figure 1: Gastrocnemius Medialis – Force and EMG of Arthritic and Healthy Leg.** Force, EMG-frequency, and EMG-intensity of the Gastrocnemius medialis during maximal voluntary plantar flexion on the arthritic (red) and the healthy lower leg (blue).

the contralateral healthy side and the normal population, posttraumatic ankle arthritis also changed the EMG signal of the surrounding muscles (gastrocnemius, tibialis anterior; Figure 1), resulting in a frequency shift towards lower frequency pattern. This phenomenon may be caused by fiber specific changes in the muscle, a hypo-/atrophy of the fast twitched fibers (200-600 Hz). It is speculated that, during maximal contraction, the atrophic muscles attempted to compensate for this shortcoming by increasing the intensity of the remaining pool of slow twitch fibers (Figure 1).

### CONCLUSIONS

To the author's knowledge, this is the first study quantifying the effect of posttraumatic ankle arthritis on lower extremity muscle activation, associated with fiber selective muscle degeneration: a fast-twitch fiber hypo-/atrophy. It is proposed that this knowledge may be applied for surgical treatment and rehabilitation programs.

email: [joeseay@excsci.umass.edu](mailto:joeseay@excsci.umass.edu)

### INTRODUCTION

Change in gait symmetry, assessed using a variety of kinetic or kinematic measures, is observed across many pathologies affecting gait [1]. The observed asymmetries are typically viewed clinically as a pathological by-product of the affliction and efforts are expended to correct the asymmetry [2]. Newer research has however suggested that some degree of asymmetry is present in healthy non-afflicted individuals and may actually be functional [1]. Further, spatio-temporal symmetry measures derived from dynamical systems techniques, such as continuous relative phase (CRP), have been shown to change in locomotion based on the constraints of the task [3]. This past research suggests that changes in limb symmetry may not be a symptom of pathology, but rather a functional mechanism utilized by the body to cope with altered mechanical constraints caused by injury.

The purpose of this study was to examine changes in spatio-temporal gait symmetry in asymptomatic female runners who had previously experienced a unilateral tibial stress fracture (TSF) compared to a control group (CTRL) of mileage matched female runners. It was hypothesized that the TSF group would show increases in limb asymmetry compared to the CTRL group.

### METHODS

Fifteen female runners with a unilateral retrospective tibial stress fracture (TSF) and 15 mileage matched control (CTRL) subjects were recruited for this study. All volunteers were female, rearfoot strikers who ran at least 20 miles per week and were free of any lower extremity injuries at the time of data collection.

Subjects ran along a 25 m runway at a speed of 3.65 m/s ( $\pm$  5%). Three-dimensional kinematic data (120 Hz) were collected using a six-camera high-speed motion capture system. Five trials were collected for both the left and right limbs. For each subject, the profiles of the ankle, knee and hip sagittal view angles were interpolated to 100% of stance.

CRP was calculated bilaterally in the hip-knee and knee-ankle coupling of both groups. Spatio-temporal asymmetry was calculated as the difference in CRP patterns between involved and contralateral limb of the TSF subjects and the right and left limbs of the CTRL subjects in the hip-knee and knee-ankle couplings. Through these calculations, a time series about 0° indicates perfect spatio-temporal symmetry across the stance phase whereas deviations from zero represent a magnitude of asymmetry.

Effect size (ES) was calculated to express differences between groups relative to the pooled standard deviation. Cohen (1988) proposed that ES values of 0.2 represented small differences; 0.5, moderate differences; and 0.8+, large differences [4]. Effect sizes greater than 0.5 were considered clinically important.

### RESULTS AND DISCUSSION

In both hip-knee (ES=0.52) and knee-ankle (ES=0.50) couplings moderate effects were seen between the TSF and CTRL group, where increases in asymmetry were seen in the TSF group (Figure 1).

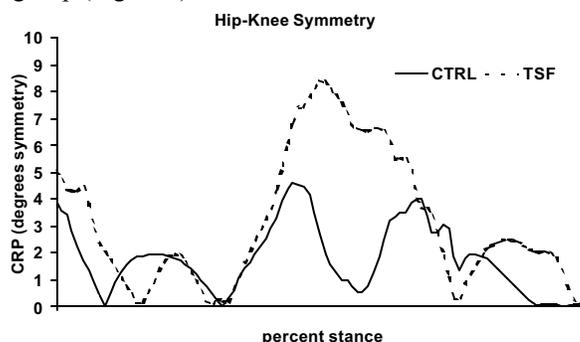

Figure 1: Between subject average of hip-knee CRP symmetry in both the stress fractured and control group.

Although effect sizes between groups were only moderate, it is interesting to note that all subjects were asymptomatic at the time of collection, showing that spatio-temporal asymmetry is present in female runners with a history of tibial stress fractures.

### CONCLUSIONS

Female runners with a history of stress fractures show differences in spatio-temporal gait asymmetry compared to a healthy group. Although prospective studies are needed to determine whether this asymmetry is a cause or a result of the injury, this study adds to a growing body of literature that suggests gait asymmetry may be a functional adaptation utilized to cope with the injury.

## INTRALIMB COORDINATION IN FEMALE RUNNERS WITH TIBIAL STRESS FRACTURES

<sup>1</sup>Joseph Hamill, <sup>1</sup>Jeffrey M. Haddad, <sup>2</sup>Clare E Milner, <sup>2,3</sup>Irene S Davis

<sup>1</sup>University of Massachusetts, Amherst, MA, <sup>2</sup>University of Delaware, Newark, DE, <sup>3</sup>Drayer Physical Therapy Institute, Hummelstown, PA  
email: [jhamill@excsci.umass.edu](mailto:jhamill@excsci.umass.edu)

### INTRODUCTION

Tibial stress fractures are a common injury suffered by female runners. Studies looking at traditional kinematic or kinetic (such as ground reaction forces) differences between injured and uninjured populations during running have been unsuccessful at determining a causal factor associated with the injury [1]. The nature of differences that exist between groups may better be captured using dynamical systems techniques that capture the spatio-temporal dynamics of gait [2]. Dynamical systems analysis techniques have been shown to be more sensitive to subtle differences in human movement analyses. For example, gait variability as measured through continuous relative phase (CRP) has been shown to decrease in subjects with patellofemoral pain relative to an asymptomatic group [3].

The purpose of this study was to examine changes in gait variability in asymptomatic female runners who had previously suffered from a tibial stress fracture (TSF) compared to a control group (CTRL) of mileage matched female runners. It was hypothesized that the TSF group would have a significant difference in CRP variability between the stress fractured limb and the contralateral limb while the CTRL group would have no difference in CRP variability between limbs.

### METHODS

Fifteen female runners with a unilateral retrospective tibial stress fracture and 15 mileage matched control subjects were recruited for this study. All volunteers were female, rearfoot strikers who ran at least 20 miles per week and were free of any lower extremity injuries at the time of data collection.

Subjects ran along a 25 m runway at a speed of 3.65 m/s ( $\pm$  5%). Three-dimensional kinematic data (120 Hz) were collected using a six-camera high-speed motion capture system. Five trials were collected for both the left and right limbs. For each subject, the profiles of the ankle, knee and hip sagittal view angles were interpolated to 100% of stance.

Bilateral hip, knee and ankle 3-D angles were calculated over each stride. Variability in intralimb coordination was assessed through measures of CRP for the hip-knee and knee-ankle coupling of both the involved and contralateral limb of the TSF subjects and the right and left limbs of the CTRL subjects. CRP variability was defined as the average standard deviation of CRP across each stride.

Effect size (ES) was calculated to express differences relative to the pooled standard deviation. Cohen (1988) proposed that ES values of 0.2 represent small differences; 0.5, moderate differences; and 0.8+, large differences.

### RESULTS AND DISCUSSION

In the control group no effect was observed between the right and left limb in either the hip-knee or knee-ankle coupling ( $ES < 0.1$ ). In the TSF group, CRP variability decreased in the involved limb relative to the contralateral limb in the hip-knee ( $ES = 0.26$ ) and the knee-ankle coupling ( $ES = 0.87$ ) (Figure 1).

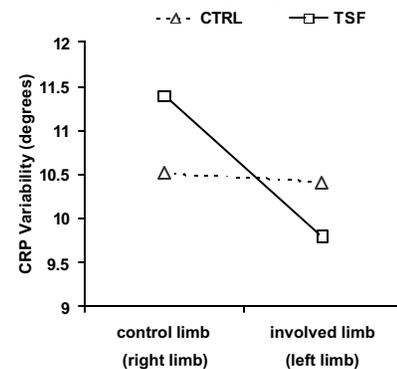

Figure 1: Mean CRP variability in the knee-ankle coupling for involved and contralateral limbs of TSF group and right and left limbs of the CTRL group.

Although the largest effect in the TSF group was observed in the knee-ankle coupling, a small effect was also observed in the hip-knee coupling, showing that a distal injury may also affect more proximal coordinative patterns. The results from both the TSF and CTRL groups support the hypothesis. It has been proposed that reduced CRP variability indicates a less flexible or less adaptable movement pattern [2, 3]. A less flexible pattern may exacerbate the injury or cause further injury to a TSF runner.

### CONCLUSIONS

While the results of this study support the hypothesis that reduced CRP variability and thus less flexible/adaptable patterns are indicative of an injured condition, it is still not evident whether this less flexible pattern is a cause or a result of the injury. Although prospective studies are needed to determine cause-effect of this phenomenon, this study adds to a growing body of literature that suggests CRP variability may be a functional adaptation utilized to cope with the injury.

## DIFFERENCES IN MIDFOOT ROTATIONS BETWEEN FOOT TYPES

<sup>1</sup>Matthew Cowley, <sup>2</sup>Lisa Berti, <sup>2</sup>Maria Grazia Benedetti, <sup>1</sup>Eric Rohr, <sup>1</sup>William Ledoux,  
<sup>1</sup>Michael Orendurff

<sup>1</sup> VA RR&D Center, Seattle, WA; email: [Matthew.Cowley@med.va.gov](mailto:Matthew.Cowley@med.va.gov), web: [www.seattlerehabresearch.org](http://www.seattlerehabresearch.org)  
<sup>2</sup> Movement Analysis Laboratory, Istituti Ortopedici Rizzoli, Bologna, ITALY

### INTRODUCTION

Typical full-body models used in gait analysis view the foot as a single rigid segment and essentially ignore the complex motions of the foot. Using newer motion capture technology and smaller markers, detailed foot models can now be incorporated into the full-body model. Several groups have reported more detailed models to determine the kinematics of various foot segments[1-3]. One of the main purposes of a foot model is to distinguish deviations from a “normal” foot. This project looks at the midfoot rotations for four different foot types to see if a novel foot model can be used to distinguish between foot types.

### STATEMENT OF CLINICAL SIGNIFICANCE

Detailed foot models can provide an important tool for studying outcomes of foot surgeries and for pre-operative planning. An improved kinematic model will enhance our understanding of foot biomechanics and subsequently help to improve surgical outcomes.

### METHODOLOGY

The left feet of 23 adult subjects walking at self-selected speeds were analyzed with an eight-camera Vicon 612 system recording at 120 Hz. The subjects were examined by an orthopedic surgeon and classified into 4 categories; 13 neutrally aligned feet (N), 6 flat feet (F), 2 high arched feet (H), and 3 slight equinus feet (E). All of the non-normal feet were asymptomatic and of mild pathology. Twenty reflective markers (9.4 mm in diameter) were placed on bony landmarks of the foot and lower leg. The following segments were studied: shank (tibia and fibula), hindfoot (calcaneus), midfoot (navicular, cuboid and cuneiforms), forefoot (metatarsals) and hallux (proximal and distal). Axial rotations were determined through a custom Vicon BodyBuilder model. Local coordinate systems were created to approximate the actual joint centers using distances and directions taken from a static trial of the subject.

### RESULTS

The Figure 1A shows that all four foot types have the same general shape, although all four curves differ in range and magnitude. The Figure 1B illustrates the normal and flat foot groups are very similar in magnitude and pattern, while the other two are similar in pattern. The Figure 1C shows all four foot types to be somewhat similar in range and shape. The Figure 1D again shows all of the foot types to have similar shapes, but not ranges of values. In the Figure 1A the flat foot group is shown to be more dorsiflexed than the high arch group. The Figure 1B rotations show that the flat foot and the normal foot are nearly identical while the high arch is more inverted and the slight equinus is more everted. Only the

means are reported because the n in each group were too small to get statistically significant results.

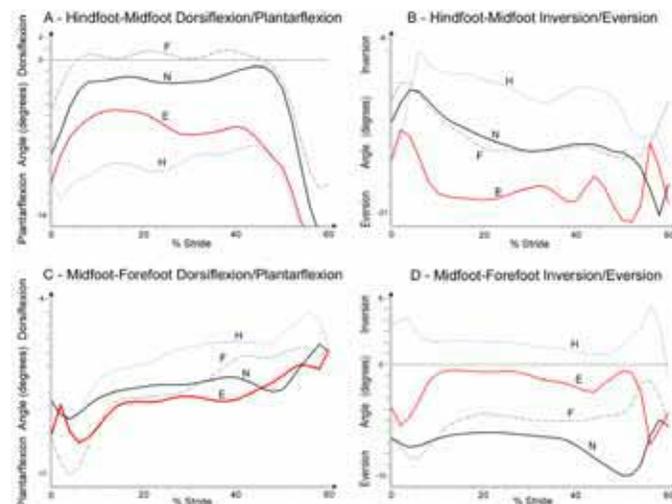

Figure 1A-1D. Mean joint rotations for the hindfoot-midfoot and the midfoot-forefoot. The four foot types shown are neutral aligned (N), flat foot (F), high arch (H), and slight equinus (E)

### DISCUSSION

The fact that the rotations in the midfoot-forefoot plantarflexion/dorsiflexion graph are all similar in curvature and range, while the hindfoot-midfoot plantarflexion/dorsiflexion and the midfoot-forefoot inversion/eversion are similar in curvature but not in ranges implies that the model seems to be sensitive enough to see differences and similarities between foot types. If the model was not able to distinguish between the foot types, one would expect to see the same general relationships in the rotations of all four of the graphs. These outcomes indicate that a large population study is feasible and needed in order to statistically analyze the findings and make any clinical predictions of foot type and function. These results look similar to the results in the aforementioned papers. The shortcomings of this study were the lack of clearly defined pathologies and the relatively small numbers of pathologic feet.

## EFFECT OF MARKER PLACEMENT METHODS ON CALCANEAL ROTATIONS

<sup>1</sup>Matthew Cowley, <sup>2</sup>Lisa Berti, <sup>2</sup>Alberto Leardini, <sup>1</sup>Eric Rohr, <sup>1</sup>William Ledoux,  
<sup>1</sup>Michael Orendurff

<sup>1</sup> VA RR&D Center, Seattle, WA; email: [Matthew.Cowley@med.va.gov](mailto:Matthew.Cowley@med.va.gov), web: [www.seattlerehabresearch.org](http://www.seattlerehabresearch.org)

<sup>2</sup> Movement Analysis Laboratory, Istituti Ortopedici Rizzoli, Bologna, ITALY

### INTRODUCTION

Most full-body models used in gait analysis view the foot as a single rigid segment and ignore the complex sub-segment motions in the foot. Newer motion capture technology and smaller markers have allowed more comprehensive foot models to be created. Several groups have reported detailed models to determine the kinematics of various foot segments (e.g., [1, 2]). Some deformities may hinder the placement or obstruct the view of markers placed on the sides of the calcaneus. This paper will compare a common method to a more robust marker placement method, which removes the side calcaneal markers and uses only the calcaneal tuberosity for the segment's primary definition.

### STATEMENT OF CLINICAL SIGNIFICANCE

Detailed foot models can provide an important tool for studying outcomes of foot surgeries and for pre-operative planning, much like the full body gait models commonly used today for lower limb procedures. An improved kinematic model will enhance our understanding of foot biomechanics and subsequently help to improve surgical outcomes.

### METHODOLOGY

The left feet of 23 adult subjects walking at self-selected speeds were analyzed with an eight-camera Vicon 612 system recording at 120 Hz. The cameras were located around the perimeter of a 30 ft. by 40 ft. room. Kinematics were determined with a custom Vicon BodyBuilder model. Joint rotation means and standard deviations for both methods were calculated and paired t-tests were performed on the min/max peak joint rotations. Both marker sets were placed on the feet at the same time to reduce marker placement error. This first method is a common calcaneal marker method (CC) where markers were placed on the most medial projection of the sustentaculum tali, the lateral apex of the peroneal tubercle, and the upper ridge of the calcaneal tuberosity. The second method used is referred to here as the paired calcaneal marker method (PC). Markers were placed superiorly and inferiorly on the calcaneal tuberosity.

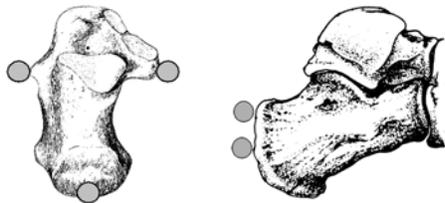

Figure 1. Marker placement for the CC method (left – superior view) and the PC method (right – sagittal view)

### RESULTS

There were no significant differences in maximum or minimum values between the two marker methods along any

axis of rotation (see Fig. 2). The paired t-test of the peak values was performed and showed no significant difference. In Inversion/Eversion the PC method has approximately 10 degrees of static offset from the CC method. Both methods have a similar pattern, but the PC method has a 140% greater range of motion. Dorsiflexion/Plantarflexion rotations of the two methods are closely aligned with no significant difference in the min/max peak values. The Internal/External rotation of both methods followed the same pattern. There is a slight static offset between the two methods of about 3 degrees, but there is no statistical difference between the two methods.

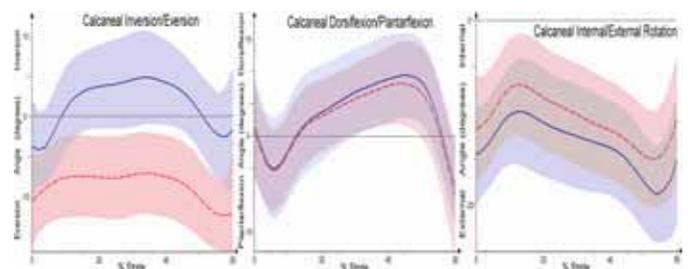

Figure 2. Rotations for the calcaneus with respect to the tibia during the stance phase of gait. The PC method is the solid blue line, the CC method is the dashed red

### DISCUSSION

The lack of statistical significance between the two methods and the good shape agreement in all three planes of rotation indicates that the two methods can be used interchangeably when looking at these particular planes of motion. The offset between the PC and CC methods in the Inversion/Eversion and Internal/External rotation is due to the difference in location of the calcaneal center and talonavicular joint, which are used to define the segmental orientations. The larger range of motion of the PC method in Inversion/Eversion is comparable to the ranges reported by a calcaneal tuberosity defined calcaneus[3]. The differences in the range are most likely the result of soft tissue movement influencing one method more than the other. Further testing can determine the accuracy of each of the methods.

## A PROSPECTIVE LOOK AT FOOT SHAPE AND FOOT ULCER DEVELOPMENT

<sup>1</sup>Matthew S. Cowley, <sup>1</sup>William R. Ledoux, <sup>1</sup>Jane B. Shofer, <sup>2</sup>Jessie H. Ahroni, <sup>2</sup>Edward J. Boyko  
<sup>1</sup>VA RR&D Center, Seattle, WA; <sup>2</sup>VA Puget Sound, Seattle, WA  
 email: [Matthew.Cowley@med.va.gov](mailto:Matthew.Cowley@med.va.gov), web: [www.seattlerehabresearch.org](http://www.seattlerehabresearch.org)

### INTRODUCTION

Diabetic foot ulceration and lower limb amputations cause significant mobility, morbidity and mortality issues as well as substantial health care costs. To date, little prospective data exists on this subject. Prospective analyses will help predict which patients may be at high risk for ulceration. We examined the foot structure of 2939 feet (1484 subjects) and the prospective ulcer occurrence of veterans with diabetes as an extension of the Seattle Diabetic Foot Study [1].

### METHODS

All patients of a general internal medicine clinic who were diabetic, ambulatory and did not have foot ulcers were eligible for the study. Exclusion criteria included current foot ulcer, non-ambulatory, or inability to cognitively participate in the study. Subjects were followed prospectively for 3.2 years  $\pm$  2.5 years (mean  $\pm$  SD), to determine which risk factors could be linked to ulceration. Subjects were removed from the study upon ulceration, amputation or death. Subjects were reexamined yearly and were contacted quarterly to ascertain any incidence of foot ulceration. A physical exam conducted by an LPN determined the foot type, presence of foot deformity and neuropathy. Either a t-test (continuous variables) or a chi-squared analysis (categorical variables) was performed to examine demographic differences between the ulcer and non-ulcer groups. A Cox regression analysis was performed to determine the Hazard Ratios (HR) and confidence intervals(CI). An  $\alpha$ -level of 0.05 was chosen.

### RESULTS

Demographic parameters that were statistically significant between the non-ulcer and ulcer group were: BMI, type 1 diabetes, diabetes duration, insulin use, sensory neuropathy, amputation history, ulcer history (Table 1). Several foot shape or foot deformity variables also significantly differed between groups (Table 2).

**Table 1:** Demographics of non-ulcer and ulcer feet (mean  $\pm$  SD or %).

Measurement	Non-ulcer (n=2709)	Ulcer (n=230)	p-value
Age (yr)	62.5 $\pm$ 10.7	62.3 $\pm$ 9.3	.7
BMI (kg/m <sup>2</sup> )	31.0 $\pm$ 6.9	30.3 $\pm$ 5.9	.083
Female	1.9	1.7	1.0
Type 1 Diabetes	4.3	8.7	.0042
Duration Diab. (yr)	10.0 $\pm$ 9.2	12.4 $\pm$ 10.1	.0003
Insulin Use	39.1	59.1	<.0001
Sensory Neuropathy	37.3	66.1	<.0001
Amputation History	3.0	13.9	<.0001
Ulcer History	20.0	45.7	<.0001

### CONCLUSION

Foot shape and foot deformity parameters such as hammer/claw toes, bony prominences, pes cavus and 'other' foot types were significantly associated with ulceration. (The foot type 'other' consisted of Charcot deformity and drop foot classifications.) Although we did not measure plantar pressure, these biomechanical deformities all tend to increase pressure on the tissues in certain areas of the foot during normal walking. Since these deformities are easily identifiable, measures to protect the feet could be implemented without difficulty. Further analyses will include the consideration of ulcer location to determine if certain foot deformities are more likely to cause ulcers at a certain location on the foot.

### INTRODUCTION

The risk of falling and injury maybe exacerbated during complex tasks such as avoiding obstacles and turning corners, which occur during daily community and household ambulation. Previous research has shown falls that occur during a turn are more likely to result in serious injury [1]. Recent publications of able-bodied subjects have highlighted the kinematic and kinetic differences associated with turning [2,3]. This study examined the effect of turning on dynamic equilibrium using phase plane portraits and first return maps [4].

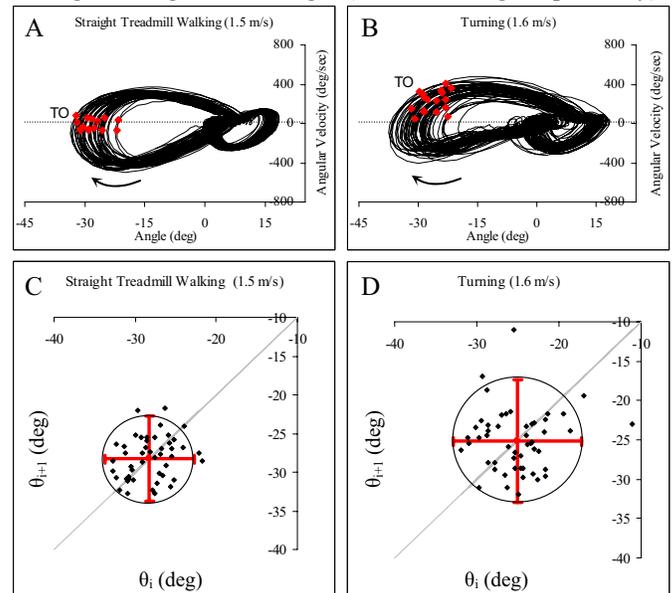

### METHODS

One able-bodied subject gave informed consent to participate in this IRB approved protocol. Average self-selected walking speed (SSWS) over five straight walking trials was determined using a timing light system. Steady-state straight-line walking data was collected over 100 continuous steps on a treadmill at SSWS. Full body gait kinematics were collected using a 10-camera Vicon 612 system and Plug in Gait (Lake Forest, CA.). Next, the subject walked along a 1m-radius circular path at the previously measured straight-line SSWS speed and data was collected over 100 steps. A constant speed 1m-radius path was selected to elucidate the mechanisms of turning while under steady-state conditions [2]. Angular velocity was calculated by numerically differentiating the angular position data. Hip, knee and ankle sagittal plane angle were then plotted versus angular velocity. Toe off was identified at the moment of peak ankle joint center vertical velocity. The toe off event was then used to create first return maps of sagittal plane angle ( $\theta_i$ ) at toe off versus the angle at the next consecutive toe off ( $\theta_{i+1}$ ).

### RESULTS AND DISCUSSION

The phase plane portraits for straight-line walking were reasonably consistent with previously reported data [4]. Average center of mass velocity was determined post data collection to be 1.6 m/s, which is within 10% of the straight-line SSWS (1.5 m/s). Therefore, differences between turning and straight kinematics were not likely related to changes in walking speed [2]. Turning demonstrated increased stride to stride variability (figure 1). Toe off during turning occurred at higher angular velocities compared to straight-line walking (figures 1A & 1B). Stride to subsequent stride ankle angle differences were larger for turning than straight ( $3.5 \pm 2.7$  vs.  $2.0 \pm 1.6$  degrees, respectively). The first return maps portray the wider distribution of stride to stride ankle angle of turning compared to straight (figures 1C & 1D). The circles in these figures, whose radii are two standard deviations from the mean and centered on the diagonal line, signify dynamic

steady-state. The standard deviation from the mean for turning was larger than straight (3.9 vs. 2.8 deg, respectively).

**Figure 1:** Ankle phase plane portraits of straight treadmill walking (A) and walking along a 1m-radius circular path (B). The red data points signify toe off (TO) over multiple strides. The arrow indicates direction of progression. Example first return maps for the ankle at toe off comparing treadmill straight-line walking (C) to turning (D). The radii of the circles signify two standard deviations from the mean.

More subjects must be examined to determine whether these differences are statistically significant. The preliminary data suggests that these graphical tools demonstrate the ability to identify increased variability associated with more complex tasks, which may relate to falls and injury. Pathologic individuals have an increased risk of falling, which may be associated with an increase in stride to stride variability. Therefore, these tools may be capable of determining the efficacy of rehabilitation treatments, surgical procedures and prosthetic componentry.

## COMPARISON OF THE KNEE JOINT BETWEEN THE SKILLED AND UNSKILLED SUBJECTS DURING THE KIP MANEUVER ON THE HORIZONTAL BAR

<sup>1</sup> Tetsu YAMADA, <sup>2</sup> Michiyoshi AE and <sup>2</sup> Norihisa FUJII

<sup>1</sup> Doctoral program in Health and Sport Sciences, University of Tsukuba, Tsukuba, Japan.  
 tetsu@lasbim.taiiku.tsukuba.ac.jp,

<sup>2</sup> Institute of Health and Sport Sciences, University of Tsukuba, Tsukuba, Japan.

### INTRODUCTION

In general, the knee joint flexion will not be used in executing the kip maneuver on the horizontal bar. However, most of the unskilled subjects bend their knees during the kip maneuver. The knee flexion will be attributed to not only body position, but also poor technique. There is little information of the effect of the knee joint on the execution of the kip maneuver. The purpose of this study was to investigate the effect of the knee joint flexion on the mechanical work, comparing the skilled with unskilled subjects of the kip maneuver on the horizontal bar.

### METHODS

Ten varsity gymnasts as skilled subjects performed the kip maneuver on the horizontal bar, and five non-gymnast subjects were selected as unskilled subjects. Their maneuver was videotaped in the sagittal plane with a VTR camera (60Hz) to obtain kinematics and kinetics data by a motion analysis technique. The data were normalized by the time from the instant that the center of mass (CoM) passed under the bar in the forward swing to the same instant in the backward swing, and then averaged. The difference between the skilled and unskilled subjects was tested by Mann-Whitney test ( $p < 0.05$ ).

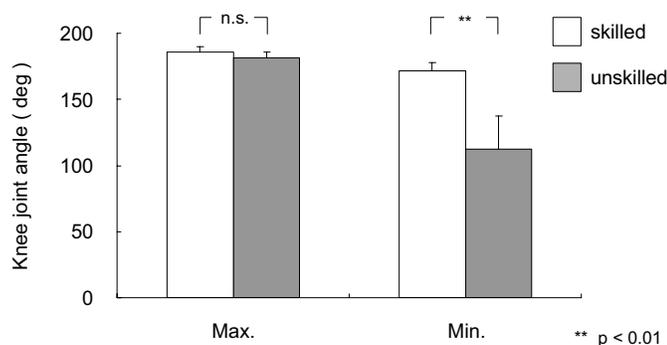

### RESULTS AND DISCUSSION

Figure 1 shows the maximum and minimum knee joint angles during the kip maneuver for the skilled and unskilled subjects. Although there was no difference in the maximum knee joint angle between the skilled and unskilled subjects, the minimum

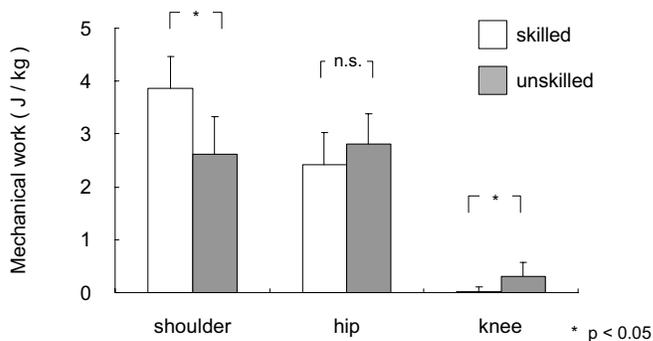

knee joint angle of the unskilled subjects was smaller than that of the skilled subjects ( $p < 0.01$ ). This indicated that the unskilled subjects flexed their knee joint deeper than the skilled subjects. This would help the unskilled subjects raise their leg easier because of smaller moment of inertia about the hip joint.

Figure 2 shows the mechanical works done by the shoulder, hip and knee joint torques for the skilled and unskilled subjects in the kip maneuver. The mechanical work of the shoulder joint for the skilled subjects was larger than that of the unskilled subjects ( $p < 0.05$ ), but there was no difference in the mechanical work of the hip joint. The mechanical work of the knee joint for the skilled subjects was close to zero and smaller than that of the unskilled subjects ( $p < 0.05$ ). Most of the mechanical work for the skilled subjects was developed by the shoulder joint torque. Although the mechanical work of the knee joint for the unskilled subjects was much smaller than those of the shoulder and hip joints, this would compensate for smaller work of the shoulder joint to increase the mechanical energy of the whole body.

Since the knee joint flexion during the execution of the kip maneuver is considered to be undesirable body position and technique, the mechanical work done by the knee joint torque will not be recommended to gymnasts. However, in physical education class, increasing the mechanical work done by the shoulder and hip joint torques should be more focused, correction of the knee joint flexion was less important in succeeding the kip maneuver.

**Figure 1:** The maximum and minimum knee joint angles during the kip maneuver for the skilled and unskilled subjects.

**Figure 2:** The mechanical works done by the shoulder, hip and knee joint torques in the kip maneuver.

## A DEVICE TO MEASURE IN VIVO TRANSLATIONAL AND ROTATIONAL LAXITY OF RABBIT KNEES

Anneliese Heiner, Jim Rudert, and Todd McKinley

Department of Orthopaedics and Rehabilitation, University of Iowa, Iowa City, IA, 52242

Email: [anneliese-heiner@uiowa.edu](mailto:anneliese-heiner@uiowa.edu) Web: [www.uihealthcare.com/depts/med/orthopaedicsurgery/](http://www.uihealthcare.com/depts/med/orthopaedicsurgery/)

### INTRODUCTION

Successful orthopaedic management of intra-articular fractures, to forestall post-traumatic osteoarthritis (OA), depends on avoidance of a mechanical environment that is deleterious to articular cartilage. Instability associated with excessive joint laxity is a factor that has been implicated in progression of post-traumatic OA. Work is ongoing to explore the pathomechanics, using New Zealand white rabbits, a well-established OA model in which transections of the anterior cruciate ligament (ACL) induce knee laxity. To measure joint laxity as a function of the degree of ACL transection, we have designed a specialized testing device to determine both translational and rotational stiffness of rabbit knees.

### METHODS

The device consists of a main cradle (Figure 1a) with an integral femur clamp, a free-floating tibia clamp, and interchangeable linear stepper motor/load cell modules – one for translational (Figure 1b) and one for rotational (Figure 1c) testing. The rotational test module incorporates a rack-and-pinion linkage to convert linear to rotary motion. Both modules include a method to adjust knee flexion angle to 90 or 135 degrees. Test control and data acquisition are by user-written LabView programs running on a laptop computer.

To prepare a rabbit for testing, coronal plane transverse pins are inserted through the leg, two in the tibia (Figure 1c) and one in the distal femur. The pins are accurately placed using a drill guide, and serve to reproducibly position the leg in the test device for repeated testing at successive time points after ligament transection. During testing, the cradle supports the rabbit on its back, with the femur held fixed vertically. The translational module draws the tibia upward for a specified distance and speed, then returns to the home position. Stepper motor displacement and load data are displayed in real time and recorded (Figure 2). The rotational module rotates the tibia in one direction and then the other, then returns to the home position; test angles, speed, and starting direction are user-defined, and angle and torque data are recorded. As a safeguard, if a preset maximum load is exceeded on either module the test will terminate and return to the home position.

### RESULTS AND DISCUSSION

A series of translational tests demonstrated that the testing device can measure the difference in stiffness of a rabbit knee when the ACL is intact, partially transected, and fully transected (Figure 3). It also demonstrated that knee flexion angle affects knee stiffness. Note that the intact knee at 90 degrees reached the preset load limit of 75 N before the full 3 mm test displacement was obtained. Multiple test sessions with this device have shown it to be an accurate and efficient method of determining rabbit knee stiffness in vivo.

### INTRODUCTION

Differences in the interspinous ligaments (ISLs) and supraspinous ligaments (SSLs) have been observed in patients with kyphotic and scoliotic spines. These differences are to be evaluated mechanically, but the appropriate test method is unclear. Specifically, a protocol to compare the combined and individual viscoelastic contributions of the ISL and SSL needs to be developed. The objective of this study was to select a rigorous but interpretable model and experimental method to use in comparing clinically obtained tissues. Sample data from porcine ligaments were evaluated using this method.

### METHODS

The quasi-linear viscoelasticity (QLV) model was chosen to model the stress-relaxation behavior of the ligaments. This method assumes separable time-dependent relaxation and strain-dependent elastic functions. The relaxation function was the focus of this study, and was represented by a three-element Maxwell model (Eq. 1):

$$Eq. 1 \quad G(t) = [G_1 e^{-\beta_1 t} + G_2 e^{-\beta_2 t} + G_3 e^{-\beta_3 t} + G_\infty]$$

Relaxation time constants ( $\beta_i$ ) were fixed at 10ms, 100ms, and 1s, respectively, in order to provide an accurate but more constrained curve fit, and to facilitate physical interpretation. Furthermore, because  $G(t)$  is normalized to the instantaneous strain,  $G(0)$  was constrained to be 1.

Models were fit to sample relaxation data acquired from porcine bone-ligament-bone ISL-SSL constructs (N=4). These constructs were preconditioned and subjected to a "step input" of 25% strain and allowed to relax for 1000s. Ligaments were returned to zero strain and tested again after separation of the ISL and SSL with a scalpel blade (without disruption of the ligament-bone interface), and after removal of the SSL (n=2) or ISL (n=2). The remaining ligament was tested to failure at 0.1 mm/s, and the failure stresses and strains were calculated. Two additional bone-ligament-bone constructs were evaluated histologically to observe the ISL and SSL fiber orientation. The mean and standard deviation were calculated for each relaxation variable.

### RESULTS AND DISCUSSION

The relaxation function fit the data well (Table 1). Separating the ligaments reduced the maximum and equilibrium stress of the bone-ligament-bone complex by 31% and 19%, respectively. Removing the SSL further reduced the

instantaneous and equilibrium stress of the ISL to approximately 90% and 89% of the respective sectioned states. With the ISL removed, the mean instantaneous and equilibrium stresses of the SSL alone were 25% and 15% of the sectioned state stresses, respectively. The ISL's failed at a mean 1122kPa and 72% strain, and SSL's failed at a mean 1720kPa and 42% strain. Histology revealed ISL fibers parallel to the spinous processes, SSL fibers perpendicular to the processes, and many fibers spanning the two ligaments.

	$G_\infty$	$G_1$	$G_2$	$G_3$	$R^2$
Specimen 1	0.643	0.152	0.112	0.107	0.997
Specimen 2	0.651	0.123	0.086	0.129	0.997
Specimen 3	0.698	0.111	0.095	0.094	0.996
Specimen 4	0.666	0.105	0.095	0.118	0.998
<b>Mean</b>	0.664	0.123	0.097	0.112	
<b>St. Dev.</b>	0.024	0.021	0.011	0.015	

**Table 1- Reduced relaxation function coefficients and residual values**

### CONCLUSIONS

The three-element relaxation function provided a close and relatively repeatable fit to stress-relaxation data to ISL-SSL construct. The stress in the intact ligaments decreased greatly when the ISL and SSL were separated. This decrease may be attributed to cutting the fibers that were seen to span the two ligaments. The stresses in the SSL alone during the relaxation experiment appeared to be lower than those for the ISL, but the failure load for the SSL appeared to be higher. This discrepancy may exist because the SSL spans several spinal levels *in vivo*, and its unloaded length may therefore differ from that of the ISL in single-level constructs.

The QLV model employed as described here will be used to test clinically obtained tissue. The ISL and SSL can be sectioned to determine the properties of the two ligaments individually, but care should be taken in considering the interaction of these non-discrete ligaments. A larger study is needed to statistically describe the findings in this study.

**QUASI-LINEAR VISCOELASTIC PROPERTIES OF THE PLANTAR SOFT TISSUE IN COMPRESSION**

<sup>1</sup>William R. Ledoux, <sup>1</sup>Joanna J. Blevins, and <sup>1</sup>Bruce J. Sangeozan

<sup>1</sup>VA RR&D Center, Seattle, WA; email: [wrl@douglas.wa.gov](mailto:wrl@douglas.wa.gov), web: [www.seattlerehabresearch.org](http://www.seattlerehabresearch.org)

**INTRODUCTION**

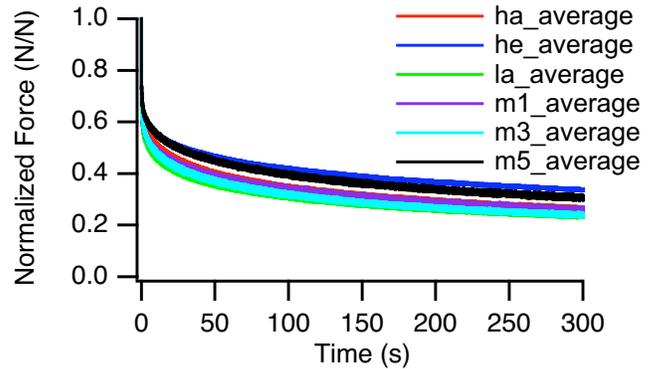

Mechanical testing of the plantar soft tissue has consisted of primarily structural heel pad testing.<sup>1-4</sup> One group studied material properties and demonstrated that the subcalcaneal tissue is homogeneous.<sup>5</sup> However, there has been little research on other areas, and temperature, age, and vascular status are often not accounted for. The purpose of this study was to model the relaxation behavior of the plantar soft tissue the using quasi-linear viscoelastic (QLV) theory<sup>6</sup> at six locations: the subcalcaneal, subhallucal, lateral submidfoot and the first, third and fifth submetatarsal.

**METHODS**

Specimens were obtained from ten fresh frozen feet ( $36 \pm 8.7$  years,  $798 \pm 131$  N) from seven non-diabetic donors. The plantar soft tissue was removed as 2 cm x 2 cm blocks without skin. The specimen was placed between two aluminum platens in a materials testing machine with an environmental chamber. The top platen was lowered until a force of 0.5 N was detected. The distance between the platens was the initial specimen thickness. Hot moist air was circulated to keep the specimen at 35° C and near 100% humidity. The target loading level for the tissue was based on ground reaction force data.<sup>7</sup> In load control, the specimen underwent ten 1Hz sine waves from 10 N to the target load. The displacement at the target load was noted. Using displacement control, a stress relaxation test was performed. In this test, the tissue was compressed to the noted displacement in 0.1 s and held at a constant strain for 300 s. The relaxation curves were normalized by the peak force value. The normalized curves were fit to the QLV with a non-linear least squares regression. An analysis of variance determined if the fit parameters differed across areas.

**RESULTS**

The long term relaxation constant,  $\tau_2$ , was significantly larger for the subcalcaneal than the other areas except for the fifth submetatarsal (Table 1). No significant differences were found for the other parameters, including the short term time constant,  $\tau_1$ , the amplitude of the viscous damping,  $c$ , and the elastic constants  $A$  and  $B$ . However, the two areas, the lateral submidfoot and the third submetatarsal, with the largest  $c$  also experienced the most relaxation (Figure 1).

**Figure 1:** The average relaxation curves for the six areas.

**DISCUSSION**

These data indicate that some differences in the relaxation properties exist between certain areas of the foot. In particular, the large values of  $\tau_2$  seen for the calcaneus and fifth metatarsal indicate that these areas require more time to achieve steady state. The curve fits were sensitive to the initial guesses. However, we did use the same initial guesses for all specimens in each area. Also, the  $\tau_2$  obtained were greater than the length of the experiment, indicating that the experiment was terminated before steady state was achieved. Therefore in future testing, the specimen should be held at the maximum strain longer than 300 s. It should be noted that other than  $\tau_2$ , there were no differences in the relaxation properties of the different areas. This has implications for computational foot models that incorporate the plantar soft tissue.

## NEUROMUSCULAR ADJUSTMENTS TO HOPPING WITH AN ELASTIC ANKLE-FOOT ORTHOSIS

Zaineb Bohra, Jamie Lukos, Catherine Kinnaird, Daniel P. Ferris  
Division of Kinesiology, University of Michigan, Ann Arbor, MI; email: zbohra@umich.edu

### INTRODUCTION

When humans hop or run on elastic surfaces, they adjust the effective stiffness of their legs to perfectly offset changes in surface stiffness [1, 2]. As a result, the addition of a surface spring in series with the leg spring does not alter global movement parameters such as ground contact time or displacement of the center of mass. The purpose of this study was to determine if humans would show similar neuromuscular adjustments when hopping with a spring in parallel to their leg spring. Farley and colleagues have demonstrated that ankle stiffness primarily determines leg stiffness during hopping [3, 4] so we focused on adding a spring in parallel with the ankle joint. We hypothesized that humans would decrease their ankle joint stiffness when hopping with a plantar flexor spring added to an ankle-foot orthosis compared to hopping without a spring added to the orthosis. This adjustment would allow them to compensate for joint stiffness added by the orthosis spring.

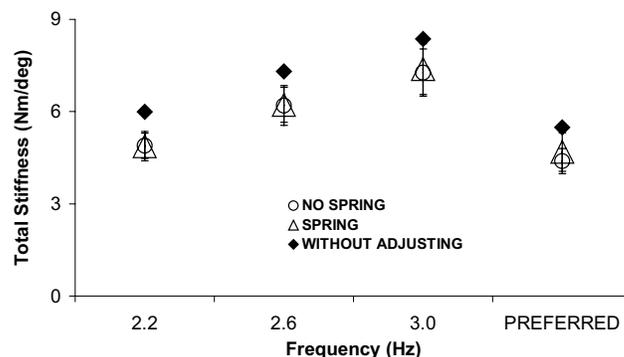

### METHODS

Four healthy subjects (ages 24-27 years) participated in this study. The University of Michigan Institutional Review Board approved the study protocol and each participant gave informed consent. Each subject hopped on their left leg at four frequencies (2.2, 2.6, 3.0 Hz, and their preferred frequency) under two orthosis conditions. In one condition (SPRING), the subjects hopped while wearing an ankle-foot orthosis with a linear extension spring providing plantar flexor torque ( $k=6.7$  kN/m, resulting in  $\sim 1.1$  Nm/deg). In the second condition (NO SPRING), subjects hopped wearing the ankle-foot orthosis without the spring attached. After subjects practiced for  $\sim 15$  seconds under the two conditions, they completed trials in a randomized order.

We collected joint kinematics, ground reaction forces, and electromyography (EMG) for two trials at each condition. We recorded spring force with a load cell. Using Visual3D software, we determined internal joint moments about the ankle, knee, and hip. We calculated leg and joint stiffnesses from vertical ground reaction force, center of mass displacement, joint displacements, and joint torques [4]. We used a three-way ANOVA to test for significant differences.

### RESULTS AND DISCUSSION

At each hopping frequency, subjects demonstrated the same effective leg stiffness for both orthosis conditions ( $p=0.07$ ). At preferred frequency leg stiffness was  $6.2\pm 2.0$  kN/m for NO SPRING and  $7.3\pm 2.2$  kN/m for SPRING conditions (mean $\pm$ s.d.). The invariant leg stiffness was possible because subjects decreased their ankle joint stiffness ( $p<0.001$ ) to offset orthosis stiffness added by the spring (Figure 1). The spring contributed  $\sim 24\%$  of the total stiffness about the ankle joint (ankle stiffness + orthosis stiffness) during the preferred frequency SPRING condition and less at faster frequencies.

**Figure 1:** Total stiffness about the ankle joint. The WITHOUT ADJUSTING values reflect what the total stiffness would have been in the SPRING condition if the subjects maintained the same ankle stiffness as during the NO SPRING condition. The total stiffness was independent of orthosis condition ( $p=0.46$ ).

As a result of the adjustments in ankle stiffness, there were no differences in peak vertical ground reaction force, center of mass displacement, or ground contact time between conditions ( $p>0.20$ ). EMG data revealed that subjects decreased soleus, medial gastrocnemius, and lateral gastrocnemius activation amplitudes during ground contact for the SPRING condition compared to the NO SPRING condition (22%, 21%, & 22% decreases, respectively;  $p<0.05$ ).

### CONCLUSIONS

When hopping unilaterally with an energy storing ankle-foot orthosis, our subjects decreased their ankle stiffness to offset the added stiffness of the orthosis. As a result, global movement dynamics were not affected by the added orthosis stiffness. Subjects appeared to achieve the decreased ankle stiffness by reducing triceps surae activation. These findings provide important insight into the neuromuscular control of bouncing gaits (i.e. hopping and running). The results also have important implications for the design of braces and orthoses for improving human performance and/or preventing injury.

## BRACING ALTERS PATELLOFEMORAL CONTACT MECHANICS DURING THE GAIT CYCLE: A DYNAMIC BIOMECHANICAL STUDY

<sup>1</sup> Nicole A. Wilson, <sup>2</sup>Tom Mazahery, MD, <sup>2</sup>Jason Koh, MD, and <sup>1,2</sup>Li-Qun Zhang, PhD  
<sup>1</sup>Rehabilitation Institute of Chicago, <sup>2</sup>Northwestern University; email: [l-zhang@northwestern.edu](mailto:l-zhang@northwestern.edu)

### INTRODUCTION

Patellofemoral (PF) pain is one of the most common knee disorders seen in orthopaedic practice [1]. However, the etiology of PF pain remains unclear and functional outcomes after treatment are unpredictable and often unsatisfactory [2]. Clinical decreases in PF pain symptoms with the application of bracing have been demonstrated [1]; yet, the mechanism by which an individual brace reduces pain is not well understood. The purpose of this study was to evaluate the effects of three PF braces in altering contact mechanics during gait.

### METHODS

Three fresh-frozen human cadaveric knees were tested during simulated free-speed walking under the following five test conditions: (1) no brace; (2) three DonJoy™ PF braces including, the Tru-Pull™, Lateral “J”, and an elastic sleeve; and (3) after a lateral release had been performed. The major individual muscles crossing the knee joint were moderately loaded according to their physiological cross-sectional areas [3]. A Tekscan™ sensor was inserted into the PF joint, through a medial parapatellar arthrotomy.

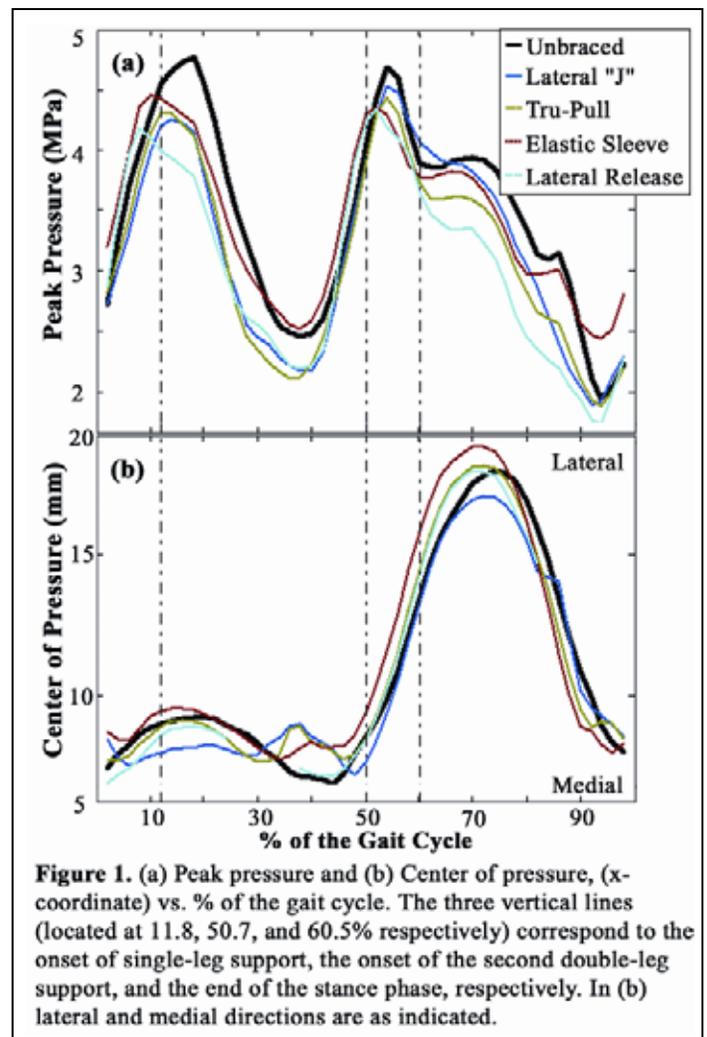

Fifteen strides were collected with each knee under each test condition. Differences in contact area, total contact pressure, peak pressure and center of pressure due to application of the three braces and the lateral release were analyzed using ANOVA with multiple comparisons (i.e. Tukey’s HSD) with the non-braced condition set as the control group.

### RESULTS AND DISCUSSION

Biomechanical variables, including peak pressure, contact area, and center of pressure, varied systematically with the gait stride (Figure 1a, 1b). Peak PF pressures during mid-stance were significantly reduced when compared with the unbraced condition by the Lateral “J”, the Tru-Pull, the elastic sleeve, and the lateral release (Figure 1a,  $p < 0.03$ ). The Lateral “J” reduced peak pressure during mid-stance by 21%; Tru-Pull by 19%; elastic sleeve by 19%; the lateral release by 22%. The Tru-Pull, elastic sleeve, and the lateral release also reduced peak pressure throughout swing phase (Figure 1a,  $p < 0.04$ ). The Lateral “J” did not significantly reduce peak pressure during the swing phase of the gait cycle. The elastic sleeve increased PF contact area by 79% during the double-support phase of the gait cycle ( $p < 0.05$ ). However, the Tru-Pull decreased contact area by 32% during mid-stance ( $p < 0.03$ ). Contact area did not significantly change with the Lateral “J”. Application of the Lateral “J” shifted the center of pressure medially during single-leg support (Figure 1b,  $p < 0.02$ ).

### CONCLUSIONS

This study presents a quantitative approach to the evaluation of PF contact mechanics with a range of clinical interventions during simulated locomotion and can aid understanding of the

factors that contribute to PF pain and the mechanisms underlying symptom reduction associated with bracing.

The demonstrated reduction in peak PF pressure, for example, is a potential mechanism for pain relief associated with bracing. Limitations of this study include the small sample size, specimens not necessarily having a PF disorder, open-chain movement, and moderate muscle loads. A follow-up study is planned.

## ENSLAVING EFFECTS OF FINGER MOVEMENT ON PRESSING FORCES OF OTHER FINGERS

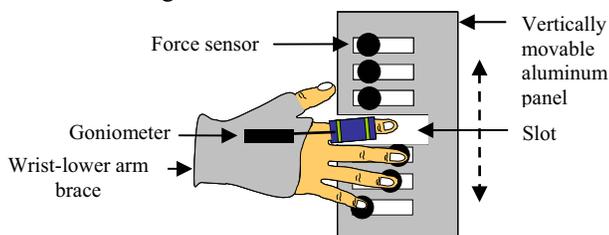

<sup>1</sup>Byung Hoon Woo, <sup>1</sup>Sun Wook Kim <sup>1</sup>Vladimir M. Zatsiorsky, <sup>1</sup>Mark L. Latash, and <sup>1,2</sup>Jae Kun Shim  
<sup>1</sup>The Pennsylvania State University and <sup>2</sup>University of Maryland  
 email: [shimjaekun@hotmail.com](mailto:shimjaekun@hotmail.com)

### INTRODUCTION

Studies of finger kinetic and kinematic interactions have shown that fingers are interdependent each other (for a review see Schieber and Santello 2004). Kinetic and kinematic enslaving effects are larger in neighboring fingers (e.g. in the index finger-middle finger or middle finger-ring finger pairs) than in the fingers positioned farther from each other (e.g. in the index finger-ring finger pair). These effects were studied both in static force production tasks (Zatsiorsky et al. 1998) and during finger movements (Hager-Ross et al. 2000; Li et al. 2004). However, interdependence between the static force production and finger movement has not been addressed. The purpose of the current study was to investigate the effects of finger movement on the finger-tip forces of other fingers. We hypothesized that the effects depend on the fingers proximity and are the larger the closer the fingers to each other (proximity hypothesis).

### METHODS

**Equipment:** One goniometer (Sensor SG65 Biometrics Ltd.) and six piezoelectric sensors (Model 208C02, Piezotronic, Inc.) were used (Figure 1) to record metacarpophalangeal (MCP) joint angles of a finger in motion (task finger) and finger-tip forces of the rest of fingers (non-task fingers). The sensors were horizontally movable on an aluminum panel, and they were fixed according to hand anatomy of individual subjects. The hand position was maintained constant, but the aluminum panel was vertically moved so that a task finger could move through the slot.

**Figure 1.** Experimental setup.

**Experimental Procedure:** Ten healthy, right-handed volunteers, five males and five females participated in the experiment. Subjects sat on a chair with their right lower arms

positioned on a table and strapped with a set of Velcros. A wrist-forearm brace (EBONITE Inc.) was used to immobilize the wrist. A small aluminum bar was used to restrict the movement of proximal and distal interphalangeal joints of a task finger. Before each trial, subjects extended all phalangeal joint angles into approximately 180° with the thumb pointing upward. Subjects flexed the MCP joint of one finger each time to its maximum range of motion through a hole at a comfortable speed, and isometric pressing forces on finger-tips of non-task fingers were recorded. Non-task finger forces at the time of the maximum range of motion of a task finger were extracted to quantify enslaving forces of non-task fingers.

### RESULTS

Neighboring fingers of a task finger produced approximately 67% of the total force, and non-neighboring fingers generated about 33%. In the tasks with two neighboring fingers (e.g. middle and ring finger tasks), index and middle fingers showed larger enslaving forces than the other neighboring fingers. During index and little finger tasks, the enslaving force magnitudes decreased with distance to the task fingers (i.e. index finger enslaving force was the smallest during the little finger task).

### CONCLUSIONS

Our observations support the proximity hypothesis; fingers positioned closer to a task finger produce larger enslaving forces. These observations extend results of the earlier studies of kinetic and kinematic enslaving (Zatsiorsky et al. 1998; Hager-Ross et al. 2000; Li et al. 2004) to enslaving of non-task finger forces in response to a kinematic movement of a task finger.

## RELATING FRACTURE ENERGY TO CLINICAL OUTCOME IN TIBIAL PILON FRACTURE CASES

Thaddeus Thomas, Donald Anderson, Evan Hermanson, Valerie Muehling, J Lawrence Marsh and Thomas Brown  
Department of Orthopaedics and Rehabilitation, The University of Iowa,  
email: [don-anderson@uiowa.edu](mailto:don-anderson@uiowa.edu), web: [poppy.obrl.uiowa.edu](http://poppy.obrl.uiowa.edu)

### INTRODUCTION

Post-traumatic osteoarthritis (OA), evidenced in part by early radiographic changes, is a frequent outcome following intra-articular fracture. Residual altered articular surface anatomy is believed a primary culprit, subjecting cartilage to chronically aberrant contact stress distributions predisposing to OA. But this dogma has evolved from clinical studies unable to control for the initial mechanical insult to peri-articular tissues, another reasonable factor predisposing to early OA.

We have implemented a CT-based technique to objectively quantify injury severity in complex fractures.[1] The technique exploits the principle that mechanical energy is required to create new free surface area in a brittle solid, and that the amount of energy required is directly related to the amount of *de novo* surface area. In tibial pilon fractures, the fracturing energy is delivered directly through ankle joint cartilage.

In the present study, fracture energy measures were used to quantify injury severity in a series of fracture cases, and these results were compared to the clinical judgment of two experienced orthopaedic surgeons. Cartilage appearance on double contrast CT scans of the healed fractures were graded and correlated with fracture energy measures.

### METHODS

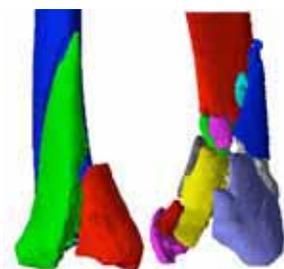

Injury severity was quantified in a series of ten tibial pilon fracture cases, utilizing CT studies obtained during standard clinical care. Contralateral limb scans provided intact bone surface areas over a comparable distal segment of the patient's tibia, for taring. Bone free surface area measurements were extracted from CT datasets using validated digital image analyses.[2] The *de novo* surface area liberated during fracture was inferred from the difference between free surface areas measured on fractured and intact tibias of each patient.

In independent grading sessions, the fracture cases were rank ordered by two experienced orthopaedic traumatologists from lowest to highest severity, based on the appearance of A-P and lateral radiographs.[3] One rater participated in two independent sessions. Raters were blinded to the surface energy data. Concordance values were calculated to measure agreement between the two raters and between each rater and the CT-based measure of fracture energy.

At the time the fracture had healed (4-8 months post-op), double-contrast (contrast agent followed by air) CT scans were obtained. Articular cartilage integrity was graded from by one of the orthopaedic traumatologists and by two musculoskeletal radiologists using a scale ranging from 0 (all cartilage apparent) to 4 (no visible cartilage). Mean values of the cartilage gradings were compared to fracture energy data.

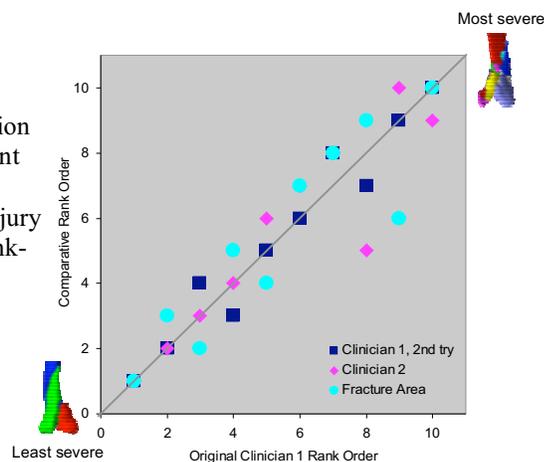

### RESULTS AND DISCUSSION

Fracture-liberated surface areas ranged from 1765 to 9406 mm<sup>2</sup>, reflecting a wide range in fracture severity (Figure 1). There was excellent agreement between all injury severity measures (Figure 2). Concordance between the raters was .912 ( $p < 0.0001$ ). The concordance between the first rater's assessment of injury severity and that of the CT-based measure was .844 ( $p < 0.0001$ ), and for the second rater it was .800 ( $p < 0.0006$ ). The range of graded cartilage integrity did not correlate as well with fracture energy measures, though results are too preliminary to warrant statistical comparisons.

**Figure 1.** These two cases span the comminution spectrum studied.

**Figure 2:** Graphical representation of agreement between different injury severity rank-orderings.

### CONCLUSIONS

We have developed estimates of the fracture-liberated bone surface area associated with a series of clinical pilon fractures. Our previous work has shown that this parameter correlates closely with fragmentation energy. The energy measures here calculated agree favorably with the clinical impression of experienced orthopaedic surgeons, in terms of a rank ordering of injury severity. This opens new possibilities in studying the link between initial injury severity and the onset of post-traumatic OA in an actual clinical population.

## SUPERPOSITION OF OPTIMAL SUBMOVEMENTS IN FEEDBACK-CONTROLLED REACHING

Kevin A. Rider, Bernard J. Martin  
University of Michigan; email: [riderk@umich.edu](mailto:riderk@umich.edu), web: [www.humosim.org](http://www.humosim.org)

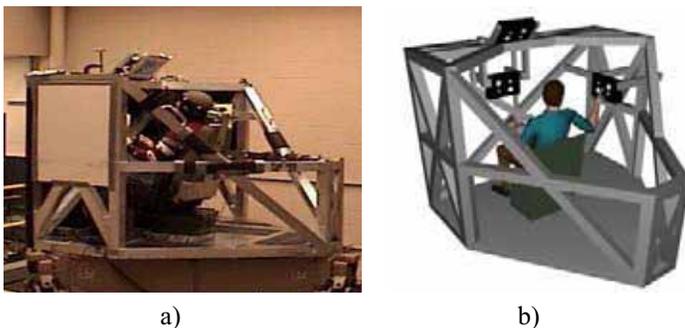

### INTRODUCTION

The inverse relationship between speed and accuracy of rapid target-directed movements is a result of the combined use of visual and somatosensory feedback systems by the central nervous system (CNS). Feedback loops allow for comparisons between the desired movement plan and actual execution in discrete intervals [1]. Optimal rapid movements have been shown to exhibit bell-shaped speed profiles [2], although speed profiles exhibit multiple peaks due to compensatory adjustments made when the movement is perceived to no longer satisfy the desired goals. Composites of superimposed optimal speed profiles of submovements were generated and compared with actual speed profiles of rapid, three-dimensional reaching tasks under stationary and random whole-body vibration.

### METHODS

Participants (N=20) performed rapid pointing tasks under stationary and motion conditions to targets presented on three touchpanel displays. A ten-camera VICON motion capture system recorded trajectories of reflective marker placed on the participants' torso, head, and arms. Fingertip trajectories were extracted and averaged to determine participant's optimal path for each motion condition [3]. Speed profiles were generated from the tangential velocity of the fingertip marker.

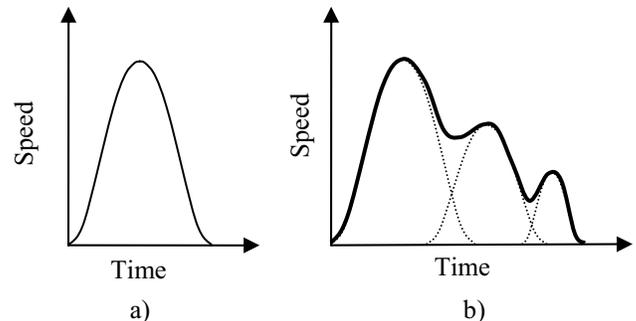

Random six degree-of-freedom (6DOF) ride motion was recorded from a High Mobility Multi-Wheeled Vehicle (HMMWV). Motion conditions (Roll, Pitch) were extracted, each with dominant vehicle acceleration about the longitudinal and lateral axes respectively. These motion files were simulated on a 6-DOF Ride Motion Simulator (RMS) (Figure 1a). Three touchpanel displays were mounted to the RMS to display targets and record endpoint locations (Figure 1b).

**Figure 1.** The RMS (left) configured with three touchpanel displays and depicted in simulation (right).

Modeling began with an optimal bell-shaped speed profile of the fingertip, initially generated based on the time and magnitude of the peak tangential velocity (Figure 2a). As the fingertip deviates from the optimal path, a compensatory submovement is made with a sensorimotor delay of 100 ms.

Submovements were assumed to have optimal bell-shaped profiles. The optimal path was then adjusted using a decreasing gradient in the vector of radial deviation to create a new optimal path, from which the continuing trajectory of the fingertip was evaluated. This recursive process continued until task completion. Submovements were superimposed to form composite speed profiles (Figure 2b).

**Figure 2.** a) Optimal open-loop bell-shaped speed profile and b) Closed-loop profile with superimposed submovements.

### RESULTS AND DISCUSSION

Composite speed profiles compared favorably with actual fingertip speed profiles in the latter portion of the movement, when the fingertip entered the field-of-view. Our results suggest that the initial phase of movement is to accelerate away from the origin without specific accuracy requirements. It is possible that somatosensory feedback is used only for movement planning and not for feedback control. It is unclear whether the CNS does not discern initial deviations from the optimal path, or if comparisons are weighted more heavily toward the destination. Reaches performed without ride motion did not have observable movement corrections, rather near-optimal speed profiles. This may be due to corrections that were either imperceptible or not present. These and other discrepancies between composite and actual speed profiles may be due to additional movement strategies such as non-linear trajectories, time-varying goals (lift-off vs. landing phases), and biodynamic responses to the vibration stimulus.

## USE OF THE LONG FLEXOR AND INTRINSIC THUMB MUSCLES TO RESTORE LATERAL PINCH IN THE TETRAPLEGIC THUMB: A CADAVER STUDY

<sup>1</sup>Joseph D. Towles, <sup>2</sup>Vincent R. Hentz, and <sup>3</sup>Wendy M. Murray

<sup>1</sup>Sensory Motor Performance Program, Rehabilitation Institute of Chicago; <sup>2</sup>Dept. of Surgery, Stanford University; <sup>3</sup>Bone and Joint Center, VA Palo Health Care System; email: towles@northwestern.edu

### INTRODUCTION

In tendon transfer surgeries designed to restore lateral pinch following tetraplegia, the donor muscle is commonly attached to the insertion of the paralyzed flexor pollicis brevis muscle (FPB), a thumb flexor [1]. However, the nominal direction of the thumb-tip force that FPB produces may cause the thumb to slip during lateral pinch [2]. The aim of this study was to evaluate if actuating additional thumb muscles via tendon transfer could orient the thumb-tip force more appropriately for lateral pinch.

### METHODS

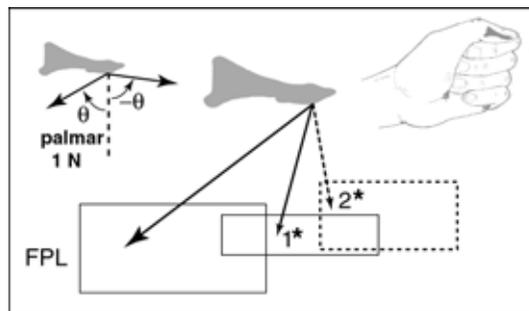

Thumb-tip forces produced by the extrinsic and intrinsic muscles of the thumb were measured in 11 upper extremity cadaveric specimens by adapting an experimental approach previously developed for the index finger [3]. Briefly, a force of 10 N was applied to the tendons of nine muscles and the resulting three-dimensional (3D) thumb-tip force was quantified using a force sensor. The wrist was positioned in neutral and the thumb was fixed so that the trapezio-metacarpal joint was extended 29°, the metacarpo-phalangeal joint was flexed 27°, and the interphalangeal (IP) joint was flexed 50° to simulate lateral pinch.

For each muscle, median components of the measured thumb-tip force vectors were computed. Using this data, we calculated the resultant thumb-tip force vector from linear combinations of (1) the forces produced by FPL and one other muscle, and (2) the forces produced by FPL and two other muscles. Direct comparisons of the directions of the force vectors resulting from the linear combinations of multiple muscles were compared to the nominal FPL direction to evaluate if actuating more than one muscle could better orient thumb-tip force. We used the Mardia-Watson-Wheeler Test for circular statistics (Kovach Computing Services, Anglesey, Wales, UK) to test for significance ( $\alpha = 0.05$ ).

### RESULTS AND DISCUSSION

When the tendon of FPL was loaded with 10 N of force, the median (interquartile range) magnitude of the force was 1.7 N (1.5 N to 3.9 N) and the force was oriented obliquely at 49° (19° to 54°) with respect to the palmar direction in the flexion-extension plane (Fig. 1). We estimate that if equal force is applied to the tendons of the ulnar head of the flexor pollicis brevis muscle (FPBu) and FPL, i.e., if these muscles were simultaneously actuated by a single donor muscle, the resultant thumb-tip force direction is 15° (-20° to 27°). A single donor muscle actuating three muscles, FPL, FPLu and the radial head of the flexor pollicis brevis, also re-orientates the force; the new orientation being -9° (-49° to 2°) with respect to the palmar direction.

Surgical restoration of lateral pinch following cervical spinal cord injury often leaves a donor-muscle-actuated FPL as the only muscle producing force at the thumb. Based on the

**Figure 1: Median thumb-tip force directions.** FPL and FPLu combined (1) and FPL, FPLu, and FPLr combined (2) yield force directions that are less oblique (more palmarly directed) than FPL alone. Boxes indicate the interquartile ranges of the thumb-tip force components. ( $*p < 0.05$ )

coefficients of friction between skin and objects of different materials [4], we estimate that the force applied to an object by the thumb should be oriented to within 15° to 33° of the palmar direction to stably grasp objects. The direction of FPL's nominal force lies outside this range. This mis-direction likely explains the need for procedures that stabilize the IP joint, frequently performed concomitantly with tendon transfers that restore lateral pinch [5]. This study suggests that simultaneously actuating additional muscles with the same donor muscle has the potential to improve thumb-tip force direction. This approach could reduce the need for joint stabilization procedures that restrict joint movement, such as percutaneous pin fixation.

Limitations of this work should be considered when interpreting the results. First, thumb-tip force directions should also be evaluated in three-dimensions to evaluate how actuating multiple muscles would influence function in other planes. Second, we assume forces produced by multiple muscles can be combined linearly. The sensitivity of our results to this assumption should be further evaluated [6].

### CONCLUSIONS

Actuating the paralyzed intrinsic musculature of the thumb via tendon transfer has the potential to improve lateral pinch function following tetraplegia.

## EXTRACTION OF THE IMPACT FROM VERTICAL GROUND REACTION FORCES

T.R. Derrick, J.C. Gillette and J.M. Thomas

Department of Health and Human Performance, Iowa State University, Ames, IA, USA

email: [tderrick@iastate.edu](mailto:tderrick@iastate.edu)

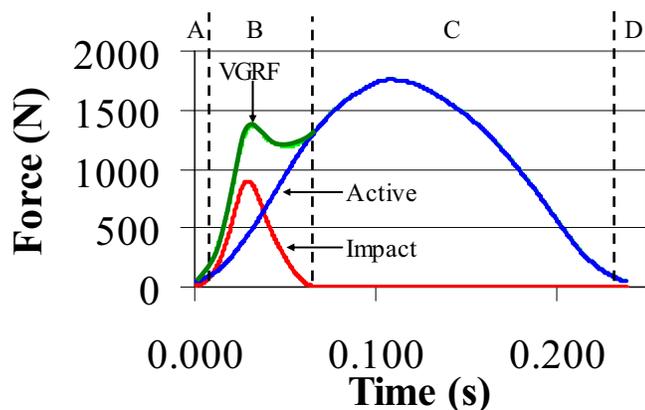

### INTRODUCTION

Vertical ground reaction forces (VGRF) are composed of a high frequency (impact) and a low frequency (active) component. The impact component is associated with the acceleration the stance leg during running [1]. This impact component has been associated with both positive (bone strengthening) and negative (injury) effects. The impact and active components are superimposed in the time domain and contain significant overlap in the frequency domain. Therefore, spectral methods are inadequate as a means of separating the components. The purpose of this research was to determine if spline techniques could be used to separate the impact from the active portion of a VGRF.

### METHODS

A cubic smoothing spline with a weighting variable was used to remove the impact peak from a VGRF curve. The curve was split into 4 regions (Figure 1). Region A consisted of the first 8 ms of the curve. The values were set to the reverse of the last 8 ms of the curve and the weights were set to 0.1. Region B was from 8 ms to approximately twice the time to the impact peak. This assumes a symmetric impact curve. The weights were set to 0.0 in this region. Region C was from the end of Region B to one data point prior to the end of the VGRF. The weights in this region were set to 0.1. The final data point was set to 1.0 to force the curve through this value. Application of the spline resulted in the active force. The impact force was obtained from subtraction of the active force from the VGRF.

A mass-spring model was used to simulate impact curves. Stiffness was originally set to 100 kN/m, mass was 8.5 kg and initial velocity was -1.0 m/s. The active curve was simulated

**Figure 1.** Spline extraction of the impact portion of an actual running vertical ground reaction force curve. Regions A, B, C and D indicate different weights of the spline.

using a Kaiser window ( $\beta=5$ ) scaled in magnitude to 1200 N and scaled in time to 0.25 s. Simulated VGRF curves were constructed by adding the impact and active curves. The ability of the spline to accurately extract the impact portion of the curve was assessed by comparing the actual mass-spring impact peaks to the extracted impact peaks while changing the parameters of spring stiffness, impact velocity and stance time.

The spline method of impact extraction was also applied to actual VGRF curves obtained while running across a force platform in 4 conditions. Seven subjects (mass:  $66\pm 7.5$  kg) were first asked to run at a normal pace. They were then asked to run at the same pace off of a raised platform while flexing the knee normally, with excessive flexion and with minimal flexion. Ten trials of force platform data were recorded at 1000 Hz for each of the four conditions. Actual running VGRF impact peaks were compared to impact peaks extracted using the spline technique.

### RESULTS AND DISCUSSION

Although simulated VGRF impact peaks ranged from 649 to 1543 N, the extracted impact peaks were never more than one N different than the mass-spring simulated impact force peaks.

Table 1 indicates the average VGRF and extracted impact peaks for each running condition. Note the magnitudes are substantially different, yet there is a correlation of 0.98 between actual and extracted peak values.

Extraction of impact peaks allows the determination of impact parameters independent of the active portion of the curve. This has applications for assessing both the injury and osteogenic potential of impacts. The extracted impact forces could be used to estimate the effective mass of an impact.

**Table 1.** Peak impact values for actual VGRF curves.

Running Condition	Peak VGRF Impact Force (N)	Peak Extracted Impact Force (N)
Normal	1182±227	705±227
Platform Normal	1925±404	1484±379
Platform Flexed	1855±479	1569±457

### INTRODUCTION

What are the features of the human hand that enable dexterous manipulation functionality that transcends that of state-of-the-art robotic hands? Understanding and emulating the biologically evolved solutions to the manipulation problem in humans would empower both biomechanists and roboticists alike. In this interdisciplinary work, we present the computational foundations to simulate and predict the functional advantages of multi-finger grasps with a biomechanically realistic model of the human hand.

### METHODS

We translated the anatomical description of the “virtual five-link” thumb kinematics into a standard robotics notation (Denavit-Hartenberg (D-H)) using 3D geometry and D-H conventions [1]. We added musculoskeletal parameters (e.g., moment arms) to the kinematics, resulting in a 50-parameter robotics-based model capable of producing thumbtip forces and torques. We then used Markov Chain Monte Carlo simulations to find parameters that achieved a least squares best fit to experimental thumbtip forces [2].

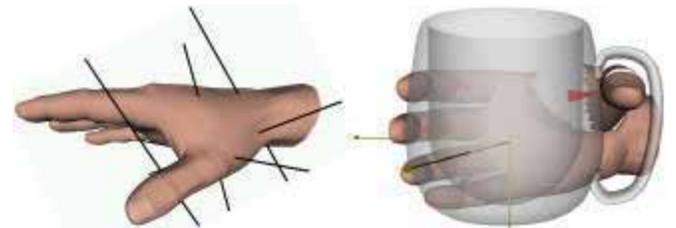

As a first approximation, we implemented these best fit D-H parameters for the thumb in *GraspIt!* [3], our visualization and simulation engine designed for the study of grasp planning in robotic hands. The other fingers were simulated using universal joints at the metacarpophalangeal joints, and simple hinges at the interphalangeal joints [4]. With this program, grasps of arbitrary objects can be dynamically simulated, optimized for grasp stability, and objectively quantified for feasibility and grasp quality.

To quantify grasp quality, we use a robotics-based mathematical representation of grasp that employs a “grasp matrix” to relate fingertip contact forces (and torques if using soft fingertips) to the effective force and torque on the grasped object (the grasp “wrench”). The rank of the grasp matrix, for given object geometry and friction characteristics, is affected by fingertip placement and the margin of error permitted by the friction cones associated with each fingertip contact force, and is a measure of how many degrees of freedom of the object can be controlled [5]. We evaluate the ability of a quasi-static grasp to reject disturbances by building the 6D space of forces and torques that can be applied by the grasp using convex hull theory. We propose the hyper-volume of this space as one possible measure of grasp quality, since a larger volume of this space means that the grasp is more efficient at rejecting force and torque perturbations [3].

### RESULTS AND DISCUSSION

The D-H representation of the anatomy-based, non-

intersecting, non-orthogonal axes of rotation for the thumb provides a new biomimetic direction for comparative kinematic studies of robotic and human hands, and may help elucidate whether and how these kinematic features enable dexterous manipulation in humans (Fig. 1). Traditionally, simple orthogonal axes of rotation are used to model thumb kinematics in robotic hands, but our work suggests these articulations cannot realistically predict 3D static thumbtip forces [6].

**Figure 1:** Left: The anatomy-based model represents more faithfully the thumb’s five non-orthogonal, non-intersecting joint axes. Right: The hand model grasps a mug.

We have adapted a computational environment to quantify grasp quality of biomimetic human hands. Our critical challenge now is to determine the level of model complexity that is necessary and sufficient for predicting realistic multi-finger manipulation function. We are currently investigating adaptive refinement finite element methods to account for finger pad compliance and skin deformation, tendon interconnections within and across fingers, and will use accurate skeletal geometry to constrain the innermost elements. This computational platform will allow us to investigate the relative contributions of passive anatomical elements and active neuromuscular elements to dexterous manipulation.

## IN VIVO ASSESSMENT OF CONGRUENCE IN THE PATELLOFEMORAL JOINT OF HEALTHY SUBJECTS

<sup>1</sup>Kim McLaughlin, <sup>1</sup>Janet Ronsky, <sup>2</sup>Richard Frayne

<sup>1</sup>Department of Mechanical and Manufacturing Engineering, University of Calgary, [kim@kin.ucalgary.ca](mailto:kim@kin.ucalgary.ca)

### Introduction

Joint congruence indicates how well mating surfaces fit together. A mismatch between contacting surfaces may cause abnormal joint forces and stresses. Joint congruency has been suggested as a potential risk factor in patellofemoral (PF) pain syndrome [1] as well as in the initiation and progression of osteoarthritis [2]. Radiography is the most widely used imaging modality for the clinical assessment of joints. However, this technique is limited for measures of joint congruency. It provides only subchondral bone shape which does not necessarily match the contour of the articulating cartilage [3]. In addition, the joint is typically examined in only one position. The complex 3D geometry of the joint throughout a range of motion may not be adequately characterized by this 2D measurement. Magnetic resonance (MR) imaging overcomes the limitations of current x-ray approaches for assessing joint congruence and has been used to study the knee joint [2]. However, the effect of joint angle and physiological joint loading on knee joint congruency has not been examined. The purpose of this research was to quantify in-vivo PF joint congruence and to examine effects of flexion in a loaded condition.

### Methods

MR imaging (3.0T GE unit, 3D FIESTA, 3 mm slice thickness, 2.5 min. data acquisition) was used to quantify the PF joint geometry of 4 healthy female adults (mean age = 25.5 years, height = 160.6 cm, weight = 61.5 kg). Ethics approval for all procedures was provided. The knee was imaged during physiological loading at three alignments (15°, 30° and 45° flexion) using a custom designed loading apparatus. A mathematical joint model was developed through image segmentation, 3D reconstruction of each surface using a thin plate spline and contact determined with a proximity algorithm (Figure 1) [4]. The principal curvatures at each surface point were calculated and averaged over the contact area for the patella and femoral surfaces [5]. Based on the average curvature for each surface, an equivalent surface was created and compared to a flat plane.

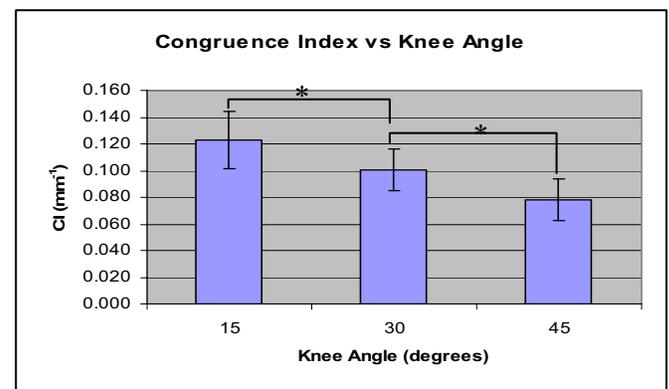

**Figure 1:** PF joint contact area plotted on the 3D reconstruction of the patellar and femoral surfaces.

The relative curvatures ( $K_{max}^c$ ,  $K_{min}^c$ ) were determined for the equivalent surface. A congruence index (CI), zero for perfect congruence, was found using:  $CI = K_{RMS}^c = [(K_{min}^c)^2 + (K_{max}^c)^2 / 2]^{1/2}$  [2]. Changes during flexion in the loaded knee joint were examined. Differences were compared using a paired t-test with a p-value < 0.05 indicating significance.

### Results and Discussion

The patellofemoral joint (n=4) became more congruent as the knee joint angle increased (Figure 2). The CI at 30 degrees was found to be significantly different from both 15 degrees (p-value = 0.008) and 45 degrees (p-value = 0.002).

**Figure 2:** Average CI (mean  $\pm$  1 SD) of the loaded PF joint at 15°, 30° and 45° of flexion. (\* = p-value < 0.05)

The CI enables detailed characterization of subject specific joint congruence over a range of motion. Increased joint congruence can be accomplished by deforming the cartilage, changing the location of the surfaces relative to one another or a combination of both. More congruent joints may allow forces to be better distributed and therefore, minimize potentially deleterious local stress concentrations with increasing flexion angle.

### Conclusions

Initial results indicated that the PF joint became more congruent as the angle increased in healthy females. Congruence could potentially be a factor in certain knee joint pathology. On-going work involves investigating the relationship of CI and knee angle in individuals with PFPS.

### INTRODUCTION

Icy and snowy surface roads near melting temperature are more slippery than normal one. There have been many fall accidents caused with slip on icy and snowy surfaces in cold regions and in the winter season in many parts of the world. The biomechanics researches on slip are an important component in the prevention of fall-related injuries. The purpose of present study was to compare the biomechanics of human gait from slippery floor surface to that from non-slippery floor surface in healthy subjects.

### METHODS

Five male subjects volunteered to participate in the laboratory experiments. The mean values  $\pm$  SD of their heights, weights, and ages were  $1.72 \pm 0.05$  m,  $65.2 \pm 8.9$  kg,  $23.2 \pm 7.8$  yrs., respectively. They received an explanation of the experimental protocol and provided informed consent prior to testing. A slippery (coefficient of friction:  $0.125-0.225\mu$ ) and non-slippery floor surface was placed on the walking track over the force plate (KYOWA, Japan). The subject was performed to walk with three different strides; preferred, long and short strides. The cadence of walking was fixed with 90 steps per a minute. The measurements of kinematic data during the walking were collected by using the VICON 460 motion analysis system (Oxford's Metrics, Oxford, UK) with six cameras at 120 Hz placed on the laboratory ceiling. The motion of the subjects' walking was recorded with this system and reflective markers. VICON Workstation software was used to calculate position of the subject's center of gravity (CG) and the relative angles between coordinate systems of each segment in the lower limb and the laboratory coordinate system. The electromyography (EMG) system (WEB-5000, Nihon Kohden, Japan) was used to collect muscle activity from the rectus abdominis, erector spinae, vastus lateralis, hamstrings, tibialis anterior and gastrocnemius. The EMG signals were amplified and recorded by a computer via an A/D converter. A Student's paired t-test was used to determination differences between the kinematic variables when walking either the slippery and non-slippery floor surface. Probability values of  $p < 0.05$  were accepted as being statistically significant.

### RESULTS AND DISCUSSION

Figure 1 shows the kinematic data of the CG when the subjects walked on slippery and non-slippery floor surface. The highest CG position during one cycle was significantly lower when walking on the slippery floor surface than on the non-slippery. Differences between the maximum and minimum value in the vertical CG position during one cycle of walking were 5.1 and 3.5 cm for non-slippery and slippery

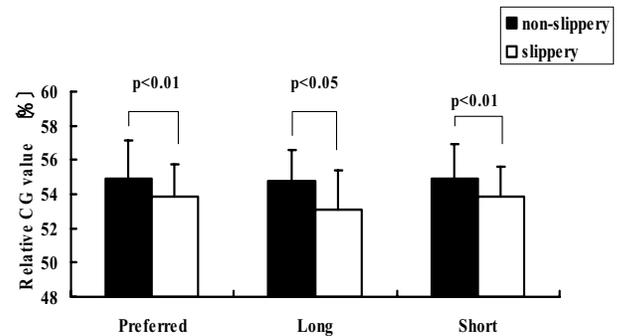

Figure 1: Comparisons of the highest value of the vertical CG position to relative body height during one cycle between slippery and non-slippery floor surface.

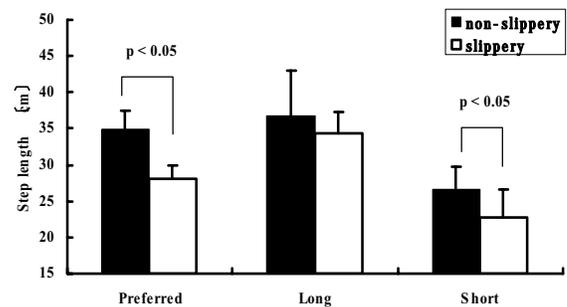

Figure 2: Comparisons of step length between slippery and non-slippery floor surface.

floor surface, respectively. This seemed to lower CG in order to stabilize the body in slippery floor surface. Figure 2 shows change of the step length when the subjects walked on slippery and non-slippery floor surface. The step length was significantly shorter slippery floor surface than non-slippery floor surface. Additionally, there was significant difference in walking speed between slippery and non-slippery floor surface. Pronounced EMG activity was found in rectus abdominis and tibialis anterior muscle during the walking on the slippery floor surface. These results indicated that the lower vertical position and smaller vertical variation of the CG during the walking on the slippery floor surface would be due to the shorter step length and larger ankle dorsiflexion and knee flexion compared to the non-slippery floor surface.

### CONCLUSIONS

These findings suggest that the gait patterns were changed with depending on slippery or non-slippery floor surface. Especially, the transition of the CG on slippery was lower because of shorter step length and larger knee flexion. This changed gait pattern on slippery seems to avoid naturally for slip and fall.

## THE EFFECTS OF MECHANOSENSITIVITY ON THE PREDICTION OF BONE FORMATION RATE

S.A. Meardon, T.R. Derrick, & T.J. Tauber

Department of Health and Human Performance, Iowa State University, Ames, IA, USA

E mail: [smeardon@iastate.edu](mailto:smeardon@iastate.edu)

### INTRODUCTION

Impacts have the potential to be an influential factor in both the etiology of overuse injury and the promotion of bone strength. Models of canalicular fluid flow [1] and recent animal studies suggest impact patterns influence variables related to osteogenesis independent of magnitude and number of impacts. Repeated impacts can saturate the sensitivity of bone to mechanical stimuli. Rest between impacts or between impact bouts allows bone to recover mechanosensitivity. Knowledge of optimal patterns of loading will allow exercise routines to be developed that maximize osteogenic potential. The purpose of this study was to determine if a model of impact activity that accounts for the effects of saturation and recovery on mechanosensitivity will better predict changes in bone formation than a stimulation model based solely on magnitude and number of impacts.

### METHODS

Animal studies which investigated the magnitude, number of impacts or time between impacts were used to evaluate the two models. Studies were included if loading was measured in units of microstrains ( $\mu\text{s}$ ) and the dependent variable was bone formation rate (BFR). At present, six studies were found to meet these qualifications. *Osteogenic stimulation* was defined as the product of impact magnitude and the total number of impacts. *Osteogenic activation* was determined by the magnitude and the pattern of impacts, as influenced by the current state of mechanosensitivity. Saturation was modeled as  $1/N$ , where N was the number of impacts [2]. Recovery was modeled as  $1-e^{-t/\tau}$ , where t was the time from the last impact [2]. In this study  $\tau$  was optimized by finding the value that maximized the Spearman correlation between the model derived activation and the BFR from all studies combined (Figure 1).

Once the optimal  $\tau$  was determined, the stimulation and activation models were correlated with BFR using a Pearson correlation for each individual study that contained more than 2 treatment conditions.

### RESULTS AND DISCUSSION

The value for  $\tau$  that was optimized across studies was 1.1 hours. This corresponds to 99% recovery in approximately six hours of rest. Data from each of the six studies is summarized

in Table 1. In all studies, Pearson correlation coefficients indicated osteogenic activation model was a better predictor of BFR than the stimulation model.

Both stimulation and activation models assume that strain magnitude is directly related to the osteogenic stimulus. In addition the activation model incorporates bone saturation and recovery effects. Previous research has shown that strain rates, which we did not include, play an important role [8]. In addition, neither model takes into consideration the effects of accommodation [9]. Future models will need to incorporate these variables for better prediction of bone formation rates.

Models used to predict optimal exercise patterns must take into account the effects of saturation and recovery. Use of such models would bring us one step closer to developing exercise routines that maximize human osteogenic potential.

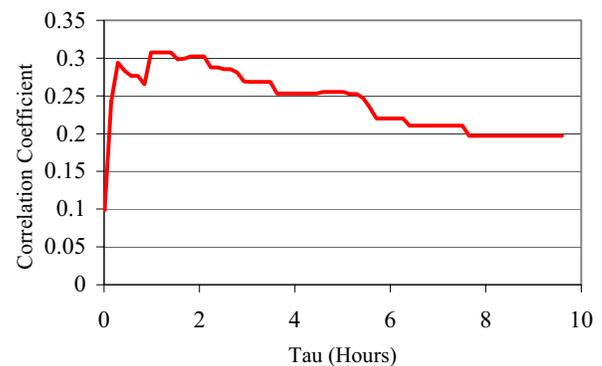

Figure 1: Optimization of tau ( $\tau$ ) across studies.

### INTRODUCTION

The identification of key parameters in acceleration profiles as a means to evaluate rowing performance has traditionally been difficult to achieve. A review of the literature shows that no publication to date has attempted this, possibly due to the mechanical complexity of rowing. In this paper a single-scull rowing model, created using MathWorks' Matlab® and Simulink®, is presented. The model has been created to investigate the feasibility of monitoring shell acceleration as a means to assess single rower technique.

### METHODS

The developed model describes the rower as linkages (Figure 1) rather than a series of lumped masses; a distinction from many of the existing rowing models [1-3]. The motivation for modelling the rower in such great detail is to generate a more realistic shell acceleration trace. Each body segment of the rower model was based on cadaver limb dimension data [4]. Input parameters and boundary conditions for the rower motion were based on 3D acceleration and video data collected from a single heavyweight male sculler in one session.

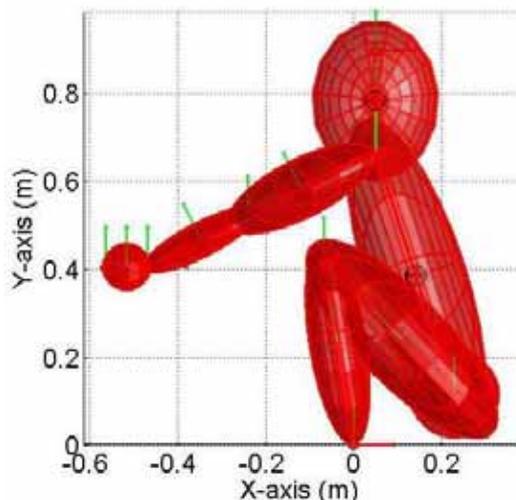

Figure 1: Rower model. The ellipsoids represent the inertial properties of the body segments.

### RESULTS AND DISCUSSION

The resultant shell acceleration trace (Figure 2) from the initial attempt in simulating the rower motion does show similar characteristics to the measured shell acceleration trace (Figure 3). Further fine-tuning of the rower motion description is now in progress.

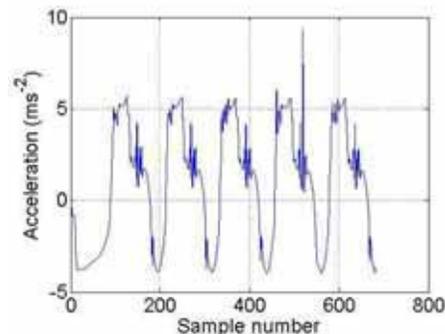

Figure 2: Simulated shell acceleration trace.

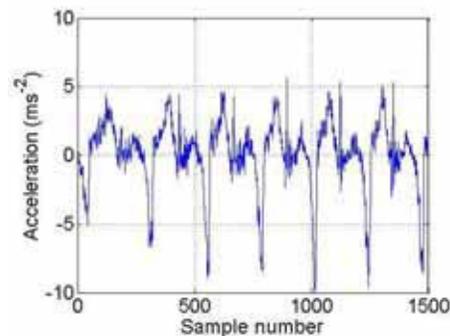

Figure 3: Measured shell acceleration trace.

### CONCLUSION

The variability of the shell acceleration profile of each stroke reflects the rower's consistency. The model is an important step towards understanding the measured acceleration profile and relating the variability in the shell acceleration profiles to the timing of the rower's motion.

## CLINICAL USEFULNESS OF FOUR FUNCTIONAL KNEE AXIS ALGORITHMS

<sup>1</sup>Adam M. Fullenkamp, <sup>1</sup>Alicia M. Adams, <sup>1</sup>David J. Hudson, and <sup>1</sup>James G. Richards

<sup>1</sup>The Human Performance Laboratory, University of Delaware, Newark, DE,

### INTRODUCTION

Four functional algorithms have been proposed to resolve the challenge of identifying the true flexion/extension (F/E) axis of the knee during gait. The functional axis algorithms of Woltring [1], Halvorsen et al. [2], Schwartz and Rozumalski [3] and Baker et al. [4] were selected for comparison. A majority of these algorithms attempt to minimize ab/adduction (A/A) motion on the premise that the knee operates as a 1 (F/E) or 2-degree of freedom joint (F/E, I/E). Woltring's method involves the calculation of instantaneous helical axis vectors between thigh and shank anatomical coordinate systems. Halvorsen's method tracks the movement of a single point on the shank within the thigh's anatomical coordinate system, and then identifies the eigenvector associated with smallest eigenvalue as the knee axis. Schwartz and Rozumalski find the knee axis by determining the null space between the thigh and shank anatomical coordinate systems. Baker manipulates the orientation of the thigh coordinate system to minimize knee A/A motion. While mathematical details of each approach are available in the literature, little information is presented as to their clinical usefulness. The purpose of this investigation was to examine the performance of each of the four algorithms with respect to their agreement with static anatomical measures of tibial torsion and their ability to minimize A/A.

### METHODS

Four subjects were used in this study. Tibial torsion was measured using ultrasound by subtracting readings from proximal and distal landmarks on the bone. The amount of torsion in the tibia approximates the axis formed by the medial and lateral malleoli WRT the knee axis in the transverse plane., The standard Helen Hayes marker set was used to test each method during walking trials. For subject A, data was collected with medial and lateral knee markers in the position identified by the clinician. For subsequent trials, each knee marker was shifted in the opposite direction along the AP axis in increments of 0.5cm until each marker was moved a distance of  $\pm 2$ cm. For each trial, the functional knee axis was calculated using each of the methods described above. In addition, functional knee axes were calculated for three additional subjects while wearing markers in standard clinical locations. Tibial torsion was calculated from marker data using the tibia coordinate system and the femur coordinate system with orientation determined by the functional axis. A/A motion was also examined for each subject.

In addition to testing the algorithms as presented in the literature, modifications were made to three of the methods in the hopes of improving accuracy and/or computational efficiency. Woltring's velocity threshold was changed to a 5° displacement threshold, Halvorsen's arbitrary selection of points separated by (n/2) frames was changed to compare pairs

of frames associated with  $\sim 5^\circ$  of tibial motion, and Schwartz and Rozumalski's method of comparing each frame of data in a trial to all other frames within the trial was changed to compare pairs of frames associated with  $\sim 5^\circ$  of tibial motion.

### RESULTS AND DISCUSSION

Data from subject A indicated that Baker's method of minimizing A/A motion produced results most consistent with the ultrasound measure of tibial torsion regardless of knee marker offset (Figure 1). Schwartz's original and modified methods produced similar deviations (7.6° and 4.2° respectively), although the modified method ran in a fraction of the time.

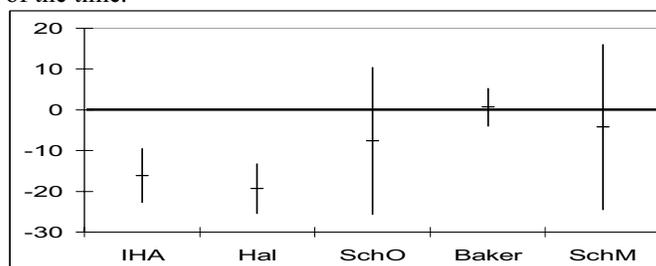

Figure 1: Rotational deviation in degrees from ultrasound measure for Subject A. Both the average and range are indicated. IHA: helical, Hal: Halvorsen modified, SchO: Schwartz original, SchM: Schwartz modified.

Data from the three additional subjects showed Baker's method to be the most consistent in the estimation of tibial torsion, while Schwartz's method performed poorly when the clinical marker placement was accurate. The remaining methods, though more consistent than those of Schwartz, showed less agreement with the ultrasound measures on average. Halvorsen's original method produced clinically irrelevant results.

### CONCLUSIONS

While many of the methods represent sophisticated attempts to identify the knee axis by minimizing A/A motion, the most direct method (Baker) produced the most anatomically consistent results relative to ultrasound measures of tibial torsion. Conversely, while Schwartz's method performed well when clinical marker placement was slightly errant, it worsened the knee axis estimate considerably when the initial placement of markers provided a close approximation of the functional knee axis.

## MECHANICAL PROPERTIES OF THE HUMAN HEEL PAD: A COMPARISON BETWEEN POPULATIONS

John H. Challis and Chloe Murdock  
Biomechanics Laboratory, The Pennsylvania State University, USA  
email: [jhc10@psu.edu](mailto:jhc10@psu.edu)

### INTRODUCTION

The initial point of impact during many footfalls is the heel pad, its role is to help absorb and dissipate the impact forces [1]. It is composed primarily of collagen reinforced chambers filled with densely packed fat cells [2]. The mechanical properties measured *in vivo* suggest the heel pad has low stiffness at loading of one body weight, and exhibits large energy losses [3].

There is evidence that human heel pad mechanical properties change with age [3], and certain disease or clinical abnormality (e.g. diabetes [4]). The reasons for these changes in mechanical properties are not clear, and one potential reason is due to changes in weight bearing activity levels. The purpose of this study was to compare the mechanical properties of the heel pad between runners, who repetitively load the heel pad during training, and cyclists, who during training do not load their heel pad.

### METHODS

Ten competitive long distance runners (height:  $1.66 \text{ m} \pm 0.06$ , mass  $56.3 \text{ kg} \pm 5.7$ ), and 10 competitive cyclists (height:  $1.77 \text{ m} \pm 0.08$ , mass  $71.1 \text{ kg} \pm 12.1$ ) volunteered for this study. All subjects had no previous or current plantar foot injury, and the cyclists had no running history (determined to be more than 2 days a week of running). The subjects provided informed consent, with all procedures approved by the Institutional Review Board.

Thickness of the unloaded heel pad was measured using real-time B-mode ultrasonography (Aloka SSD-625, Connecticut, USA) with a 7.5 MHz linear array scanhead. Measurements were taken after the subject had not placed weight on their heel pad for 10 minutes. The ultrasound images were digitized (Scion Image for Windows) and the mean of five measurements used to compute heel pad thickness.

A heel pad indentation device, adapted from the one described in Rome and Webb [5], was used to measure the mechanical properties of the heel pads. Heel pad deformation and applied force were measured via the indentation device, for 5 trials per subject. The displacement and force data were low pass filtered with a second order Butterworth digital filter (cutoff = 4 Hz). Numerical integration was used to compute the ratio of the area within the hysteresis loop and the area under the loading curve; this indicated the energy loss between loading and unloading. A model was fitted to the force-deformation data [6], and then used to estimate heel pad stiffness at the same relative loading for each subject (5 % of body weight).

To evaluate the differences between the runners and cyclists heel pad properties a repeat measures analysis of variance (ANOVA) was used ( $p < 0.05$ ).

### RESULTS AND DISCUSSION

Heel pad thickness was statistically significantly greater for the cyclists ( $14.9 \text{ mm} \pm 1.5$ ) compared with the runners ( $13.6 \text{ mm} \pm 1.2$ ), but if this thickness was expressed relative to subject height then there was no significant difference (cyclists:  $0.75 \% \pm 0.07$ ; runners:  $0.82 \% \pm 0.08$ ).

There was no significant difference between the groups in percentage energy loss during loading and unloading (runners:  $61.4 \% \pm 8.6$ ; cyclists:  $62.5 \% \pm 4.6$ ). Model fits to the data produced  $R^2$  values in excess of 0.96. Heel pad stiffness for the runners was significantly less than that of the cyclists (runners:  $17.1 \text{ N}\cdot\text{mm}^{-1} \pm 3.0$ ; cyclists:  $20.4 \text{ N}\cdot\text{mm}^{-1} \pm 4.0$ ).

### CONCLUSIONS

The two populations showed no differences in heel pad thickness or energy loss due to hysteresis, but did have different pad stiffnesses. This difference in heel pad stiffness would influence the forces experienced by the body during gait containing a heel strike [7]. The indentation device used for measuring the mechanical properties only applied low loads to the heel pad, but has the advantage that measurements can be made *in vivo*, and that compared with other methods for making these measurements *in vivo* soft tissue motion does not contaminate the results [8]. These results indicate that the nature of the activity undertaken by subjects influences their heel pad properties. This finding may be important, for example, when considering differences in heel pad properties between the young and elderly [e.g., 3].

## THE RULE OF CREEP IN THE SEX DIFFERENCES OF LONG BONE RESISTANCE TO FATIGUE FAILURE

<sup>1,2</sup> Luisa Moreno, <sup>2</sup>Angela Cheung and <sup>1</sup>Marc Grynpas

<sup>1</sup>Samuel Lunenfeld Research Institute, Mount Sinai Hospital, <sup>2</sup>Osteoporosis Program, University Health Network and Mount Sinai Hospital, University of Toronto; e-mail: moreno@mshri.on.ca

### INTRODUCTION

Stress fractures can be caused by prolonged exercise and are associated to cyclic loading. Fatigue is the accumulated damage that results from cyclic loading. This is of special concern for athletes and army recruits. Existing literature shows that the rates of stress fracture for female athletes and army recruits are higher than for their male counterparts [1].

In this study we used an ex-vivo rat model to investigate the fatigue response of female and male rat bones.

### METHODS

In this model, 16 weeks old Sprague-Dawley rats were used. Fresh excised tibias were loaded at different strains from 0.5% to 1%  $\epsilon$  to determine the strain versus cycles to failure curve (S/N curve) and endurance limit at the physiological frequency of 2Hz.

The tibias were loaded in three-point bending under load control on the medial side, using a servo-hydraulic material testing machine (Instron 8511) equipped with a 220N load cell. Displacement was measured by means of an external high precision LVDT with 10mm travel. The gauge length was 32 mm, and it was kept constant for male and female bones. Strain was calculated from the individual cross sectional dimensions directly measured with calipers at the point of striker contact. Bones were wrapped in gauze continuously soaked with saline and kept moist for the duration of the test. Using MATLAB® the individual cycle data was fitted using the least-squares method. The tangent stiffness was determined by the slope of the line that passes through the minimum and maximum points of the hysteresis curve.

To study the creep behavior, the accumulated strains from each cycle was plotted versus time. The data fitted a characteristic creep curve, with an initial fast creep followed by a steady-state deformation and a subsequent tertiary creep, followed by sudden failure. The strain damage rate was determined by the slope of the line that best fit the steady-state region of the creep data. Strain-to-failure was defined as the maximum strain the bone undergoes before fracture. The statistical analysis was done using SPSS software.

### RESULTS AND DISCUSSION

The fatigue data revealed that for the same strain level the endurance limit of the female bones is 20% lower than the males. It has been suggested that the high levels of stress fracture among athletic women occur because their bones are subjected to higher strains [1]. This study shows that even if

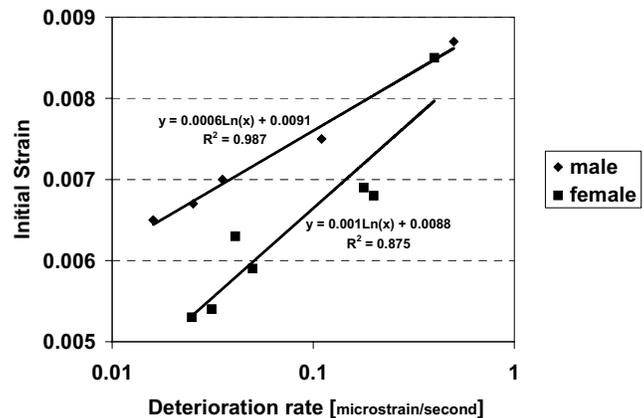

Figure 1: Plot of strain versus deterioration rate for male and female rat tibia

female bones are subjected to the same strains as males the female bones are still at higher risk of stress fracture.

The creep data revealed that the strain-to-failure is similar for both genders; it seems that there is a maximum strain limit before bone fractures. However the higher deterioration rate of the female bones versus strain data (Figure 1), indicate that female bones reach this critical strain at a faster rate than male bones.

### CONCLUSIONS

From this study we learned that independently from muscular of biological body response, female bones stressed to the same strain levels as male bones over a period of time, are more likely to experience stress fracture.

In the context of our study, we concluded that the female whole 'bone material' is relatively weaker, i.e. has a lower fatigue resistance than male bone material. For a given initial strain, the deterioration rate was higher for female than male bones. Hence we concluded that the fatigue life of the tibia might be determined by how fast the bone deteriorates.

This study suggests that less intensive exercises may not be enough to address the fast deterioration rate of female bones. Hence, shorter training sessions or frequent training interruptions may allow bone creep relaxation, which may prolong bone fatigue life. This may reduce the rates of stress fractures within female athletes and army recruits.

## Electromyography and leg stiffness comparison between old and young adults in descent stair walking

<sup>1</sup>Chia-Huei Shen, <sup>2</sup>Ming-Feng Kao and <sup>1</sup>Chien-Lu Tsai

<sup>1</sup> Department of Physical Education, National Taiwan Normal University,

<sup>2</sup> Department of Physical Education, National Taiwan College of Physical Education; email: [true\\_shen@yahoo.com.tw](mailto:true_shen@yahoo.com.tw),

### INTRODUCTION

Old people experience an increased susceptibility to falls. Four out of five falls on stairs occur in descent stair walking. Descent stair walking challenges elder person's sensorimotor reaction because it requires the elder person to overcome the perturbation from rapid change in ground reaction force. Initial mechanism of overcoming this perturbation is to adjust leg stiffness rapidly. Intrinsically, muscle activity of the lower extremity must also be alternated. Understanding leg stiffness and muscle activity during descent stair walking for elder person may provide strategy in prevention of fall occurrence. Therefore, the purpose of this study was to investigate the differences in EMG of knee extensors and flexors and leg stiffness between old and young men during descent stair walking.

### METHODS

Subjects for the study were 16 old men ( $72 \pm 4.5$  years old) and 16 young men ( $21.2 \pm 0.5$  years old). Subjects performed one test session of descent stair walking from designed stairs to an elevated force plate. In order to perform quantifiable analysis, the movement was divided into three phases: pre-landing ( $T_1$ ), impact ( $T_2$ ), and push-off. ( $T_3$ ). Electromyography (EMG) signals were recorded from the rectus femoris and biceps femoris of each subject's right leg, while an electrogoniometer measured knee joint angle changes. Leg stiffness was calculated by dividing the first relative maximum of force applied on hip by its corresponding leg displacement. The Student's t-test was used to examine the differences between the two test groups. The significant difference was set at  $\alpha < 0.05$ .

### RESULTS AND DISCUSSION

Table 1 lists the data of all the parameters. During the pre-landing phase, the old subjects were found greater EMG readings for knee extensor muscle control and greater muscle

co-contraction. This suggests that the old subjects used greater anticipatory control of the lower limb's muscles to have a safer descent stairs movement. The old subjects had greater leg stiffness at impact phase may indicate that they used a conscious effort to set the limb position prior to impact. This may have helped them anticipate a safer landing, but this posture would result in greater reliance on the skeletal system for impact absorption during landing, and less reliance on the muscles [1]. At push-off phase, in order to decrease sudden ground reaction force applied on the lower extremity, the strategy in old subjects was to increase time in push-off leg. This compensatory mechanism could increase the stability but could also be associated with degradation of muscle strength and slower rate of muscle force production [2].

### CONCLUSIONS

Old individuals developed a different strategy for descent stair walking. They relied much more on skeletal system instead of muscle system of the lower extremity to anticipate a safer descent stair walking. The characteristics of their descent stair walking strategy included increased pre-activity and coactivity in thigh muscles at the pre-landing phase; increased leg stiffness at the impact phase; and increased support time at the push-off phase. These changes in mediating leg stiffness and muscle activity might help them anticipate safer descent stair walking.

### INTRODUCTION

Mechanical loading of bone has been shown to enhance extravascular molecular transport [1]. This convective transport of nutrients and bioactive molecules from the blood supply to the osteocytes embedded in the mineralized bone matrix, and between osteocytes, osteoblasts and osteoclasts, acts in addition to baseline diffusive and intracellular transport mechanisms. Due to the inaccessibility of the fluid spaces in bone for direct experimental observation, theoretical and computational models aid substantially in understanding the generation and effects of load-induced fluid movement.

Bone, like most biological tissues, is a highly hierarchical structure and possesses fluid spaces at several different length scales. It is therefore important to apply methods that are appropriate to simulate interstitial fluid flow effects at a given level of porosity. In our laboratory we have developed poroelastic finite element models to predict interstitial fluid movement in mechanically loaded bone on an organ level [2], and stochastically generated network models [3] to study the influence of cell density and connectivity on the bone tissue permeability on a tissue level. In this study we report on a method to integrate insights gained from tissue level simulations into calculations on an organ level in order to improve the accuracy of the computational predictions.

It has been reported that porosity of bone is site specific with respect to the distance from the bone surfaces (near endosteum, mid-cortex, or near periosteum), as well as with respect to the loading mode, to which a given area of the cross section is predominantly subjected to (*i.e.* tensile- or compressive load). In addition, porosity and permeability (one of the most important parameters for the prediction of interstitial fluid movement of a tissue) are intimately related. The goal of this study was to determine to what degree varying porosities in different aspects of the bone cross section affect the predicted macroscopic fluid movements. For this purpose we measured the site-specific porosities in a rat ulna, used these values to determine the local tissue permeability, which was then applied to predict the pore pressure distribution in a mechanically loaded bone model.

### METHODS

The porosity attributed to the vascularity of a rat ulna was measured from high resolution  $\mu$ CT scans (6  $\mu$ m,  $\mu$ CT 40, Scanco Medical AG, Switzerland). Photomicrographs from histological sections were used to measure the lacunocanalicular pore spaces and the osteocyte connectivity. The measured parameters served as input for stochastically

generated network models [3] that allowed for the calculation of site specific, anisotropic permeability. These values, in turn, were used in an idealized, cylindrical bone model, representing a rat ulna, to calculate the fluid pore pressure in a bone subjected to a cyclic, combined compression-bending load acting at a frequency of 1 Hz.

### RESULTS AND DISCUSSION

Most blood vessels within the bone cortex, and therefore the highest vascular porosity, were found in the region adjacent to the endosteal surface, as the analysis of the  $\mu$ CT scans showed. With respect to the lacunocanalicular porosity, the photomicrographs unveiled that for the specific case of the rat ulna the bone cortex can be divided into 3 concentric shells. Two of the shell layers are located near the endosteal and near the periosteal surfaces, respectively, where a relatively low number of osteocytes, and therefore low lacunocanalicular porosity, are arranged with a high degree of organization. A mid-cortex shell can be identified with a much lower degree of organization but higher number of osteocytes and therefore bigger porosity. A shell model incorporating these findings was therefore used for the parametric finite element study, whereas the site-specific material properties for each shell layer were calculated using the stochastically generated network models. While the overall pore fluid pressure distribution calculated with this poroelastic shell layer model was comparable to the pressure distribution determined with a model with uniform material parameters, local fluid pressures and fluid velocities changed significantly. Higher porosity and therefore permeability generally lead to lower fluid pressures, but higher fluid velocities. However, all calculated fluid velocities remained within the same order of magnitude.

### CONCLUSIONS

This study confirmed the importance of site specific material parameters in the prediction of interstitial fluid flow in mechanically loaded bone. These insights will lead to the development of a next generation of computational models that will allow for a direct comparison with the results of experimental tracer studies.

## THE MOUSE AS A MODEL ORGANISM FOR HUMAN SKELETAL DISEASES – A BIOMECHANICAL STUDY

<sup>1</sup>Nils Goetzen, <sup>2</sup>Tobias Kummer, <sup>2</sup>Arndt Schilling, <sup>2</sup>Michael Amling and <sup>1</sup>Michael M. Morlock

### INTRODUCTION

Our understanding of the biology of the skeleton has been transformed dramatically since the first successful introduction expression of selected genes into the germline of mice [1]. Transgenic, knock-out or knock-in strategies – particular through the use of homologous recombination in embryonic stem cells – allow the generation of specific animal models for human diseases to study the regulation and function of genes within mammalian organisms. The power of genetics has also initiated the molecular understanding of the skeleton system and identification of genes responsible for murine and human skeletal abnormalities. Since decades many inbred strains of mice are available, which helped to detect the loci of specific genes responsible, for instance, for the bone mineral density. The biomechanical description of these phenotypes is, although straight, quite challenging due to the size of the analyzed bones. The objective of this study is the integrated biomechanical analysis of various mouse models – inbred and transgenic – representing a broad spectrum of skeletal defects or abnormalities.

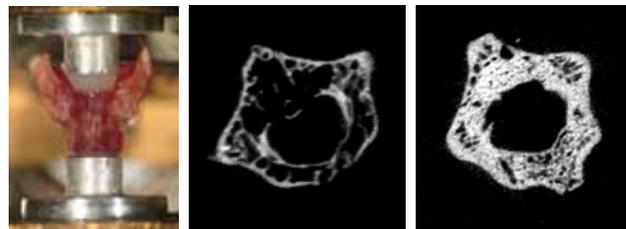

### METHODS

Five mice-models were selected from the variety of available types: C57BL/6 and FVB/N (age: 12 weeks) as a typical starting model for transgenesis [2,3]; SAM/P6 (age: 12 & 52 weeks) as a model for senile osteoporosis [4]; Calc-A<sup>-/-</sup> (12 weeks) as a calcitonin knock-out [5]; and src<sup>-/-</sup> (12 weeks) as an osteopetrosis model [6]. The biomechanical analyses were conducted at the lumbar vertebrae (L4-L6) because they contain a higher amount of trabecular bone than femora. The following methodologies were used: Morphometry: all vertebrae were  $\mu$ CT-scanned (Scanco  $\mu$ 40; resolution: 10 $\mu$ m) and typical parameter like BV/TV, MIL, and trabecular thickness/separation etc. were quantified; Densitometry: bone mineral content (bmc) and density (bmd) were determined experimentally and with the help of a specially designed integrated  $\mu$ CT phantom.; Biomechanics: the failure load and overall stiffness of the vertebrae was determined experimentally with micro-compression test (Figure 1 left) and specimen specific finite element analysis were generated to allow an estimation of yield and ultimate stress at a local tissue-level. These methodologies were combined to improve the quality of the analysis and inferences

### RESULTS AND DISCUSSION

SAM/P6 shows no age-dependent variation in BMD but a distinct loss of BV/TV (from 25 to 17%). Trabecular thickness did not change either but separation increased from 360 to 530 $\mu$ m. Fracture load increased with age although corrected for the size effect of the vertebrae.

FVB has a slightly lower bmd-level than BL6 and failure load is not significantly different when only corrected for the size

**Figure 1:** left: micro-mechanical compression test of a vertebra, middle: transverse cross-section of BL6-L4 and right: SRC-L4.

effect but lower when also corrected for the BV/TV influence – indicating a less strong tissue.

Calc-A has a surprisingly high BV/TV-level compared with the BL6 strain (22% versus 25%) but a reduced trabecular thickness (66 $\mu$ m versus 72 $\mu$ m). The size corrected failure load did not show any significant difference.

The failure load of the src<sup>-/-</sup> mice is extremely higher than in all other models: 113.7N compared with 32.7 (BL6) but the same is true for the BV/TV-ratio (Figure 1 middle/right): 90% versus 25% (BL6). BMD is also highest of all analyzed mice-models but the difference in the failure load can be largely explained by the size effect and the BV/TV ratio yielding a slightly lower fracture strength in the src-model than in the BL6-strain.

### CONCLUSIONS

The analyzed mice-models represent a broad spectrum of skeletal phenotypes and large variations in morphometrical, densitometrical, and biomechanical parameter were measured. The src-model shows the most dramatic variations and indicates the effect of missing osteoclastic activities – yielding a highly mineralized and compact but less strong bony tissue. SAM/P6 shows typical (human) osteoporotic indications like lower BV/TV and higher trabecular separation but lacks reduced compressive strength. Final results of the numerical analyses will additionally give more insight into the tissue strength than current analyses. All vertebrae show a high degree of inhomogeneity and derived morphometric parameters should be treated carefully.

## PREDICTING ANKLE JOINT MOMENTS IN SUBJECTS WITH NORMAL AND ABNORMAL GAIT

Daniel N. Bassett, Kurt Manal, Qi Shao, and Thomas S. Buchanan  
Center for Biomedical Engineering Research, University of Delaware, Newark DE 19716

### INTRODUCTION

Biomechanical models have been developed to analyze the motion of healthy individuals that walk with normal gait patterns. Such models are important for the study of muscle stimulation, prototype design, and limb control. We have created a biomechanical model of the ankle designed to predict joint moments in both unimpaired subjects and those who have had neuromuscular disorders. In this paper we will use this approach to study ankle moments in patients who have had strokes. Future research could apply the model to help subjects having abnormal gait patterns learn how to correct their muscle activation patterns through increased limb control and functional electrical stimulation.

### METHODS

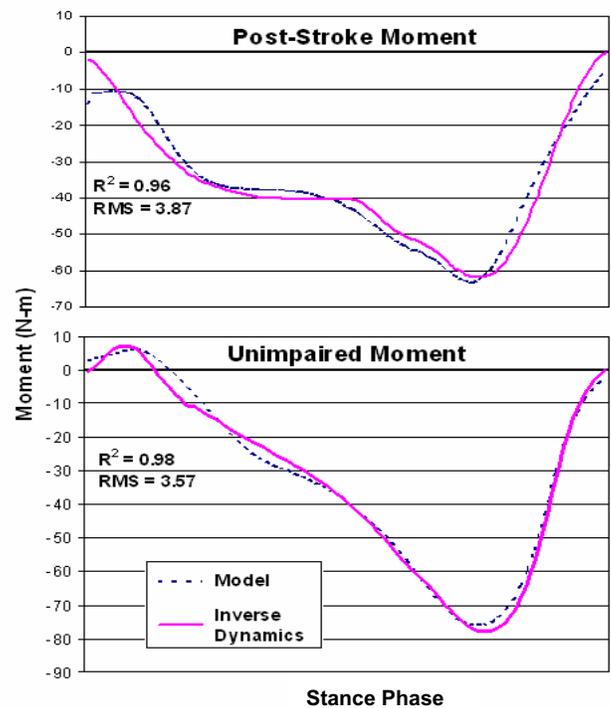

Three types of data were collected on normal and stroke affected subjects during isokinetic and gait trials: EMG from the tibialis anterior, medial gastrocnemius, lateral gastrocnemius, and soleus, joint position, and reaction forces (from the ground or dynamometer). Forward dynamics, using EMG and joint position data, were used to estimate the joint moments. This was verified by comparison with the inverse dynamics calculation.

The forward dynamics calculation was comprised of three elements: (1) muscle activation dynamics, (2) muscle contraction dynamics, and (3) musculoskeletal geometry. Muscle activation dynamics started from raw EMG which was rectified, filtered, and normalized. The EMG activation was then passed through a discretized recursive filter that gave neural activation. Muscle activation was calculated by non-linearizing neural activation. Muscle contraction dynamics was based on a Hill-type model approach deriving muscle force from a combination of active, passive, and fiber-velocity-dependent forces which were calculated from muscle activation and the muscle tendon lengths [1]. Calculation of both activation and contraction dynamics involves the use of unknown physical parameters. Relevant musculoskeletal geometry was the muscle moment arms which, along with muscle force, gave total joint moment [2].

The model was calibrated by optimizing the forward dynamics joint moment to fit the inverse dynamics calculation. The calibration process was done by varying unknown parameters using simulated annealing [3]. Once the fit was achieved, the parameters were used in the forward dynamic prediction of joint moment for trials for which the model had not been calibrated.

### RESULTS AND DISCUSSION

The results of the calibrations and predictions of joint moments for unimpaired and post-stroke subjects were very similar, (Figure 1). The joint moment patterns (from both the model and inverse dynamics), r-squared values, and RMS error were all comparable. Muscle forces and fiber lengths were consistent with literature, indicating the model is

**Figure 1:** Comparison of calibration between a stroke patient and healthy subject.

potentially a valuable tool to deliver realistic joint moment predictions.

The differences noted between subject groups were in the muscle activations and force. According to the model, an unimpaired person produces the predominance of the joint moment with their medial gastrocnemius and soleus while walking, the rest created by the lateral gastrocnemius, implying insignificant torque contribution by the tibialis anterior. Whereas a post-stroke patient produces an antagonist moment with the tibialis anterior to compensate for the enlarged moment generated by the gastrocnemii and soleus. The discrepancy is not deemed to be an error of the model; it can be explained by the fact that an individual who has spasticity due to a stroke has increased triceps surae forces.

### CONCLUSIONS

In our testing, the model was able to accurately predict joint moments in novel trials for subjects with normal and abnormal gait patterns.

## VERTICAL GROUND REACTION FORCE DIFFERENCES IN RUNNERS WITH LEG LENGTH DISCREPANCY

<sup>1</sup>Carla Sonsino Pereira, <sup>1</sup>Mariane Silva de Andrade, <sup>1</sup>Isabel de Camargo Neves Sacco and <sup>1,2</sup>Eneida Yuri Suda.

<sup>2</sup>Centro Universitário Capital - Physical Therapy Course

### INTRODUCTION

Leg Length Discrepancy (LLD) is so common that is considered normal by many authors and frequently it has occurred concomitant to low back pain (LBP), stress fractures (SF) and osteoarthritis (OA). The investigators have not found yet how many difference of LLD is necessary to provide these problems [3]. Large differences are generally diagnosed in youth, but smaller amounts of LLD may be unrecognized until some symptom come up. An anatomic disparity could be partial or totally compensate by functional adaptations. Biomechanical gait analysis could help discriminating between functional and structural LLD [2]. Therefore, we compared vertical ground reaction force (GRF) during running in two LLD groups of runners and one control group without inequality in order to identify if this structural inequality may cause changes and dynamic adaptations of gait.

### METHODS

175 physically active subjects were submitted to a personal interview and anthropometric measurements of the lower limbs to investigate run training, symptoms and to identify possible leg differences. Subjects with LLD detected by clinical measurements done in the first stage of the study were oriented to perform a Scanogram to certify the difference. From these subjects, we formed our experimental groups: Discrepancy and Symptom Group (DSG)-40 LLD runners higher than 0.3cm with LBP and/or SF, mean age 31±5 yrs; Discrepancy Group (DG)-15 LLD runners higher than 0.3cm without symptoms, mean age 27±4 yrs; and Control Group (CG)-15 physically active subjects with zero to 0.3cm leg discrepancy, mean age 32±5 yrs. Vertical GRF were analyzed during running at a self-selected speed using a Force Plate AMTI [2]. The subjects wore their habitual running shoes during analysis. Five trials of each lower limb of each subject were acquired at a sampling rate of 200 Hz. The vertical GRF variables analyzed were: first peak of force (Fy<sub>1</sub>); second peak of force (Fy<sub>2</sub>); time to reach Fy<sub>2</sub> (Δt<sub>2</sub>) and rate of loading (RL=Fy<sub>1</sub>/Δt<sub>1</sub>). The groups were compared using ANOVA post hoc Scheffé and between legs for each group dependent t-test. We adopted p<0.05 for significant differences.

### RESULTS AND DISCUSSION

GRF data and p values are showed in the table 1. According to literature [1], DG presented greater Fy<sub>2</sub> at the longer limb, and greater values in comparison to CG and DSG. These findings

could be related to the smaller values of Δt<sub>2</sub>, it could represent high mechanical loads at toe-off phase in subjects with LLD. The cumulative effect of overload during long periods on the longer limb could generate symptoms, as OA of the hip. The inclination of the pelvis to the shorter side could create a decreased area of loading at the acetabulum and the association of higher loads at the longer limb could lead to the OA [1]. Contradicting literature, that assume higher values of Fy<sub>1</sub> at longer limb, DSG and DG presented higher Fy<sub>1</sub> at shorter limb [2, 3, 4]. In agreement to some authors [1, 2, 3], this could represent a light compensatory mechanism adopted in mild discrepancies capable to minimize overloads. DSG showed significant lower values of Fy<sub>1</sub> related to CG. This fact might be related to symptoms observed in DSG subjects and could be explained as a dynamic strategy adopted in both sides to minimize mechanical overloads. DSG subjects also showed smaller values of RL in comparison to the other groups and this finding could be possibly explained as an anticipatory reaction in order to reduce overload at heel strike [1, 4]. DSG presented higher values of Δt<sub>2</sub> at shorter limb in comparison to CG, and at longer limb in comparison to CG and DG, representing greater time to reach a small Fy<sub>2</sub>.

### CONCLUSIONS

DSG presented smaller vertical force peaks and greater time to reach them in comparison to the other experimental groups. These results could be related to a dynamic strategy adopted in both sides of subjects with LLD in order to reduce overloads that might be leading to the symptoms observed in LLD subjects. DG showed higher Fy<sub>2</sub> at longer side and it could generate symptoms as LBP, stress fractures and precocious joint degeneration.

## INFLUENCE OF THE PERICELLULAR MICROENVIRONMENT ON CHONDROCYTE MODELLING

<sup>1</sup>Sang-Kuy Han, <sup>1</sup>Salvatore Federico, <sup>2</sup>Alfio Grillo, and <sup>1</sup>Walter Herzog

<sup>1</sup>University of Calgary, Calgary, Alberta, Canada, <sup>2</sup>University of Catania, Catania, Italy

### INTRODUCTION

Chondrocytes, the living cells in articular cartilage, synthesize and maintain the extracellular matrix. The mechanical environment of chondrocytes is known to influence the health of joints. Previous experimental studies have shown that the magnitude of cell deformation is less than what would be expected based on the large differences in material properties between cell and extracellular matrix [1]. This means that cells may have a mechanism to protect themselves from high deformation in the surrounding extracellular matrix. A possible protective mechanism may be the presence of the pericellular matrix and the capsule, which, together with the chondrocyte itself, constitute the chondron. The function of the chondron is not fully understood. It has been speculated that it functions to protect chondrocytes during cartilage loading [2]. This hypothesis is supported by theoretical models of cell-matrix interactions in cartilage [3]. However, previous theoretical cell-matrix models did not entirely explain the cell deformations observed in experiments. Therefore, we hypothesized that the pericellular microenvironment, represented by the material gradient in pericellular matrix and capsule, may be responsible for the observed cell deformations.

### METHODS

In order to model cell deformation, we used a multi-scale step method [3] [4]. Cartilage was assumed to be biphasic, and the elastic solid phase was modelled as a transversely isotropic, transversely homogeneous composite material [5] comprised of a proteoglycan matrix, cell inclusions, and a depth-dependent, statistically oriented collagen fibre inclusion phase. The fluid phase was assumed to be inviscid, incompressible, and associated with a deformation-dependent permeability. The cartilage specimen was assumed to be cylindrical, 1.0mm thick, and with a diameter of 6.0 mm. A spherical cell (5  $\mu\text{m}$  radius) from the middle zone was modelled as a biphasic inclusion embedded in the extracellular matrix (ECM). In order to model the pericellular microenvironment, we assumed that the pericellular matrix (PCM) is 2.5  $\mu\text{m}$  thick, and the pericellular capsule (PC) is 0.5  $\mu\text{m}$  thick with a high volume fraction of collagen fibres, which has been observed by scanning electron microscopy [2]. All material properties for the cartilage, cell model were taken from the literature [6] [7]. Numerical simulations were performed by means of the commercially available software ABAQUS v6.3. The cartilage specimen was subjected to a 15% unconfined compression test, at a constant rate during a ramp period of 300 s, and the deformation was then kept constant until 1200 s.

### RESULTS

The study of the axial displacement fields shows that the presence of the pericellular capsule influenced the discontinuity of the normal strain in the axial direction at the interface between the chondron and the surrounding matrix

(Fig 1). The prediction of the ratio between cell height decrease ( $H_c$ ) and local tissue strain ( $E_t$ ) is more accurate when considering the capsule (Figure 2) compared to the case when the capsule is neglected, which causes an overestimation of, the predicted cell height decrease and the ratio  $H_c/E_t$ , observed in experiments (Fig 2).

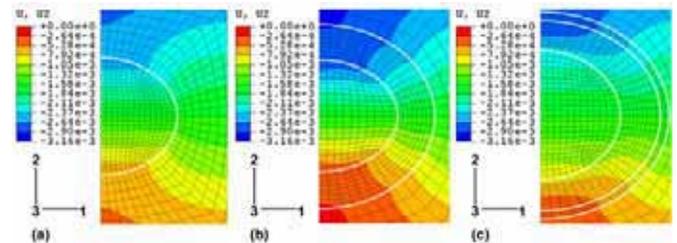

Figure 1. Comparison of the axial displacement around cell inclusions; (a) cell and ECM model (b) cell, PCM and ECM model (c) cell, PCM, PC, and ECM model.

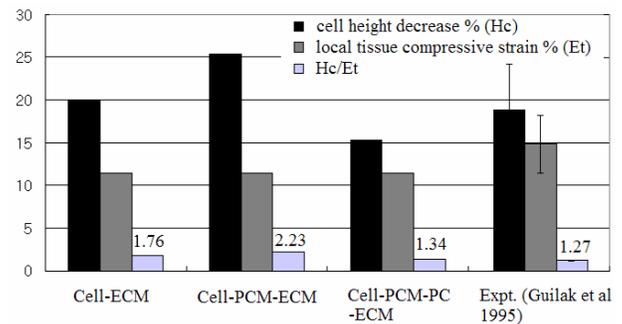

Figure 2. Comparison of cell height decrease, local tissue compressive strain, and the ratio between the two for different cell inclusion configurations.

### DISCUSSION

The present analysis demonstrated that the pericellular microenvironment might explain why cells deform much less than expected during articular cartilage loading. In further studies, cell modelling should be extended to the superficial and the deep zones, where cells are no longer spherical (i.e., they are flattened and elongated, respectively). Another improvement of the current model might be achieved by incorporating the osmotic and biochemical environments.

### INTRODUCTION

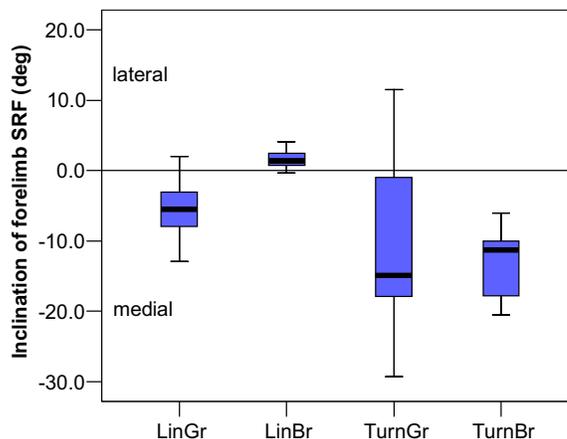

Long bone cross-sectional geometry has been used in anthropological studies to infer activity patterns of fossil primates (e.g. Trinkaus and Ruff, 1999). However, our knowledge about how activity patterns of living non-human primates translate into loading patterns, and the variability of those patterns, is limited.

The goal of this study was to examine the variability in direction of substrate reaction forces (SRFs) in the locomotor repertoire of the primate species *Le mur catta*. These Malagasy primates travel predominantly on the ground with quadrupedal gaits, while in trees they travel by performing a series of runs and leaps. An attempt was made to experimentally simulate this combined terrestrial and arboreal locomotor repertoire, additionally incorporating quick changes in direction to simulate obstacle or predator avoidance and rapid movement across 3-dimensional arboreal substrates.

### METHODS

Three adult individuals of *L. catta*, two females and one male ( $3.1 \pm 0.2$  kg) were included in this study. The substrate reaction forces (SRF) of the animals were recorded as they traversed a 10.5m Lexan-enclosed runway with a standard forceplate (Kistler 9281B) embedded in the center. For simulated arboreal locomotion, a 5 cm long piece of 3.2 cm diameter PVC tubing was attached to the force plate and aligned with 2 m long PVC poles of the same diameter on either side. The simulated branch was mounted 15 cm above the runway. Quick changes in movement direction were imposed by installing obstacles along the runway around which the animals were required to move, resulting in a weaving, zig-zag movement. The four test conditions were therefore: 1. linear movement on ground (LinGr, n=39); 2. linear movement on the simulated branch (LinBr, n=45); 3. turning movement on ground (TurnGr, n=26); and 4. turning movement on branch (TurnBr, n=18).

Vertical, fore-aft, and mediolateral force components were recorded digitally at 2700 Hz. Forces were low-pass filtered at 65 Hz and normalized by body weight. The direction of the peak resultant force vector was computed and normalized according to direction of travel and limb side such that a braking force was negative, propulsive force was positive, medially-directed force was negative, and laterally-directed force was positive. The forelimbs and hindlimbs were assessed separately.

**Figure 1:** Mean inclination of SRF vector in the frontal plane for the forelimb in the four locomotor conditions.

### RESULTS AND DISCUSSION

There is variability in the inclination of the peak SRF vector in both frontal and sagittal planes across substrates and movement tasks. The mean angle of inclination in the frontal plane ranges from -10.6 to 1.7 degrees in the forelimb (Figure 1) and -14.5 to -1.0 degrees in the hindlimb. In particular, angles associated with turning behaviors differ from those associated with linear locomotion. The mean angles in the sagittal plane range from -9.2 to -8.6 degrees in the forelimb and -0.5 to 8.4 degrees in the hindlimb. This suggests that limbs experience a range of substrate reaction force directions indicative of variation in loading regimes.

### CONCLUSIONS

These data suggest that treadmill or purely linear locomotion studies of limb loading (e.g., Lieberman, 2004) may not adequately capture the range of limb loadings experienced by animals in their natural habitat. Animals such as arboreal primates with a versatile locomotor repertoire experience a range of substrate reaction force directions and their limb bones are likely exposed to multidirectional bending.

### INTRODUCTION

Measuring bilateral ground reactions forces in persons with post-stroke hemiparesis can be quite difficult because of the wide range of asymmetry in step lengths with which they present. The purpose of this work is to outline considerations and propose solutions for laboratory design related to recording ground reaction force data (Fx,y,z; Mx,y,z) from these individuals. Design considerations include: 1) force platform (FP) placement 2) resonant frequency signals from mounting materials, 3) order of FP strikes (paretic/non-paretic) and 4) mobility aid use (i.e. cane, AFO).

This presentation primarily addresses optimal FP placement, which we define as allowing for the collection of two consecutive footfalls in order to enable analysis of forces associated with one complete walking cycle: paretic stance, non-paretic stance and the transition between stance phases. Force platform positioning is primarily dependent on step length because it determines whether ipsilateral and contralateral steps will strike two separate platforms cleanly in one stride. Specifications for spacing multiple FPs based on 76 measured step lengths are described.

### METHODS

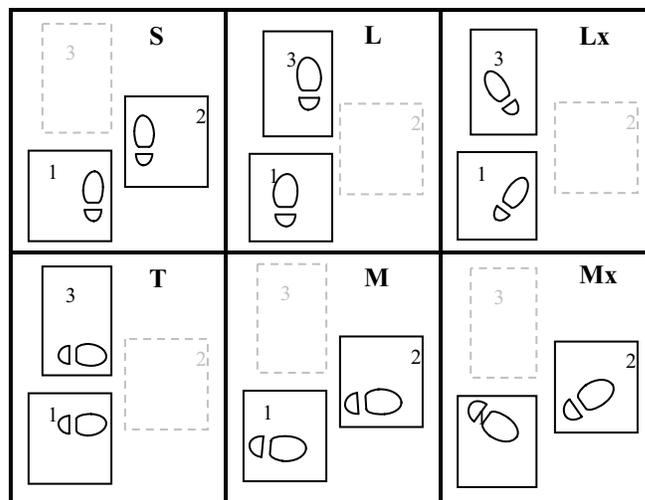

Step length data from 38 independent ambulators with post-stroke walking deficits, collected as part of a separate study, were analyzed. All volunteers demonstrated Functional Independent Motor scores of 5 to 7 (max = 7). Step length data were acquired and calculated using a 4.6 meter long GAITRite portable walkway system (CIR Systems, Inc., Clifton, NJ 07012). Paretic and non-paretic data were grouped because collecting two footfalls requires knowing only one step length.

### RESULTS AND DISCUSSION

Step lengths ranged from 19.57 to 79.60 cm. While the range of step lengths demonstrated a continuum of values, step lengths were grouped into four step clearance patterns in order to make decisions about FP positioning: minimal (T) or step-to-gait, short (S), medium (M) and long (L). In addition, within the S, M and L patterns (not T), volunteers demonstrated midline cross (x), i.e. a narrow base of support in which the contralateral heel crossed in front of the ipsilateral heel (Figure 1), or no midline cross.

Six of the seven step length patterns (not Sx) were accommodated with three FPs and two orthogonal walkway usage orientations (Figure 1). We related step lengths to commercially available FP dimensions: 40 x 60 cm and 46.4 x 50.6 cm. In step pattern analyses, to account for recommended space between FPs, 2 mm were added to each side length. Group T step lengths did not clear the shortest length of 40.2 cm. Group S cleared 40.2 but not 46.6 cm. Group M cleared 46.6 but not 60.2 cm. Group L cleared 60.2 cm (Table 1).

Based on these findings, Figure 1 below illustrates the design implemented to accommodate the six patterns. One 10-meter walkway (direction AB) plus a second, orthogonal, 6-meter walkway (direction CD) were created. The overlapping, central walkway area was equipped with embedded FPs: FP1 and 2 dimensions are 46.4 x 50.6cm (Advanced Medical Technology, Inc., Watertown, MA), and FP3 dimensions are 40 x 60 cm (Bertec Corporation, Columbus, OH). Note that different step patterns may be required depending on whether the paretic or non-paretic footfall is desired to be first for subjects with a substantial step length asymmetry.

**Figure 1.** Step patterns are illustrated. Drawing not to scale. Top row = AB & bottom row = CD walkway orientation.

**Table 1.** Step pattern data presented by group.

Step Pattern	Walkway Orientation	Platforms	n (76 total)	Step Length Mean	Step Length Range
T	CD	1 & 3	17	29.21	19.57-38.49
S	AB	1 & 2	11	43.30	41.71-45.99
M/Mx	CD	1 & 2	26	53.77	46.72-60.20
L/Lx	AB	1 & 3	22	68.56	60.28-79.60

## THE DODGE MOVEMENT DURING THE LAT PULL-DOWN EXERCISE INCREASED SCAPULA ROM

### INTRODUCTION

There is a skilled technique, known as the “dodge movement”, in the Beginning Movement Load Training (BMLT) method developed by Y. Koyama (1994). Numerous Japanese athletes, including Ichiro Suzuki (Mariners) and Isao Aoki (golfer), have trained with the BMLT technique. The dodge movement at lat pull-down exercise involves rapid supination and then pronation of the forearm at the transition from the eccentric to concentric contractions under rather relaxed conditions. The BMLT movement is expected to suppress the coactivation of agonist and antagonist muscles, and thereby enhance optimal power output during multi-joint movements (ISEK 2004, ACSM 2005). The purpose of this study was to determine the effect of the dodge movement during the lat pull-down exercise on the ROM of the scapula.

**Figure 1:** Lat pull down exercise with BMLT machine.

### METHODS

Five healthy male subjects (28.6±5.1 yrs; 1.72±0.37 m; 71.2±3.8 kg), who were familiar with the BMLT, performed the lat pull-down exercise under the condition of having or not having the dodge movement at a moderate speed (ca 1.6 s per cycle) with a load of 30% 1RM (Fig. 1). Two digital video cameras operating at 60 Hz captured the entire motion for subsequent measurement of the superior and inferior angles of the scapula,

L1 lumbar SP, elbow and wrist joints of the right side. The locations of the superior and inferior scapula angles were identified and marked by palpation before the experiment, and the medial-lateral and elevation-depression displacements were determined.

### RESULTS AND DISCUSSION

The vertical displacement of the wrist joint in the up-down direction was not significantly different for the two conditions. In contrast, the ROM in the medial-lateral and the elevation-depression directions for scapula angles were greater when the dodge movement was performed during the lat pull-down exercise compared with when it was not performed (Table 1). The maximal ROM of the superior and inferior scapula angles during the lat pull-down exercise with the dodge movement were 4.3 and 11.4 cm, respectively, in the medial-lateral direction and 4.3 and 7.5 cm, respectively, in the elevation-depression direction.

### CONCLUSION

Inclusion of the dodge movement during the lat pull-down exercise increased the range of motion of scapula.
