# Welcome

**XXth Congress of the International Society of Biomechanics  
and  
29th Annual Meeting of the American Society of Biomechanics**

We are delighted to welcome you to Cleveland, Ohio, for a combined meeting of the International and American Societies of Biomechanics. The last time the ISB held its congress in the USA was in 1989, in Los Angeles, California. In the intervening 15 years, researchers in biomechanics have continued to make significant breakthroughs in a variety of fields including the understanding and treatment of musculoskeletal disorders, preventing workplace injuries and optimizing athletic performance at the elite levels. New medical imaging technologies, microsensors, and computer algorithms add to these breakthroughs on a daily basis. The work of our two societies is in the forefront of advancement of the discipline of biomechanics, in both its academic and applied arenas. Such advancement is especially significant as we progress through what the World Health Organization has designated "The Bone and Joint Decade." From July 31st through August 5th, 2005, we look forward to meeting colleagues many of whom last gathered in Dunedin in 2003 and to making new acquaintances that will spur collaborations. The underlying emphasis of the Congress this year is to create a program that encourages student participation, with a great variety of educational offerings in all aspects of biomechanics. We have two main objectives for the 2005 meeting: (i) to present an academic program of the highest quality, and (ii) to have a rich social program that will complement the scientific meetings and allow new and old friends to experience all that Cleveland has to offer.

We are confident you will find the meeting to be an outstanding congress that does credit to both ISB and ASB.

Peter R. Cavanagh, Ph.D., D.Sc.  
Virginia Lois Kennedy Chairman of  
Biomedical Engineering  
The Cleveland Clinic Foundation

Patrick E. Crago, Ph.D.  
Allen H. and Constance T. Ford Professor and  
Chairman of Biomedical Engineering  
Case Western Reserve University

# Organization

## **Organizing Committee**

Brian Davis (Co-Chair)

Ton van den Bogert (Co-Chair)

Peter Cavanagh

William Jirousek

Patrick Crago

Robert Kirsch

George Chatzimavroudis

Melissa Knothe Tate

Susan D'Andrea

Scott McLean

Todd Doehring

Katie Root

A. Seth Greenwald

Paul Sung

Elizabeth Hardin

Ronald Triolo

John Jeziorowski

# ISB and ASB Information

## **ISB Council Members**

Mary Rodgers  
Sandra Onley  
Brian Davis  
Julie Steele  
Maarten Bobbert  
Ewald Hennig  
Senshi Fukushima  
Mark Grabiner  
Robert Gregor  
Walter Herzog  
Jill McNitt-Gray  
Joseph Hamill  
Alex Stacoff  
Karen Sogaard  
Graeme Wood  
Motoshi Kaya

## **ASB Council Members**

J.J. Trey Crisco  
Walter Herzog  
Ted Gross  
Don Anderson  
Art Kuo  
Irene Davis  
Julianne Abendroth-Smith  
Steve McCaw  
Kathy Simpson  
Andrew Karduna  
Melissa Scott-Pandorf

## **ISB General Assembly**

The International Society of Biomechanics will hold its General Assembly on Wednesday, August 3<sup>rd</sup> at 12.00 p.m. in Waetjen Auditorium.

## **ASB General Assembly**

The American Society of Biomechanics will also hold its General Assembly during the Congress. Details will be announced.

## **ISB Desk**

The ISB desk is located in the University Center Atrium (see Map, inside cover). ISB membership questions can be answered throughout the Congress.

# General Information

## **Congress Venue**

The Welcome Reception and Scientific program will be held at Cleveland State University Main Campus, from Sunday July 31<sup>st</sup> through Friday August 5<sup>th</sup>. Lunches and refreshments will also be provided, Monday through Friday at the congress site. Detailed maps of the congress venue and more information on the scientific and social programs can be found within this booklet. Volunteers will be available on-site throughout through the entire congress to assist you with any queries or concerns. Keep an eye out for the people in the green polo shirts with the congress logo.

## **Registration Desk**

The conference registration desk is located in the University Center Atrium and will be open on Sunday between 8.30 AM and 6.00 PM, and during the remainder of the congress. Please check in at this desk to pick up congress materials or if you have any registration related queries.

## **Exhibitors**

A number of national and international companies will be on hand to exhibit their latest products. All exhibitors will be located in the University Center (Atrium, basement and 2<sup>nd</sup> Floor), from Sunday 8:30 AM to Wednesday 1:00 PM. See the map on page 9 for details. Please stop by during the conference to see what is the latest and greatest in biomechanics.

## **Information and Message Service**

A congress message board will be provided next to the registration desk. All congress participants are invited to use this board at their convenience.

## **Banks and ATM's**

There three Automatic Teller Machines located on Cleveland State University Main Campus. Each of these is open 24 hours and will take major bank and credit cards. There is also a major bank (Huntington National Bank, 917 Euclid Ave) Bank within walking distance (0.66 miles) from the Congress Center, which is open Monday to Friday between 9.00 a.m. and 4.00 p.m. if you should require additional assistance. Both Bank and ATM locations are included on the Accommodations map for your convenience (page 8).

## **Internet Cafe**

A free internet café will be available throughout the conference, located in the University Center, adjacent to the Atrium. The Cleveland State University is also a wireless network hub for those bringing their own laptops. Please use the following login information to access the CSU computing network (Login: isbasb, Password: csuguest).

**Congress Badges**

Delegates and accompanying persons are required to wear their official congress identification badges for entrance to all congress activities including the social events and functions.

**Fitness Facilities**

Access will be provided to Cleveland State University Weight Room and Running Track facilities between 4:00 – 8:00 PM, on Monday, Tuesday and Wednesday. If you are interested in using these facilities, please contact the registration desk for more details.

**Safety**

As with most large cities, Cleveland has its share of do’s and don’ts in terms of keeping safe. We also realize that part of the Congress experience is about exploring what the host city has to offer. To assist you in this process, free transportation will be provided to various destinations on Wednesday afternoon. We strongly encourage you to take advantage of this offer during your stay, both for ease of access and safety reasons. Additional shuttles may be added at other times throughout the conference. Please ask for an update at the information desk. If at any time you require immediate assistance, please contact Cleveland State University Conference Services (216-523-7203) or if it is an emergency, Campus Security (216-687-2020).

# Social Program

Sunday, July 31 <sup>st</sup>	Welcome reception on CSU Campus
Tuesday, August 2 <sup>st</sup>	Open House at Cleveland Museum of Natural History
Wednesday, August 3 <sup>nd</sup>	Tours and excursions
Thursday, August 4 <sup>th</sup>	Baseball: Cleveland Indians and New York Yankees
Friday, August 5 <sup>th</sup>	Banquet at Rock and Roll Hall of Fame

## Opening Ceremony

The Organizing Committee welcomes you to Cleveland and the XXth ISB Congress and 29<sup>th</sup> Annual Meeting of the ASB for what promises to be a fantastic scientific and social event. Festivities begin with the Opening Ceremony at 3:00 PM on Sunday July 31<sup>st</sup>, held in the Waetjen Auditorium (MU Building), followed by the Wartenweiler Memorial Lecture at 4:00 PM. The order of events is listed below.

**Music:** Students from the Cleveland Institute of Music

### Welcomes

Mary Rodgers – ISB President

Trey Crisco – ASB President

Ton van den Bogert – Cleveland Organizing Committee

This is Cleveland (Video)

Mark Tumeo – Vice Provost for Research and Dean, College of Graduate Studies

Patrick Crago – Chairman of Biomedical Engineering, CASE

**Opening Address:** From Marey to Mars – through Ohio

Peter Cavanagh, Chairman of Biomedical Engineering, The Cleveland Clinic

**Music:** Students from the Cleveland Institute of Music

### Introduction to the Wartenweiler Lecture

Benno Nigg, University of Calgary

**Wartenweiler Lecture:** Bruce Latimer, Director, The Cleveland Museum of Natural History. *Biomechanics and Evolution*

**Music:** Students from the Cleveland Institute of Music

## Welcome Reception

The welcome reception and barbecue will follow the opening ceremony and Wartenweiler Memorial lecture, beginning at 5:00 PM in the area outside the UC building, and will provide an excellent opportunity to meet and socialize with friends and colleagues.

## Open House Reception

After the poster session on Tuesday, hop on a trolley at CSU and join your colleagues for an evening at The Cleveland Museum of Natural History in University Circle (6:30 – 10\_30 PM). Highlights include planetarium shows, a Late Jurassic sauropod skeleton with a 6-foot, 4-inch femur, a cast of “Lucy’s” originally discovered skeletal materials and her reconstruction; her genuine remains were returned. Also, see live animals native to North America and a Foucault pendulum. Since this is an “Open House”, you can come and go throughout the evening as you please. Trolley shuttles will leave approximately every 20 minutes from CSU for the museum and return you to CSU. This event is free for all registrants and includes food, drinks, exhibits and planetarium shows. If you are still hungry after the reception, you can venture over to Little Italy for a continental dinner. The last trolley back to CSU will depart from the museum at 10:30 p.m.

## Wednesday Afternoon Activities

A number of organized (paying) tours are set for the free afternoon on Wednesday. In addition, there will be free transport for the “Cleveland Exploration Excursion”, which incorporates tours of local landmarks and museums, as well as the Orthopaedic Biomechanics Laboratories at Lutheran Hospital, VA Motion Studies Laboratory, Case Western Reserve University Campus, and the Cleveland Clinic Foundation Department of Biomedical Engineering.

## Baseball

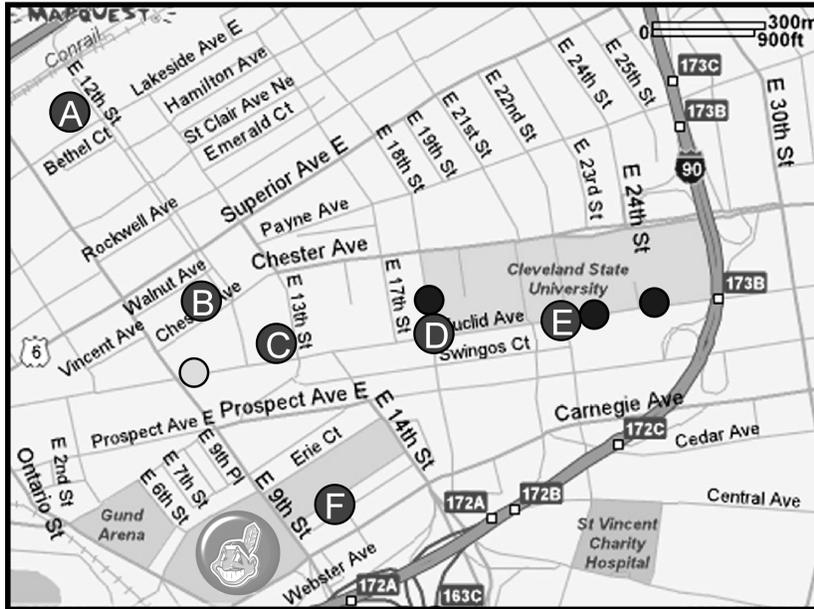

Join us on Thursday evening at Jacob’s Field to watch our beloved Cleveland Indians take on the New York Yankees. See Newton’s laws of physics in action at this truly amazing sporting extravaganza. Of course, if you would prefer, Shakespeare is also playing at Playhouse Square.

## Banquet

The Congress will conclude with a gala banquet on Friday August 5 from 7.00 p.m. until 10.00 p.m. at the Rock & Roll Hall of Fame on Lake Erie. Trolley shuttles will again take you too and from the Banquet.

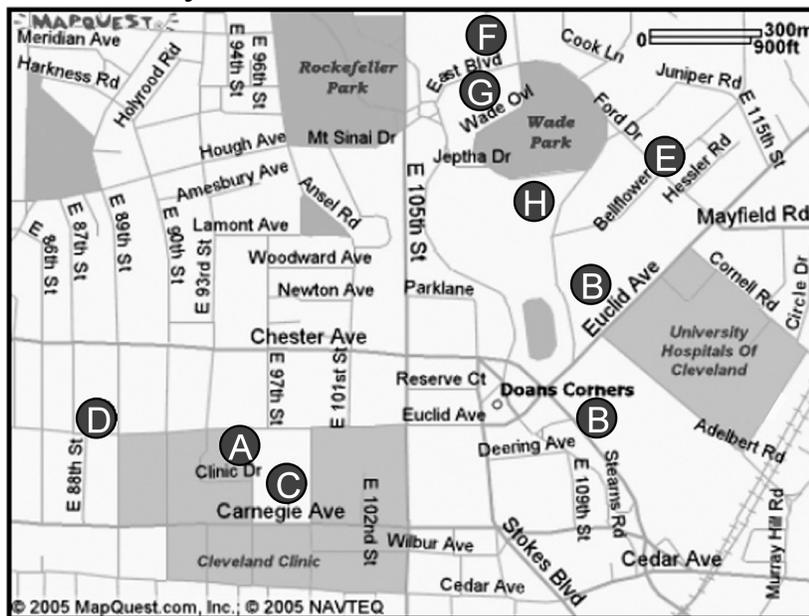

# Accommodations and Places of Interest

## Downtown

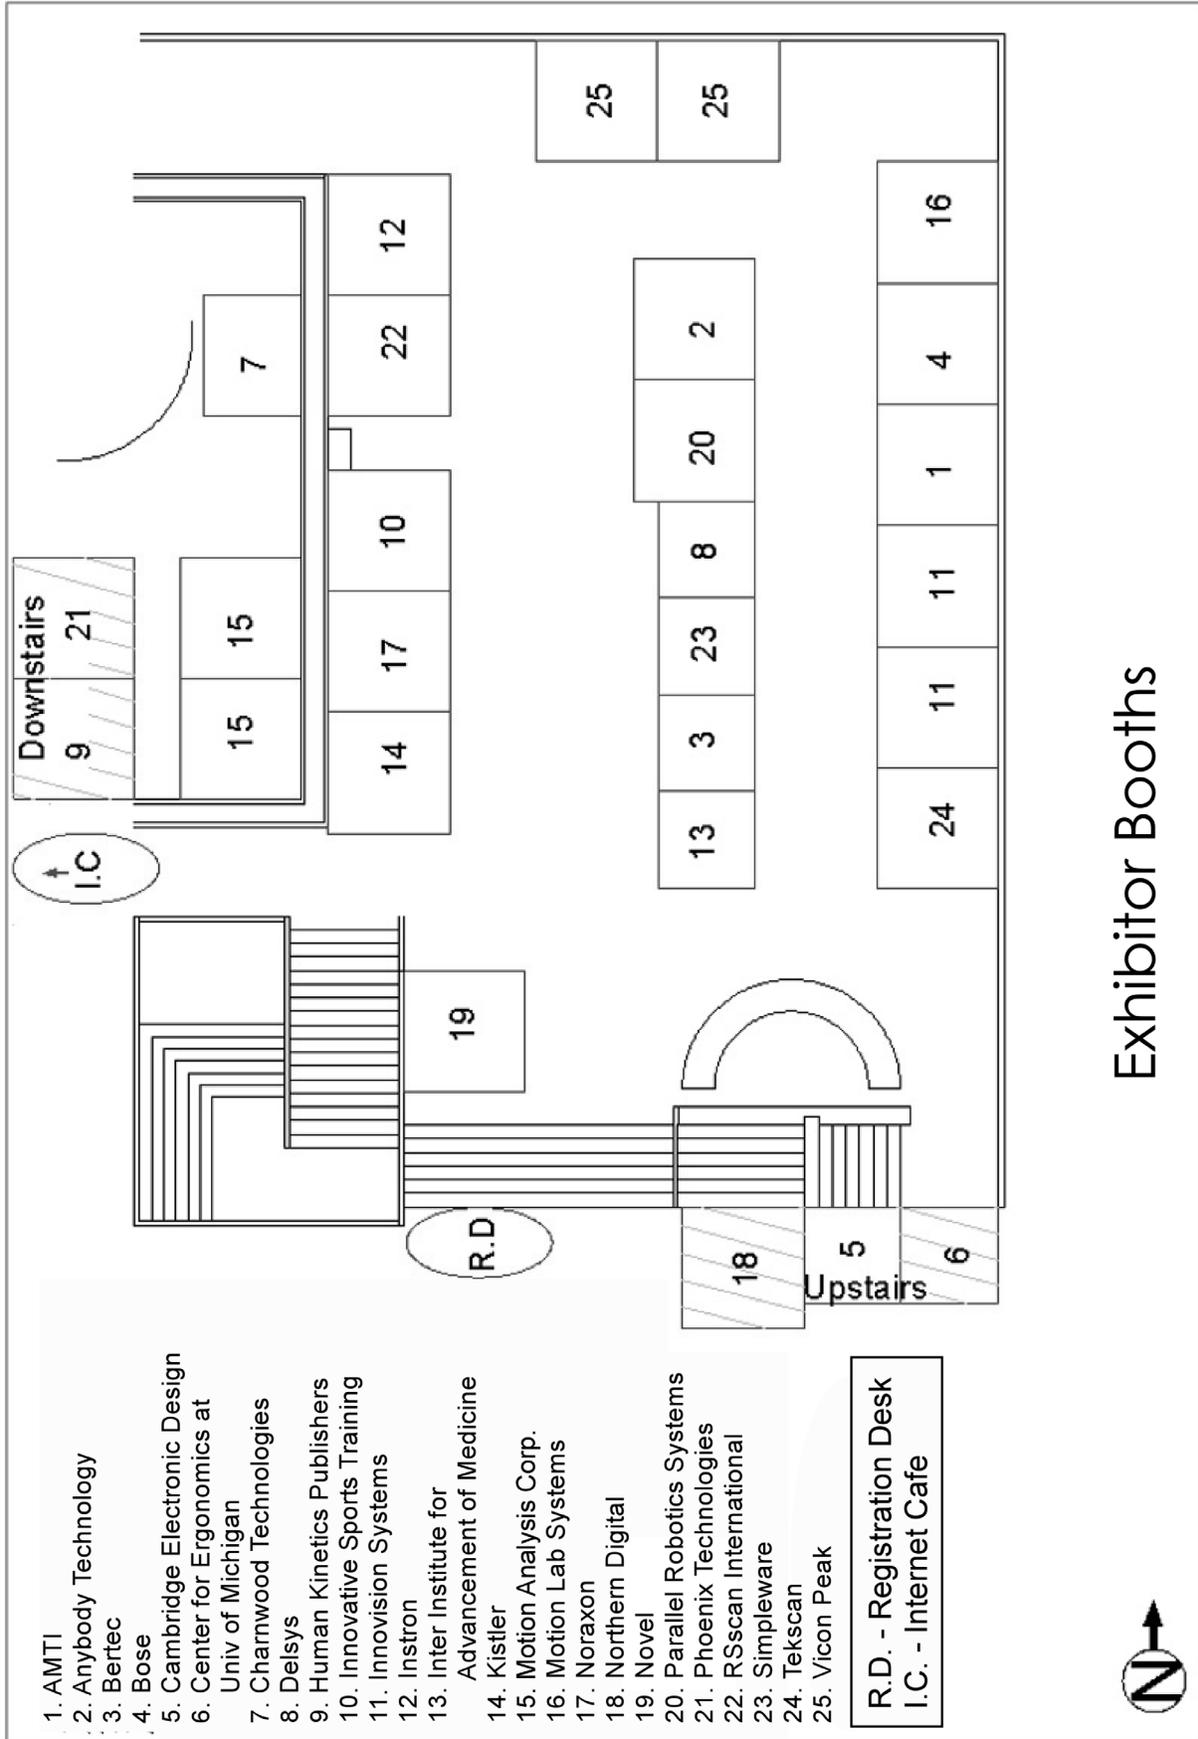

- A. Holiday Inn Select
- B. Embassy Suites Hotel
- C. Wyndham Playhouse Square
- D. Comfort Inn Downtown
- E. Viking Hall (CSU)
- F. Hilton Garden Inn
- Huntington National Bank
- Automatic Teller Machines
- ⚾ Baseball

## University Circle

- A. Cleveland Clinic Foundation
- B. Case Western Reserve Univ.
- C. Intercontinental Hotel
- D. Intercontinental Suites
- E. Glidden House
- F. VA Medical Center
- G. Cleveland Museum of Natural History
- H. Cleveland Museum of Art

# Presentations

## **Podium Presentations**

Each podium presentation will be limited to ten minutes, allowing five minutes for questions and discussion. Presenters have the option of using their own laptop, or using the computer provided in each room throughout the congress. Those using the latter must have their presentation in PowerPoint format, and saved either on CD, Compact Flash Card, or Memory (USB) Stick. You must go to the speaker ready room (UC - Kiva, near UC1 and UC6) at least 24 hours prior to your presentation. Our Audio-visual (AV) staff will make a copy of your presentation, make sure it works, and install it on the computer in your presentation room. At this time, you should make sure that all fonts appear as expected and that all sound/video clips are working correctly. AV staff will assist you and answer any questions that you may have. If you plan on using your own computer, you must still visit the speaker ready room at least 24 hours prior to your session to test the connection and to inform AV staff that you have arrived. If during your presentation any video files remain black, try switching the laptop from "screen + projector" to "projector only". There will be speaker timers in each of the presentation rooms. Speakers will be shown a green warning light at nine minutes and a red light at ten minutes.

## **Chairpersons of Podium Presentations**

Please arrive in the presentation room 15 minutes before the session in order to introduce yourself to the presenters and AV staff. At the beginning of each presentation please introduce the presenter, their affiliation and title of the presentation. Please ensure that each presentation begins and ends on time so that participants wishing to hear preceding and following talks in other rooms can do so. There will be speaker timers in each presentation room, which will be controlled by the chairpersons. If you have any problems, please contact the AV staff member in your room immediately. In rare cases where the presenter does not show, please take a break for that 15 minute time period rather than move on to the next speaker. This will again ensure no-one misses talks of personal interest.

## **Poster Presentations**

The Tuesday and Thursday poster sessions will be held in rooms UC201 and UC201 and UC Atrium respectively. People with odd numbered posters will be required to stand at their poster from 3:45 PM – 4:45 PM. Those with even numbered posters will need to be at their board for the next hour (4:45 PM – 5:45 PM). For the Tuesday session, presenters should have their posters up by no later than Monday 2 p.m., and should be taken down by 9.00 a.m. Wednesday. For the Thursday session, posters should be up no later than Thursday 9.00 a.m., and should be removed by Friday 6:00 PM. Any posters that are not removed by the required time will be disposed of.

# Awards

During the Cleveland-ISB/ASB-2005 Congress, a number of scientific awards will be presented to recognize outstanding scientific contribution in the field of biomechanics. These awards and the respective winners/finalists are listed below.

## ISB Awards

### Muybridge Award

Winner: Rik Huiskes, Eindhoven University of Technology, The Netherlands  
Presentation: Wednesday, August 3, 11:00 AM, Waetjen Auditorium  
Sponsor: ViconPeak

### Clinical Biomechanics Award

Winner: Magnus Kjartan Gislason, University of Strathclyde, UK  
Presentation: Wednesday, August 3, 9:00 AM, Waetjen Auditorium  
Sponsor: *Clinical Biomechanics*, Elsevier Science Ltd.

### Young Investigator Award (Podium Presentation)

Finalists: Ann Barkowitz, Jill Higginson, Emma Johnson, Craig McGowan,  
and Thomas Withrow  
Presentation: Wednesday, August 3, 9:30 AM, Waetjen Auditorium  
Sponsor: Elsevier Science Ltd.

### Young Investigator Award (Poster Presentation)

Finalists: Jingzhi Liu, Alena Grabowski, David Suprak, Sicco Bus, Yasushi  
Enomoto, Elizabeth Chumanov, Steven Blackburn, Sarah Kruger, Veronica  
Santos, Smita Rao  
Presentation: Poster sessions on Tuesday and Thursday

### Promising Young Scientist Award

2003 Winner: Constantinos Maganaris, Manchester Metropolitan Univ, UK  
Presentation: Wednesday, August 3, 8:30 AM, Waetjen Auditorium  
2005 Winner: Kermit Davis, University of Cincinnati, USA  
Sponsor: ViconPeak

## **ASB Awards**

### **Borelli Award**

Winner: Kai-Nan An, Mayo Clinic, Rochester, Minnesota  
Presentation: Thursday, August 4, 1:15 PM, Waetjen Auditorium

### **Jim Hay Award for Sports Biomechanics**

Winner: Mont Hubbard, University of California, Davis  
Presentation Time: Thursday, August 4, 8:30 AM, Waetjen Auditorium

### **Predoctoral Young Scientist Award**

Winner: Katherine Holzbaur, Stanford University, California  
Presentation: Thursday, August 4, 9:30 AM, Waetjen Auditorium

### **Postdoctoral Young Scientist Award**

Winner: Stefan Duma, Virginia Polytechnic and State University  
Presentation: Thursday, August 4, 9:45 AM, Waetjen Auditorium

### **Microstrain Award**

Winner: Azita Tajaddini, Cleveland Clinic Foundation, Ohio  
Presentation: Thursday, August 4, 2:15 PM, Waetjen Auditorium  
Sponsor: Microstrain

### **Clinical Biomechanics Award**

Finalists: Wendy Murray and Robert Siston  
Presentation: Thursday, August 4, 2:30 PM, Waetjen Auditorium  
Sponsor: *Clinical Biomechanics*, Elsevier Science Ltd.

### **Journal of Biomechanics Award**

Finalists: Joseph Crisco and Eun-Jeong Lee  
Presentation: Thursday, August 4, 3:00 PM, Waetjen Auditorium  
Sponsor: *Journal of Biomechanics*, Elsevier Science Ltd.

## **Other Awards**

### **NAC-Miyashita Award for best paper from east Asia:**

Sponsor: NAC Inc.  
To be announced at congress

### **Delsys Recognition for EMG Innovation**

Sponsor: Delsys, Inc.  
To be announced at congress

# Tutorials

ISB tutorial lectures will be held on Sunday July 31<sup>st</sup> in the MC building and are limited to registered participants only. Each tutorial requires a separate registration fee of \$30. Lunch will be provided for all registered participants between the morning and afternoon tutorial sessions. A list of tutorial sessions is provided below.

Time	Presenter	Title	Room
9:30 AM – 11:30 AM	Mark Latash	Motor Control: The Equilibrium-Point Hypothesis and Internal Models	MC201
9:30 AM – 11:30 AM	Rik Huiskes	Bone and Osteoporosis: Computational Diagnostics	MC202
12:30 PM – 2:30 PM	Richard Baker	3-D Analysis of Movement	MC201
12:30 PM – 2:30 PM	Jeff Weiss	Soft Tissue Mechanics	MC202

# Workshops

Two technical workshops will also be held during the congress, which you are welcome to attend. You are required to register for each workshop prior to commencement, but registration is free in each case. For the Novel workshop, you can register online via the congress home page (<http://www.isb2005.org>). You can register for the Tekscan workshop via their web site (<http://www.tekscan.com/medical/meetings.html>). Each workshop will present state-of-the-art technologies in pressure distribution measurement and analysis. Workshop sessions will be held at the following times.

Date	Start Time	Session	Room
Monday August 1 <sup>st</sup>	5:30 PM	Novel Workshop	MC201
Monday August 1 <sup>st</sup>	2:00 PM	Tekscan Workshop	UC364

# Scientific Program

**Sunday, July 31**

**4:00 PM**

**Wartenweiler Memorial Lecture**

MC 201

Chair: DirkJan Veeger, Ed Chadwick

4:00	Paula Ludewig	Alterations In Scapular Kinematics In Patients With Shoulder Impingement
4:15	Alexis Wickwire	Position Of The Humeral Head Shifts In The Glenoid Due To The Presence Of Osteoarticular Lesions
4:30	Jurriaan de Groot	Arm Mobility Versus Glenohumeral Stability
4:45	Andrew Karduna	Suprascapular Nerve Block Disrupts The Normal Pattern Of Scapular Kinematics
5:00	Jules Dewald	The Effect Of Generating Anti-Gravity Shoulder Torques On Upper Limb Discoordination Following Hemiparetic Stroke
5:15	Thomas Bandholm	Force Steadiness, Neuromuscular Activation And Maximal Muscle Strength In Subjects Suffering From Subacromial Impingement Syndrome

**ISB Technical Group: Footwear Biomechanics**

MC 202

Chair: Joe Hamill, Elizabeth Hardin

4:00	Keith Williams	The Development Of The Footwear Technical Group
4:15	Mario Lafortune	The Footwear Technical Group and Industry
4:30	<i>Award winners are not known yet</i>	Nike Award presentation
4:45		Adidas Award presentation
5:00		New Balance Award presentation
5:15		Rsscan Award presentation

**ISB Technical Group: Computer Simulation**

UC 1

Chair: Rick Neptune, Federico Casolo

4:00	Mont Hubbard	History Of the ISB Technical Group Computer Simulation
4:10	Federico Casolo	TGCS Chairman's Report
4:15	Knoek van Soest	Prescribing Skeletal Motion Can Substantially Enhance Mechanical Power Output; A Simulation Study
4:30	Fred Yeadon	The Effect Of Anatomical And Robustness Constraints On Optimum Jumping Performance
4:45	Francisco Valero-Cuevas	Shifting To Population-Based Models And Inferring Model Structure From Data Are Two Directions That Will Enhance The Clinical Usefulness Of Modeling
5:00	B.J. Fregly	Predicted Gait Modifications To Reduce The Peak Knee Adduction Torque
5:15	Alison Sheets	Approximation Of Balanced Landings In Gymnastic Dismounts

**Tuesday, August 2**

**8:30 AM**

**Keynote Lecture**

Waetjen Auditorium

Chair: Tim Hewett

8:30	Julie Steele	Developing Textile Biofeedback Technology: From Brassieres to Noisy Knees
------	--------------	---

**Tuesday, August 2**

**9:30 AM**

**Knee Injuries 1**

Waetjen Auditorium

Chair: Li-Qun Zhang, Julie Steele

9:30	Steven Blackburn	Knee Joint Moments During Sports Activities On Artificial Turf
9:45	Kevin Ford	Effect Of Gender On Knee Abduction And Flexion During Medial And Lateral Landings
10:00	Kelly McKean	Kinematic & Kinetic Differences Between Male & Female Soccer Players
10:15	Mette Kreutzfeldt Zebis	The Effect Of Acute Fatigue On Neuromuscular Activation Pattern During Side-Cutting In Female Team Handball Players

**EMG**

UC 6

Chair: Carlo De Luca, Graeme Wood

9:30	Michael Hahn	Neural Network Estimation Of Isokinetic Knee Torque
9:45	Paul Sung	Comparison Of Power Spectrum Measures To Entropic Measures Of Electromyography Time Series: Diagnostic Tools For Low Back Pain
10:00	Janessa Drake	Elimination Of ECG Contamination From EMG Signals: An Evaluation Of Currently Used Removal Techniques.
10:15	Didier Staudenmann	Improving EMG Based Muscle Force Estimation Using Principal Component Analysis On A High-Density EMG Array

**Muscle Mechanics**

MC 201

Chair: Maarten Bobbert, Constantinos Maganaris

9:30	Dilson Rassier	Phase Transition Of Force During Ramp Stretch Of Muscle Fibers Treated With BDM
9:45	Hanneke Meijer	Myofascial Force Transmission Is More Important At Low-Frequency Stimulation
10:00	Mir Ali Eteraf Oskouei	Force Enhancement In Sub-Maximal Voluntary Contractions
10:15	Thomas Sandercock	Cat Hindlimb Muscle Response To Slow Movement Shows Poor Relationship To Length-Tension Properties

**Sport 1**

MC 202

Chair: Peter Milburn, Tzyy-Yuang Shiang

9:30	Federico Casolo	Biomechanics Related To Racket Design And Customization
9:45	Lin-Hwa Wang	Momentum Transfer Of Trunk And Upper Extremity In Tennis Backhand Stroke
10:00	Young-Kwan Kim	Does Warming Up With A Weighted Bat Help Or Hurt Bat Speed In Baseball?
10:15	Hwai-Ting Lin	The Role Of Muscle In Glenohumeral Joint Stability During Baseball Pitching

**Bone Modeling**

UC 1

Chair: Ted Gross, Anja Niehoff

9:30	Daisuke Tawara	Patient-Specific Dynamic Stress Analysis Of Osteoporosis Vertebrae
9:45	Linping Zhao	Three Dimensional Finite Element Analysis Of Maxillary Palate With A Unilateral Cleft
10:00	Carmen Muller-Karger	Finite Element Bone Model Incorporating Heterogeneity And Anisotropy From CT
10:15	Andrea Tami	Finite Element Analysis Of Shockwave Propagation In Cortical Bone

**Tuesday, August 2**

**11:00 AM**

**Knee Injuries 2**

Waetjen Auditorium

Chair: Scott McLean, Tim Hewett

11:00	Tim Hewett	Coupled Biomechanical-Epidemiological studies for the Assessment Of ACL injury Risk.
11:15	Robert Shapiro	Biomechanical Differences Between Genders When Executing A Land And Cut Maneuver
11:30	Gregory Myer	The Effects Of Plyometric Versus Dynamic Stabilization And Balance Training On Lower Extremity Biomechanics
11:45	Ajit Chaudhari	Knee Loading Patterns That Endanger The ACL: Insights From Experimental and Simulation Studies
12:00	Bing Yu	Hamstring Co-Contraction Does Not Necessarily Reduce ACL Loading
12:15	Scott McLean	Sagittal Plane Biomechanics During Sports Movement Does Not Explain Higher Incidence Of ACL Injuries in Females

**Gait and Osteoarthritis**

UC 6

Chair: Fong-Chin Su, David Sanderson

11:00	Marius Henriksen	Effect Of Intra-Articular Lidocain Injections On Knee Joint Kinetics During Walking In Knee Joint Osteoarthritis Patients
11:15	Michael Anthony Hunt	Dynamic Lower Limb Alignment And Knee Joint Load During Gait In Patients With Knee Osteoarthritis
11:30	Laura Diamond	Adduction Moment During Gait In Patients With Moderate Or End-Stage Knee Osteoarthritis
11:45	Tom Jenkyn	Toe Out Gait And Reduction Of Knee Osteoarthritis Pain
12:00	Jennifer Erhart	Predicting Changes In Knee Adduction Moment Due To Load-Altering Interventions For Medial Compartment Knee OA From Pressure Distribution
12:15	Anne Muendermann	Hip Abductor Strength May Be Critical For Successful Gait Compensation In Patients With Medial Compartment Knee Osteoarthritis

**Muscle In Vivo**

MC 201

Chair: Richard Lieber, Walter Herzog

11:00	Glen Lichtwark	Gastrocnemius Muscle Tendon Unit Interaction Under Variable Gait Conditions
11:15	Sami Kuitunen	Behavior Of The Triceps Surae Muscle In Hopping
11:30	Stacie Ringleb	Bilateral Symmetry Of The Gastrocnemius Stiffness Measured With Magnetic Resonance Elastography In Healthy And Pathologic Muscle
11:45	Wendy Murray	Muscle Operating Range Includes Optimal Length At Extended Joint Postures Following Brachioradialis Tendon Transfer
12:00	Boris Prilutsky	In Vivo Fascicle Velocity Of Cat Gastrocnemius And Soleus Muscles During The Paw-Shake
12:15	Amanda Felder	Sarcomere Length Measurement Permits High Resolution Normalization Of Muscle Fiber Length In Architectural Studies

**Sport 2**

MC 202

Chair: Fred Yeadon, Richard Nelson

11:00	Mark King	Optimised Tumbling Performances That Are Robust To Perturbations
11:15	Maarten F. Bobbert	Explanation Of The Bilateral Deficit In Human Vertical Jumping
11:30	Alison Sheets	Effects Of Low Bar Avoidance And Gymnast Size On High Bar Dismount Performance
11:45	AJ "Knoek" van Soest	Does Strapping The Rower To The Seat Enhance Rowing Performance?
12:00	Blake Ashby	Optimal Control Simulations Demonstrate How Halteres (Hand-Held Weights) Increase Standing Long Jump Performance
12:15	Rene Ferdinands	Forward Solution Simulation Of The Mixed Action In Cricket Fast Bowling

**Hip Replacement**

UC 1

Chair: Tom Brown, Seth Greenwald

11:00	A Heijink	Generic Design Of The Hip Resurfacing Prosthesis
11:15	Jui-Ting Hsu	The Stability Of Acetabular Cup Under Screw Fixation
11:30	Liam Glennon	Direction-Dependence Of UHMWPE Wear For Metal Counterface Scratch Traverse
11:45	J P Little	A Multiple Material Parameter Finite Element Model Of Hip Resurfacing Arthroplasty
12:00	Marco Viceconti	Subject-Specific FE Model For The Prediction Of The Relative Micromotion In A Total Hip Implant: Verification And Validation
12:15	Jihui Li	Locating Fatigue Microcracks Occurring In Cemented Total Hip Arthroplasty

**Tuesday, August 2**

**1:15 PM**

**Keynote Lecture**

Waetjen Auditorium

Chair: Seth Greenwald

1:15	Masahiro Kurosaka	History and Future of Anterior Cruciate Ligament Reconstruction
------	-------------------	---

**Tuesday, August 2**

**2:15 PM**

**Knee Mechanics 1**

Waetjen Auditorium

Chair: Leendert Blankevoort, Masahiro Kurosaka

2:15	Rochelle Nicholls	Implantation Of A Total Knee Arthroplasty Prosthesis Imposes Abnormal Strain On Local Soft Tissues
2:30	David Fung	Changes To The Rat ACL Resulting From Subfailure Impingement Loading
2:45	Choongsoo Shin	Combined Valgus And Internal Rotation Moments Strain The ACL More Than Either Alone: Implications For Non-Contact ACL Injuries
3:00	Kiyonori Mizuno	Gender Dimorphism In Knee Joint Mechanics Affects ACL Loading
3:15	Naveen Chandrashekar	Sex Based Differences In Tensile Properties Of Human Anterior Cruciate Ligament

**Methods 1**

UC 6

Chair: Tim Derrick, Peter Quesada

2:15	Daniel Benoit	Skin Movement Artifact During Gait And Cutting Movements Measured In Vivo
2:30	Anthony Schache	Influence Of Thigh Marker Cluster Design On The Estimation Of Hip Axial Rotation
2:45	Tung-Wu Lu	A Kinematic Model Of The Upper Extremity With Globally Minimized Skin Movement Artefacts
3:00	Lars Muendermann	Validation Of A Markerless Motion Capture System For The Calculation Of Lower Extremity Kinematics
3:15	Stefano Corazza	Lower Limb Kinematics Through Model-Free Markerless Motion Capture

**Spine 1**

MC 201

Chair: Trey Crisco, Takahiro Ishii

2:15	Ryutaro Fujii	In Vivo Three-Dimensional Motion Analysis Of The Lumbar Spine :Coupling Motion Of The Lumbar Spine During Rotation
2:30	Ruth Ochia	In Vivo Segmental Motion Measurement In Asymptomatic And Chronic Low Back Pain Subjects Using Volume Merge Method
2:45	Heydar Sadeghi	Perturbation In Trunk Motion Of Low Back Patients
3:00	Ralph Gay	The Neutral Zone In Human Lumbar Spine Sagittal Plane Motion: A Comparison Of In Vitro Quasistatic And Dynamic Force Displacement Curves
3:15	William Anderst	Three-Dimensional In Vivo Rotation Of Fused And Adjacent Lumbar Vertebrae

**Ankle**

MC 202

Chair: Don Anderson, Tom Buchanan

2:15	Shing-Jye Chen	Effects Of Impeded Foot Arch Height On Calcaneal Eversion And Ankle Joint Forces During Gait
2:30	Yuki Tochigi	The Contribution Of Articular Surface Geometry On Ankle Stabilization
2:45	Leendert Blankevoort	Three-Dimensional Bone Kinematics In An Anterior Drawer Test Of The Ankle Joint
3:00	Kristin Zhao	Mechanical Efficacy Of Tendon Transfer Operations For Foot Drop
3:15	Jane Goldsworthy	Chronic Stress Exposure Following Intra-Articular Ankle Fractures

**Head Injury**

UC 1

Chair: Lars Janshen, David Dean

2:15	Trey Crisco	An Approach To Calculating Linear Head Accelerations Is Not Affected By Rotational Head Accelerations
2:30	Sarah Manoogian	Head Acceleration Is Less Than 10 Percent Of Helmet Acceleration During A Football Impact
2:45	Matthew Craig	Human Mandible Response To Impact Loading Of Chin
3:00	David Pearsall	Durability Of Ice Hockey Helmets To Repeated Impacts
3:15	S. W. Gong	A Novel Approach For A Solid Object Impact On Human Head

**Tuesday, August 2**

**3:45 PM**

**Poster Session: Ergonomics 3**

UC 201

1	Carol Murphy	Children's Postural Changes At Adult Computer Workstations
2	Taylor Murphy	A Comparison Of Task And Muscle Specific Isometric Submaximal EMG Data Normalization Techniques For The Analysis Of Muscle Loads During Hydraulic-Actuation Joystick Controller Use
3	Joshua S. Danker	Investigation Of Shoulder Range Of Motion Limits For Application To Ergonomic Analysis
4	HyunWook Lee	Trunk Stiffness Improvement By Physical Therapy/Exercise During Unstable Sitting
5	Reuben Escorpizo	Work Time And Rest Percentage During Pick-And-Place Task
6	Luke Wooldridge	Kinetic Evaluation Of Right Shoulder And Elbow During Spiccato Technique Violin Bowing
7	Timothy N. Judkins	Electromyographic Correlates Of Robotic Laparoscopic Training
8	Sivaram Shanmugam	Hand Movement Analysis Of The Elderly When Using A Remote Control
9	Kristine Krajnak	The Biodynamic And Physiological Responses Of The Rat Tail To A Single Bout Of Vibration Exposure

**Wednesday, August 3**

**8:30 AM**

**ISB Promising Young Investigator Award**

Waetjen Auditorium

Chair: Walter Herzog

8:30	Constantinos Maganaris	Adaptive Response Of Tendon To Paralysis
------	------------------------	--

**ISB Clinical Biomechanics Award**

Waetjen Auditorium

Chair: Kim Burton, Sandra Olney

9:00	Magnus Kjartan Gislason	The Three Dimensional Load Transfer Characteristics Of The Wrist During Maximal Gripping.
------	-------------------------	---

**Wednesday, August 3**

**9:30 AM**

**ISB Young Investigator Award finalists**

Waetjen Auditorium

Chair: Maarten Bobbert

9:30	Emma A. C. Johnson	The Analysis Of Pressure Response In Head Injury: A Validation Study
9:45	Craig P. McGowan	The Mechanics Of Jumping Vs. Steady Hopping In Yellow-Footed Rock Wallabies.
10:00	Thomas J. Withrow	Valgus Loading Causes Increased In Vitro ACL Strain In Simulated Jump Landing
10:15	Ann M. Barkowitz	A Novel Robotic Device With Haptic Feedback For Lower Limb Rehabilitation
10:30	Jill Higginson	Reduced Plantarflexor Contributions To Support In Post-Stroke Hemiparetic Gait

**Posture and Balance 1**

UC 6

Chair: Alan Walmsley, Tammy Owings

9:30	Ian Loram	Paradoxical Muscle Movements In Human Standing
9:45	Erin Wilson	Lumbar Extensor Fatigue Changes Postural Recovery Strategy
10:00	Sukyung Park	The Effect Of Initial Lean On Human Postural Scaling
10:15	Peter M. Quesada	Effects Of Smooth vs "Prickly" Surface Conditions On Tiltboard Performance

**Spine 2**

MC 201

Chair: Jim Potvin, James Dickey

9:30	Robert Parkinson	Does Load Magnitude Alter Cumulative Load Tolerance? "Weighting" For An Answer
9:45	Erik Cattrysse	3D Arthrokinematic Analysis Of Coupled Motion In The Human Upper-Cervical Spine: In Vitro Analysis Of High Velocity Thrust Techniques
10:00	Dave Glos	Intra-Annular Bilateral Spinal Compression: Novel MEMS Sensors
10:15	David Nuckley	Compressive Mechanics Of The Maturing Human Spine

**Lower Extremity Injury**

MC 202

Chair: Paul DeVita, Kathy Simpson

9:30	Rebecca Zifchock	Kinetic Asymmetry In Left And Right Dominant Female Runners: Implications For Injury
9:45	Tine Willems	Relationship Between Foot Progression Angle And Exercise-Related Lower Leg Pain
10:00	Joseph Seay	Dynamic Symmetry In Female Runners With A History Of Tibial Stress Fractures
10:15	Sara Novotny	The Effects Of Quantitative Feedback On The Reduction Of Landing Force

**Prosthetics and Orthotics**

UC 1

Chair: Sandra Olney, Bob Gregor

9:30	Jack R. Engsberg	Comparison Of Rectified And Unrectified Sockets For Transtibial Amputees
9:45	Martin Twiste	The Effect Of Prosthesis Compliance On Residual Limb-Socket Interface Forces
10:00	Alexander Razzook	Can Passive Dynamic Ankle Foot Orthoses Replicate Natural Ankle Stiffness
10:15	Steven H. Collins	Controlled Energy Storage And Return Prosthesis Reduces Metabolic Cost Of Walking

**Wednesday, August 3**

**11:00 AM**

**Muybridge Award Lecture**

Waetjen Auditorium

Chair: Mary Rodgers

11:00	Rik Huiskes	Bone: The Engineer's Ultimate Dream Material
-------	-------------	--

**Thursday, August 4**

**8:30 AM**

**ASB Jim Hay Award Lecture**

Waetjen Auditorium

Chair: Walter Herzog

8:30	Mont Hubbard	Spinning Sports Balls
------	--------------	-----------------------

**Thursday, August 4**

**9:30 AM**

**ASB Young Scientist Awards**

Waetjen Auditorium

Chair: Walter Herzog

9:30	Katherine Holzbaaur <i>Winner of ASB Predoctoral Young Scientist Award</i>	Scaling Of Muscle Volumes In The Upper Extremity
9:45	Stefan Duma <i>Winner of ASB Postdoctoral Young Scientist Award</i>	A Computational Model Of The Pregnant Occupant: Local Uterine Compression Effects The Risk Of Fetal Injury

**Gait Simulation**

UC 6

Chair: John Chow, Andre Seyfarth

9:30	Taku Komura	Simulating Pathological Gait Using The Angular Momentum Inducing Inverted Pendulum Model
9:45	Saryn Goldberg	The Influence Of Gastrocnemius Geometry On Its Action At The Knee During Stance
10:00	Ajay Seth	A Neuromuscular Tracking Method For Computing Individual Muscle Forces During Human Movement
10:15	Richard R. Neptune	Ankle Plantar Flexor Force Capacity During Toe Walking

**Functional Electrical Stimulation**

MC 201

Chair: RonTriolo, Bob Kirsch

9:30	Alicia Koontz	Effects Of Functional Electrical Stimulation On Manual Wheelchair Propulsion
9:45	Anirban Dutta	EMG Based Triggering And Modulation Of Stimulation Patterns For FES-Assisted Ambulation - A Conceptual Study
10:00	Jason Gillette	Lower Back FNS For Stabilization During One- And Two-Handed Reaching Tasks
10:15	Dimitra Blana	Feedback Control For A High Level Upper Extremity Neuroprosthesis

**Sport 3**

MC 202

Chair: Graham Caldwell, Mike Madigan

9:30	Dieter Rosenbaum	Plantar Pressure Distribution Patterns Used As Biofeedback Information Improve Technical Training And Performance In In-Line Speed-Skating
9:45	Gerald Smith	Ski Skating Force Characteristics: Comparisons Across Speed
10:00	Matthew Major	Aggressive Inline Skating: Biomechanics Of Landing And Balancing On A Grind Rail
10:15	Federico Formenti	Biomechanical And Physiological Determinants Of Skiing Locomotion Development

**Injury Biomechanics**

UC 1

Chair: Jeff Wheeler, Uwe Kersting

9:30	Amber Rath	A Fiber Optic Based Sensor For Measuring Chest And Abdominal Deflection Under Impact Loading
9:45	Robert Catena	Maintenance Of Gait Stability In Concussed College Patients During Dual Tasks
10:00	Sriram Rajagopal	Development And Validation Of The Finite Element Human Body Model For Less - Lethal Ballistic Impacts
10:15	Eric Kennedy	Rupture Pressures For Human And Porcine Eyes Under Static And Dynamic Loading

**Thursday, August 4**

**11:00 AM**

**Hand and Wrist 1**

Waetjen Auditorium

Chair: Trey Crisco, Zong-Ming Li

11:00	William L. Buford	Moment Arms And Moment Potential Balance At The Index MCP Joint
11:15	Jie Tang	Kinematics Of Thumb Opposition
11:30	Sang-Wook Lee	Dynamic Modeling And System Identification Of Finger Movement
11:45	Jaewon Choi	3-Dimensional Kinematic Model For Predicting Hand Posture During Certain Gripping Tasks
12:00	Saurabh Mahapatra	A Mathematical Definition Of Feasible Finger Postures And Movements
12:15	Patrick Salvia	In Vivo Kinematics Of Human Wrist Joints: Combination Of Medical Imaging And Three-Dimensional Electrogoniometry

**Diabetic Foot**

UC 6

Chair: Peter Cavanagh, Gautham Gopalakrishna

11:00	Robert van Deursen	Functional Outcome In People With Diabetic Neuropathy At Different Stages Of Complications
11:15	Claudia Giacomozzi	Altered Foot Loading In Diabetics. The Role Of Achilles Tendon And Plantar Fascia
11:30	Matthew Cowley	A Prospective Look At Foot Shape And Foot Ulcer Development
11:45	Steve Goske	Reduction Of Plantar Heel Pressures: Insole Design Using Finite Element Analysis
12:00	Sicco Bus	Sub-Calcaneal Fat-Pad Infiltration And Its Effect On Plantar Heel Pressures In The Diabetic Neuropathic Foot
12:15	Brian L. Davis	Metatarsal And Toe Loading Patterns In Diabetic Patients: Possible Role In The Etiology Of Charcot Foot Complications

**Gait and Aging**

MC 201

Chair: Mike Pavol, Phil Martin

11:00	Chris McGibbon	Neuromuscular Adaptations In Gait With Age And Musculoskeletal Pathology
11:15	Masato Takanokura	Biomechanical Analysis Of Four-Wheeled Walker For An Elderly Person
11:30	Justus Ortega	Elderly Adults Perform Less Limb Work During Walking
11:45	Samantha Winter	The Force-Length Curve Of The Human Gastrocnemius In Vivo.
12:00	Zachary Domire	The Influence Of Seat Height On Sit To Stand In The Elderly: A Simulation Study
12:15	Sukhoon Yoon	Effects Of Short-Term Walking Exercise In Elderly

**Running**

MC 202

Chair: Julianne Abendroth-Smith, Mark Lake

11:00	Anton Arndt	Transmission Of Controlled External Plantar Impacts Along The Tibia In Relation To Muscular Activity
11:15	Katherine Boyer	Soft Tissue Compartment Response To An Unexpected Surface Change
11:30	Caroline Digby	A Preliminary Assessment Of The Effects Of Foot Type On The Movement Coupling Of The Foot And Shank During The Stance Phase Of Barefoot Running
11:45	Stephen C. Swanson	Kinetic Limitations Of Maximal Sprinting Speed Revisited
12:00	Christopher L. MacLean	Short And Long-Term Influence Of A Custom Foot Orthotic Intervention On Lower Extremity Dynamics In Injured Runners
12:15	Uwe G. Kersting	Impact Forces, Rearfoot Motion And The Rest Of The Body In Heel-Toe Running

**Wheelchair Biomechanics**

UC 1

Chair: Mary Rodgers, Joe Sommer

11:00	Shun-Hwa Wei	Joint Workspace Of Shoulder and Elbow Associated with Various Axis Positions During Manual Wheelchair Propulsion
11:15	Jennifer L. Mercer	Kinetic Analysis Of Manual Wheelchair Propulsion Over Three Surfaces
11:30	S. van Drongelen	Shoulder Load During Weight Relief Lifting: A Simulation Study
11:45	Sharon Eve Sonenblum	Kinematics Of Lateral Transfers: A Pilot Study
12:00	Philip S. Requejo	Upper Extremity Kinetics During Wheelchair Lever Propulsion
12:15	W. Mark Richter	Biomechanics Of The Flexrim Low Impact Wheelchair Handrim

**Thursday, August 4**

**1:15 PM**

**ASB Borelli Award Lecture**

Waetjen Auditorium

Chair: Kenton Kaufman

1:15	Kai-Nan An	The Evolving Journey of Tendon and Joint Mechanics: Clinical Impacts from Humble Concepts
------	------------	---

**Thursday, August 4**

**2:15 PM**

**ASB Awards**

Waetjen Auditorium

Chair: James Ashton-Miller

2:15	Azita Tajaddini <i>Microstrain award winner</i>	Laser Induced Auto-Fluorescence (LIAF) As A Method For Assessing Skin Stiffness Preceding A Diabetic Ulcer Formation
2:30	Robert A. Siston <i>ASB Clinical Biomechanics Award finalist</i>	In-Vivo Passive Kinematics Of Osteoarthritic Knees
2:45	Wendy Murray <i>ASB Clinical Biomechanics Award finalist</i>	Significance Of Surgical Attachment Length For Hand Function Following Brachioradialis Tendon Transfer
3:00	Eun-Jeong Lee <i>ASB Journal of Biomechanics Award finalist</i>	Modulation Of Passive Force In Skeletal Muscle Fibers
3:15	Trey Crisco <i>ASB Journal of Biomechanics Award finalist</i>	Scaphoid And Lunate Rotations Are Minimized With Wrist Motion Along

**Posture and Balance 2**

UC 6

Chair: Ge Wu, Robert van Deursen

2:15	Kimberly Ryland	Nonlinear Analysis Of Postural Control In Different Positions And Vision Conditions
2:30	Shirley Rietdyk	Stationary Visual Cues Reduced Centre Of Pressure Displacement In A Dynamic Environment For Experienced Roofers
2:45	Sukyung Park	Optimal Control Model Of Human Postural Scaling With Biomechanical Constraints
3:00	H.J. Sommer III	Postural Control Related To Flexibility Of The Hindfoot When Bearing Heavy Loads
3:15	Kodjo E. Moglo	The Threshold Of Balance Recovery Is Not Affected By The Type Of Postural Perturbation

**Rehabilitation Robotics**

MC 201

Chair: Jay Alberts, Susan D'Andrea

2:15	Margaret Finley	Upper Extremity Robotic Therapy In Stroke Patients With Severe Upper Extremity Motor Impairment
2:30	H.A.M. Seelen	Evaluation Of Upper Extremity Muscle Activity During Manipulation In Robot-Simulated Task Environments
2:45	Theresa Sukal	Discoordination In Stroke Measured Dynamically Using The ACT-3D Robot
3:00	Gregory Sawicki	Therapist Controlled Powered Lower Limb Orthoses To Assist Locomotor Training
3:15	Gail F. Forrest	The Effects Of Locomotor Training On Neural And Muscle Activation.

**Cartilage**

MC 202

Chair: Tammy Haut Donahue, Jaw-Lin Wang

2:15	Salvatore Federico	A Non-Linear, Anisotropic, Inhomogeneous Model Of Articular Cartilage
2:30	Doug Bourne	Cartilage Cell Viability After In Vivo Impact Loading
2:45	Tammy L. Haut Donahue	Biochemical Response Of Meniscal Tissue To Altered Loading
3:00	Matthew Koff	T2 Values Of Patellar Cartilage In Patients With Osteoarthritis
3:15	Seungbum Koo	3D Laser Scan Based Accuracy Test Of In-Vivo Cartilage Thickness Measurement From MRI

**Instrumentation**

UC 1

Chair: Mark Grabiner, Stefan Duma

2:15	Thomas Baer	Calibration And Monitoring Of Piezoresistive Contact Stress Sensor Arrays Using A Travelling Pressure Wave Protocol
2:30	Jennifer Megesi	Validation Of Intramuscular Pressure Sensor In Rat Gastrocnemius
2:45	Philippe Pourcelot	Achilles And Patellar Tendon Loading During Gait Measured Using A Non-Invasive Ultrasonic Technique
3:00	Stephen F. Levinson	Doppler Myography: Ultrasonic Localization Of Acoustic Myographic Signals
3:15	Stephen F. Levinson	Anisotropic Elasticity And Viscosity Deduced From Supersonic Shear Imaging In Muscle

**Thursday, August 4**

**3:45 PM**

**Poster Session: Musculoskeletal Modeling**

UC 201

1	Thomas Pressel	Functions Of Hip Joint Muscles
2	Samuel J. Howarth	Using The Eigenvector To Locate Spinal Instability
3	Martijn Klein Horsman	Morphological Muscle And Joint Parameters For Musculoskeletal Modelling Of The Lower Extremity

397	Jeremy Mogk	Modeling Extrinsic Finger Flexor Tendon Kinematics
398	Jae Kun Shim	Enslaving Effects Of Finger Movement On Pressing Forces Of Other Fingers
399	Jessica Woodworth	Impact Of Restricted Pip Joints On MCP Joint Motion In The Human Hand

**Thursday, August 4**

**3:45 PM**

**Poster Session: Joint Mechanics**

UC Atrium

400	James Cubillo	Numerical Analysis Of A Femur Resurfacing Cup
401	Natasha Lee Shee	In-Vitro Testing Of Knee Joints Using Robotics: Computer Programming Theory
402	Ralph Howald	Factors Affecting The Cement Penetration Of A Hip Resurfacing Implant: An In-Vitro Study
403	Raed Itayem	The Role Of The Femoral Stem In The Stability Of A Metal On Metal Hip Resurfacing Implant. An RSSA Study
404	Lijkele Beimers	Subtalar Joint Kinematics In Healthy Individuals Using Computed Tomography
405	Thomas J. Withrow	Lack Of Hamstring Tension Causes Increased ACL Strain In A Simulated Jump Landing
406	Shahram Amiri	A Simplified Topology For The Tibial Plateau And Meniscal Surfaces And The Role Each Of Its Geometric Features Play In Guiding The Passive Motion
407	Mariana Kersh	Deformation Patterns From A Pre-Clinical Patellar Component Test
408	Andrew R. Fauth	3D Geometrical Optimization Of The Talar Dome
409	Hannah J. Lundberg	Quantifying Fluid Ingress To The Joint Space During Total Hip Implant Subluxation
410	Andrew R Hopkins	Development Of An FE Model Of Uni-Compartmental Knee Replacement
411	Matthew Moran	Computational Assessment Of Anteroposterior Laxity Following Partial PCL Release In Cruciate-Retaining TKR
412	Jihui Li	Initiation And Propagation Of Fatigue Microcracks From A Defect In A Cemented Total Hip Arthroplasty
413	Elena Varini	Primary Hip Stem Micromotion Assessment: Correlation Between Rasp And Stem Stability
414	Frances T. Sheehan	The Talocrural And Subtalar Helical Axes Are Not Fixed During Plantarflexion
415	Robert H. Deusinger	Comparison Of Arthrometer (Passive) And Functional Activity (Active) Anterior Tibial Displacements
416	Ajit Chaudhari	Patellar Ligament Insertion Angle Influences Quadriceps Use During Stair Climbing: Effect Of An Anterior Cruciate Ligament Deficit
417	Jacob Scott	The Effect Of Tibiofemoral Loading On Proximal Tibiofibular Joint Motion

**Friday, August 5**

**8:30 AM**

**Keynote Lecture**

Waetjen Auditorium

Chair: Ton van den Bogert

8:30	Martyn Shorten	Cushioning: Mechanics and Biomechanics of Attenuating Loads on the Human Body
------	----------------	---

**Friday, August 5**

**9:30 AM**

**Rehabilitation**

Waetjen Auditorium

Chair: John Jeziorowski, Glenn Klute

9:30	Li Li	Body Weight Support System Influence On The Patterns Of Vertical Forces Applied To The Body
9:45	Janessa Drake	Do Exercise Balls Provide A Training Advantage For Trunk Extensor Exercises? A Biomechanical Evaluation.
10:00	Tine Alkjaer	Biomechanical Analysis Of The Walking Pattern In Healthy Subjects With And Without Rollator
10:15	Janice Flynn	Trunk Muscle Activation Patterns Comparing Cable Press And Body-Blade Exercises

**Motor Control – Upper Extremity**

UC 6

Chair: Pat Crago, Andy Karduna

9:30	Jae Kun Shim	Prehension Synergies: Trial-To-Trial Variability And Principle Of Superposition During Static Prehension In Three Dimensions
9:45	Yin Fang	Different Motor Planning During Eccentric And Concentric Elbow Muscle Contractions
10:00	D.A. Kistemaker	An Intermittent EP-Model For Fast Point-To-Point Movements
10:15	Eric Perreault	Influence Of Voluntary Posture Selection On Endpoint Stiffness

**Muscle Adaptation**

MC 201

Chair: Véronique Feipel, Paul Sung

9:30	Robert G. Cutlip	Characterization Of Changes In Eccentric Work In Vivo During A Chronic Exposure Of Stretch-Shortening Cycles: Age Effects
9:45	Timothy A Butterfield	The Interaction Between Surface Grade And Exercise Duration For Serial Sarcomere Number Adaptations Following Treadmill Running In Rats
10:00	Sherry Di Jorio	Mitochondrial Adaptation During Rehabilitation And Its Importance In Musculoskeletal Modeling
10:15	Victor Valderrabano	Fiber Selective Muscle Atrophy In Ankle Arthritis

**Knee Replacement**

MC 202

Chair: Dwight Davy, Kiyonori Mizuno

9:30	Christopher J Barr	Knee Kinematics Of Total Knee Replacement Patients: Pre And Postoperative Analysis Using Computer Generated Images
9:45	Monika Zihlmann	3D Kinematic And Kinetic Data Of Total Knee Arthroplasty During The Stance Phase Of Level Walking Using A Moving Video-Fluoroscope
10:00	Elise Laende	Migration Of Medial-Pivot And Posterior Stabilized Implants
10:15	Brendan Joss	Gait Affects Tibial Component Migration In Unicondylar Knee Arthroplasty

**Sport 4**

UC 1

Chair: Brian Davis, Stefan Duma

9:30	Karine J. Sarro	Rib Cage Motion Patterns In Swimmers During Respiratory Maneuvers
9:45	Hiroyuki Nunome	Segmental Dynamics Of Soccer Instep Kicking
10:00	Ricardo M. L. Barros	Representation And Analysis Of Soccer Players' Trajectories
10:15	Sumiyo Toki	Quantitative Match Analysis Of Soccer Games With Two Dimensional DLT Procedures

**Friday, August 5**

**11:00 AM**

**Musculoskeletal Modeling**

Waetjen Auditorium

Chair: Richard Neptune, Douglas Pedersen

11:00	Kotaro Sasaki	Muscle Contributions To The Flight Phase In Running
11:15	Robert F. Kirsch	Musculoskeletal Modeling Of An EMG-Based Neuroprosthesis For Arm Function
11:30	Samuel R. Ward	Scaling Of Human Lower Extremity Muscle Architecture To Skeletal Dimensions
11:45	Clayton Adam	Gravity-Induced Torsion And Vertebral Rotation In Idiopathic Scoliosis
12:00	Serge Van Sint Jan	3D Muscle Moment Arms Using Musculoskeletal Modeling
12:15	Veronica J. Santos	Implementing Data-Driven Models Of The Human Thumb Into A Robotic Grasp Simulator To Predict Grasp Stability

**Methods in Gait Analysis**

UC 6

Chair: Gordon Robertson, Kit Vaughan

11:00	At Hof	Handling Of Impact Forces In Inverse Dynamics In Landing After A Jump
11:15	Lei Ren	A Three-Dimensional Whole-Body Walking Model Based Only On Gait Kinematics
11:30	Raziel Riemer	An Analysis Of Uncertainties In Inverse Dynamics Solutions For Gait
11:45	George Chen	Induced Acceleration Contributions To Locomotion Dynamics Are Not Physically Well-Defined
12:00	Zachary Domire	Comparison Of Methods Used To Determine Induced Vertical Ground Reaction Force
12:15	Ben Stansfield	Optimisation Or Antagonism? Muscle Force Solutions In The Lower Limb

**Hand and Wrist 2**

MC 201

Chair: Kai-Nan An, Zong-Ming Li

11:00	Zong-Ming Li	Gender Difference In Carpal Tunnel Compliance
11:15	Haoyu Wang	Evaluation Of Five Ligamentous Stabilizers Of The Scaphoid And Lunate
11:30	Fong-Chin Su	Joint Load Of The Thumb In Jar Opening
11:45	Asimakis Kanellopoulos	An Investigation Of Wrist Joint Function Under Load
12:00	Haoyu Wang	Variations In Scapholunate Gap With Various Types Of Ligamentous Sectioning
12:15	Joseph D. Towles	Use Of The Long Flexor And Intrinsic Thumb Muscles To Restore Lateral Pinch In The Tetraplegic Thumb: A Cadaver Study

**Knee Mechanics 2**

MC 202

Chair: Scott McLean, Jack Engsberg

11:00	Sietske Aalbersberg	Co-Contraction In ACL Deficient Subjects
11:15	Janie Astephen	Postural Gait Changes Are Seen With Severe, Not Moderate, Knee Osteoarthritis
11:30	Hyung-Soon Park	Passive Knee Joint Properties In Tibial Rotation In Men And Women
11:45	Aaron Derouin	Knee Stability: Mechanical Contributions Of Individual Muscles
12:00	Frances T. Sheehan	In Vivo Patellar Tendon Moment Arm And Tibial-Femoral Helical Axis
12:15	Anneliese D. Heiner	A Device To Measure In Vivo Translational And Rotational Laxity Of Rabbit Knees

**Running Injuries**

UC 1

Chair: Irene McClay Davis, Elizabeth Hardin

11:00	Mark Creaby	Comparison Of Static And Dynamic Biomechanical Measures In Military Recruits With And Without A History Of Third Metatarsal Stress Fracture
11:15	Siriporn Sasimontonkul	Estimation Of Stresses And Cycles To Failure Of The Tibia During Rested And Fatigued Running
11:30	Tracy Dierks	Kinematics Of Runners With And Without Patellofemoral Pain During Prolonged Treadmill Running
11:45	Clare Milner	Does Free Moment Predict The Incidence Of Tibial Stress Fracture?
12:00	Wolfgang Potthast	Influence Of Muscle Pre-Activation And Knee Joint Angle On Axial Tibio-Femoral Shock Transmission
12:15	Robert J. Butler	Does Footwear Affect Lower Extremity Variability In High And Low Arched Runners?

**Friday, August 5**

**1:15 PM**

**Keynote Lecture**

Waetjen Auditorium

Chair: Mark Grabiner

1:15	J.J. Collins	Noise-Enhanced Sensorimotor Function
------	--------------	--------------------------------------

**Friday, August 5**

**2:15 PM**

**Motor Control**

Waetjen Auditorium

Chair: Jim Collins, Guang Yue

2:15	Scott K. Lynn	Is Lower Limb Joint Proprioception Systemic?
2:30	Daniel M. Krainak	FMRI Brain Imaging During Six DOF Mechanical Measurements Of Upper Limb Isometric Contractions
2:45	Joseph S. Soltys	Velocity Sense In The Lumbar Spine Is Modulated By The Vestibular And Proprioceptive Systems
3:00	J. Maxwell Donelan	Sensory Regulation Of Muscle Activity During Walking In Conscious Cats
3:15	Dirk Jan Veeger	Proprioceptive Disturbances In RSI: A Comparison With CRPS

**Locomotion Energetics**

UC 6

Chair: Art Kuo, Steve McCaw

2:15	Rodger Kram	Metabolic Costs Of Forward Propulsion And Leg Swing At Different Running Speeds
2:30	Brian Umberger	Mechanical Efficiency During Walking At Different Stride Rates
2:45	Jiro Doke	Metabolic Cost Of Generating Force During Human Leg Swinging
3:00	Peter Gabriel Adamczyk	Metabolic Cost Of Walking Varies With Foot Roll-Over Radius
3:15	Manoj Srinivasan	Energetics Of Legged Locomotion: Why Is Total Metabolic Cost Proportional To The Cost Of Stance Work?

**Falling and Fall Prevention**

MC 201

Chair: Jill McNitt-Gray, Mark Grabiner

2:15	Michael Madigan	Age-Related Joint Torque Analysis During Support Phase Of Single Step Recovery
2:30	Karen L. Reed-Troy	Recovery Responses To Surrogate Slips Are Different Than Actual Slips
2:45	Vivi M. Thorup	Ground Reaction Forces In Pigs During Gait On Dry And Greasy Floor
3:00	Lisa Case	Arrest Of Forward Falls Onto Outstretched Hands In Healthy Young Women
3:15	Charles Cejka	Control Of Reach-To-Grasp Reactions During Perturbed Locomotion In Familiar And Unfamiliar Environments: When Does Visual Fixation Of The Handrail Occur?

**Knee Mechanics 3**

MC 202

Chair: Stephen Piazza, Thor Besier

2:15	Yu Jen Chen	Validation Of A Three Dimensional Model To Quantify Patellofemoral Joint Forces
2:30	William Anderst	Assessment Of Functional Joint Space Repeatability During In Vivo Dynamic Loading
2:45	Josh MacNeil	Preservation Of Periarticular Cancellous Morphology And Mechanical Strength In Post-Traumatic Experimental Osteoarthritis By Antiresorptive Therapy
3:00	Kim McLaughlin	In Vivo Assessment Of Congruence In The Patellofemoral Joint Of Healthy Subjects
3:15	Elvis Chen	Ligament Estimation From In Vivo Knee Motion: An Inverse-Kinematics Model

**Animal Biomechanics**

UC 1

Chair: Boris Prilutsky, Gail Perusek

2:15	Melanie Scholz	Scaling And Jumping: Gravity Loses Grip On Small Jumpers
2:30	Anne Su	Variability In The Direction Of Substrate Reaction Forces In The Locomotor Repertoire Of The Primate Lemur Catta
2:45	Monica A. Daley	Dynamic Stability In A Rough Environment: The Influence Of Initial Limb Posture On Body Dynamics During An Unexpected Perturbation
3:00	David Lee	Proximo-Distal Distribution Of Mechanical Work And Capacity For Elastic Energy Storage In The Limb Joints Of Running Goats
3:15	Peter Zani	The Energetics And Biomechanics Of Turtle Locomotion

**Friday, August 4**

**4:00 PM**

**ISB President's Lecture**

Waetjen Auditorium

Chair: Brian Davis

4:00	Mary Rodgers	Rehabilitation & Biomechanics (Do The Locomotion)
5:00	CLOSING CEREMONY

# look inside.

BODY WORLDS 2, the most highly attended touring exhibition in the world, presents an in-depth view of the human body as you have never seen it before. Examine the muscles you use to run, the joints that help you jump, and the heart that keeps your blood pumping. It's your body up close and personal. So get here today, and see how truly amazing you are.

Gunther von Hagens'  
**BODY WORLDS**  
The Anatomical Exhibition of Real Human Bodies **2**

APRIL 9 - SEPTEMBER 18

601 Erieside Ave. Cleveland, OH 216-694-2000 • [www.greatscience.com](http://www.greatscience.com)

The Science Center is located at Northcoast Harbor - only minutes from I-90, I-71 and I-77. Take advantage of the special discounted visitor rate in our attached garage.

OFFERS VALID THROUGH AUGUST 15, 2005

XXth Congress of the International Society of Biomechanics • July 31 - August 5, 2005

**SPECIAL DISCOUNTED ADMISSION TO  
BODY WORLDS 2 FOR ISB CONGRESS ATTENDEES!!**

**\$3.00 off**

**PRESENT THIS COUPON AT THE GREAT LAKES SCIENCE CENTER BOX OFFICE.**

**adult admission price.**  
Valid Everyday from 9:30am - 9:90pm.

We recommend you allow a minimum of 1 1/2 hours to fully experience this amazing exhibit.  
Not valid with any other discount or offer.

## Sunday July 31, 2005

3:00 PM	Opening Ceremony
4:00 PM	Wartenweiler Memorial Lecture: Bruce Latimer - Biomechanics and Evolution
5:00 PM	Welcome reception and barbecue - University Center

## Monday August 1, 2005

8:30 AM	Keynote Lecture: Don Chaffin				
9:30 AM	Ergonomics 1	Locomotion 1	Soft Tissue 1	Space Biomechanics	Bone 1
10:30 AM	Break - University Center				
11:00 AM	Ergonomics 2	Locomotion 2	Soft Tissue 2	Foot 1	Bone 2
12:30 PM	Lunch - University Center				
1:15 PM	Keynote Lecture: Andre Seyfarth				
2:15 PM	Legged Robots	Gait Analysis	Shoulder	Foot 2	Simulation
3:30 PM	Break - University Center				
4:00 PM	Pelvic Organ and Muscle Biomechanics	ISB Technical Group: 3D Analysis	ISB Technical Group: Shoulder	ISB Technical Group: Footwear	ISB Technical Group: Simulation
5:30 PM	NOVEL workshop on pressure distribution measurement - MC 201 (registration required)				

## Tuesday August 2, 2005

8:30 AM	Keynote Lecture: Julie Steele				
9:30 AM	Knee Injuries 1	EMG	Muscle Mechanics	Sport 1	Bone - Modeling
10:30 AM	Break - University Center				
11:00 AM	Knee Injuries 2	Gait and OA	Muscle In Vivo	Sport 2	Hip Replacement
12:30 PM	Lunch - University Center				
1:15 PM	Keynote Lecture: Masahiro Kurosaka				
2:15 PM	Knee Mechanics 1	Methods 1	Spine 1	Ankle	Head Injury
3:30 PM	Break and Poster Sessions - UC 201				
7:00 PM	Reception at Cleveland Museum of Natural History				

## Wednesday August 3, 2005

8:30 AM	ISB Promising Young Scientist Award: Constantinos Maganaris				
9:00 AM	ISB Clinical Biomechanics Award: Magnus Kjartan Gislason				
9:30 AM	ISB Young Investigator Awards	Posture and Balance 1	Spine 2	Lower Extremity Injury	Prosthetics and Orthotics
10:30 AM	Break - University Center				
11:00 AM	ISB Muybridge Award Lecture: Rik Huiskes				
12:00 PM	ISB General Assembly (until 12:45)				
12:00 PM	Lunch - University Center				
afternoon	Lab tours and excursions				
2-7 PM	Tekscan workshop on pressure distribution measurement - UC 364 (registration required)				

## Thursday August 4, 2005

8:30 AM	ASB Jim Hay Memorial Award Lecture: Mont Hubbard				
9:30 AM	ASB Young Scientist Awards	Gait Simulation	Functional Electrical Stimulation	Sport 3	Injury Biomechanics
10:30 AM	Break - University Center				
11:00 AM	Hand and Wrist 1	Diabetic Foot	Gait and Aging	Running	Wheelchair
12:30 PM	Lunch - University Center				
1:15 PM	ASB Borelli Award Lecture: Kai-Nan An				
2:15 PM	ASB Awards	Posture and Balance 2	Rehabilitation Robotics	Cartilage	Instrumentation
3:30 PM	Break and Poster Sessions - University Center				
7:00 PM	Baseball: Cleveland Indians vs. New York Yankees at Jacobs Field				

## Friday August 5, 2005

8:30 AM	Keynote Lecture: Martyn Shorten				
9:30 AM	Rehabilitation	Motor Control - Upper Extremity	Muscle Adaptation	Knee Replacement	Sport 4
10:30 AM	Break - University Center				
11:00 AM	Musculoskeletal Modeling	Methods in Gait Analysis	Hand and Wrist 2	Knee Mechanics 2	Running Injuries
12:30 PM	Lunch - University Center				
1:15 PM	Keynote Lecture: James J. Collins				
2:15 PM	Motor Control	Locomotion Energetics	Falling and Fall Prevention	Knee Mechanics 3	Animal Biomechanics
3:30 PM	Break - University Center				
4:00 PM	ISB President's Lecture: Mary Rodgers				
5:00 PM	Closing Ceremony (until 6:00)				
7:00 PM	Conference Banquet at Rock & Roll Hall of Fame				

## NUMERICAL ANALYSIS OF A FEMUR RESURFACING CUP

### INTRODUCTION

Wagner [1] developed a method of hip joint arthroplasty by surface replacement. The first clinical trial was in 1976; since then research in this area has continued, and operative techniques and implantation systems have been refined. Hip joint resurfacing offers several advantages over other techniques, most importantly the fact that the femoral neck is left intact.

However, the effects of various designs of femoral resurfacing cup have not yet been fully understood. In this paper, the femoral resurfacing cup was modelled and investigated. Different bone cement materials and various designs of resurfacing femur cup were numerically simulated.

### METHODS

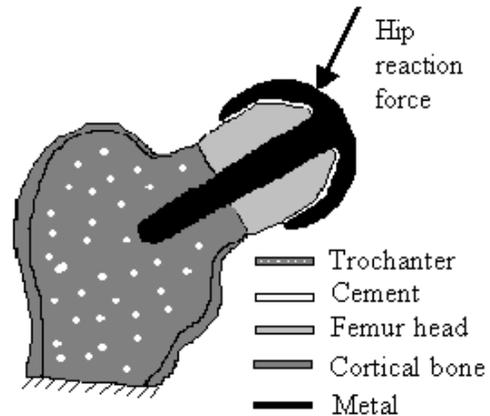

A 3D finite element model consisting of a resurfacing cup, bone cement and proximal femur was created using the ANSYS finite element package. The coronal section of the model is shown in Figure 1.

Two types of cancellous bone were considered within the proximal femur. The cancellous bone within the femur head has a Young's modulus of 1300 MPa, and the cancellous bone within the femur trochanteric region has a Young's modulus of 320 MPa [2]; the cortical bone around the trochanter has a Young's modulus of 17000 MPa. The cup is made of Cobalt Chromium, the Young's modulus of which is 210000 MPa and Poisson's ratio 0.3. Two types of bone cement were analysed in this paper with a Young's modulus of 2200 MPa [3] and 2800 MPa respectively.

In this research, we were interested in the region of femoral head and femoral resurfacing cup; only the hip reaction force was applied. In a one-leg stance, a 3 kN load was applied to the femoral head [2]. Ascending and descending stairs and rising from a chair are all activities that increase the posterior component of the joint reaction force and generate large torque, and the anterior-posterior component of force in the joint reaction is up to 45% of the resultant force [4]. The applied forces were distributed over the assumed load-bearing area on the femur head.

For comparative analysis, the following parameters were considered and compared; stress in the cement layer, stress in the bone around the metal stem, and load sharing between the stem and the bone of the femoral neck.

The factors related to the cup design were investigated and discussed. Firstly, the effect of femoral stem bonded or contacted with surrounding bone was investigated. Secondly,

**Figure 1:** Coronal section of the model and material

the role of the stem in the femoral cup was studied. Finally, the effects of cement thickness, cement material properties, femoral cup depth, stem diameter, and osteoporosis were all investigated.

### RESULTS AND DISCUSSION

A femoral cup with a stem reduced the stress in the cement greatly in comparison to a cup without a stem. If a stem was used, the shorter the stem the higher the stress in the cement and femur head bone. When the diameter of stem was decreased, the stress in the cement and femur head bone increased. When the resurfacing cup's depth was reduced, the stress in the cement and femur head bone decreased slightly. Changes in the thickness of the cement layer from 0.5 to 1 and 2 mm did not make much difference to the stresses in the cement and bone. Different material properties of the cement did not change the load sharing between the stem and bone. The more osteoporosis developed in the bone, (i.e. the lower the Young's modulus of the bone), the higher the stress resulted in the cement. All the results showed that the femoral bone carries most of the forces and the stem bears only one quarter to one third of the applied forces in the direction of the stem axis. If the stem were simulated bonded with the bone rather than just in contact with the bone, the stress in the cement was reduced. However, this case may result in stress shielding around the femoral neck with subsequent bone thinning problems.

## A BIOMECHANICAL MODEL OF SACRO-ILIAC JOINT DYSFUNCTION AS A CAUSE OF LOW BACK PAIN

Munier Hossain, Leonard DM Nokes  
 Cardiff School of Engineering, Cardiff, UK

email: [munierh@doctors.org.uk](mailto:munierh@doctors.org.uk), web: [www.orthobiomech.info](http://www.orthobiomech.info)

### INTRODUCTION

A biomechanical model of sacro-iliac (SI) joint dysfunction is proposed. It was hypothesized that sacro-iliac joint dysfunction in the form of abnormal activation of gluteus maximus and biceps femoris gives rise to lumbopelvic pain by failing to stabilize the sacro-iliac joint during weight bearing. The model was tested on a pilot study of two volunteers.

### METHODS

Two male volunteers participated in the study. One subject had no complaint of sacro-iliac joint pain. The other subject had sacral sulcus tenderness, pain over the sacroiliac joint on right side and standing asymmetry of the posterior superior iliac spine.

Electromyogram (EMG) was recorded using pairs of disposable bipolar surface Ag/AgCl electrodes on the symptomatic side for the lumbar multifidus, gluteus maximus and biceps femoris muscles in walking. The surface electrodes were positioned as advised by Snijders et al[1]. Baseline activity was recorded at rest. Subjects were asked to walk in a straight line. Each test was taken three times for two full gait cycles. EMG data was taken on the patient before and after a session of physiotherapy. Two dimensional high speed video was used to capture data of walking motion. Surface EMG data were sampled at 1000 Hz and pre amplified at the source. The raw EMG data of the three muscles were full-wave rectified and base line corrected. Then the rectified data were smoothed by passing it through a second order low pass filter with a Butterworth response at 2- 27 Hertz .

### RESULTS AND DISCUSSION

Table 1 compares the EMG values from the volunteers. Multifidus was activated throughout the gait sequence but increased activity in swing phases. There was little difference in activity.

Biceps femoris muscle activated in mid swing phase to peak and subsequently relax before initial contact to allow gluteus peak at loading response in the normal volunteer. Gluteus activation remained low in mid stance and terminal stance, but

showed another peak activity in pre-swing event .In the patient biceps was activated at terminal swing and at the time of initial contact, it was still relatively active. Gluteus activation was generally poor in the symptomatic individual and failed to reach a peak in loading response. There was consistent activation of biceps on terminal swing event with another peak activation in ipsilateral pre-swing event. Unlike the normal volunteer, gluteus failed to show increased activity in terminal stance to pre swing events. After physiotherapy, there was general decrease in biceps femoris activity and increase in gluteus activity.

SI joint is the key linkage in transmission of weight from the upper limbs to the lower. The joint is vertically oriented and subject to a large shear force and forward momentum on weight bearing. Gluteus is strongly active during initial contact and loading response events when we experience an abrupt limb loading and as such need for SI joint stability is at a premium. Sub-optimal activity of gluteus could disrupt weight transference. Body would attempt to compensate by recruiting biceps femoris, which could exert its influence through its proximal attachment to sacrotuberous ligament [2]. This compensatory strategy might in itself also give rise to pain due to prolong biceps contraction or stretching of long dorsal ligament .

The study showed a difference in gluteus maximus and biceps femoris activity in key events of gait between the two volunteers. A larger study is planned to validate the model.

### INTRODUCTION

Articular cartilage is a biological composite material made of a proteoglycan matrix, and of chondrocyte and collagen fibre inclusions. We have modelled articular cartilage by means of a linearly elastic Transversely Isotropic, Transversely Homogeneous (TITH) model [1]. Here, we extend the TITH model to non-linear elasticity by using a class of transversely isotropic potentials [2,3]. The use of a non homogeneous potential (i.e., explicitly dependent on the point) enables us to identify non-uniformities in the simulation of compression tests.

### METHODS

The stress strain relationship for a hyperelastic material is:

$$\sigma_{ij} = \frac{2}{J} F_{ir} \frac{\partial U}{\partial C_{rs}}(C) F_{js} \quad (1)$$

where  $\sigma$  is the Cauchy stress, and  $U$  is the strain energy potential which is a function of the right Cauchy stretch,  $C$ . For a transversely isotropic material, with transverse plane orthogonal to the unit vector  $w = e_1$ ,  $U$  is a function of the three principal invariants of  $C$ , and the two additional invariants for transverse isotropy [4]. By expressing the invariants explicitly in terms of the components of  $C$ , we have:

$$\begin{aligned} U(C) &= a \exp(f(C)) \\ f(C) &= -b \ln(\det(C)) + \alpha_1(C_{rr} - 3) + \\ &+ \frac{1}{2} \alpha_2((C_{rr})^2 - C_{rs} C_{sr} - 6) + \quad = \quad (2) \\ &+ \alpha_3(C_{rr} - 3)(w_r C_{rs} w_s - 1) + \alpha_4(w_r C_{rs} w_s - 1) + \\ &+ \alpha_5(w_r C_{rs} w_s - 1)^2 + \alpha_6(w_r C_{rs} w_s - 1)^2 + \alpha_7(C_{rr} - 3)^2 \end{aligned}$$

The coefficients  $a$ ,  $b$ ,  $\alpha_1, \dots, \alpha_7$  are determined by imposing that, for small strains, Eq. (1) must reduce to the linear theory. If we use Cohen's potential [3], then  $b = 1$  and  $\alpha_7 = 0$ . For a confined compression test, the stress strain relationship is:

$$\sigma_{rr} = 2a(2P\lambda + Q\lambda^{-1} - \lambda^{-3}) \exp(P\lambda^4 + Q\lambda^2 - R\lambda^2) \quad (3)$$

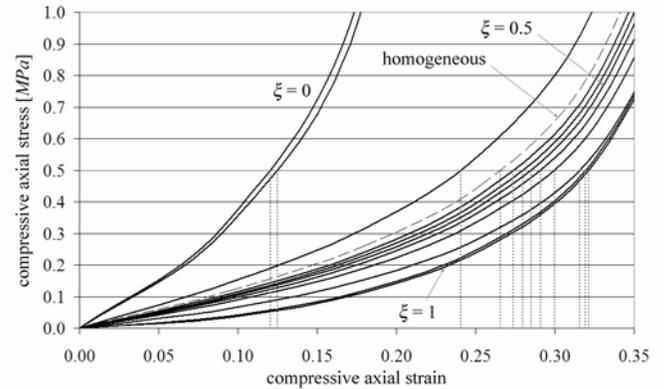

where  $\lambda$  is the axial Cauchy stretch, and  $P$ ,  $Q$  and  $R$  are linear combinations of  $\alpha_1, \dots, \alpha_6$ . In the non-linear TITH model, these coefficients explicitly depend on the tissue depth via the non dimensional coordinate,  $\xi$ , running from the tidemark ( $\xi = 0$ ) to the articular surface ( $\xi = 1$ ). We plotted the stress-strain curve for several values of  $\xi$  (Fig. 1). We assumed that, for a transversely homogeneous material in confined compression, the axial stress must be uniform, and imposed a 0.5 MPa stress (Fig. 1). We then plotted the corresponding values of the strain at each depth  $\xi$  (Fig. 2) and obtained the spatial distribution of the Green strain,  $\varepsilon = (\lambda^2 - 1)/2$ , for the non-linear TITH model, and Cohen's non-linear homogeneous model.

### RESULTS AND DISCUSSION

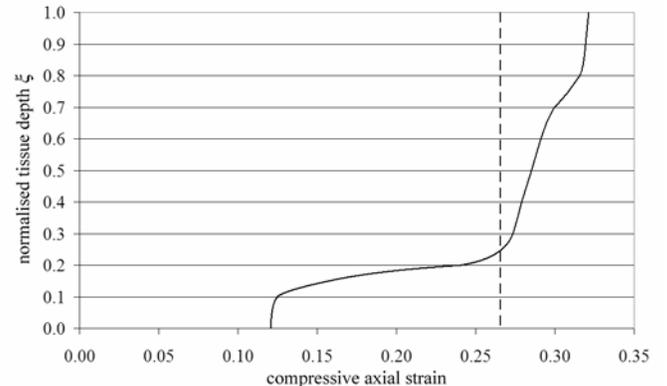

The results of this study show that, while the homogeneous model can only give rise to an intrinsic uniform solution (Fig. 2), the non-linear TITH model is able to predict non uniformities in axial strain, due to the variation of the tangent stiffness with depth: the superficial layers deform more than

the deep layers because they are softer, a result that is consistent with experimental evidence [5].

Implementation of this model into a Finite Element code might help in studying the mechanical behaviour of chondrocytes during cartilage deformation, which might prove to be an essential piece towards understanding biological responses of articular cartilage as a function of mechanical loading.

**Figure 1:** stress-strain curves at various  $\xi$  for the non-linear TITH model (solid lines) and Cohen's homogeneous model (dashed line); the dotted lines indicate the strain at each  $\xi$ , for a  $-0.5$  MPa stress.

**Figure 2:** spatial distribution of the strain for the non-linear TITH model (solid line) and Cohen's homogeneous model (dashed line).

## COMPUTER SIMULATION OF THE TAKEOFF IN SPRINGBOARD DIVING

Pui W. Kong, Maurice R. Yeadon and Mark A. King  
Loughborough University; email: m.r.yeadon@lboro.ac.uk, web: www.lboro.ac.uk

### INTRODUCTION

In springboard diving the diver aims to generate sufficient time in the air and angular momentum for somersault and twist, and travel safely away from the board. Since the linear and angular momentum that the diver possesses in the air are determined by the end of the takeoff phase, it is crucial to understand the mechanics of the takeoff in terms of gaining dive height, generating angular momentum and keeping a safe distance. The aim of this study was to develop a computer simulation model in order to investigate springboard diving takeoff techniques in the forward and reverse groups.

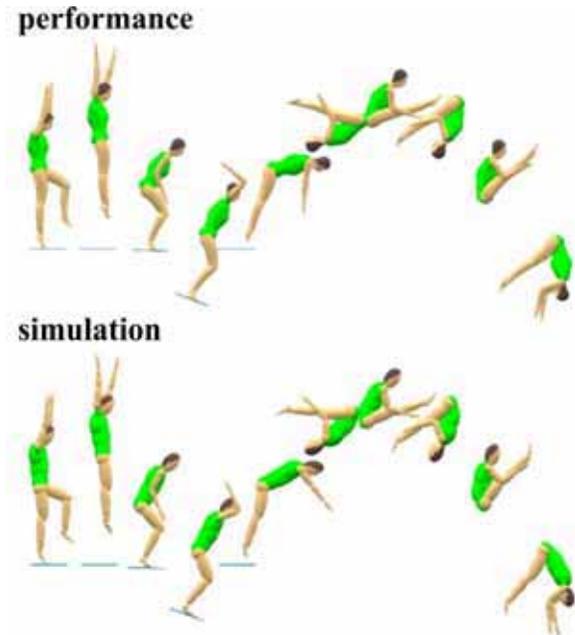

### METHODS

A planar simulation model of a springboard and a diver was developed using the Autolev 3.4<sup>TM</sup> software package based on Kane's method of formulating equations of motion [1]. The diver was represented by an eight-segment linked system comprising the head, upper arm, lower arm, trunk, thigh, shank and a two-segment foot. There were extensor and flexor torque generators acting at the metatarsal-phalangeal, ankle, knee, hip and shoulder joint. The torque produced was the product of an activation level and the maximum torque calculated from a torque / angle / angular velocity function. Each activation level was specified using two quintic functions with six parameters.

Input to the model included initial conditions at touchdown obtained using high speed video and activation time histories throughout the simulation. Output of the model comprised time histories of the springboard displacement, the diver's joint angle and angular velocity at each joint, body orientation, CM velocity and whole-body angular momentum. The model was customised to an elite female diver so that simulation output could be compared with the diver's own performance. Model parameters including springboard, strength, inertia and visco-elastic parameters were determined either directly from experiments or indirectly using an angle-driven model. A score was calculated as the average percentage difference in joint angles, orientation, linear momentum, angular momentum, and springboard characteristics. Sixty muscle activation parameters were varied until the best match between simulation and performance was found by minimizing this score using the Simulated Annealing optimisation algorithm [2]. Four dives which required different angular momenta in the forward and reverse groups were selected for this matching process. After satisfactory evaluation, the model was used to optimise takeoff techniques in terms of gaining maximum dive height.

### RESULTS AND DISCUSSION

All four simulations matched the performance well with an average score of 6.3%. Graphics comparison of the

**Figure 1:** Comparison of the performance and matching simulation of the forward two and one-half somersault pike.

performance and matching simulation of the forward two and one-half somersault pike (105B) is shown in Figure 1. In the optimisation for height for 105B, there is a 12.7 cm increase in dive height. The good agreement between simulation and performance for all four dives suggests that the model can successfully reproduce springboard diving takeoff movements. The optimised simulation shows that by changing the activation alone the diver can gain more dive height. This model will be further applied to investigate other optimal takeoff techniques.

### CONCLUSIONS

This study presents a torque-driven simulation model of a springboard and a diver which successfully reproduces realistic springboard diving takeoffs. This model will be used to investigate optimal takeoff techniques in the forward and reverse dive groups.

## PERFORMANCE AFTER PROLONGED CYCLING AT FREELY CHOSEN AND OPTIMAL PEDAL RATE

<sup>1</sup>Ernst Albin Hansen, <sup>2</sup>Kurt Jensen and <sup>3</sup>Preben K Pedersen

<sup>1</sup>National Institute of Occupational Health, Copenhagen, Denmark; email: [eah@ami.dk](mailto:eah@ami.dk)

<sup>2</sup>Team Danmarks Testcenter, University of Southern Denmark, Odense.

<sup>3</sup>Institute of Sports Science and Clinical Biomechanics, University of Southern Denmark, Odense.

### INTRODUCTION

The major part of a long cycling road race (>3 h) consists of sub-maximal cycling [1] where cyclists exercise using high pedal rates. In fact, the freely chosen pedal rate (FCPR) is much higher than the one resulting in minimum energy turnover, i.e., the optimal pedal rate (OPR) [2]. Supposing that the choice of a high pedal rate, despite its higher energetic cost, might serve a practical purpose, we examined whether performance was higher after prolonged cycling with FCPR compared to OPR.

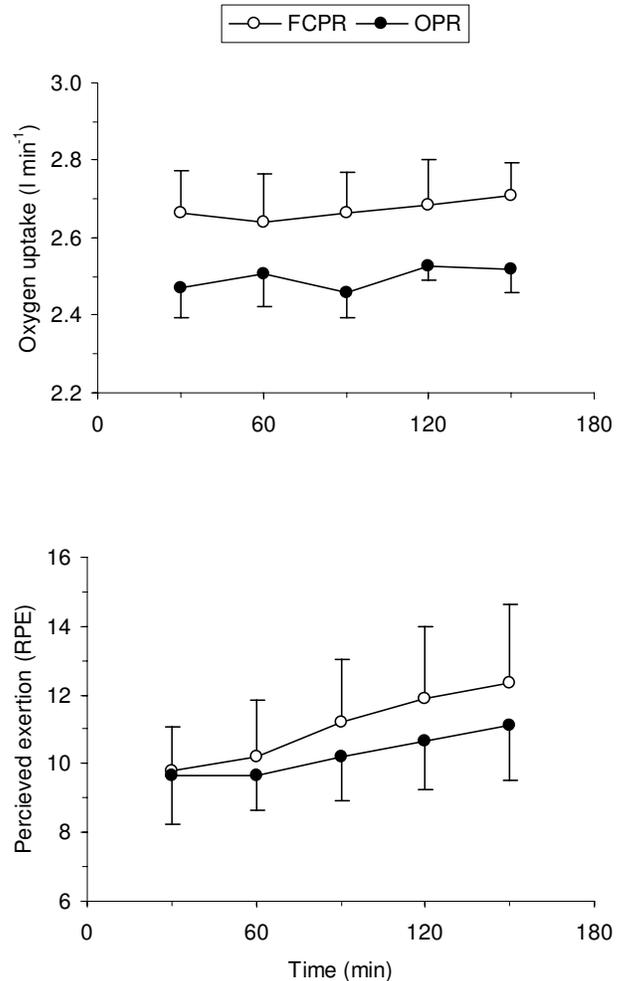

### METHODS

Nine trained cyclists or triathletes (average±SD: 27±2 years, 73.2±6.7 kg, 179±6 cm) were tested on three different days. On day 1 the subjects performed at random order (without pauses) six 180 W, 6-min, cycle ergometer bouts with 35, 50, 65, 80, 95 rpm, and FCPR. Oxygen uptake ( $\text{VO}_2$ ) was measured continuously, and subsequently plotted against pedal rate for determination of OPR. Afterwards the subjects performed a 5 min time trial test with FCPR for determination of average power output ( $W_{5\text{min}}$ ), peak  $\text{VO}_2$  and blood lactate concentration. On days 2 and 3 they cycled 2.5 h at 180 W with either their FCPR or OPR (randomised order) followed by the 5 min time trial test.  $\text{VO}_2$  and perceived exertion (RPE) were recorded at 30 min intervals during the prolonged cycling.

### RESULTS AND DISCUSSION

U-shaped relationships between pedal rate and  $\text{VO}_2$  were observed for 8 out of 9 subjects (for one subject the minimum  $\text{VO}_2$  occurred at the highest preset pedal rate). The mean OPR was 73±11 (range: 65-95) rpm while FCPR averaged 95±7 (range: 89-106) rpm ( $p<0.05$ ). Initial peak values averaged for  $\text{VO}_2$ : 4.65±0.5 l min<sup>-1</sup>, blood lactate concentration: 13.6±2.3 mM, and  $W_{5\text{min}}$ : 399±33 W. A workload of 180 W, accordingly, corresponded to 45±4% of the initial  $W_{5\text{min}}$ .  $\text{VO}_2$  during the prolonged cycling was consistently ~7% higher at FCPR than at OPR ( $p<0.05$ ) (Fig 1). RPE increased during prolonged cycling ( $p<0.05$ ) and more so with FCPR than with OPR ( $p<0.05$ ) (Fig 1). The final  $W_{5\text{min}}$  (359±47W after FCPR and 368±31 W after OPR) was ~10% lower than the initial value ( $p<0.05$ ), which indicated fatigue. The tendency for a greater performance reduction following FCPR, however, did not reach statistical significance.

A high  $\text{VO}_2$  reflects a high energy turnover, which at least theoretically, depletes the energy stores sooner. However, performance reduction may also be caused by other mechanisms e.g. linked to neuromuscular function, which could be affected by the relatively high pedal force and muscle stress that follows with the quite low OPR.

**Figure 1:** Oxygen uptake and perceived exertion as a function of time during 2.5 h of prolonged cycling.

### CONCLUSIONS

Time trial performance was reduced after 2.5 h cycling at 180 W with FCPR and OPR. The reduction of performance did not differ between the two pedal rates, despite  $\text{VO}_2$  and RPE being higher with FCPR.

### INTRODUCTION

Mechanical properties of canine bone are important for a better understanding of skeletal pathologies and are a prerequisite for numerical simulations of the bone. As hip diseases are of particular importance in dogs, we investigated the mechanical properties of trabecular bone in canine femoral heads.

### METHODS

Both femora were obtained from eight euthanized dogs and 10x10x10 mm cubic specimens which were oriented along the main pressure trajectories were cut from the centre of the femoral heads (Figure 1). Specimen weights were recorded and sample edge lengths measured. From these results, specimen densities were calculated (Equation 1). Using a custom 100 MHz ultrasound testing device, the runtime through each specimen was recorded ten times in each direction (X, Y and Z) and average runtimes were calculated. From these results the velocity of the ultrasound waves (Equation 2) and the elastic moduli in the three orthogonal directions (Equation 3) could be calculated. Degrees of anisotropy (ratio of elastic modulus to moduli in the other orthogonal directions) were also determined. Statistical analysis using one-way ANOVA (software package SPSS 12.0, Chicago IL, USA) tested the directional moduli for significant differences.

**Figure 1:** Photograph of a cubic bone specimen which was cut from a canine femoral head

$\rho = \frac{m}{V}$  **Equation 1:** density  $\rho$  calculated from specimen mass  $m$  and volume  $V$

$c_{long} = \frac{s}{t_1 - t_0}$  **Equation 2:** transmission velocity  $c$  calculated from edge length of the specimen  $s$  and runtime through the specimen  $t_1 - t_0$

$E_{x,y,z} = \rho \cdot c_{long}^2$  **Equation 3:** directional Young's modulus  $E$  along  $x$ ,  $y$  and  $z$  axes is calculated from density  $\rho$  and transmission velocity  $c$

### RESULTS AND DISCUSSION

The edge lengths of the specimens varied by  $\pm 0.1$  mm ( $\pm 1\%$ ). Elastic moduli were found ranging from 6.3 to 14.3 GPa. A mean specimen density of  $1.40 \pm 0.09$  g/cm<sup>3</sup> was calculated. Standard deviations between specimens were much smaller for  $E_x$  (the elastic modulus along main pressure trajectories of the femoral head) than for the other orthogonal directions ( $E_y$  and  $E_z$ ). As could be expected from *equation 3*, significant correlations between specimen densities and elastic moduli were calculated ( $p < 0.005$ ). No significant differences between directional elastic moduli could be found indicating approximately isotropic specimens ( $p = 0.34$ ).

Several authors also have examined trabecular bone in canine and human bone. Works investigating bone of the femoral head [1] or the distal radius [2] found lower elastic moduli, while other authors using ultrasound testing or nanoindentation calculated similar or higher values [3-5]. The differences could be caused by specimens from different sites (e. g. radius or distal femur) and by different properties of human bone. One aspect could also be that several works did not load specimens along the main pressure trajectories which might result in lower elastic moduli.

### CONCLUSIONS

The study indicated isotropy of the specimens obtained from canine femoral heads; the results are comparable to similar studies and might provide data for further biomechanical analysis of canine bone.

## FUNCTIONS OF HIP JOINT MUSCLES

<sup>1</sup>Thomas Pressel and <sup>2</sup>Markus Lengsfeld

<sup>1</sup>Department of Orthopaedic Surgery, Hannover Medical School, Hannover, Germany; E-mail: [pressel@annastift.de](mailto:pressel@annastift.de)

<sup>2</sup>Department of Orthopaedic and Trauma Surgery, Hessisch Lichtenau, Germany

### INTRODUCTION

Functions of hip joint muscles are important for physical therapy and rehabilitation, but are also useful for reconstructive surgery involving e. g. tendon transfer after plexus or peripheral nerve injuries. Main muscle functions in the neutral position of the joint are well known, but secondary functions or function changes in different joint positions remain under debate. Hence we used a multibody computer model of the hip and knee for further investigation of hip joint muscle functions.

### METHODS

A 50<sup>th</sup> percentile rank male adult model regarding body height was chosen. The mass characteristics and joint positions were determined using the ADAMS/Android software package for the multibody simulation system ADAMS 7.0 (MSC Software, Santa Ana CA, USA). The attachment areas of 27 muscles crossing the hip joint were measured and centre points of the areas were calculated in a previous work[1]. The muscles were represented by straight lines connecting the muscle origin and insertion point; when the course of a muscle differed noticeable from a straight line, one additional wrapping point was used. Hip joint movements were investigated in steps of 20° using a physiological range of motion found in the literature. In each joint position, muscle lengths were determined and muscle lever arms were calculated. Additionally, the new concept of relative torques (torque acting around a single joint axis divided by the total torque which is generated by a standard muscle force) was introduced and relative torques around the three joint axes were calculated. With these parameters the functions of each muscle could be assessed in all investigated joint positions.

### RESULTS AND DISCUSSION

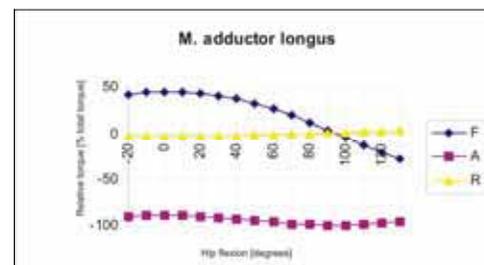

Lengths, lever arms and relative torques for 27 muscles of the hip joint were calculated. Due to the large amount of data, two muscles whose functions are under debate in the literature are presented here. There is agreement in the literature that M. adductor longus is an adductor of the hip. In our data, the muscle additionally is a flexor of the hip up to 90° of flexion. At flexion angles greater than 90°, the muscle becomes an extensor (Figure 1). The muscle also was found to be an external rotator of the hip in flexion positions up to 80° or internal rotation of the hip. The rotational function change is

not described by most of the authors and internal or external rotation is reported instead.

M. iliopsoas is a flexor of the hip in all anatomical works. In this study, when exceeding 110° of flexion the muscle became an extensor of the hip. We also found an internally rotating moment of the muscle in positions up to 80° flexion and 30° external rotation. In externally rotated positions of the hip the muscle also generated an abducting moment.

In interpretation of our data, the effects of the simplified representation of muscles which were modelled as straight lines have to be accounted for. However, as manifestly curved muscles were modelled by additional wrapping points, the errors due to this simplification were reduced.

The primary functions of hip muscles were the same as in similar studies and in the anatomical literature. Function changes during different hip joint motions were also found in other studies, but there is some debate about the exact joint position of the function change. The data presented here is in most of the cases supported by several authors.

**Figure 1:** Relative torques of M. adductor longus. *F* designates flexion torque, *A* abduction torque, *R* external rotation torque. Negative values characterise the opposite motion (i. e. negative abduction torque designates an adduction moment)

### CONCLUSIONS

The study presented here provides a comprehensive data set of hip joint muscle functions which might be of interest for physical therapy, rehabilitation and further research.

**THE GAIT INITIATION PROCESS IN UNILATERAL LOWER-LIMB AMPUTEES STEPPING TO A NEW LEVEL**

<sup>1</sup>Steven F. Jones, <sup>1</sup>Peter C. Twigg, <sup>2</sup>Andrew J. Scally and <sup>3</sup>John G. Buckley

<sup>1</sup>School of Engineering, Design and Technology, <sup>2</sup>School of Health Studies and <sup>3</sup>School of Life Sciences, University of Bradford, Richmond Road, Bradford, West Yorkshire, UK; email: [s.f.jones1@bradford.ac.uk](mailto:s.f.jones1@bradford.ac.uk)

**INTRODUCTION**

Because feedback originating from cutaneous receptors within the foot and leg is only present unilaterally [1], or at best is available via re-mapped receptors within the stump [2], unilateral lower-limb amputees will need to adopt alternative balance and postural control strategies when initiating gait. Also, because amputees are taught to lead with their intact limb when stepping up and with their prosthetic limb when stepping down, they may employ a different gait initiation strategy for each stepping direction. The aim of the present study was to determine the balance and postural control adaptations used by unilateral lower-limb amputees when stepping up and when stepping down to a new level.

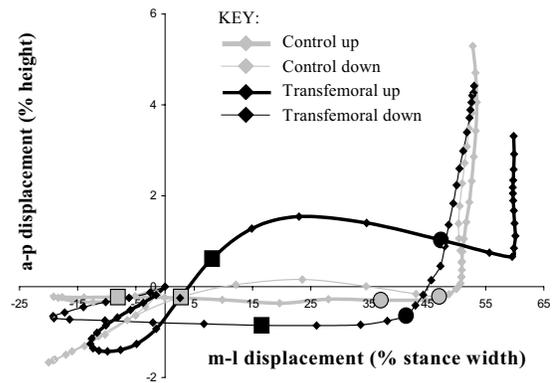

**METHODS**

Ten unilateral amputees (5 transfemoral and 5 transtibial) and 8 able-bodied controls performed single steps up and single steps down to a new level (73 and 219 mm). Amputee subjects stepped up leading with their intact limb and stepped down leading with their prosthesis.

Phase duration, a-p and m-l centre of mass (CoM) and centre of pressure (CoP) peak displacements and CoM peak velocity of the anticipatory postural adjustment (APA) and step execution (SE) phase were evaluated for each stepping direction by analysing data collected using a Vicon 3D motion analysis system. Data were analysed using a random effects population averaged model. Also, to highlight differences in CoM/CoP interactions between each group, data were compared qualitatively (exemplar, Figure 1).

**RESULTS AND DISCUSSION**

There were significant differences (in the phase duration, peak a-p and m-l CoP displacement, and peak a-p and m-l CoM velocity at heel-off and at foot-contact) between both amputee sub-groups and controls ( $P < 0.05$ ), but not between amputee sub-groups. These group differences were mainly a result of amputees adopting a different gait initiation strategy for each stepping direction (Table 1). In transfemorals this may have been a way, when stepping up, of ensuring the GRF vector was anterior of the knee joint centre; this would have helped to keep the knee of the prosthetic limb fully extended (locked). In transtibials it may have been a way to reduce the knee extensor moment, thereby reducing the force of the prosthesis against the distal end of the tibia. When stepping down (landing on the prosthesis) both amputee sub-groups adopted a ‘cautionary’ approach.

**Figure 1.** ‘Ensembled average’ CoP trajectories for transfemoral amputees vs. controls when stepping up to and down from the low step height. Distance between points represents movement speed. Data are shown from movement initiation up to swing limb foot-contact. □ and ○ indicates the instant of heel- and toe-off of the swing limb respectively.

**CONCLUSIONS**

Findings indicate the gait initiation process utilised by lower-limb amputees was dependent on the direction of stepping and, more particularly, by which limb the amputee led with. This suggests that the balance and postural control of gait initiation is not governed by a fixed motor program, and thus that an amputee will require time and training to develop alternative neuromuscular control and coordination strategies. These findings should be considered when developing training and/or rehabilitation programs.

**THE EFFECT OF A REFERENCE POSTURE ON THE RELATIONSHIP BETWEEN RELAXED CALCANEAL STANDING MEASUREMENT AND FRONTAL PLANE REARFOOT MOTION DURING WALKING IN PATELLOFEMORAL PAIN SYNDROME SUBJECTS**

Pazit Levinger and Wendy Gilleard  
 Southern Cross University, NSW Australia.  
 email: wgilleard@scu.edu.au

**INTRODUCTION**

The choice of a reference posture used in angular motion calculations may play an important role in finding a relationship between the static posture and rearfoot frontal plane of motion in a clinical population such as patellofemoral pain syndrome (PFPS). By using the relaxed standing as a reference posture <sup>1</sup>, a frontal plane deviation in the reference posture may mask any appearance of abnormal frontal plane rearfoot motion during walking. This study examined the relationship between rearfoot inversion/eversion during the stance phase of walking and the static relaxed standing measurement in females with PFPS and healthy controls and examined the influence of reference postures used when calculating these measures. Two reference postures were investigated: (1) Vertical Alignment between the rearfoot and the lower leg and (2) Relaxed Calcaneal Standing.

**METHODS**

Fourteen healthy and 13 females with PFPS were videoed barefoot during five walking trials using a four-camera (50Hz) motion analysis system. External markers attached to a tibia shell and the calcaneus measured peak inversion/eversion motion of the rearfoot relative to the tibia. Two reference postures were assessed: 1. Relaxed Calcaneal Standing posture and 2. Vertical Alignment i.e with the posterior calcaneus and lower leg vertically aligned. For Relaxed Calcaneal Standing reference posture, subjects stood relaxed in a self selected comfortable position. Vertical Alignment posture was achieved when the subjects elevated or lowered their medial longitudinal arch. While this posture was maintained the frontal plane alignment of the rearfoot relative to the tibia was recorded. For Vertical Alignment posture, to enable normalization of the study population to the same zero reference posture for inter-group comparison of the rearfoot relative to the tibia in the frontal plane, the vertical axis was rotated <sup>2</sup> through the individual's angle in the frontal plane previously recorded. All walking trial angles were calculated relative to both the Relaxed Calcaneal Standing and Vertical

Alignment postures. Pearson's Correlation was used to investigate the relationship between the Relaxed Calcaneal Standing and stance phase peak inversion and eversion when using the two reference postures.

**RESULTS AND DISCUSSION**

When using the Relaxed Calcaneal Standing reference posture a significant correlation was found between static relaxed standing measurement and maximum eversion in the control group only (Table 1). When using the Vertical Alignment reference posture, significant correlation was found in PFPS only for both maximum eversion/inversion (Table 1). Thus, indicating that with a more everted posture during relaxed standing there is more eversion and less inversion during walking. As subjects in the control group did not demonstrate an increased calcaneal eversion during static relaxed standing measurement, it is unlikely that these subjects would demonstrate abnormal foot function during walking. A mathematical relationship is therefore unlikely to be found. The relationship between the rearfoot static clinical measurement and dynamic function of the rearfoot during walking therefore may be present in a clinical population rather than healthy control subjects.

**CONCLUSIONS**

As the Relaxed Calcaneal Standing reference posture may eliminate the inherent compensated foot during dynamic foot function, the use of neutral posture may be necessary. The positive relationship found in the PFPS group between dynamic angular measure and static relaxed standing based on a neutral reference posture indicated that PFPS subjects the clinical rearfoot measurement relaxed standing can be used to explain the pattern of rearfoot motion during walking.

## Body Weight Support System Influence on the Patterns of Vertical Forces Applied to the Body

Li Li and Robin Cropper  
 Louisiana State University, email: [lli3@lsu.edu](mailto:lli3@lsu.edu)

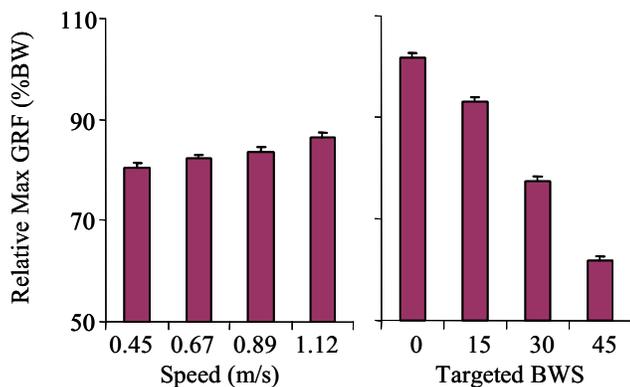

### INTRODUCTION

More and more physical rehabilitation related clinics are using some types of body weight support system (BWSS) in their practices. The use of the BWSS together with the repetition and consistent nature of walking on the treadmill makes the patient repeatedly practice the movement under controlled conditions. In addition to providing postural support, the body weight support system promotes coordination of the lower extremities, which traditional pre-gait training was unable to provide. Furthermore, the BWSS also helps to evaluate patients' gait without requiring the therapist to be at the patient's side to provide physical support. There is little information regarding how BWSS influence the actual gait pattern during treadmill walking. The purpose of this study was to examine how the BWSS influence the external forces at the vertical direction, and how the external forces were influenced by walking speed and the targeted body weight support.

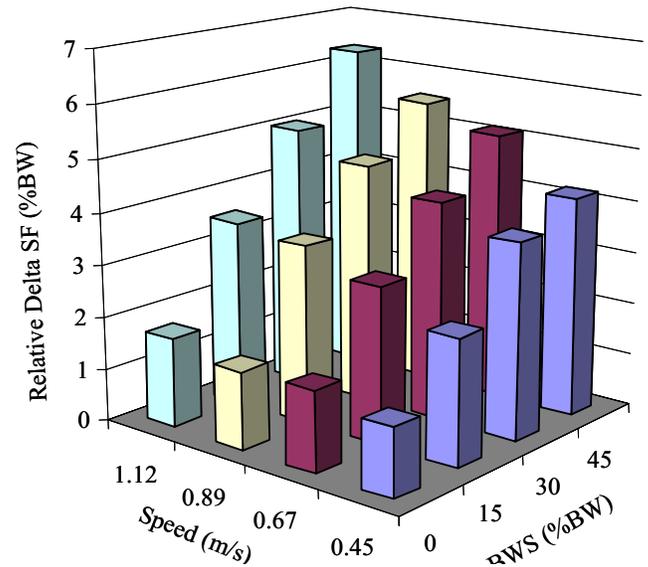

### METHODS

Sixteen college students have volunteered for the study. Their mean age (mean  $\pm$  SD) and body mass were  $22 \pm 2$  years old and  $63 \pm 11$  kg, respectively. The subjects were instructed to walking on a force platform embedded treadmill (Gaitway, Kistler, Amherst, NY, USA) with a body weight support system (Vigor, Stevensville, MI, USA). They were walking at four different speed (.45, .67, .89, and 1.12 m/s) combined with four different levels of targeted body weight support (BWS) at 0, 15, 30, 45 %BWS. The testing order was balanced to prevent any possible order effects. Vertical ground reaction forces were measured by the force plates embedded within the Gaitway treadmill. The actual body weight being supported was measured by a force sensor installed between the harness and the supporting structure of the BWSS.

Maximum vertical ground reaction forces (RMVGRF), maximum and minimum (RMAXSF and RMINSF) suspension forces were calculated relative to participants'

**Figure 1:** Maximum vertical ground reaction forces increases with walking speed and decreases with the amount of body weight being supported.

**Figure 2:** Body weight support amplifies the fluctuation of suspension forces larger than the proportion of body weight support. This influence was enhanced by greater walking speed.

body weight and expressed as percentage body weight (%BW). Two factor (speed X %BW) ANOVA with repeated measures were used to analyze the data.

### RESULTS AND DISCUSSION

The mean and standard error of mean (SEM) of RMVGRF are reported in **Figure 1**. RMVGRF increased with walking speeds ( $F_{3,45} = 512$ ,  $P < 0.001$ ) linearly ( $F_{1,45} = 50.3$ ,  $P < 0.001$ ). It decreased with the increase of the targeted BWS ( $F_{3,45} = 17$ ,  $P < 0.0001$ ) with both significant linear ( $F_{1,45} = 1518$ ,  $P < 0.001$ ) and quadratic ( $F_{2,45} = 16.3$ ,  $P = 0.0002$ ) trends. RMVGRF reduced from 101 to 92 %BW when %BWS increased from 0 to 15%, a reduction of approximately 9% BW. RMVGRF further reduced to 77 and 62 %BW (reductions of 15 %BW) when targeted BWS increased to 30 and 45%BW, respectively. RMAXSF ranged from 1.4 to 13.7 %BW and was influenced by both speed and %BWS (interaction,  $F_{9,135} = 2.01$ ,  $P < 0.05$ ). The greatest RMAXSF was observed with 45% BWS and walking at 1.12 m/s. The fluctuation (RMAXSF-RMINSF) of the suspension force is reported in **Figure 2**. The magnitude of this fluctuation changed from 1.3 %BWS, with the lowest speed and targeted BWS, to 6.3, with the highest level of speed and targeted BWS. The fluctuation was influenced by both speed and targeted BWS (interaction,  $F_{9,135} = 6.41$ ,  $P < 0.0001$ ).

### CONCLUSIONS

Body weight support system does not provide consistent lift to the body being supported. The fluctuation of suspension force was amplified with greater proportion of body weight support and greater walking speed.

## COMPARISON OF RECTIFIED AND UNRECTIFIED SOCKETS FOR TRANSTIBIAL AMPUTEES

<sup>1</sup> Jack R. Engsborg, <sup>2</sup> S. Wayne Sprouse <sup>1</sup> Mary L. Uhrich, <sup>2</sup> Barbara R. Ziegler and <sup>2</sup> F. Daniel Luitjohan

<sup>2</sup>Precision Prosthetics and Orthotics; email: engsbergj@nsurg.wustl.edu, web: [hpl.wustl.edu](http://hpl.wustl.edu)

### INTRODUCTION

The traditional strategy for fabricating a transtibial amputee (TTA) socket is based upon the assumption that the residual limb is not uniform in its ability to tolerate load.<sup>1</sup> Thus, the contours of the residual limb mold are modified by the prosthetist (i.e., rectified socket). We have investigated a new method of shaping the socket using alginate gel.<sup>2</sup> Except for a distal end pad, the mold is shaped to the contours of the patient's residual limb (i.e., unrectified socket). The purpose of this investigation was to objectively compare rectified and unrectified sockets in adults with a TTA.

### METHODS

Forty-three adults with a TTA participated (mean age 47±10 years, 36 males 7 females, height 176±8 cm, mass 84±17 kg). Subjects had mature residual limbs. Except for the socket shape, the prostheses were the same.

The prosthetist fabricated the rectified socket using the traditional method. The positive mold was made from a plaster cast and modified by filing down and building up different regions to account for the residual limb's inability to uniformly tolerate load. No more than three check sockets were permitted. In the unrectified socket fabrication process, the positive plaster mold was made using an alginate casting method. The subject placed his/her residual limb into alginate liquid and stood for approximately 5 minutes while the alginate gelled to a semi-solid state. The subject removed the residual limb from the gel leaving a negative mold. Plaster was immediately poured into the mold. This positive plaster mold was removed and very slightly smoothed with sanding screen. A distal end pad was included during socket fabrication, but no other modifications were made.

Subjects were tested after wearing the first randomly assigned socket for at least 4 weeks. They then wore the second socket and were tested after another 4 weeks. Data were collected: 1) from a gait analysis, 2) during a sub-maximal treadmill test (energy expenditure), and 3) from a Prosthetic Evaluation quality of life Questionnaire [PEQ].<sup>3</sup> After participation, the subject chose the socket he/she wished to have on the final prosthesis. Repeated measures ANOVA

**Table 1. Means and standard deviations ( ) for key variables.**

Socket	Gait Speed	P/NP VGRF ratio	Minimum stance knee flexion (deg)		VO <sub>2</sub>	PEQ Total	Final Socket Selection <sup>c</sup>
			P	NP			
	cm/s	%			ml/(kg*min)	%	
<b>Rectified</b>	125 (22)	95 (7)	11 (6)	11(5)	13.4 (2.3)	82 (11)	16
<b>Unrectified</b>	125 (22)	96 (6)	10 (5)	11 (6)	13.5(2.6)	81 (13)	25
<b>Able-bodied</b>	133 (17) <sup>a</sup>	100	4 <sup>b</sup>	4 <sup>b</sup>			

<sup>a</sup> Waters et al., 1988; <sup>b</sup> Murray et al., 1964; <sup>c</sup> Two subjects decided to use both sockets; P = Prosthetic leg; NP = Nonprosthetic leg; Maximum Vertical Ground Reaction Force [VGRF] ratio

and a Chi square test were used to determine if significant differences existed (p<0.05).

### RESULTS AND DISCUSSION

There were no significant differences for any of the variables (Table 1). The present study adds to the body of knowledge in at least two areas. First, there appears to be more than one paradigm for fitting a TTA socket. Despite the two different socket fabrication strategies, the results of the tests for gait, energy expenditure, the quality of life questionnaire (PEQ), and final socket selection were not different.

The second area is related to the simplicity of the alginate method. No shaping is done to the negative mold as it is applied to the residual limb, no modifications are made to the positive mold, and multiple check sockets are not needed. The omission of these steps saves time. The process may not require a prosthetist. The simplicity of the method could be valuable in third world countries where prosthetists and fabrication facilities are scarce or nonexistent. The simplicity of the method might also be beneficial to new amputees, since the effort associated with making a new socket is substantially reduced. Sockets could be fitted more frequently to better account for residual limb volume changes. The simplicity of the method could also save time in a typical prosthetic clinic.

### CONCLUSIONS

It is concluded that more than one paradigm exists for shaping prosthetic sockets, and the alginate method is simpler than the traditional method. The alginate method may be helpful in third world countries, permit more frequent socket changes for new amputees, and save time in the typical prosthetic clinic.

**INTRODUCTION**

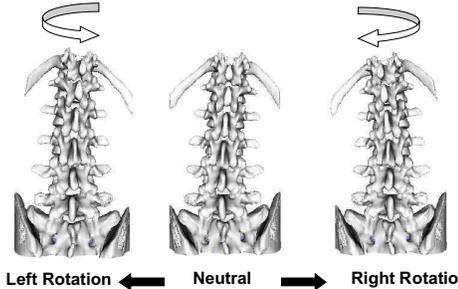

*In vivo* 3D kinematics of the lumbar spine during rotation has not been well evaluated by the conventional methods because of inaccuracy. Only *in vitro* studies reported quantitative data in 3D intervertebral motions. However, the lack of physiologic muscle activity makes the results of *in vitro* study impractical [1]. Peacy et al [2] attempted to document *in vivo* coupled motion with axial rotation using biplanar radiography but failed to accurately demonstrate complex coupled motion, because their methods depended greatly on subjective assessments by examiner in tracking bony landmarks on plain radiographs. Considering those facts, in order to evaluate accurately, we developed a 3D imaging system for the relative motion of individual vertebra *in vivo* and reported the kinematics of the cervical spine using this original method [3,4]. The purpose of this study was to evaluate *in vivo* 3D intervertebral motions of the lumbar spine during rotation.

**METHODS**

Ten healthy volunteers underwent 3D-MRI of the lumbar spine in 9 positions with 15° increments during trunk rotation using a 1.0-T imager. Relative motions of the lumbar spine were calculated by automatically superimposing a segmented 3D-MRI of the vertebra in the neutral position over images of each position using voxel-based registration. 3D motions of adjacent vertebrae were represented with six degrees of freedom by Euler angles and translations on the coordinate system defined by Panjabi, and visualized in animations using surface bone models.

**RESULTS AND DISCUSSION**

The mean axial rotation of T12/L1, L1/2, L2/3, L3/4, L4/5 and L5/S1 in maximum trunk rotation (56.1°) to each side was 1.3°, 1.6°, 1.5°, 2.0°, 2.1° and 1.7°, respectively. Coupled lateral bending of L1/2, L2/3, L3/4, and L4/5 according to axial rotation was 2.0°, 3.6°, 3.8°, and 1.9°, respectively in the

**Figure 1:** Coupled lateral bending with axial rotation was observed in the opposite direction as axial rotation from L1/2 to L4/5 level, in the same direction T12/L1 and L5/S1 level.

opposite direction and that of T12/L1 and L5/S1 was 0.9° and 0.8° in the same direction (Figure 1). Coupled flexion with axial rotation was observed (L1/2;1.0°, L2/3;1.5°, L3/4;1.5°, L4/5;1.2°, L5/S1;2.5°), while in thoracolumbar junction, extension was coupled with axial rotation (T12/L1;0.1°). These results are consistent with a previous *in vivo* study by Peacy et al (Table 1).

**CONCLUSIONS**

We investigated the 3D intervertebral motions of the lumbar spine during trunk rotation using a novel *in vivo* 3D motion analysis system, and this is a first report for the *in vivo* coupled motions with accuracy. This result will be helpful for the analysis of other lumbar kinematic abnormalities.

## PLANTAR PRESSURE DISTRIBUTION IN THE DIABETIC FOOT DURING PUSH-OFF: NUMERICAL SIMULATION USING THE P-VERSION OF THE FINITE ELEMENT METHOD

<sup>1</sup> Ricardo L. Actis, <sup>1</sup> Liliana B. Ventura, <sup>2</sup> Barna A. Szabo  
<sup>3</sup> Paul K. Commean, <sup>3</sup> Kirk E. Smith, <sup>3</sup> Donovan J. Lott and <sup>3</sup> Michael J. Mueller

<sup>2</sup> Center for Computational Mechanics, Washington University  
<sup>3</sup> Washington University School of Medicine

### INTRODUCTION

The most common cause for diabetic plantar ulcers is excessive plantar pressures in the presence of sensory neuropathy and foot deformity. Proper footwear fitted with a total contact insert (TCI) or TCI with a metatarsal pad are the standard of care for reducing forefoot plantar pressures, although research has not clearly indicated optimal size, location and material properties of orthotic components. One key aspect for achieving this goal is to develop three-dimensional computational models of the foot for enhancing and evaluating a broad range of orthotic device components.

### METHODS

In modeling a complex system like the human foot, it is necessary to make simplifying assumptions regarding topological details, constitutive laws, material properties and boundary conditions. Such simplifications are acceptable only if they do not significantly affect the data of interest, in this case the pressure distribution in the regions of the metatarsal heads at push-off. In our investigation, the complexity of the model was increased hierarchically, until the computed pressure distribution was no longer affected by the restrictive assumptions incorporated in the simpler models. The three-dimensional internal structure of the foot was determined using data from SXCT [1], while the reference pressure distribution was measured using the F-scan system [2] with the pressure sensor taped to the subject's foot.

We considered the structure of the foot to be characterized by bone, cartilage, flexor tendon, fascia and tissue. The material properties for the bones were assumed to be linear. Cartilage with linear elastic material properties was included between bones to simulate the flexibility of the connection between bony structures. Muscles and fat were lumped into a single material type (tissue) with nonlinear elastic properties obtained for each individual using an indenter testing device [3]. Fascia and flexor tendon were also incorporated into the model and the properties were assumed to be linear elastic.

### RESULTS AND DISCUSSION

Figure 1 shows the section taken through the second metatarsal of the foot in the push-off position of a 63 year-old, male, diabetic subject, with a history of a plantar ulcer. Simpler models were constructed by removing the cartilage between phalanges, or by not including the fascia or the flexor tendon in the model in various combinations.

The p-version FEA program StressCheck was used for the numerical simulation. The influence of the different modeling considerations in the pressure distribution in a region 15 mm proximal and 20 mm distal from the center of the metatarsal

head was compared with the one obtained with the F-scan system.

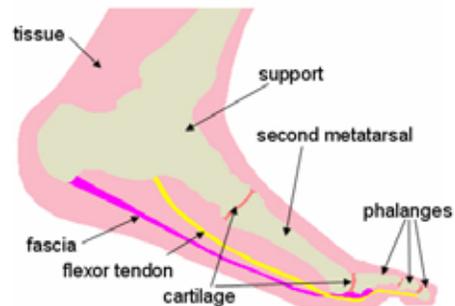

Figure 1: Segmentation for the most complex model considered for analysis.

Predicted and measured pressure distributions were compared in four patients with diabetes and a history of neuropathic ulcer and the agreement was found to be generally good (typically within 12% error in L2 norm) as shown in Figure 2.

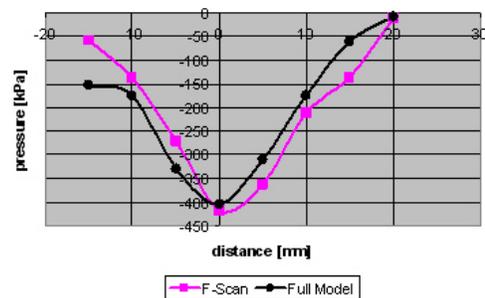

Figure 2: Measured (F-Scan) and computed (Full Model) pressure distributions under the 2<sup>nd</sup> metatarsal head.

### CONCLUSIONS

Initial validation of our computational model is reasonable and future work will seek to determine optimal characteristics of orthotic devices and footwear to distribute plantar pressures evenly.

## EFFECT OF ARM USE ON HEAD AND TRUNK SEGMENT MOTION WHEN RISING FROM A CHAIR

<sup>1</sup>Wendy Gilleard, <sup>2</sup>Jack Crosbie and <sup>2</sup>Richard Smith

<sup>1</sup>Southern Cross University, Lismore Australia

<sup>2</sup>University of Sydney; email: wgilleard@scu.edu.au

### INTRODUCTION

Dynamic analyses during rising to stand from a chair, of the head, and trunk segments have been rarely investigated. Much of the research to date has examined a constrained motion in that the subjects rise with arms folded and kept as close to the body as possible. The use of the upper limbs, however, have been found to significantly affect movement strategies for the body's centre of mass (COM) [1]. When the arms were restricted the COM had a reduced forward displacement, and lowered horizontal and vertical linear momentum [2]. Although a significant difference was found in the ankle joint displacement [1], the effect of restricted arm motion on the motion of the head and trunk segments is unknown. The purpose of the study was to investigate the peak displacement of the head, thoracic and pelvic segments for a rise to stand from a chair when using the arms in a natural manner in comparison to crossed across the chest.

### METHODS

Twelve female subjects rose to stand for three trials of each condition: in a natural manner and with the arms crossed across the chest. Data were collected using an 8 camera motion analysis system and a height adjustable chair set to 110% of fibular head to floor distance while standing. Retro-reflective markers were used to define the pelvis, thoracic and head segments with three markers per segment. Sagittal plane displacement of the head, thoracic and pelvic segments, and the thoracolumbar and cervicothoracic spines were calculated throughout the motion. Relative motion of the head and thoracic, and thoracic and pelvic segments were taken as the cervicothoracic and thoracolumbar spines respectively. A single marker each on the right humeral lateral epicondyle and greater tubercle allowed sagittal plane range of motion (ROM) of the right shoulder to be investigated. Paired Students t-tests were used to compare peak displacements.

### RESULTS AND DISCUSSION

The head, thoracic and pelvic segments first flexed forward and then extended as the rise continued. During the pre-extension phase the thoracic segment flexed more than the pelvis causing relative thoracolumbar flexion. The thoracic segment flexion then slowed relative to the pelvic segment causing thoracolumbar extension for the remainder of the movement. For the cervicothoracic spine, the head and thoracic segment initially flexed forward, however the head segment forward flexion was less than that for the thoracic segment causing relative cervicothoracic spine extension prior to seat off. Extension of the thoracic segment then resulted in flexion of the cervicothoracic spine as the rise continued.

There was no significant difference between a natural and constrained rise to stand for the peak flexion of the thoracic

and pelvic segments and the thoracolumbar spine (Table 1). The head segment was significantly more flexed during a constrained rise and the cervicothoracic spine was consequently less extended (Table 1). It is possible that greater head forward rotation was utilized to compensate for the reduced input to upper body momentum from the restricted arm motion of a constrained movement.

During a natural rise all subjects first flexed the shoulder prior to seat-off, then extended. During a constrained rise some subjects followed a similar movement pattern while others first extended the shoulder joint then flexed ie the upper limbs were brought closer into the trunk. The former strategy was similar to the motion used when the upper limbs were free to move and therefore may be considered a curtailed normal motion in an attempt to minimize the shoulder flexion motion. The latter strategy, however, is opposite in direction to the overall movement. Bringing the upper limbs closer to the chest may, however, increased the thoracic segment forward flexion and therefore the upper body centre of mass was brought forward and assisted in compensating for the loss of normal upper limb contribution to the overall movement. No differences were noted between the thoracic segment peak flexion for a free or constrained rise, however the differences may have been masked by the use of the two shoulder motion strategies within the group.

As would be expected there was a significant increase in shoulder joint ROM with a natural arm movement (Table 1). During the constrained motion, despite requesting the arms be held against the chest, motion still occurred at the shoulder joint as previously reported [1]. Forward upper limb motion was therefore thought to be concomitant to lower limb motion during rising to stand [1].

Table 1: Peak displacement (°).

	Natural	Constrained	p
Head	3.35 ± 4.75	8.39 ± 6.46	0.005*

### INTRODUCTION

Chronic motor deficits in the upper limb are a major contributor to disability following stroke. Although it has been shown that improvements in motor function are most likely in the initial three months following stroke, recent research has demonstrated that gains in motor function can occur with intensive motor learning-based rehabilitation in people even many years post-stroke (1,2). The purpose of this study was to investigate the effect of robotic therapy on motor function and robot derived performance measures in patients with chronic, severe upper extremity (UE) impairments after stroke.

### METHODS

As part of a larger study, 15 individuals with chronic, severe UE paresis (Fugl-Meyer <15) after stroke (> six months post onset) performed 18 sessions of robot-assisted UE rehabilitation consisting of goal-directed, planar reaching tasks over a period of three weeks. The robot testing involved the subject reaching for each target, clockwise around the circle pattern without movement assistance from the robot. A movement began when the speed first became greater than 2% of the peak speed and ended after the speed dropped and remained below the 2% threshold again. Kinematic variables derived from the robot evaluation data were aiming error (mean absolute angle between actual direction and a straight line between start and target), mean speed (total distance traveled over total movement duration), peak speed, mean-to-peak speed ratio (mean speed divided by the peak speed which has previously been used as a metric of movement smoothness) (3) and movement duration. Outcome measures included the Fugl-Meyer Assessment, the Motor Power Assessment, the Wolf Motor Function Test, and five robot derived measures (aiming error, mean speed, peak speed, mean: peak speed ratio and movement duration). Student t-tests evaluated differences between baseline and post-

treatment outcomes ( $p \leq 0.05$ ). Cohen's  $d$  was calculated to determine the effect size of treatment on the clinical and robot-derived measures.

### RESULTS AND DISCUSSION

Training produced statistically significant improvements from baseline to discharge in the Fugl-Meyer and Motor Power Assessment scores, and in the quality of motion (quantified by a reduction in aiming error and movement duration with an increase in mean speed and speed ratio variables-Table 1). These findings provide evidence that persons with severe UE paresis long after stroke onset can demonstrate reduced motor impairment with a brief, intense robot-assisted intervention. Previous research showed that early in recovery post-stroke, a patient's movements are composed of short, sporadic sub-movements with a series of peaks and valleys. As subjects improved with training, reaching movements became smoother with fewer stops, suggesting improved inter-joint coordination and neural recovery processes (3). In the present study, large treatment effects for the robot-derived measures indicate that movement accuracy and smoothness did improve with practice in these individuals with severe, chronic paresis.

### CONCLUSIONS

Our findings indicate that robot-assisted UE rehabilitation can reduce UE impairment and improve the quality of motion in patients with severe UE impairments from chronic stroke.

### INTRODUCTION

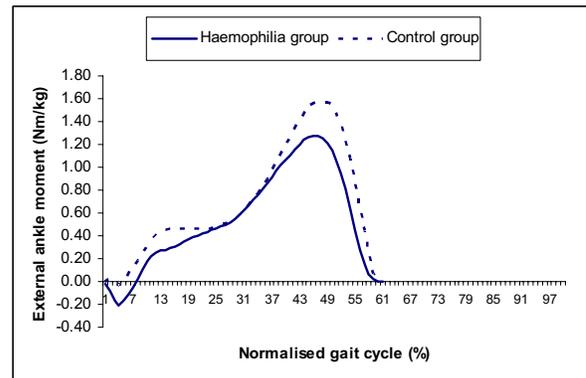

Haemophilia is an inherited bleeding disorder in which the blood does not clot normally and is characterised by spontaneous and traumatic musculoskeletal bleeding into joints and muscles [1,2]. This paper provides for the first time a description of the gait pattern of children with severe haemophilia who have experienced at least 3 episodes of bleeding into the ankle joint and how this gait pattern deviates from normal gait.

### METHODS

Five children, (mean  $\pm$  SD, age  $10.02 \pm 2.82$  years) with severe haemophilia and 4 age-matched normal controls, ( $10.05 \pm 2.53$  years) volunteered to take part in this pilot study. Kinematic and kinetic data for the pelvis and lower limb was collected using a 10 camera Vicon 612 Motion Analysis System (Oxford Metrics Ltd, UK) and 2 Bertec Force Platforms (Model MIE Ltd, Leeds, UK). The force platforms were positioned in the middle of a 7.5 metre walkway and subjects walked barefoot at a self-selected comfortable walking speed. Mean and peak angles and moments in the gait cycle, initial contact and toe off were analysed for differences between the haemophilia subjects and healthy matched controls using the Mann-Whitney U independent t-test for non parametric data. Spearman rank correlations were also used to investigate the relationship between an established clinical haemophilia assessment score [3] and gait changes.

### RESULTS AND DISCUSSION

Children with a history of bleeding into the ankle joint adopted a gait pattern which differed from that of normal children. Table 1 shows the differences seen in the ankle and knee angles, while Figure 1 shows the significantly greater ankle plantarflexion ( $p=0.01$ ) and smaller ankle dorsiflexion moments ( $p=0.05$ ). Significantly greater knee flexion moments ( $p=0.01$ ), greater knee flexion angles ( $p=0.01$ ), smaller ankle adduction angles ( $p=0.02$ ), smaller ankle external rotation angles ( $p=0.04$ ) were also found in children with haemophilia.

**Figure 1.** Graph showing sagittal plane ankle moments

Gait velocity was significantly reduced ( $p=0.02$ ) in the children with haemophilia with no apparent relationship was shown between velocity and the clinical haemophilia score [3].

Increased flexion and loading at the knee joint may lead to greater susceptibility to haemarthrosis and disability at the knee joint for these children that may affect lower limb muscle function.

### CONCLUSIONS

The results of this pilot study demonstrate that children with haemophilia alter their walking possibly to protect and decrease the load and forces at the ankle joint and increase the load and forces at the knee joint that may affect lower limb muscle function. The subtle gait abnormalities in these children were undetected in either clinical examination or the clinical assessment score.

## DOES GRAVITY INFLUENCE THE STRUCTURE OF CHAOTIC GAIT PATTERNS?

### INTRODUCTION

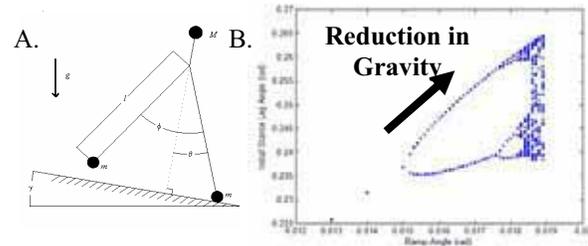

Historically, fluctuations in human gait patterns were considered to be random noise or error in the output of the nervous system. However, recent investigations have suggested the contrary and have indicated that such fluctuations have a chaotic structure. A chaotic structure means that the lower extremity kinematics fluctuate from one step to the next with a deterministic pattern. Changes in the chaotic structure appear to be related to the health and stability of the neuromuscular system [1].

The Lyapunov exponent (LyE) is used to quantify the chaotic structure present in a gait pattern [1]. The LyE for a periodic signal (e.g. sine wave) is zero, which indicates no separation in the attractor's trajectory. Alternatively, the LyE for Gaussian noise is positive (+0.469) and indicates divergence in the attractor's trajectory. Hence, a time series that has LyE value close to +0.469 indicates instability, while a time series with LyE close to zero indicates stability or possibly rigidity. The chaotic structure of human locomotion lies somewhere between these two extremes [1]. The degree of stability of a gait pattern can be explored from a chaotic perspective by investigating whether the LyE value shifts towards one of the two extremes, as the independent variable is scaled.

The influence of Newtonian forces on gait stability is not yet completely understood. Here we explore the influence of gravity on chaotic gait stability with a passive dynamic bipedal walking model and experiments where humans walk at simulated micro-gravities.

### METHODS

The passive dynamic bipedal model consisted of two rigid legs connected by a frictionless hinge at the hip (Figure 1; [2, 3]). Slight increases in the ramp angle of the walking surface promote a cascade of bifurcations that lead to a chaotic gait pattern [2, 3]. Different micro-gravities were simulated by decreasing gravity in the model's governing equations at the respective ramp angles. A custom built body weight suspension (BWS) system was used to experimentally explore the influence of various micro-gravities on human chaotic locomotion. The BWS supplied a constant upward force on the subject's center of gravity via a cable-spring-winch system that was monitored with a force transducer [4]. Five subjects walked on a treadmill for two minutes under the following micro-gravities: 1.0, 0.9, 0.8, and 0.7 Gs. LyE values were calculated for the sagittal plane joint angle time series of the hip, knee and ankle with an embedding dimension of five.

**Figure 1.** The passive dynamic walking model (A). Bifurcation map of the model's locomotive patterns for the respective ramp angles. Chaotic gait exists when ramp angle is greater than 0.1839 radians [3] (B).

### RESULTS AND DISCUSSION

Our simulations provided initial evidence that gravity influences the structure of chaotic gait patterns. As gravity was reduced the model's gait bifurcated towards a chaotic gait pattern that was closer to instability (Figure 1B). The human experiments complemented our model's simulations (Table 1). In general, as gravity was reduced the human chaotic gait patterns shifted towards instability. A significantly increasing linear trend was found for the ankle joint ( $p = 0.03$ ) where lower micro-gravities were associated with less stability. Hence, changes in gravitational forces influenced the performance of the ankle for maintaining stable gait patterns. Although a reduction in gravity is associated with a more economical gait [4], our results indicate that it is not associated with a more stable gait. Alternative counter measures for maintaining a stable gait in micro-gravity environments (i.e. the Moon or Mars) may be necessary. Our future investigations will reveal how changes in other Newtonian forces influence chaotic gait patterns.

## AN ARTIFICIAL NEURAL NETWORK THAT EXPLORES THE ROLE OF SENSORY INFORMATION FOR LEARNING THE NEURAL CONNECTIONS FOR LOCOMOTION

Max J. Kurz and Nicholas Stergiou

HPER Biomechanics Laboratory, University of Nebraska at Omaha, Omaha, NE

E-mail: mkurz@mail.unomaha.edu Web: <http://www.unocoe.unomaha.edu/hper/bio/home.htm>

### INTRODUCTION

Human and animal research has indicated that the spinal locomotive neural network wiring is depended on appropriate sensory information. Previous studies have indicated that the loading of the stance limb and the stretch of the hip musculature during the terminal portion of the stance phase are important sensory variables for establishing the spine's neural network connections [1]. However, it is currently not clear which sensory information has a greater influence on the neural wiring. Such difficulties may lie in the fact that it is difficult to completely separate the sensory variables in humans and animals [1].

Artificial neural networks (ANN) are composed of biologically inspired neuron like elements that can be use to model the behaviors of spinal neural networks [2]. ANN are unique because they can be used to simulate the influence of isolated sensory inputs on the wiring of the network's neural connections. Here we use ANN models to further elucidate the effect of limb loading and hip joint sensory information on the development of the neural connections for locomotion.

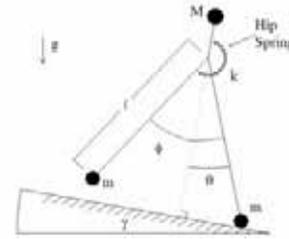

### METHODS

Two feed-forward ANN models that each had six input neurons, three hidden neurons and one output neuron were developed. Neurons between each layer were connected via a series of weighted edges ( $w_{ij}$ ). Each  $i$ th neuron had an input value  $x_i$  and an output value  $y_i = g(x)$ . A sigmoid function  $g(x) = (1 + e^{-x})^{-1}$  was used to determine the excitation of the neuron where the value of  $x$  was given by  $x_i = \sum w_{ij}y_j$ . Through training, the two ANNs learned the proper neural connections to supply a toe-off impulse that actively powered a passive dynamic bipedal model [3] (Figure 1). The simple bipedal model consisted of two rigid legs connected by a torsional spring at the hip. The potential energy of the spring (PE) at the terminal portion of each step was used to model the hip joint sensory information (Eq 1).

$$PE = \frac{1}{2} k (\phi - \theta)^2 \quad \text{Equation 1.}$$

Where  $k$  was the stiffness of the hip spring,  $\theta$  was the stance leg angle, and  $\phi$  was the swing leg angle.  $k$  was constant in the bipedal model and was set at  $0.01 \text{ s}^{-2}$ . The loading force (LF) of the new stance leg was modeled by geometrically calculating the force that occurred at heel-contact (Eq 2).

$$LF = \text{Cos}(90 - \theta) * \dot{\theta} \quad \text{Equation 2.}$$

**Figure 1.** The passive dynamic bipedal walking model [3] that the ANN learned to actively power with a toe-off impulse.

The six sensory inputs for each ANN model were as follows:  $\theta$ ,  $\dot{\theta}$ ,  $\phi$ ,  $\dot{\phi}$ , PE and LF. The first ANN model was not provided with LF, but was provided with PE. The second ANN model was not provided PE, but was provide LF. The initial edge weights for the neurons that were common between the two ANN models were the same. Sensory nodes that were not used in the respective ANN models were set to null. A total of 120,000 training epochs were used in this investigation. The ANN model with the largest mean square error at the respective epochs had a worse learning curve.

### RESULTS AND DISCUSSION

Our simulations indicate that the PE and LF played different roles for learning the locomotive neural connections. The ANN trained with LF had a faster initial learning rate. However, as the training exceeded 3000 epochs, the amount of learning that occurred with the LF did not substantially change. Sensory information provided by the PE resulted in a more gradual learning curve and did not influence the neural connections as drastically during the early learning stages. However, as the number of epochs increased, the learning curve from the ANN trained with EPE eventually surpassed the performance of the ANN model trained with LF. These simulations suggest that during the early portions of locomotor training, sensory information from the loading forces may be vital to accelerate the learning process. However, as training progresses, hip joint sensory information may provide more meaningful information for the establishment the neural connections for stable locomotion. These simulations provide insight on the interactive role of these two sensory variables for learning the locomotive neural connections.

### INTRODUCTION

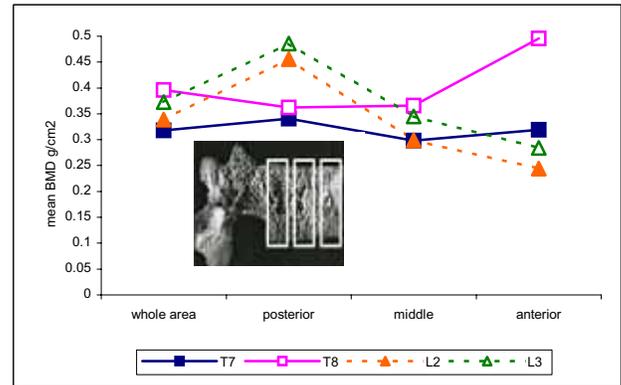

Vertebral fractures are considered to be one of the hallmarks of osteoporosis. The aetiology of these fractures remains unclear, since individuals with comparable bone mineral density (BMD) measured with DXA demonstrate different prevalence rates for fracture. Previous research has demonstrated heterogeneity of bone properties within the vertebral centrum [1]. The distribution of BMD within the centrum may help to explain the aetiology of these fractures. The majority of vertebral fractures occur in the mid thoracic spine. However, DXA cannot be used to measure BMD in this area *in vivo*. The aims of the current study were to determine if regional differences exist in BMD in thoracic and lumbar vertebrae and to determine if the patterns of BMD distribution were similar between these levels.

### METHODS

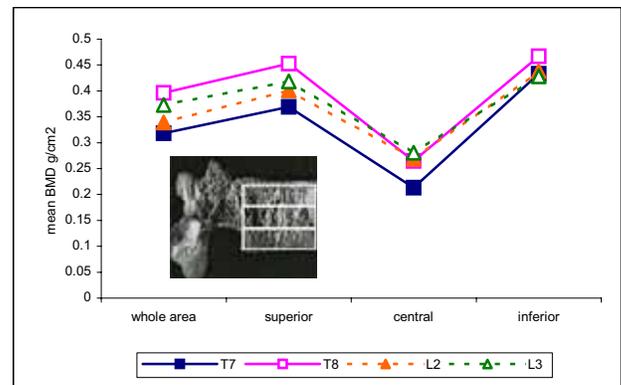

Six embalmed cadaver spines were used for this study (mean 81yrs). Antero-posterior and lateral DXA scans were performed on each specimen with an Hologic QDR4500 densitometer. The lateral scan was used to calculate areal BMD for the whole vertebral body and in 3 subregions orientated longitudinally (posterior, middle, anterior) and 3 subregions orientated transversely (superior, central, inferior) for T7, T8, L2 and L3. Vertebral areas were defined manually by the raters and were of equal size in each plane for each vertebral body. Differences in subregional BMD were examined using a one way repeated measures ANOVA with 4 levels set *a priori* (whole vertebral body with 3 subregions) to prevent *post hoc* comparisons of overlapping subregions.

### RESULTS AND DISCUSSION

A significant difference in subregional BMD was found for T7, T8, L2 and L3 ( $p < 0.05$ ). Post hoc tests revealed significantly lower BMD in the central zone of T7, T8, L2 and L3 ( $p < 0.05$ ) (see Figure 1), and in the anterior zone of L2 and L3 ( $p < 0.05$ ) (see Figure 2). Volumetric BMD, rather than areal BMD may be a better variable for longitudinal subregion comparisons due to differences in their 3D geometry. These results confirm the ability of a commonly used clinical tool, DXA, to detect differences in BMD within vertebral bodies. The results also demonstrate that interpretation of whole vertebral BMD in isolation can obscure potentially important regional density characteristics. The lower BMD observed in the central subregion of thoracic and lumbar vertebrae may help to explain the mechanisms underlying vertebral crush fracture. Compared to the other subregions, the central subregion contains minimal cortical bone and maximal trabecular bone. Therefore, this area may be of significant clinical importance given that trabecular bone is known to be

**Figure 1:** Mean BMD for whole vertebral area and posterior, middle and anterior (transverse) subregions at T7, T8, L2, L3

**Figure 2:** Mean BMD for whole vertebral area and superior, central and inferior (longitudinal) subregions at T7, T8, L2, L3

the dominant structural component in resisting compressive load [2]. Significantly lower BMD in the anterior zone of lumbar vertebrae may help to explain a mechanism for vertebral wedge deformity. Figure 2 illustrates a similar density distribution profile between thoracic and lumbar vertebrae. Given that thoracic BMD cannot be measured *in vivo* with DXA, it may be plausible to assume that measurement of lumbar subregional BMD could be used to predict thoracic BMD distributions.

### CONCLUSIONS

DXA can be used to detect differences in BMD within vertebral bodies. These differences may explain, in part, mechanisms underlying vertebral fracture. Intra-vertebral density profiles show some similarities between thoracic and lumbar vertebrae.

### INTRODUCTION

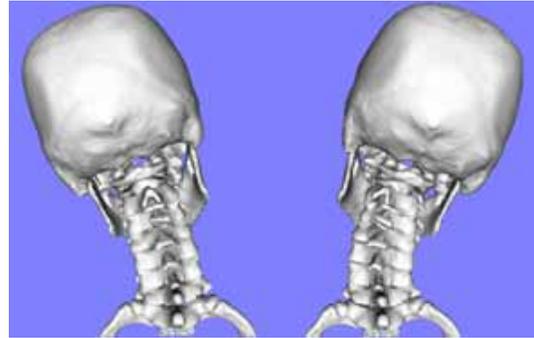

*In vivo* 3D motion of the cervical spine has not been documented until now, since they are too complicated to follow with conventional radiographs or CT. Although *in vitro* studies using cadaver specimens reported data on the cervical 3D motion, it might not actually reflect physiological motion due to the lack of tonus of musculature. Moreover, understanding 3D motions with only a numerical combination of rotations and translations was difficult. To overcome these problems, we developed a quite unique *in vivo* 3D motion analysis system using 3D-MRI, which can make the 3D animation of the motion, and reported the kinematics of the cervical spine in rotation using this system [1,2]. The purpose of this study is to demonstrate for the first time *in vivo* 3D intervertebral motions of the cervical spine in lateral bending.

### METHODS

Twelve healthy volunteers underwent 3D-MRI of the cervical spine in 7 positions with 10° increments during lateral bending using a 1.0-T imager. Relative motions of the cervical spine were calculated by automatically superimposing a segmented 3D-MRI of the vertebra in the neutral position over images of each position using volume registration, which is a method to determine relative position between two volume images by means of superimposing two 3D images to make each voxel value coincide each other maximally, and correlation coefficient was used as similarity measure. Three-dimensional motions of adjacent vertebrae were represented with six degrees of freedoms by Euler angles and translations on the coordinate system defined by Panjabi, and visualized in animations using surface bone models reconstructed with marching cubes algorithm in the Visualization Toolkit (VTK). As we have already declared, the accuracy of this system was 0.24° for flexion-extension, 0.31° for lateral bending, and 0.43° for axial rotation. Mean absolute translational error was 0.52 mm for superoinferior translation, 0.51 mm for anteroposterior translation, and 0.41 mm for lateral translation. [1].

### RESULTS AND DISCUSSION

Mean maximum lateral bending of the cervical spine to one side in maximum head lateral bending (30.3°) was 1.9° at Oc/C1, 1.6° at C1/2, 3.7° at C2/3, 3.5° at C3/4, 3.3° at C4/5, 4.3° at C5/6, 5.7° at C6/7, and 4.1° at C7/T1. C6/7 showed the larger lateral bending than other levels ( $P < 0.05$ ). Coupled axial rotation in the opposite direction to that of lateral

**Figure 1: Cervical motion in left and right lateral bending**

bending was observed in the upper cervical levels (Oc/C1, 0.2°; C1/2, 17.1°), while in the subaxial cervical levels, it was observed in the same direction as lateral bending except for C7/T1 (C2/3, -0.9°; C3/4, -1.8°, C4/5, -1.1°, C5/6, -1.2°; C6/7, -0.8°; C7/T1, 0.4°). Coupled flexion-extension was small at all vertebral levels ( $< 1.1^\circ$ ).

In our previous study, we documented that axial rotation of subaxial cervical spine accompanied lateral bending in the same direction as axial rotation. Thus, coupling patterns of subaxial cervical spine were similar between lateral bending and axial rotation. We speculated that the upper cervical spine compensates for subaxial ipsi-axial rotation during head lateral bending by contra-axial rotation.

We could investigate *in vivo* 3D motions of the cervical spine accurately, quantitatively and non-invasively with the use of 3D-MRI to eliminate radioactive exposure. Our system facilitates not only mathematical descriptions of 3D motions, but also 3D visualization of this information, and enabled us to easily understand complicated coupled motion of the cervical spine.

### CONCLUSIONS

1. We developed a novel *in vivo* 3D motion analysis system and succeeded in disclosing the *in vivo* coupled motions of the cervical spine in lateral bending for the first time.
2. Lateral bending increases as the cervical level goes downwards, and coupled axial rotation of subaxial cervical spine is in opposite direction to that of the upper cervical spine.

### **INTRODUCTION**

Experimental measurement of ligament strain behaviour is made challenging by the complex geometry of the tissue and the often-invasive nature of measurement devices. There is no gold standard for measurement method, and no direct comparison of the results obtained by implantable and non-invasive measurement methods has ever been made. In this study, two methods for measuring ligament strain *in vitro* were compared: non-invasive optical measurement (OPT) and the implantation of a differential variable reluctance transducer (DVRT).

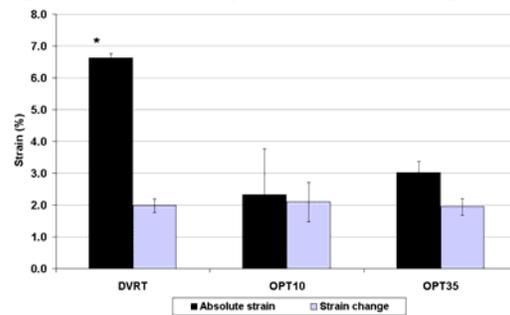

### **METHODS**

The equivalence of DVRT and OPT was first tested in an isolated tensile test. The anterior fibres of the medial collateral ligament (MCL) were resected from 8 bovine stifle (knee) joints and mounted in a Zwick Z10 materials testing machine. A sub-miniature DVRT (Microstrain, VA.) was implanted parallel to the primary ligament fibre direction. Two optical markers were painted at the extremities of the device (10 mm apart), and also at each end of the ligament (35 mm). A uniaxial tensile load was applied to the ligament at 30 N.s<sup>-1</sup> until 150 N of force was reached. The ligament was allowed to relax to 30 N of internal force and the process repeated for 3 cycles. Each ligament was tested 4 times at 10 min intervals. DVRT data was sampled at 50 Hz using a National Instruments BNC connector block and 12-bit DAQ card. The optical markers were tracked using a 50 Hz digital camcorder and SIMI Motion Analysis software. Tensile strain ( $\epsilon$ ) was computed using reference MCL length at 0 deg ( $l_0$ ) and instantaneous length ( $l$ ):  $\epsilon = (l - l_0)/l_0$ . Strain change ( $\Delta\epsilon$ ) was defined as the difference between peak and minimum strain.

Quasi-static tests were conducted using intact bovine stifle joints (n=3). Ten cycles of passive flexion and extension were applied via a customised rig at 30 deg s<sup>-1</sup> between 0-120 deg. DVRTs were implanted in mid-anterior and proximal-anterior MCL fibres. Corresponding optical markers were tracked with two calibrated 50 Hz cameras and SIMI software was used to reconstruct the 3D coordinates using DLT methodology.

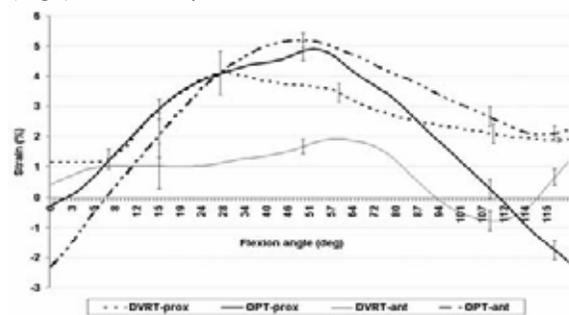

### **RESULTS AND DISCUSSION**

There was no significant difference in  $\Delta\epsilon$  detected using OPT or DVRT during cyclic uniaxial tension testing (p=0.184) (Fig.1). The DVRT did report significantly mean higher absolute strain (p=0.001).

**Figure 1: Isolated test results**

The DVRT results for quasi-static tests may have been influenced by the motion of deep MCL fibres around the device. OPT can measure only surface strains (Fig2), which may account for the difference in results.

**Figure 2: In vitro test results**

### **CONCLUSIONS**

While no significant difference for measurements of  $\Delta\epsilon$  using DVRT or OPT was shown, practical issues with each method were identified. Ideally for strain measurement in soft tissues, a non-invasive method will be utilized to preserve the ligament structure. However this is unsuitable for intra-articular or multi-layered ligaments. The sensitivity of OPT is dependent on the chosen gage length. Implantable devices should be small and compliant enough to avoid abnormal tissue deformation, and caution used in interpretation of results from multi-layered ligaments.

## ACUTE EFFECTS OF INTRAMUSCULAR APONEUROTOMY ASSESSED BY FINITE ELEMENT MODELING

### INTRODUCTION

Aponeurotomy is a surgical technique executed to correct functional problems due to contractures occurring secondary to spastic paresis. Despite its clinical potential importance, the mechanical mechanism of this intervention is not clearly understood. The goal of this study was to investigate this mechanism using finite element modeling. The specific point addressed is modeling changes in lengths of sarcomeres within aponeurotomy muscle due to intramuscular myofascial force transmission [e.g., 1].

### METHODS

Finite element modeling of extensor digitorum longus muscle of the rat [see 2 for a description of the model] was performed for two conditions (1) intact and (2) aponeurotomy.

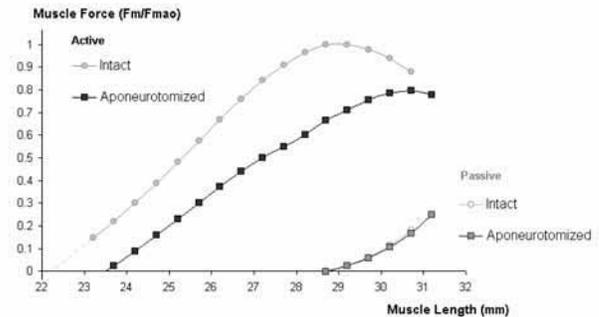

In surgery, aponeurotomy is performed by cutting the intramuscular aponeurosis transversely to its line of pull. In the present study, proximal aponeurotomy was modeled by disconnecting the common nodes of two neighboring aponeurosis elements located in the middle of the proximal aponeurosis of the modeled muscle. Earlier experiments on dissected aponeurotomy rat muscle showed after isometric lengthening that below the location of the intervention a progressive tear occurred in the intramuscular connective tissue in the direction of muscle fibers [3]. As a consequence, a gap opened between the cut ends of the aponeurosis. Present modeling of aponeurotomy muscle allows such a gap and a limited tear.

### RESULTS AND DISCUSSION

Major changes in muscle length-active force characteristics were found (Figure 1) after aponeurotomy (1) both active slack length (by approximately 1.2 mm) and optimum length (by 2.0 mm) shifted to higher muscle lengths and the length range of force exertion increased. (2) Muscle active force decreased (e.g., optimum force decreased by 21%).

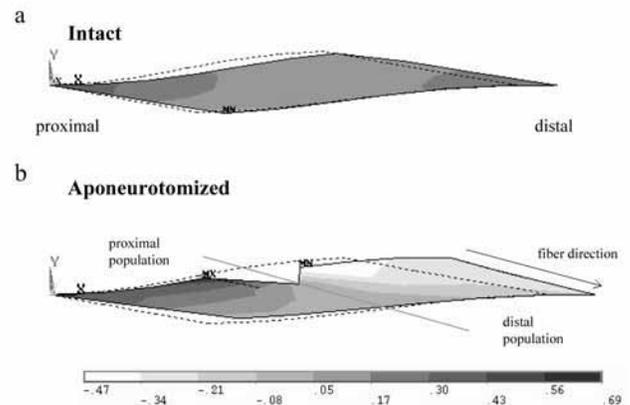

On lengthening after aponeurotomy, two cut ends of the proximal aponeurosis were separated by a gap and tearing of intramuscular connective tissue along the fiber interface caused the muscle to be divided into a proximal and a distal population of muscle fibers.

Unlike the fairly homogeneous strains in the fiber direction of the intact muscle (Figure 2a), for the aponeurotomy muscle myofascial force transmission was shown to lead to a major strain distribution and thus sarcomere length distributions. Note the contrasting effects for the two fiber populations (Figure 2b): (1) In the distal population (fibers with no myotendinous connection to the muscles' origin), sarcomeres were much shorter than the ones of the proximal population (fibers with intact myotendinous junction at both ends) (2) From proximal ends of muscle fibers to distal ends, the serial distribution of sarcomere lengths varied from the lowest length

**Figure 1:** The isometric muscle length-force characteristics of modeled intact and aponeurotomy EDL muscles.

to higher lengths in the distal population and in a reversed manner in the proximal population. Such distributions of sarcomere lengths explain the shifts in muscle active slack and optimum lengths. Muscle force reduction was explained primarily by the short sarcomeres in the distal population. However, fiber stress distributions showed that majority of the sarcomeres (even in the distal fiber population) still contribute to muscle force: myofascial force transmission prevents them from shortening to their active slack lengths.

**Figure 2:** Distributions of fiber direction strain within modeled (a) dissected intact and (b) dissected aponeurotomy EDL muscles at high muscle length.

### CONCLUSIONS

We conclude that the mechanism mechanically determining the effects of aponeurotomy is dominated by myofascial force transmission. Accounting for the general characteristics of sarcomere length changes shown in the proximal and distal populations of muscle fibers may help the surgeon make a more controlled decision on the location of the intervention.

### INTRODUCTION

When a standing person initiates a step, the center of pressure (COP) shifts in the medio-lateral (ML) direction towards the supporting foot and in the anterior-posterior (AP) direction backwards [1,2]. Apparently, COP cannot be shifted beyond the available dimensions of the support area. However, humans can initiate a step forward after balancing for a short time on a support that is very narrow in the AP direction. One possibility is that people use horizontal forces to move the body forward; this would violate the balance and initiate a fall of the body in the required step direction.

We investigated mechanical and electromyographic (EMG) events prior to making a step and their changes associated with changes in the AP dimension of the support area. We hypothesized that a constraint on possible COP shifts will be associated with increased changes in the horizontal force and with changed neural strategies reflected in changes in EMG signals from the leg muscles.

### METHODS

Eight healthy subjects participated in the experiment. A force platform recorded the reactive forces and moments. Disposable electrodes were used to record the surface EMG of the following muscles from both sides of the body: tibialis anterior (TA), soleus (SOL), rectus femoris (RF), and biceps femoris (BF), and of the rectus abdominis (RA) and erector spinae (ES) on the left side of the body.

The subjects stood barefoot on the force plate or on one of two specially constructed wooden boards with the same horizontal dimensions as the force plate. One of the boards was fitted with a narrow beam on the undersurface (3.3 cm wide, 5.3 cm high). This board was placed over the force plate such that its narrow dimension was in the AP direction. In other trials, a similar wooden board was placed on the top ridge of a triangular metal wedge (4.9 cm in height, 91.4 cm in length). The wedge was placed on the force plate such that its upper ridge ran horizontally in the ML direction. The subjects performed self-paced steps from quiet stance while standing on either the force plate, or the board fitted with the narrow beam ("narrow support"), or the board resting on the upper ridge of the wedge ("ridge support").

All trials were aligned by the first visible shift of the moment about the vertical axis (time zero,  $t_0$ ). After alignment, sets of trials performed by the same subject, with the same leg, in the same condition were averaged. Changes in the background EMG were quantified using rectified signals integrated over 100 ms intervals starting 300 ms prior to  $t_0$  and ending 300 ms after  $t_0$ . COP shifts and changes in the force in the AP

direction ( $F_x$ ) were quantified within the interval  $\{-300 \text{ ms}; +300 \text{ ms}\}$  with respect to  $t_0$ .

### RESULTS

Stepping from the force plate was associated with COP shifts towards the support foot and backwards and an increase in  $F_x$  acting forward on the subject. Stepping from the "narrow support" led to smaller AP COP shifts. Stepping from the "ridge support" was associated with very small COP shift in AP direction, smaller COP shifts in ML direction, and larger  $F_x$  changes (Fig. 1). There was a general increase in the level of activation of leg and trunk muscles during stepping from the "narrow support" and "ridge support". Such differences in the activity of ankle extensors were seen in the stepping leg only at the beginning of the preparation period and in the supporting leg over the whole time interval of analysis.

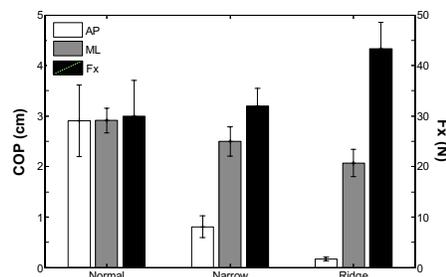

Fig. 1 Shifts of the COP (AP-white bars; ML-grey bars) and  $F_x$  (black bars) averaged across the subjects.

### DISCUSSION AND CONCLUSIONS

Our observations demonstrate the existence of alternative mechanical strategies that can be used in a task-specific manner to initiate a step. We suggest a hypothesis that a subjectively perceived postural instability may prevent the subjects from using the most common method of step initiation, namely a COP shift backwards. Then, an alternative strategy of an increased  $F_x$  change is discovered. If this is correct, training of persons who show an impaired ability to initiate a step may benefit from providing feedback on the horizontal force and practicing on a surface with high friction.

## EFFECT OF STRETCH OR SHORTENING AMPLITUDE ON SUBSEQUENT ISOMETRIC MUSCLE FORCE

Sharon Bullimore, Tim Leonard, Dilson Rassier and Walter Herzog  
Human Performance Lab, Faculty of Kinesiology, University of Calgary, Canada.  
email: [sbullimore@kin.ucalgary.ca](mailto:sbullimore@kin.ucalgary.ca)

### INTRODUCTION

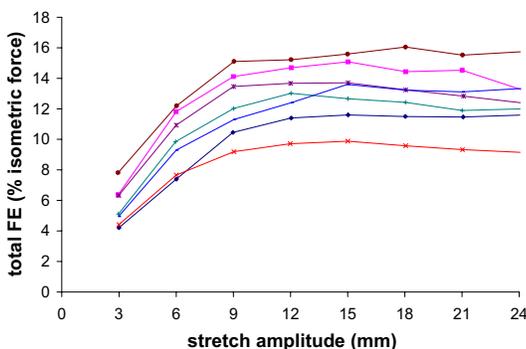

It is well-known that the force that a muscle can develop during an isometric contraction is influenced by its contractile history [1]. Active stretch increases the force developed during a subsequent isometric contraction ('force enhancement', FE), while active shortening decreases subsequent isometric force ('force depression', FD). The mechanisms underlying these two phenomena are not well understood, although a number of possibilities have been suggested and the causes of FE and FD are thought to be different [2]. In order to be able to choose between proposed mechanisms, it is necessary to have a detailed knowledge of the characteristics of FE and FD. Here we determine the relationship between the amount of FE or FD and the amplitude of stretch or shortening, respectively. We hypothesised that the nature of this relationship would be different for FE and FD.

### METHODS

The experiments were performed using seven cat soleus muscles, as described previously [3]. The muscles were isolated *in situ* and were activated through electrical stimulation of the tibial nerve. An isometric force-length relationship was obtained and optimal length was defined as the length at which active muscle force was highest.

The isometric force developed at a muscle length 9mm longer than optimal length was measured following active stretches of between 3 and 24mm. Total FE was defined as the difference between the isometric force developed after stretch and the force during a purely isometric contraction at the same length. Passive FE [4] was defined as the difference between passive force following a stretch trial and passive force following a purely isometric trial at the same length.

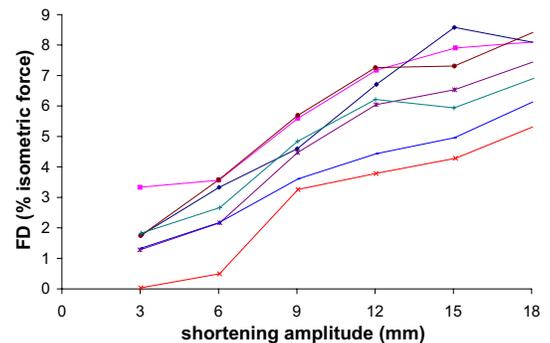

The isometric force developed at a muscle length 9mm shorter than optimal length was measured following shortening contractions of between 3 and 18mm. FD was defined as the difference between the isometric force developed after shortening and the force during a purely isometric contraction at the same length.

**Figure 1:** Relationship between total force enhancement (FE) and stretch amplitude in seven cat soleus muscles.

### RESULTS AND DISCUSSION

As hypothesised, FE and FD showed different relationships to stretch/shortening amplitude. Total FE increased with stretch amplitude up to approximately 9mm stretch and then levelled off (Figure 1). Passive force enhancement increased with stretch amplitude up to approximately 9mm, then decreased. The relationships of total and passive FE to stretch amplitude were well-fitted by third order polynomials ( $R^2 > 0.96$ ). FD increased with shortening amplitude without levelling off (Figure 2). The relationships of FD to shortening amplitude were well-fitted by second order polynomials ( $R^2 > 0.94$ ). These differences in the behaviour of FE and FD support the hypothesis that they arise from different causes. Any mechanism that is proposed to explain FE must be able to account for the fact that FE increases with stretch only over a limited range of amplitudes before the effect appears to become saturated. Further investigation of the passive component of FE is important for understanding this behaviour.

**Figure 2:** Relationship between force depression (FD) and shortening amplitude in seven cat soleus muscles.

## IMPLANTATION OF A TOTAL KNEE ARTHROPLASTY PROSTHESIS IMPOSES ABNORMAL STRAIN ON LOCAL SOFT TISSUES

<sup>1</sup>Rochelle L. Nicholls, <sup>2</sup>Ben Jeffcote and <sup>1,2,3</sup>Markus S. Kuster

### INTRODUCTION

Tension in the medial and lateral collateral ligaments is used to regulate joint tightness during total knee arthroplasty (TKA). Despite accurate ligamentous balancing during surgery, many patients experience restricted range of motion after TKA compared to a healthy knee joint [1]. The reason is not well understood. Preoperative range of motion and altered kinematics such as lack of femoral rollback has been suggested [2]. Our hypothesis was that the medial and lateral ligamentous structures and the extensor envelope are tensioned beyond physiological limits after TKA and prevent further flexion. However, the demands placed on these passive tissues are unknown. The purpose of the present study was to investigate the effect on the soft tissue envelope of TKA implantation.

### METHODS

Six fresh cadaver knee joints were tested. A novel method was developed for assessment of soft tissue tension in the intact and TKA knee (Fig.1). A stainless steel rod was inserted in the intra-medullary canal of the tibia and secured using 3 screws through the tibial shaft. At the proximal end, the tibial slope was adjustable via a series of inclined plates connected to the inner rod. A 40 N spring was enclosed in the distal aspect of the device below the inner rod to maintain tibio-femoral contact. To insert the device in the knee, 8 mm of bone was resected beneath the tibial plateau (10 mm below the proximal surface). The plateau was then screwed to the bearing surface of the device. Vertical displacement of the device during motion represented the variation in tibio-femoral forces generated by the collateral ligaments and soft-tissue envelope.

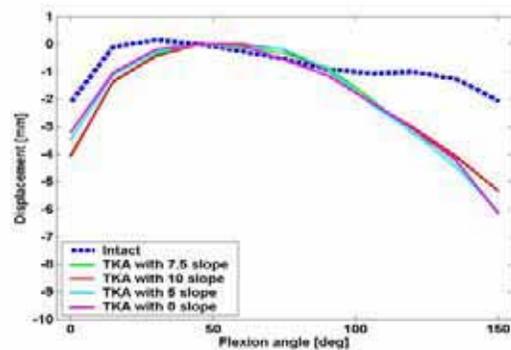

**Figure 1: Custom device to assess soft tissue tension.**

Each knee was mounted in a customized passive motion rig with the femur secured horizontally. A 40 N spring sutured to the quadriceps tendon mimicked the effects of passive muscle tension. Motion was applied in 15 deg increments from 0 to 150 deg flexion. The procedure

was repeated after implantation of an LCS rotating platform TKA prosthesis (De Puy), in which the tibial trial was screwed to the bearing surface of the device. Measurements were obtained using the (standard) 7.5 deg tibial slope, and with 0, 5, and 10 deg slopes.

### RESULTS AND DISCUSSION

The device position at 45 deg flexion was selected as the zero reference point as minimal tissue tension was expected in mid-flexion. Fig.2 illustrates the displacement of the tibial plateau by soft tissue tension in the natural and TKA knee relative to this point. In both cases, the joint becomes looser (displacement approaches zero) between 0-45 deg. This is markedly more so after TKA. In the intact knee, the joint remains within 1 mm of the zero position until 135 deg and within 2 mm throughout the full range of motion. After TKA, greater soft tissue tension in flexion was indicated by a mean 6 mm displacement at 150 deg. Changing the slope of the tibial plateau did not approach the behaviour of the intact knee.

**Figure 2: Example of tibial plateau displacement.**

### CONCLUSIONS

TKA prosthesis implantation imposes additional demands on passive soft tissues beyond 110 degrees and particularly at the extremes of range of motion. This explains the extension deficits and lack of flexion in many knee joints after TKA, and has implications for prosthesis design and implantation technique.

### INTRODUCTION

The Royal Marine (RM) Commando training course is believed to be the longest basic infantry training course in the world. Tibial stress fracture is one of the most common injuries in this population [1]. Lower limb structure, joint range-of-movement, gait kinematics and kinetics have all been associated with this injury in different populations, however conclusions are ambiguous. The intensity, frequency and duration of the physical stress experienced during RM training may exacerbate potential risk factors not identified in other populations. The aim of this study was to identify biomechanical differences between RM Commando recruits with, and without tibial stress fracture history.

### METHODS

Twenty RM recruits; ten with tibial stress fracture history and ten controls participated in the study. All recruits had failed to complete the full 30-week commando training course due to injury or illness. Recruits were passed fit to return to training at the time of assessment. Measures of lower limb structure and range-of-movement were taken by a state registered podiatrist. Barefoot and shod running gait kinematics (120Hz; Peak Performance Technologies Inc., CO), and ground reaction forces (960Hz; AMTI, MA) were collected. Coordinate data were reconstructed using the procedures of Cole et al [2]. Movement data were referenced to a standing neutral trial.

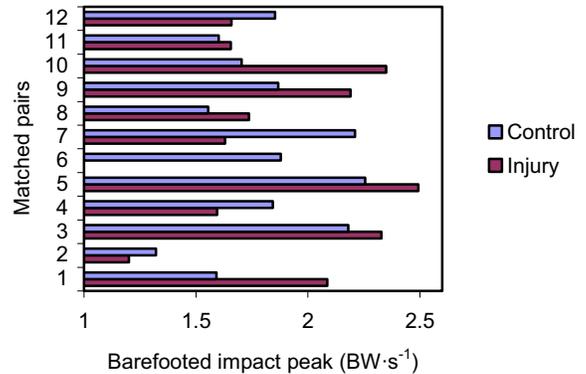

All data were analyzed using the Wilcoxon signed rank test for matched pairs ( $P \leq 0.05$ ). Twelve tibia with stress fracture history were identified in the injury group, each of these limbs were paired with a limb from the control group. Recruits were matched for the number of weeks of the full training course they completed prior to injury or illness.

**Table 1:** Selected measures of lower limb structure, barefoot (BG) and shod (SG) running gait (mean  $\pm$  SD; \*  $p < 0.05$ ).

		Tibial stress fracture	Controls
Medial hip rotation (deg)		26.6 $\pm$ 5.5	32.1 $\pm$ 10.1*
GRF impact peak time (sec)	BG	0.012 $\pm$ 0.004	0.017 $\pm$ 0.007*
	SG	0.028 $\pm$ 0.005	0.026 $\pm$ 0.005
Peak subtalar eversion (deg)	BG	5.5 $\pm$ 3.3	4.6 $\pm$ 4.7
	SG	6.0 $\pm$ 3.5	7.3 $\pm$ 3.5

### RESULTS AND DISCUSSION

The reduced passive medial rotation of the hip ( $p < 0.05$ ; Table 1) observed in the stress fracture group is suggestive of greater hip retroversion, this is consistent with previous findings [3]. Hip retroversion is believed to result in limited subtalar

**Figure 1:** Individual (subject paired) GRF impact peaks.

pronation during gait [4], however this is not supported by the running gait data. During standing hip retroversion results in a supinated foot [4]. This may have masked differences in gait kinematics between the experimental groups because of the defined neutral position employed.

The vertical ground reaction force (GRF) impact peak occurred significantly earlier in the tibial stress fracture group during barefoot running ( $p < 0.05$ ; Table 1), but not during shod running ( $p > 0.05$ ). Large variation in measured variables within the study groups contributed to no other significant differences between the groups. Figure 1 illustrates the variation observed in barefoot impact peak values, this is typical of many of the other variables measured. Evidently no cut-off point can be identified between individuals at high and low risk of tibial stress fracture.

### CONCLUSIONS

Limited medial rotation of the hip is associated with tibial stress fracture injury. This may be related to increased retroversion of the hip and subsequent implications upon gait. The vertical GRF impact peak time may also be important in tibial stress fracture development, however findings were not consistent between barefoot and shod conditions.

## COMPARISON OF STATIC AND DYNAMIC BIOMECHANICAL MEASURES IN MILITARY RECRUITS WITH AND WITHOUT A HISTORY OF THIRD METATARSAL STRESS FRACTURE

<sup>1</sup>Sharon Dixon, <sup>1</sup>Mark Creaby, <sup>2</sup>Kate McNally and <sup>3</sup>Jonathon Palmer  
<sup>1</sup>School of Sport and Health Sciences, University of Exeter, Exeter, EX1 2LU, UK.

 email: [s.j.dixon@exeter.ac.uk](mailto:s.j.dixon@exeter.ac.uk), web: <http://www.exbirt.co.uk>

### INTRODUCTION

For Royal Marines in training, the third metatarsal is the most common site for stress fracture occurrence [1]. Previous evidence regarding factors contributing to stress fracture development is conflicting [2,3], possibly due to the lack of differentiation between stress fracture sites. It has recently been demonstrated that the third metatarsal is less able to withstand horizontal than vertical loads [4], suggesting horizontal loading may be important in development of this injury. The present study compares static anatomical and dynamic biomechanical variables for Royal Marine recruits with and without a history of third metatarsal stress fracture.

### METHODS

Ten Royal Marine recruits with a history of third metatarsal stress fracture were matched with control subjects with no previous stress fracture. Selected static variables, including subtalar neutral position, ankle dorsi-flexion and forefoot varus, were measured to describe the anatomy of the lower limb. Each subject also performed running trials in the laboratory wearing military boots. Synchronized ground reaction force and kinematic were collected for 10 trials for both sides of the body. Force plate data were collected at 960 Hz using an AMTI force plate (AMTI, Massachusetts, USA), and three-dimensional kinematic data at 120 Hz using a Peak realtime system (Peak Technologies, USA). For each running trial, peak ankle dorsi-flexion, rearfoot eversion and knee flexion were identified. Horizontal ground reaction force (GRF) was characterized using the peak resultant horizontal force magnitude (contributed to by the anterior/posterior and medial/lateral force components) and the angle of application of this force during braking and propulsion. Application angle was defined as the angle of the resultant horizontal force relative to the sagittal plane, with a negative angle indicating a medially applied force. A matched-pairs Wilcoxon test was used to detect significant differences between the study groups, using data for the stress fracture side for the injury subjects and the same side for each matched control ( $p < 0.05$ ).

### RESULTS AND DISCUSSION

No significant differences in static anatomical variables were identified between study groups ( $p > 0.05$ ). Both static and

dynamic ankle dorsi-flexion were lower for the stress fracture group (Table 1), but differences were not significant. During running, rearfoot eversion was found to occur significantly earlier for the stress fracture group than for the matched controls ( $p < 0.05$ , Table 1), suggesting an increased time spent loading the forefoot. No significant differences were identified in peak magnitude of horizontal braking or propulsive force, but the peak horizontal braking force was directed significantly more medially for the stress fracture group ( $p < 0.05$ , Table 1). This suggests a difference in horizontal loading of the foot at this time. Since the third metatarsal is more vulnerable under horizontal than vertical loading [4], this may have implications regarding the mechanism of this injury.

### CONCLUSIONS

The measurement of dynamic biomechanical data has highlighted variables associated with third metatarsal stress fracture, indicating the importance of dynamic measurements when investigating risk factors for this injury. The earlier peak eversion, together with the difference in horizontal loading direction during the braking phase, suggest a difference in loading of foot structures that may contribute to this stress fracture development and thus warrants more detailed investigation.

## DEVELOPMENT OF A COMPUTER APPLICATION TO CALCULATE CYCLISTS FRONT AREA IN STUDIES ABOUT AERODYNAMICS

<sup>1,2</sup> Felipe Pivetta Carpes, <sup>1</sup>Mateus Rossato, <sup>2</sup>Alexandre Dias da Silva and <sup>1</sup>Carlos Bolli Mota

### INTRODUCTION

Aerodynamic studies are usually accomplished in the wind tunnels. In the cycling, variables as aerodynamics drag coefficient, surface of the object, front area, were found in the literature [2,3,4,5] and are necessary for the calculations about aerodynamic of the cyclist and/or equipments. Limitations related to this calculation are found. For example, the front area has been considered as constant, and relative at 18% of the total corporal surface obtained by prediction equations [1]. The aim of this study was to propose a method to calculate the cyclist front area through tools of images processing, with the development of a computer application, searching to provide results that can be used in the analysis of aerodynamics in cycling.

### METHODS

The first step in the development of the computer application is to determine how to obtain the necessary information. For the development of the computer application the IDL 6.0 (Research Systems Inc.) was used, allowing the work with different forms of data, through computational mathematics. One of the causes of the choice of the IDL was his characteristic multi-platform, facilitating its use in many operating systems. To compile the computer application is only necessary the installation of an IDL Virtual Machine (Virtual IDL Machine – freeware - [www.rsinc.com](http://www.rsinc.com)), don't depending of the installation or acquisition of software. Inside of the possibilities of images processing, the second step went verify which would bring a better result. Thus, the computer application was developed based in the image segmentation, with the Roberts operators, the oldest and simple algorithm of detection of borders, using a matrix 2x2 to find the changes in the directions x and y through the Roberts mask (Figure 1).

$$\begin{matrix} \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} & \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \\ G_x & G_y \end{matrix}$$

Figure 1: Roberts mask

With the mask, if the calculated magnitude is larger than the smallest entrance value (defined in agreement with the nature and quality of the image processed), the pixel is considered, or not, be part of a border. The small size of the mask for the

operator of Roberts is easy to implement, and also fast to calculate. The analyses are very sensitive to the image noise. After image segmentation, a method for the calculation of the area is necessary, because the image didn't possess defined dimensions. The third step involved the use of an object of well-known dimensions, photographed with the cyclist, and that supplied parameters for the space calibration in meters.

### RESULTS AND DISCUSSION

The tests were accomplished with digital pictures obtained with photographic camera Nikon Coolpix 885 and the computer application presents the necessary characteristics to the front area analysis, with easy use. Using the commands options in the graphic interface of the computer application, the user follows the necessary steps for the analysis. After, the results with image information could be record in a text file for posterior analysis.

### CONCLUSIONS

In summary, the computer application has success in the front area calculation and showed an applicable methodology to the cycling, many influenced and dependent of the aerodynamics, as the cyclist body position and equipments or accessories.

## IN-SHOE PRESSURE ANALYSIS DURING *AERO JUMP* IN DIFFERENT CADENCES

Juliana Koehler Ribeiro, Gabriela Fischer, Felipe Pivetta Carpes & Carlos Bolli Mota  
 Biomechanics Laboratory, Federal University of Santa Maria, Brazil  
 julianakr@uol.com.br

### INTRODUCTION

The *Aero Jump* is a gym modality with aerobics characteristics, realized with movements and jumps above a little trampoline (figure 1).

**Figure 1:** Little trampoline of *Aero Jump*

The quantitative description of biomechanical aspects of the human movement is related to the forces that cause the observed movement, as the repercussions in the analyzed phenomenon [2]. The ground reaction forces investigation and the distribution of dynamic pressure in the foot surface, provide important knowledge about the characteristics of the mechanical overload on the human body, in static and sporting situations [1]. The popularizing of the physical activity, besides the benefits for the promotion and maintenance of the health can cause a consequence: injuries [3]. The purpose of this study was to describe the distribution of dynamic pressure during five movements of *Aero Jump* accomplished in different cadences: 132 bpm (beats per minute) and 145 bpm.

### METHODS

The sample was composed by three female (age between 18 and 23 years old, average height of 1.69 m and average weight of 602.66 N), with experience in the *Aero Jump*. The acquisition data was realized by F-Scan version 3.821 (Tekscan, Inc.) and little trampoline *Physicus*<sup>®</sup> (Physicus, BRA), with dimensions of 20 cm (height) and 96 cm (diameter), supporting until 1500 N. The acquisition frequency selected was 120 Hz, during five seconds to each trial.

**Table 1:** Peak pressure ( $g/cm^2$ ) in different cadences.

Movement	Cadence 132 bpm		Cadence 145 bpm	
	Right foot	Left foot	Right foot	Left foot
Basic	2583.4	2221.31	2984.48	1864.26
Double punchinello	2590.08	1961.9	2930.22	1642.88
Simple punchinello	2311.27	1712.61	2962.57	1708.6
Double twist	2373.95	1756.58	2082.67	1728.47
Simple twist	2594.67	1911.07	2157.9	1884.65

selected movement was: basic, double punchinello, simple punchinello, double twist and simple twist. Each subject repeats three times the movements, in each cadence investigated. The all intervals of support were included in the descriptive statistical analysis.

### RESULTS AND DISCUSSION

According to table 1, the pressures in the right foot were larger than in the left foot in all movements and in both cadences, varying from 12.7% for the movement simple twist until 43.9% for the movement double punchinello, both in the cadence of 145 bpm. In the movements basic, double punchinello and simple punchinello, the larger pressures was observed in the cadence of 145 bpm. For the double twist and simple twist the larger pressure was observed in the cadence of 132 bpm.

### CONCLUSIONS

The results suggest that when cadence increases an increase in the pressure was observed for movements basic, double punchinello and simple punchinello. For movements double twist and simple twist was observed a decrease in pressure according to cadence increased. In summary, the movements of *Aero Jump* realized in elevated cadences don't have a linear relationship with the increase in the pressure.

### INTRODUCTION

Tumors that affect the distal femur and/or the proximal tibia require a resection of the knee joint, which may be reconstructed with modular prostheses. It is reported that current treatment achieves long-term, disease-free survival rates around 60% [1, 2]. Until now, patient activity after tumor prostheses was assessed with questionnaires which do not provide objective and quantitative information about patients' activity in daily living. Thus, the present study assessed the activity patterns of patients with portable measurement devices. Furthermore, the relationship between clinical gait parameters and activities of daily living is unclear.

### METHODS

From a larger sample of patients with successful prosthetic treatment, a subgroup of 22 subjects (14 male, 8 female) volunteered. Their mean age was  $35 \pm 18$  years, the follow-up ranged from 2 to 17 years (mean  $6 \pm 4$  yrs.). The tumor was located in the distal femur (n=18) or the proximal tibia (n=4). Clinical outcome was assessed with MSTS and TESS score.

Two measurement devices were applied: The Dynaport® ADL monitor (McRoberts, Den Haag, NL) uses three uniaxial accelerometric sensors and is able to distinguish between different modes of activity, i.e. lying, sitting, standing, walking and cycling. The system is worn around the waist, the third sensor in a strap around the left thigh. The second system is the SAM® Step Activity Monitor (Cyma Inc., Seattle, OR), a 2-dimensional accelerometer that counts and stores steps for several weeks in daily profiles.

The patients were instructed how to handle the devices before taking them home, older patients were visited at home. On the first measurement day, both devices were worn simultaneously from getting up until going to bed. The following six days, the SAM was worn alone.

Data of a clinical gait analysis was available for 14 subjects. In these cases, relations between the number of steps (SAM), activity categories (ADL-Monitor) and main gait parameters (e.g. gait speed, maximum knee flexion) were analyzed.

### RESULTS AND DISCUSSION

Three ADL-Monitor measurements had to be excluded due to a handling error. The predominant activity "sitting" accounted for  $53.7 \pm 15.4\%$  of the total time, followed by standing ( $27.4 \pm 15.6\%$ ), locomotion ( $9.7 \pm 5.4\%$ ) and lying ( $8.2 \pm 6.3\%$ ). Only 0.2% of the data could not be classified.

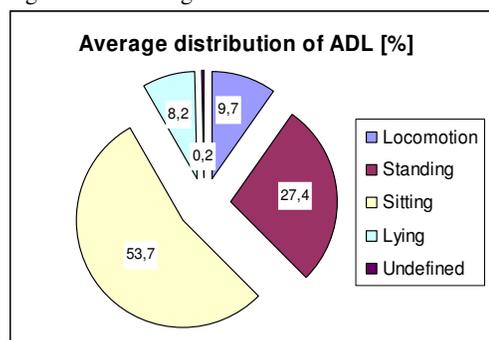

The SAM counted an average of  $4786 \pm 1770$  (Min: 2045, Max: 8135) gait cycles per day which extrapolates to 1.75 million gait cycles per year. These numbers of gait cycles were similar to hip and knee patients assessed in a different study using identical methods, but were slightly lower

compared to a group of patients with well functioning hip arthroplasty [3].

Regarding the distribution of daily activities, the activity level of the selected patients was similar to patients with limb salvage surgery and superior to an amputation group reported from the Netherlands [4].

No correlation was found between the number of gait cycles and the clinical scores, age or follow-up of the subjects, whereas the clinical scores (MSTS:  $24.7 \pm 3.8$  out of 30, TESS:  $83.6 \pm 15.3$  out of 100) were nearly identical to tumor patients assessed by Brown in 2002 [2].

If the right knee was affected, the number of steps correlated inversely to the right step length ( $r = -0.78$ ,  $p = 0.7$ ). This trend was not seen if the left knee was affected and related to the step length of the left leg.

**Fig. 1:** Average distribution of activities of daily living (ADL-Monitor, n=19)

### CONCLUSIONS

Overall, the patients showed a fairly good activity level, whereas strong inter-individual differences were detected, given that the most active subject performed the fourfold number of gait cycles compared to the least active subject. The weak correlations between the clinical gait parameters and the activity level suggest that an estimation of patients' activity from clinical gait parameters is not solid. Instead, objective devices should be used for a reliable assessment of patients' activities of daily living.

### INTRODUCTION

With modern technology, it is possible to assess and analyze human activities precisely in laboratory settings. However, there is an increasing demand to acquire information about physical activities of subjects under free-living conditions. Spatio-temporal gait parameters can be assessed based on a three-dimensional accelerometer attached to the lower trunk [1]. Until quite recently the measurement systems that are needed for obtaining these acceleration signals were rather bulky and heavy. Recently, the DynaPort MiniMod (McRoberts B.V., The Netherlands) was developed. This miniature device includes three orthogonally mounted accelerometers and it can be used for monitoring human posture and gait parameters. In order to become a useful tool for the assessment of daily activities and gait parameters of children, the system ought to be able to discriminate single steps and to determine the walking distance from the acceleration signals.

### METHODS

Group 1: 20 healthy children (aged 3 to 16 years) walked four times 40 meters for the detection of steps in an indoor environment, with no obstacles nearby, at the University Hospital of Muenster. An additional distance, blinded for the analyzer of the data, was walked for detection of walking distance.

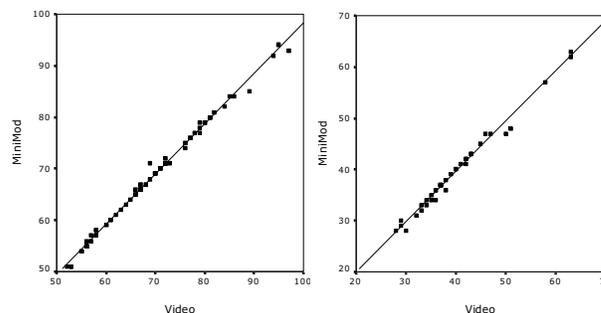

Group 2: 20 CP children (aged 5 to 17 years) from the outpatient clinic of the Orthopedic Department walked twice a distance of 20 meters for the detection of steps on a floor in the hospital. Like in group 1, an additional distance was walked for detection of walking distance. The degree of limitations caused by CP was assessed using a self-made classification scale.

Both groups were videotaped for counting steps and distance. Accelerometer signals of the lower back were measured by the MiniMod, a small and lightweight device (5.6 x 6.1 x 1.5 cm, 54g, 100 Hz) and stored on a SD card. The device was firmly fixed to the lower lumbar spine at the level of the second sacral vertebrae with double-sided adhesive tape to avoid movement artifacts. The data sets were sent to McRoberts for analysis [2] and compared to the results taken from the video.

### RESULTS AND DISCUSSION

Group 1: On average, the healthy children needed 273.7 steps (MIN: 207, MAX: 377) on the 160m tracks for step detection, as counted from the video. The software detected 273.5 steps on average (99.97%, range: 98.5 – 101.5%) regarding the total number of steps. If each misclassified step is counted as an error, regardless if under- or overestimated, the accuracy is 99.6%. The automatically computed walking distance revealed

100.6% of the actually walked distance. The correlation between the medio-lateral displacement of the COM and the age of the subjects was significant ( $r = -0.63$ ,  $p < 0.01$ ).

**Figure 1: Steps calculated from the MiniMod compared to the counting from the video for healthy (left) and CP (right) children.**

Group 2: One track of one child had to be excluded because of a handling error. On average, the CP children needed 79.8 steps (MIN: 57, MAX: 126) on the 40m tracks for step detection, as counted from the video. The software detected 78.9 steps on average (98.9%, range: 94.1 – 101.8%) regarding the total number of steps. If each misclassified step is counted as an error, the accuracy is 98.7%. The computed distance revealed 101% of the actually walked distance.

The DynaPort MiniMod allows for an accurate assessment of important spatio-temporal walking parameters. Due to its small size and the placement on the back, it does not interfere with most activities and it is comfortable to wear. The opportunity to estimate the medio-lateral displacement of the COM with the MiniMod offers a new tool to analyze the variation of gait within non-laboratory environments.

In healthy children, the displacement decreases with age, whereas this trend does not exist in CP children. Provided that our scale truly reflects the degree of CP, there is no association between the degree of CP and the variation of gait represented by the SDCOM. In both groups, the error of the calculated walking distance was negligible.

Further research will be performed to validate the DynaPort MiniMod for other groups (e.g. children with walking impairments, various adult patient populations) and to enhance the outcome of the device in order to monitor daily activities (e.g. the percentage of standing, sitting, walking).

## LONGITUDINAL STUDY OF GAIT STABILITY AFTER CONCUSSION

Tonya M. Parker, Robert Catena, Louis Osternig, Paul van Donkelaar, and Li-Shan Chou  
Motion Analysis Laboratory, Department of Human Physiology, University of Oregon  
email: chou@uoregon.edu, web: http://biomechanics.uoregon.edu/chou

### INTRODUCTION

The need to identify functional impairment following a brain injury is critical to prevent re-injury during the period of recovery. Research to date has focused on neuropsychological tests and static postural control during quiet standing. Little is known about the effect of concussion on dynamic motor function [1,2,3]. A recent study suggested that the ability to control and maintain stability in the frontal plane during walking is diminished in young individuals following a concussion while walking under a divided attention [4]. However, this study did not resolve the issue of how long this pattern continues. Therefore, the purpose of this study was to perform a longitudinal quantification of deficits in maintenance of dynamic stability during gait of individuals following concussion.

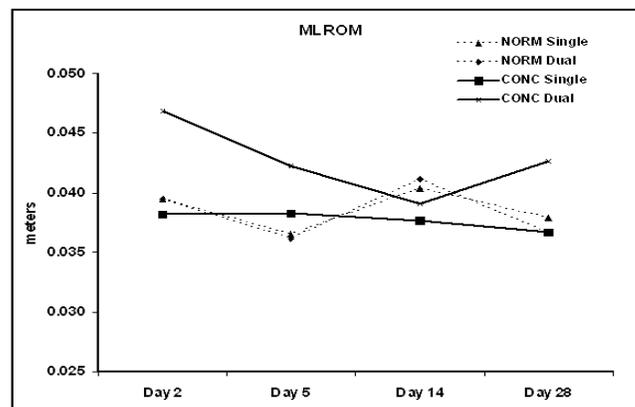

### METHODS

Fifteen college-age subjects with Grade 2 concussions (CONC) and 15 uninjured controls (NORM) were observed while walking under two conditions: 1) undivided attention (single-task) and 2) while simultaneously completing simple mental tasks (dual-task). Testing began within 48 hours of injury (day 2) and repeated at 5, 14, and 28 days post injury. NORMs were evaluated at the same intervals.

Whole-body motion data were collected using a six-camera motion analysis system and two force plates. A 13-link biomechanical model was utilized to compute whole body center of mass (COM). Center of pressure (COP) was computed with ground reaction forces. In addition to temporal distance gait parameters, anterior and medial-lateral COM motion (APROM, MLROM), peak anterior velocity of the COM (ANTVEL), and the maximum separation between the COM and COP (APMAX) were used to examine dynamic stability. Three-way repeated-measures mixed design ANOVA and Tukey *post hoc* tests were completed to determine differences between group, task, and testing day.

### RESULTS AND DISCUSSION

Group by day as well as task by day interactions were found for gait velocity and stride length. Gait velocity was significantly decreased for the CONCs on the dual-task compared to single-task for all days while NORMs were only significantly decreased on the dual-task for days 2 and 5. The CONCs' stride length was significantly decreased compared to the NORMs on both tasks on days 2 and 14. In addition, the stride length on the dual-task was significantly smaller than the single-task for the CONCs on days 2 and 5. Significant group by day interactions were found for MLROM and APMAX. A significant task by day interaction was found for APROM and ANTVEL. Follow-up analyses revealed medial-lateral COM sway was significantly increased for days 2, 5, and 28 for CONCs compared to NORMs on the dual-task

**Figure 1:** Medial-lateral range of motion of the COM

(Figure 1). One possible explanation may be that when required to divert their attention to a concurrent task, the CONCs could not adequately adjust to the challenge and therefore sway more, compromising their stability. By the last testing the CONCs have returned to play and this increase in activity is likely the cause of the decrease in performance seen on day 28. The CONCs displayed decreased APMAX at days 2, 14, and 28 compared to the NORMs. For CONCs under the dual-task condition, APROM was significantly decreased on days 2 and 5 and ANTVEL was significantly decreased on all 4 days.

### CONCLUSIONS

Concussed individuals continue to display significant differences in anterior velocity and COM movement when compared to uninjured controls up to four weeks after injury. The demands of performing a dynamic motor task combined with a mental activity that divides attention may effectively approximate the demands of an athlete in competition. However, if the concussed individuals have difficulty maintaining stability in a controlled environment they may well have difficulty adjusting to the multiple input environment of the athletic arena. The findings of this study demonstrate that concussion has an observable and measurable effect on the body's ability to maintain and control dynamic stability for up to four weeks after injury.

## EFFECTS OF IMPEDED FOOT ARCH HEIGHT ON CALCANEAL EVERSION AND ANKLE JOINT FORCES DURING GAIT

Shing-Jye Chen and Li-Shan Chou

Motion Analysis laboratory, Department of Human Physiology, University of Oregon, Eugene, Oregon, USA  
 E-Mail: [chou@uoregon.edu](mailto:chou@uoregon.edu), web: <http://biomechanics.uoregon.edu/chou/>

### INTRODUCTION

Therapeutic footwear is prescribed to not only control excessive rearfoot motion by aligning tibia and calcaneus, but also retain the medial longitudinal arch (MLA) functions to appropriately attenuate shock and accommodate uneven surface while walking. Changes in the MLA height during midstance have been found to be positively correlated with calcaneal eversion [1]. Excessive calcaneal eversion could be successfully limited by therapeutic footwear [2]. However, small and unsystematic changes of the rearfoot motion [3] and inconsistent peak calcaneal eversion control [4] were found during running with inserted orthoses in shoes. These inconclusive findings may suggest constrained MLA height changes due to the inserted orthoses could affect the calcaneal motion during walking. Therefore, the purpose of this study was to determine effects of impeded MLA height on the calcaneal motion and on 3D ankle joint force (AJRF) in healthy young adults during walking.

### METHODS

Fourteen adults (mean age:  $25.3 \pm 4.7$  years, body mass:  $71.3 \pm 9.8$  kg) were tested after being examined by a podiatrist who ruled out any foot-related pathologies. A six-camera motion analysis system (Motion Analysis Corp., Santa Rosa, CA) was used to collect eleven skin based reflective markers placed on left shank/foot during quiet stance and while walking with self selected pace in barefoot (BF) then two types customized arch supports: one deformable (AS1) and one rigid (AS2). Arch supports were directly attached to the plantar surface of the feet using double sided adhesive tapes. Heel cup of the arch support was removed to eliminate any effects on rearfoot motion. KinTrak 6.2 software (Motion Analysis Corp., Santa Rosa, CA) was used to analyze the motion data and 3D AJRF. The MLA height was defined as the perpendicular distance from the navicular marker to the line connected between distal calcaneal and 1st metatarsal head markers. The dynamic change of the MLA height was calculated as differences in heights between walking and standing for each testing condition (BF, AS1 & AS2, respectively). Subject means of MLA height changes were calculated over the stance period. The peak calcaneal eversion (CE) and peak AJRF across subjects were also calculated.

Planned contrasts with one way within-subjects ANOVA (SPSS 10.1) was performed to detect arch constrained effect (AS1 and AS2) on changes of the MLA height, peak CEV and peak AJRF,  $p < .05$ .

### RESULTS AND DISCUSSION

Average walking speeds ( $M = 1.31 \pm 0.02$  m/s) were found to be consistent across all subjects and among three testing conditions. Mean MLA height changes across stance periods in AS conditions (AS1  $M = 0.93 \pm 0.33$  mm; AS2  $M = 0.36 \pm 0.47$  mm) were found to be significantly less than that in BF condition ( $M = 1.91 \pm 0.18$  mm). Significant differences in the peak CE were found between BF ( $M = 1.51 \pm 1.93^\circ$ ) and AS2 condition (AS2  $M = 2.59 \pm 1.85^\circ$ ,  $p = .03$ ). Significant arch support effects were found in vertical AJRF (\*) at the 1<sup>st</sup> peak (p1↑) and trough (t1↓) as well as in the AP AJRF at trough 1 (t1↑). Impeded changes of arch height resulted in an increased peak calcaneal eversion and a corresponding increased vertical AJRF during early midstance (Figure 1a and 1b).

### SUMMARY

When the MLA vertical motion was impeded, the increased calcaneal eversion might be a compromise for the lack of arch height changes, meanwhile, limiting the arch function in shock absorbing. When therapeutic footwear is designed to control rearfoot motion, its possible effects on the midfoot MLA motion should be considered.

## STABLE LOCOMOTION OF FEEDFORWARD CONTROLLED ONE-LEGGED ROBOT

<sup>1</sup> Juergen Rummel, <sup>1</sup> Andre Seyfarth and <sup>1,2</sup> Fumiya Iida

<sup>1</sup>Locomotion Lab, Institute of Sport Science, Friedrich-Schiller University Jena, Dornburger Str. 23, D-07743 Jena, Germany,

<sup>2</sup>Artificial Intelligence Laboratory, Department of Information Technology, University of Zurich, Andreasstrasse 15, CH-8050, Zurich, Switzerland; email: [juergen.rummel@uni-jena.de](mailto:juergen.rummel@uni-jena.de), web: [www.lauflabor.de](http://www.lauflabor.de)

### INTRODUCTION

An accepted model for understanding the dynamics of legged locomotion is the simple spring-mass model introduced by Blickhan [1] and further researched by Seyfarth, et. al. [3]. In reality, however, humans and animals use segmented legs for locomotion instead of simple springs. The combination of both in a motor-driven mechanical application should therefore be more biologically inspired. The aim of this study was to investigate, whether an actuated mechanical system allows stable locomotion without sensory feedback.

### METHODS

The mechanical application used in this investigation is a one-legged robot with two segments. The robot body is 150 mm in length, 50 mm in width and 155 mm in height. One motor at the hip actuates a connected thigh segment, that is elastically joined with a shank segment. Two elements of rubber serve as dampers when hitting the ground.

According to Raibert [2], a retaining mechanism constrains motion leaving just two degrees of freedom (vertical and horizontal direction). Rotation about the pitch axis is disabled. Therefore, other stabilizing the robot body is not required.

The hip actuator is realized by a position controlled motor. Here, we used a simple sine oscillation as position signal as follows:

$$P(t) = \alpha \cdot \sin(2\pi \cdot f \cdot t) + \alpha_0 \quad (1)$$

Frequency  $f$  and bias angle  $\alpha_0$  are independent parameters and were varied in experiments ( $f = 1.5 \dots 8$  Hz and  $\alpha_0 = -25 \dots +25$  deg). The amplitude  $\alpha$  depends on frequency. This control strategy did not need global sensory feedback.

During experiments, the robot moved in a circle on a wooden plate for 30 seconds for every parameter set and were repeated 3 times. For kinematic analysis of robot movement we attached reflective markers. A high-speed (240 Hz) motion capture system measured and tracked 3D-trajectories of the

markers. The Trajectories were split into cycles defined by motor oscillation. For every parameter set, 120 movement cycles were randomly selected for analysis.

The stability of resultant locomotion will be described as equal patterns in horizontal direction whereas standard deviation is used as an opposing reference number in this study.

### RESULTS AND DISCUSSION

As shown in figure 1, there are two significant regions with a mean speed of 0.3 m/s in positive horizontal direction. For frequencies between 4 and 6 Hz and bias angles with a range of 0 to 20 deg the robot has a local maximum in speed by using mostly one support point. More important is, that this gait describes a local minimum in variability of speed as shown in figure 2. In the range of the second maximum ( $f = 2 \dots 5$  Hz,  $\alpha_0 < 0$  deg), the robot uses two point contacts. There, horizontal velocity increases and causes low variance in locomotion for a wide area (Fig. 2)

### CONCLUSIONS

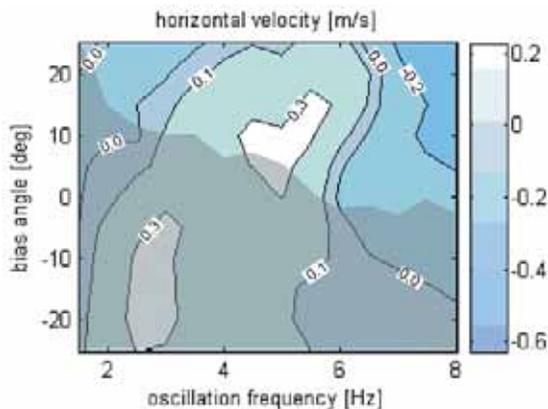

In this study we observed that feed-forward controlled one-legged locomotion is possible. In two cases we found stable ranges with a remarkable speed.

## LEG STIFFNESS IN WALKING AND RUNNING

<sup>1,2</sup> Susanne Lipfert, <sup>1</sup> Andre Seyfarth and <sup>2</sup> Reinhard Blickhan

<sup>1</sup> Locomotion Laboratory, Friedrich Schiller University, Jena, Germany

<sup>2</sup> Biomechanics Laboratory, Friedrich Schiller University, Jena, Germany

### INTRODUCTION

There is a good deal of published research available on the mechanics of running regarding leg stiffness and stability [2, 4]. A simple spring-mass model for running had been proposed [1, 5], which provides a basis for further investigations. The work of Seyfarth et al. (2002) exposes spring-like leg operation, minimum running speed, and adjusted leg stiffness and angle of attack as prominent requirements of mechanically self-stabilized running. For walking, however, it seems to be a much greater challenge when attempting to propose respective simple templates. This study targets the leg stiffness, to determine whether running and walking patterns are stable. Aims of this study therefore were a) calculating the correlation coefficients of leg stiffness in running and walking, and b) comparing leg stiffness of both gaits. We hypothesized that vertical ground reaction forces (GRFs) and displacement of the center of mass (CoM) would correlate significantly in a positive linear way for running as well as for walking. We also hypothesized no significant intra- or inter-individual differences for leg stiffness.

### METHODS

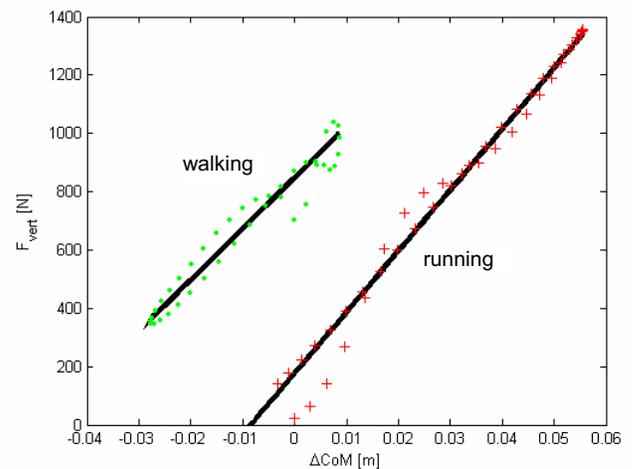

9 healthy subjects (4 women and 5 men) were randomly selected from an athletic population. Subjects had a number of reflective markers placed over anatomical landmarks to calculate positions of body segments. Ground reaction forces (GRFs) during running and walking were measured on a special split-belt treadmill, where each belt covered a Kistler force plate (2000Hz). 3D coordinates of the reflective markers were recorded simultaneously via six high-speed (150Hz) video cameras (Qualisys). Subjects were required to perform 13 gait transitions (6 x walking, 6x running) at their individual transition speeds, determined in a pretest. Time of transition was signaled by an acoustical signal occurring every 10 seconds. Raw force plate data was processed using custom software (Matlab, Mathworks Inc.). For each stance phase (heel-strike to toe-off), the vertical CoM displacement was calculated by numerically integrating the vertical force. Total vertical GRF (right GRF + left GRF) was then plotted over CoM displacement for each stance phase in running and walking to represent leg stiffness. Correlation coefficients between vertical GRF and CoM displacement and regression lines were calculated on individual stance phase data. A simple analysis of variance (ANOVA) was conducted to determine for significant differences within and between subjects. Both, walking and running were analyzed.

### RESULTS AND DISCUSSION

High correlation coefficients of over 0.95 were observed for all data. The results also showed that neither intra-individual nor inter-individual stance phase data did differ statistically with p values being near zero (Figure 1).

Given the fact that stance phase data of both, running and walking, was collected at the same forward speed, it is well justified to compare leg stiffness across both gaits. Two main

observations emerged from our comparisons: the vertical stiffness of the leg can be considered as a linear spring not only for running but also for walking. While not exactly the same regressions, there is still a close proximity of the spring-like leg behaviors apparent. The observed smaller vertical excursions of the CoM in walking correspond to the absence of flight phases, where instead single support occurs as opposed to double support.

**Figure 1** Mean vertical GRFs and CoM displacement data shown as scatter plot and regression line representing leg stiffness in walking (left) and running (right).

### CONCLUSION

Mathematical models have already been successfully applied to describe experimentally observed GRFs for running [3, 6]. Further research is currently done to extend these models by a second spring-like leg.

## AN INVERTED PENDULUM MODEL INDICATES THAT PARKINSON'S DISEASE RESULTS IN ALTERED NEUROMUSCULAR STIFFNESS FOR CONTROLLING GAIT

<sup>1</sup>Max J. Kurz, <sup>1</sup>Nicholas Stergiou, <sup>2</sup>Ekaterini Markopoulou and <sup>1</sup>Ugo Buzzi

<sup>2</sup>Neurological Sciences, University of Nebraska Medical Center, Omaha, NE

E-mail: mkurz@mail.unomaha.edu Web: http://www.unocoe.unomaha.edu/hper/bio/home.htm

### INTRODUCTION

Inverted pendulums have been used to model locomotion [1,2]. Furthermore, the organization of the dynamic resources available in the neuromuscular system determines the behavior of the inverted pendulum system. These resources can be categorized as the ability of the muscles to produce functional joint torques, passive and active characteristics of the muscles and tendons, and the exchange of potential and kinetic energy [1,2]. An escapement-driven inverted pendulum model has been used successfully to explain how pathological populations (i.e. Cerebral Palsy) utilize these dynamic resources (Figure 1) [1,2].

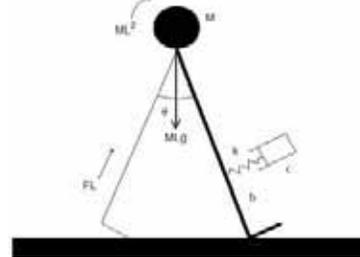

Parkinson's disease (PD) is a disorder of the basal ganglia that results in a loss of normal motor function [3]. PD patients have irregular stepping patterns and altered lower limb coordination [3]. These movement deficiencies may be related to the inability of PD patients to effectively utilize the available dynamic resources for functional gait. Here we use an escapement-driven inverted pendulum model to reveal how PD patients use the stiffness and dampening resources to control gait.

### METHODS

Three-dimensional kinematics of the lower extremity were collected as five subjects with idiopathic PD (Age = 64 ± 7.0 yrs) and five healthy controls (66 ± 7.7 yrs) walked on a treadmill at the self-selected pace. All PD subjects were off dopamine treatment and had a Unified PD Rating Scale in the 53<sup>rd</sup> percentile. Equation 1 represents the dynamics of the escapement-driven inverted pendulum model used in this investigation (Figure 1).

$$ML^2 \ddot{\theta} = FL + MLg\theta - kb^2\theta - cb \dot{\theta} \quad \text{Equation 1.}$$

where M is the mass of the body,  $\theta$  is leg angle, L is the distance from the axis of rotation to the center of mass of the physical pendulum, F is the active muscle force from the opposite leg, k is the stiffness, b is the distance of the spring from the axis of rotation, g is gravity, c is the dampening, and  $\dot{\theta}$  and  $\ddot{\theta}$  represent the angular derivatives of the inverted pendulum. Anthropometric measurements were utilized to fit subject's physical characteristics to the model [1,2]. The period of the leg pendulum was computed under the assumption that the time from the start of the stance phase to maximum angular displacement of the leg pendulum represented half of the natural period ( $\tau$ ). The stiffness and dampening of

**Figure 1.** The escapement-driven inverted pendulum model.

the model was calculated from Equation 2 and 3 respectively [1,2].

$$kb^2 = \frac{ML^2}{(\tau / 2\pi)^2} + MLg \quad \text{Equation 2.}$$

$$cb^2 = 2 * \sqrt{ML^2 (kb^2 - MLg)} \quad \text{Equation 3.}$$

The stiffness and dampening values were normalized by the subject's walking speed and MLg in order to control for differences in walking speeds and anthropometrics between the two groups [1,2].

### RESULTS AND DISCUSSION

PD subjects had significantly less stiffness during locomotion (Table 1). Stiffness in the model is a result of the elastic tissues and active muscular tension [1,2]. The altered stiffness may be related to the impaired reflexes and muscular activation found in PD patients [3]. Stiffness deficiencies may be related to the irregular stepping patterns and higher incidence of falls found in PD patients [3]. Future investigations will investigate if dopamine therapy restores the use of effective dynamic resource strategies in PD patients.

### INTRODUCTION

The walk-to-run behavioral transition has been widely examined in the literature. It has been found that the preferred transition speed from walk to run is approximately  $2.0 \text{ ms}^{-1}$  [2]. However, the corresponding speed for the behavioral transition from run-to-sprint is unknown. Differences have been reported between run and sprint [3, 5], but it is not clear if run and sprint are two different modes of locomotion or if sprint is actually a fast run [1]. Hreljac et al. [1] found that joint kinetics increased from run-to-sprint over a continuum; without any significant change at some discrete speed. However, they suggested that an analysis of intralimb coordination, based on the principles of Dynamical Systems Theory (DST), might be more sensitive in distinguishing a specific behavioral transition point. In DST, the interacting components are examined while scaling up a control parameter that elicits a new pattern of coordination [4]. The purpose of this study was to examine the intralimb coordination strategies used during running at different speeds that range from a jog to a sprint. By using DST, we investigated the interacting segments, while scaling up the speed as a control parameter.

### METHODS

Seven male subjects, all of whom exhibited a heel strike pattern at their preferred running speed, ran at their preferred speed (0%) and at 15%, 30%, 45%, 60%, 75%, and 90% greater than this speed, while sagittal plane kinematics were collected (240 Hz) from the right lower extremity. To examine segmental interactions, the phase portraits from segmental angular position and velocities were used to calculate phase angles [4]. Relative phase curves were calculated for two segmental relationships (foot-shank [F-S] and shank-thigh [S-T]) by subtracting the phase angle of the proximal segment from the distal.

Mean relative phase (MRP) was calculated from the relative phase curves of each subject and for each condition. This was done by averaging the absolute values of all points of the curve for the braking and the propulsive periods of stance. A single factor repeated ANOVA was performed on the MRP group means for each segmental relationship and for each stance period. A Tukey test was performed in comparisons that resulted in a significant F-ratio ( $p < 0.05$ ).

### RESULTS AND DISCUSSION

Statistical significance for both segmental relationships was found only during the braking period of the gait cycle but not for the propulsion period (Table 1). Both MRP F-S and S-T significantly decreased, indicating a more-in-phase relationship between the interacting segments as speed increased. Based on the post-hoc analysis, the 30% speed condition had the greatest effect. It is possible that this is the speed that the landing strategy changed from a heel-strike to a forefoot strike, and may indicate that there is a specific speed where the runner transitions from run to sprint.

Our results indicated that increasing the running speed from a run to a sprint elicited behavioral changes. These changes occurred during the braking period. The 30% above the running self-selected speed condition seems to be a critical speed for the observed changes.

### INTRODUCTION

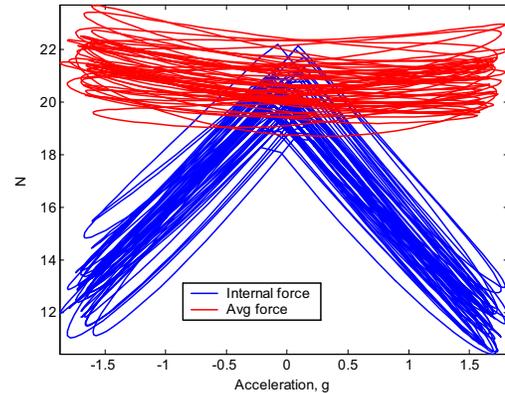

In multi-digit grasping, a vector of contact forces and moments  $f$  can be broken into two orthogonal vectors: the resultant force vector  $f_r$  (manipulation force) and the vector of the internal force  $f_i$  ( $f = f_r + f_i$ ) [1]. Internal force is a set of contact forces which can be applied to an object without disturbing its equilibrium [2,3]. The elements of the internal force vector  $f_i$  cancel each other and, hence, do not contribute to the manipulation force. The mathematical independence of the internal and manipulation forces allows for their independent (decoupled) control. Such a decoupled control is realized in robotic manipulators [4]. The purposes of this study are to examine whether in human internal force is coupled with the manipulation force and what grasping strategy the performers utilize.

### METHODS

The subjects ( $n=6$ ) were instructed to make cyclic arm movements with a customized handle. Six combinations of handle orientation and movement direction were tested. These involved *parallel manipulations*: (1) VV task - vertical orientation & vertical movement and (2) HH task - horizontal orientation & horizontal movement, *orthogonal manipulations*: (3) VH task - vertical orientation & horizontal movement and (4) HV task - horizontal orientation & vertical movement, and *diagonal manipulations*: (5) DV task - diagonal orientation & vertical movement and (6) DH task - diagonal orientation & horizontal movement. Handle weight (from 3.8 to 13.8 N), and movement frequency (from 1 Hz to 3 Hz) were systematically changed. The analysis was performed at the thumb-virtual finger level (VF, an imaginary finger that produces a wrench equal to the sum of wrenches produced by all the fingers). At this level, the forces of interest could be reduced to the *internal force* (the grip force) and *internal moment*.

### RESULTS AND DISCUSSION

During the parallel manipulations, the internal force was coupled with the manipulation force and the thumb-VF forces increased or decreased in phase. During the orthogonal manipulations, the thumb-VF forces changed out of phase; the plots of the internal force vs. object acceleration resembled an inverted V letter (Figure 1). The HV task was the only task where the relative phase (coupling) between the normal forces of the thumb and VF depended on oscillation frequency. During the diagonal manipulations, the coupling was different in the DV and DH tasks. A novel observation of substantial internal moments is described: the moments produced by the normal finger forces were counterbalanced by the moments produced by the tangential forces such that the resultant moments were close to zero.

**Figure 1:** Internal force and average normal force versus the handle acceleration (load, 11.3 N; frequency, 3 Hz).

Internal forces do not affect equations of motion [3] and hence control of manipulation can be broken up into two sub-tasks—‘holding’ and ‘tracking’—which can be controlled independently. Such a control strategy (which is commonly used in robotic grippers – [4]) simplifies the control. This strategy requires, however, exerting unnecessarily large forces and is in this sense uneconomical. This study, however, suggests that the CNS prefers to face larger computational costs rather than produce excessive forces. The CNS uses different patterns of the thumb-VF coordination when the manipulation force is in a tangential direction as compared with the manipulation in the normal direction. When the manipulation force is in a tangential direction, the symmetric pattern of the thumb-VF coordination is used: The thumb and VF work in synchrony to grasp the object stronger or weaker. In contrast, when the manipulation force is in the normal direction the anti-symmetric force changes are recorded: When the normal force of either thumb or VF increases, the force exerted by the opposing digits decreases. It is not clear to which degree such coordination is a consequence of task mechanics as compared with the neural control.

## POSTURAL LOCAL DYNAMIC STABILITY IS NOT PREDICTIVE OF THAT DURING LOCOMOTION

Hyun Gu Kang and Jonathan B. Dingwell

Nonlinear Biodynamics Lab, Department of Kinesiology, University of Texas at Austin  
 email: [jdingwell@mail.utexas.edu](mailto:jdingwell@mail.utexas.edu) web: [www.edb.utexas.edu/faculty/dingwell/](http://www.edb.utexas.edu/faculty/dingwell/)

### INTRODUCTION

Clinical measures of postural stability have been used to predict falls in the elderly with variable success. In particular, several do not predict falls that occur during walking well [1] and these constitute the majority of falls [2]. This could be because inherently different control mechanisms are used to maintain stability during standing and walking [3].

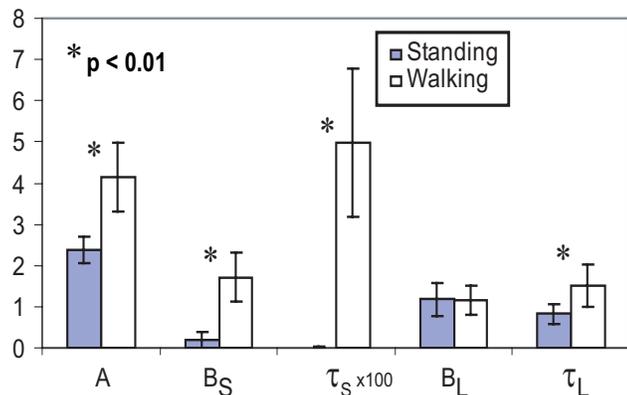

Prior studies comparing postural to locomotor stability [4,5] used different metrics for the different tasks and used metrics that were not *direct* measures of stability *itself*. We resolved these problems by using appropriately defined metrics to define *local dynamic stability* [6] in the same way for standing and walking. We hypothesized that standing stability would be different from walking stability and would not predict walking stability. We also validated our metrics for standing stability against traditional center of pressure (COP) measures.

### METHODS

20 healthy subjects (age 18-73) performed three 5-min. trials walking on a motorized treadmill at their preferred speed, and three 5-min. trials standing eyes open on a force plate. Trunk motions were recorded using VICON and used to construct a 12-dimensional state space comprised of the 3D linear and angular trunk positions and velocities. Local dynamic stability was quantified using these trunk trajectories in the 12-D state spaces. The mean divergence over time  $\langle d_j(i) \rangle$  of locally perturbed trajectories was calculated to quantify local dynamic stability [6,7]. Mean divergence curves were parameterized using a double exponential function (Equation 1):

$$\langle d_j(i) \rangle = A - B_S e^{-t/\tau_S} - B_L e^{-t/\tau_L} \quad (1)$$

The parameters ( $A$ ,  $B_S$ ,  $\tau_S$ ,  $B_L$ , and  $\tau_L$ ) were averaged over the 3 trials of each task. A repeated measures ANOVA was used to determine if standing and walking exhibited different stability

**Figure 1:** Magnitudes of all mean local divergence curve parameters except for  $B_L$  were significantly larger ( $p < 0.01$ ) during walking than during standing.

properties. Pearson correlations were used to determine if standing stability predicted walking stability. Correlations were also computed between standing stability metrics and traditional COP measures of standing balance: COP excursion, mean speed and mean power frequency (MPF).

### RESULTS AND DISCUSSION

Local dynamic perturbation responses during standing and walking exhibited different magnitudes and different time scales (Figure 1). Furthermore, local stability metrics for standing were not correlated with those for walking (Figure 2). These results support the idea that postural and locomotor stability are indeed governed by different mechanisms.

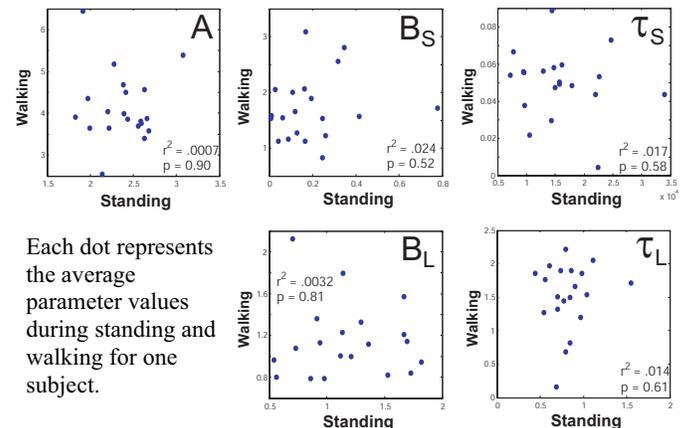

COP mean speed and MPF were significantly correlated to  $A$  and  $B_L$  for standing ( $r^2 > 47\%$ ;  $p < 0.001$ ). Thus, our local dynamic stability metrics are consistent with traditional COP measures for standing balance. None of the COP measures were correlated to any of the local stability metrics for walking ( $r^2 < 14\%$ ;  $p > 0.12$ ). These findings support the notion that traditional postural stability measures based on COP measurements are not predictive of locomotor stability.

## EFFECT OF DIFFERENT WEDGE CONDITIONS ON JOINT ANGLE CHANGES DURING SINGLE-LIMB STANCE

<sup>1</sup>Mansour Eslami, <sup>1</sup>Mehrdad Anbarian, <sup>1</sup>Paul Allard, <sup>2</sup>Clarice Tanaka, <sup>1</sup>Sébastien Hinse, <sup>3</sup>Nader Farahpour

<sup>1</sup>Department of Kinesiology, University of Montreal, Montreal, Canada. <sup>2</sup>Department of Physical Therapy, Speech Therapy and Occupational Therapy, University of São Paulo, São Paulo, Brazil. <sup>3</sup>Department of Physical Education, Bouali University, Hamedan, Iran; email: [mansour.eslami@umontreal.ca](mailto:mansour.eslami@umontreal.ca)

### INTRODUCTION

Wedge foot orthotics are widely prescribed to promote the mechanical alignment of foot joints. However, wedged orthoses can also affect lower limb proximal joints and axial segment as an effect of the weight-bearing closed chain. Therefore, the wedged orthoses prescription should consider the functional relationship between the foot and proximal segments [1]. Conversely, the effect of wedged orthoses on the lower limb proximal joints and axial segment alignment is still unclear. The purpose of this study was to assess the effect of different wedge conditions on angle changes in the subtalar joint, ankle, knee, hip, pelvis, and upper trunk.

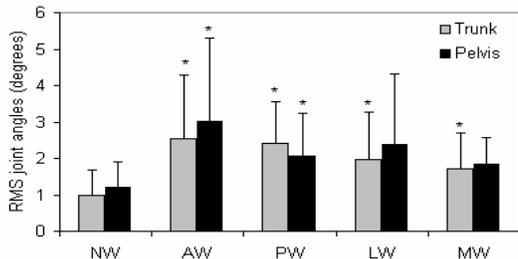

### METHODS

Fourteen able-bodied young male participated in this study. Participants were tested in single-limb stance under five wedge placements: no wedge (NW); anterior (AW); posterior (PW); lateral heel (LW); medial heel (MW). A Motion Analysis System using five cameras with EVaRT software was used to capture (3 trials of 60s each) joint angle in the trunk and pelvis in horizontal plane, ankle, knee, hip in sagittal plane, and subtalar and hip joint in the frontal plane.

### RESULTS AND DISCUSSION

Two repeated-factor (wedge by joint) ANOVA revealed main effect of wedge condition ( $F_{4,52}=5.76, p=0.002$ ). Protected t test comparison was conducted on the main effect of wedge condition to detect the significant difference between no wedge condition and the wedge conditions.

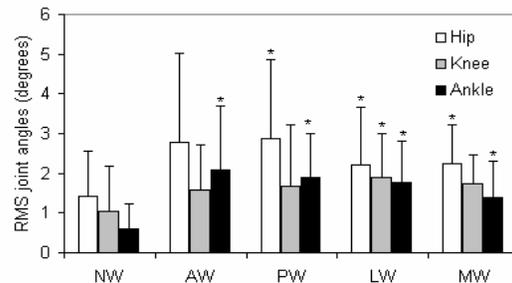

In horizontal plane, angle changes in the upper trunk were revealed for all conditions (AW>PW>LW>MW>NW), whereas in pelvis rotation (Fig. 1) were shown in AW and PW conditions (AW>PW>NW).

**Figure 1:** RMS value and standard deviation of upper trunk and pelvis in the horizontal plane across wedge conditions. \*statistical difference compared to NW.

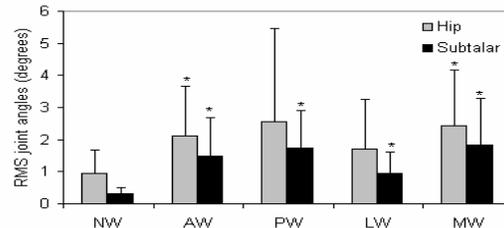

NW (no wedge), AW (Anterior wedge), PW (posterior wedge), LW (lateral wedge), MW (medial wedge).

In the sagittal plane (Fig. 2), ankle joint was affected by all wedge conditions (AW>PW>LW>MW>NW). Angle changes in the hip joint was shown in MW, LW and PW conditions (PW>MW>LW>NW) while knee joint revealed in LW (LW>NW) only.

**Figure 2:** RMS value and standard deviation of hip, knee and ankle joints in the sagittal plane across conditions. \*statistical difference compared to NW.

In the frontal plane (Fig. 3), the subtalar joint consistently exhibited angle changes for all wedge conditions (MW>PW>AW>LW>NW), while the hip joint in AW and MW conditions (MW>AW>NW) only.

**Figure 3:** RMS value and standard deviation of hip and subtalar joints in the frontal plane across conditions. \*statistical difference compared to NW.

### CONCLUSION

Upper trunk, ankle and subtalar joint showed statistically significant changes regardless the wedge conditions. This shows the participation of different planes of movement to compensate a wedge placement. Furthermore, a particular wedge condition changes differently the especial proximal joints in a weight-bearing chain. Thus, it is essential to notice the effect of different posted orthotic on proximal joints and three planes of movement.

## Functional outcome in people with diabetic neuropathy at different stages of complications

<sup>1</sup>Robert van Deursen, <sup>1</sup>Rajani Kanade, <sup>2</sup>Patricia Price and <sup>2</sup>Keith Harding

<sup>1</sup>Research Centre for Clinical Kinaesiology, School of Healthcare Studies & <sup>2</sup>Wound Healing Research Unit, School of Medicine, Cardiff University, Cardiff, UK; email: [vandeursenr@cardiff.ac.uk](mailto:vandeursenr@cardiff.ac.uk)

### INTRODUCTION

Diabetic neuropathy (DN) frequently leads to ulceration and these patients have an increased risk of lower limb amputation [1,2]. Limited knowledge exists on the functional outcome at various stages of this process. The aim of this study is to investigate multiple aspects of functional outcome/mobility of patients with DN at different stages of complications with trans-tibial amputations (TTA) as the last stage.

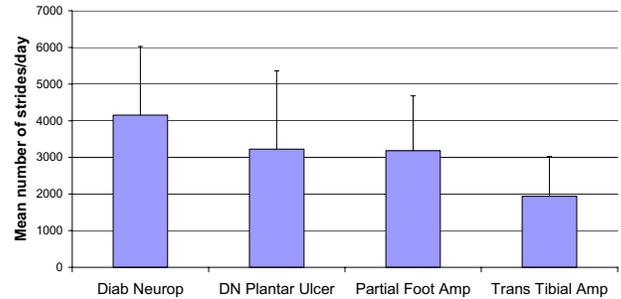

### METHODS

To date in this ongoing study, 24 subjects with DN and no history of ulceration (control group), 13 with DN and a current plantar ulcer, 9 with DN and partial foot amputation and 21 with DN and unilateral trans-tibial amputation were studied. Informed consent was obtained and functional status was assessed based on the fundamental activities of mobility, largely focused on walking. Physical activity was recorded using Stepwatch Activity Monitors. Patient's perception of mobility was assessed with a self-administered Rivermead Mobility Index (RMI). Plantar pressure was measured with the Pedar in-shoe system while participants walked at their self-selected pace. Gait parameters were measured using digital video. Total Heart Beat Index (THBI), as an indicator of functional capacity/energy expenditure, was measured with a Polar Heart Rate Monitor. Statistical differences between the TTA group and the control group, matched on marginal distributions (age, gender, height, weight), were tested by means of independent t-tests ( $\alpha = 0.05$ ). The other two groups were not sufficient in number and not sufficiently matched to be included in the inferential statistical analysis.

### RESULTS AND DISCUSSION

Average daily strides were significantly reduced in the TTA group compared to controls (Table 1). The other two groups showed intermediate activity levels in comparison (Figure 1). Subject's own perception of level of mobility (RMI), gait velocity and functional capacity (THBI) were all significantly different between the TTA group and the controls. Daily plantar cumulative stress [3] was significantly reduced for the TTA group. However, peak pressure over the MT1-2 region was not significantly different between these two groups

### Activity level

**Figure 1:** Activity levels measured as a one week average of number of strides per day. Mean and standard deviations are shown for four groups of subjects with DN.

(Table 1). This also applied to other foot regions but these results are not reported here.

### CONCLUSIONS

All groups in this study demonstrated relatively low to very low levels of activity compared to normative values from healthy subjects [3]. Reduced physical activity levels and reduced walking speed seem to limit plantar loading in the TTA group. However, the surviving foot may be at risk of plantar ulceration if functional performance is improved during rehabilitation. This may also apply to the groups at other stages of complications. Therefore, efforts to increase fitness and activity levels should not occur at the expense of foot injury prevention.

### INTRODUCTION

Triathletes report a perception of reduced lower limb coordination when running after cycling. This perceived reduction in lower limb coordination may result from interference with control of movement and muscle recruitment. Studies of upper limb coordination have demonstrated interference with control of movement when two previously learnt tasks are performed in sequence or with only short interim periods [1]. These findings can be extrapolated to suggest that control of movement and muscle recruitment in triathletes during running after cycling may be less skilled when compared to running without prior cycling because of interference with movement control. However, interference with control of movement and muscle recruitment in triathletes during running following cycling has not been studied in the absence of fatigue, which is another potential cause of altered control of movement. Therefore, this study investigated the influence of the triathlon transition on movement and muscle recruitment in highly trained triathletes using a protocol designed to provide the triathletes with exposure to cycling without causing fatigue.

### METHODS

Participants were nine highly trained Australian national or international level triathletes. Pelvic and lower limb movement (three dimensional kinematics), activation of tibialis anterior (TA, surface electromyography recordings) and stride and stance durations were compared between a control run, which occurred without any prior exercise, and a transition run that was preceded by 20 min of cycling. TA activity during running and cycling was compared using coefficients of multiple correlation (CMC) to test the hypothesis that changes to muscle activity between control and transition runs resulted in activation that more closely resembled that used for cycling. Myoelectric indicators of fatigue (initial values and rate of change of the mean spectral frequency (MNF), average rectified value (ARV), and neuromuscular efficiency (NME)) were measured using a protocol previously described [2] and were used to test the hypothesis that altered TA recruitment was not due to fatigue. Furthermore, repeatability of transition effects was examined and ratings of perceived control of movement were used to investigate if athletes' perceptions of coordination were correlated with transition effects.

### RESULTS AND DISCUSSION

Group data of pelvic and lower limb movement, TA EMG, and stride and stance durations did not vary between control and transition runs. Analysis of individual triathlete movement patterns also showed that motion of the pelvis and lower limb, including individual variance of movement patterns and inter-

joint coordination, did not vary in any triathlete between control and transition runs. Stride and stance durations also did not vary between control and transition runs in any triathlete. However, analysis of individual triathlete data revealed a decrease in the amplitude of TA EMG during the stance phase of running, which occurred immediately following the cycle leg and continued for the duration of the 30 min control run, in two of the nine triathletes. In these two triathletes, the pattern of activation of TA was more similar to that used for cycling (triathlete three control run-cycling CMC = 0.536 vs. transition run-cycling CMC = 0.746, and triathlete six control run-cycling CMC = 0.444 vs. transition run-cycling CMC = 0.610). Altered recruitment of TA during the transition run was not associated with myoelectric indications of fatigue as initial values and rate of change of MNF, ARV and NME did not vary between pre- and post exercise measures. Interestingly, these two triathletes were not different to the remaining seven triathletes in their ratings of perceived control of movement. Furthermore, the amplitude of TA EMG during the swing phase of running, times of EMG onset, offset and peak amplitude, EMG modulation and individual variance of EMG did not vary between control and transition runs in any triathletes. With the exception of the amplitude of TA EMG during the stance phase of running, absolute magnitudes of all kinematic and EMG variables during running did not vary between triathletes. Data of TA EMG and pelvic and limb kinematics was repeatable (CMC TA EMG =  $0.846 \pm 0.019$ , CMC kinematics  $0.911 \pm 0.029$ ).

### CONCLUSIONS

This study suggests that kinematics of the pelvis and lower limb are not influenced by the transition from cycling to running in highly trained triathletes. While activation of TA was not influenced by the cycle-run transition in a majority of highly trained triathletes, the data suggest that leg muscle activity during running may be influenced by cycling in some highly trained triathletes despite years of training and practice of the sequence. Altered recruitment of TA was not associated with myoelectric indications of fatigue but was more similar to that used for cycling, suggesting that it was the cycling task that directly affected running muscle activity. This transition effect was consistent between sessions.

**A METHOD TO DIAGNOSIS THE KINETIC CHARACTERISTIC OF THE STRAIGHT KICK PERFORMANCES**

Xin-Hai Shan Yun-Xiang Li

Biomech. Lab, College of Phys. Edu., Shandong Normal University, Jinan 250014, China, Xhshan\_jn@yahoo.com.cn

**INTRODUCTION**

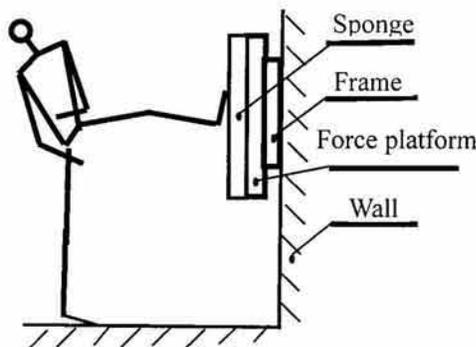

Just like the Round Kick[1], the Straight Kick (SK) is another attack method to get score in Chinese Wushu competition. In order to get high effect, the key factor in SK performance is to reach the kick force as large as possible in a short period of time.

However, up to now few have been published related to the kinetic characteristic of this performance. Maybe it was related to the difficulty to test the horizontal kinetic variables of SK by using the force platform directly. Then T-Y Shiang, et al.[2] gave an idea. In order to get the impact data of the baseball, they mounted the force plat vertically on the wall, which makes it possible to test the kinetic characteristic. Therefore, the purpose of this paper is to try to develop a method used to diagnosis the kinetic characteristic of SK performances of China elate Wushu athletes and to present some references for the further research in this area.

**METHODS**

Particpate: 8 Chinese elate Wushu athletes with (age, height, weight)  $22.32 \pm 0.45$ year,  $1.76 \pm 0.03$ m,  $72.65 \pm 6.62$ kg.

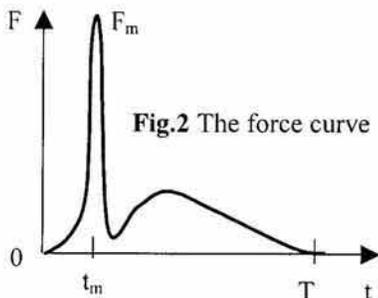

Apparatus: just as Fig. 1, the metal frame was fixed on the

**Fig. 1** The experimental apparatus setup

wall. Then the Kistler force platform (9287B) was fixed on the frame. In order to minimize the sore of the foot, a sponge was fixed on the platform with an adhesive tape.

Procedures: in order to avoid injury, every subject was required to warm up

more than 5 minutes including running and stretching the tendons. At hearing the start instruction, the athlete moved one step forward to the force platform with One leg standing on the ground, and the other

straight kicking horizontally onto the platform with the maximum force.

Fig.2 is the typical force curve. At beginning, the force is zero.

After a short time  $t_m$ , the force reaches the top  $F_m$ . At time  $T$ , the force gets down to zero.  $\Delta F/\Delta t$  was calculated by the function  $F_m/t_m$ , which was the average force gradient within the time from the contact to the maximum force. Because of the explosive style of the performance, the force data were sampled at 2000Hz for 5s duration.

In the experiment, every athlete was required to complete three trials with the right foot and then with the left foot respectively. The Preferred Leg (PL) was defined in this paper to be the leg with the larger maximum kick force, and the non-Preferred Leg (non-PL) was to be with the less force. The best one of three trials in PL and non-PL respectively was selected as the statistics sample.

Statistics: T-test was used to determine the differences between kinetic variables of PL and non-PL with significant level at 0.05, and 0.01.

**RESULTS AND DISCUSSION**

From the contact to the maximum force, the time was about 20ms. The total time from contact to separate is about 170ms. In the aspect of time  $t_m$  and  $T$ , there was no significant difference ( $p>0.05$ ) between the PL and non-PL.

In the maximum force, however, the force of PL was significant larger ( $p<0.01$ ) than that of non-PL. The PL had maximum force  $925.51 \pm 122.48$ kgf, while the non-PL was 35.6% lower. The maximum force was about 12 times of Body Weight, which is much larger than the maximum force of vertical jump[3].

**Table 1** the kinetic variables of the athletes (n=8)

Variables	PL(M±SD)	Non-PL(M±SD)
$t_m$ (ms)	20±3	21±2
T(ms)	170±21	170±35
$F_m$ (kgf)	925.51±122.48**	595.66±104.44
$\Delta F/\Delta t$ (kgf/s)×10 <sup>3</sup>	46.17±9.12**	29.61±6.39
Impact (kgfs)	19.24±5.49*	13.40±5.1

Note. \* Significant different ( $p<0.05$ ); \*\*highly significant different( $p<0.01$ )

In aspect of force gradient, the difference between LP and non-LP was highly significant ( $p<0.01$ ). The  $\Delta F/\Delta t$  of LP is  $(46.17 \pm 9.12) \times 1000$ kgf/s, while that of non-LP was 35.7% lower. In the impact, there is still significant difference between the LP and non-LP ( $p<0.05$ ). The Impact of LP is about 19.24kgs, while the non-LP was only about 13.40kgs with 30.4% lower.

## Comparison of power spectrum measures to entropic measures of electromyography time series: Diagnostic tools for low back pain

<sup>1</sup>Paul Sung, <sup>2</sup>Ulrich Zurcher and <sup>2</sup>Miron Kaufman

<sup>1</sup>Department of Health Sciences, <sup>2</sup>Department of Physics  
Cleveland State University, Cleveland, Ohio

### Introduction

The use of surface electromyography (EMG) as a diagnostic tool for low back pain (LBP) is based on the possibility that changes in the fatiguing process can be monitored before the point of mechanical failure has been reached. However, back muscle fatigue studies do not consistently report endurance levels for patients with or without low back pain (LBP). This study is to evaluate a reliable diagnostic tool for low back pain based on power spectrum and novel technique based on nonlinear time series analysis, including entropy and mean square displacement.

### Methods

Ten subjects with chronic LBP and ten gender-matched volunteers were recruited as a control group. The endurance of the erector spinae muscle was determined using a modified version of the isometric Sorensen fatigue test. Using standard fast Fourier transform (FFT) of the surface EMG data, the median frequency, the slope of the median frequency, and the coefficient of determination ( $R^2$ ) were obtained. The signal was interpreted as a random displacement for each discrete time step, and the entropy and mean square displacement as functions of time were computed.

### Results and Discussion

The power spectrum measures do not provide a clear differentiation between LBP and healthy individuals. The median frequency was not statistically different between groups ( $T_{1,18} = 0.91$ ,  $p > .05$ ). However, the entropy and the mean-square displacement versus time exhibit a plateau for  $10\text{msec} < t < 1\text{sec}$  and both of these results were statistically different in the two groups (Figure 1).

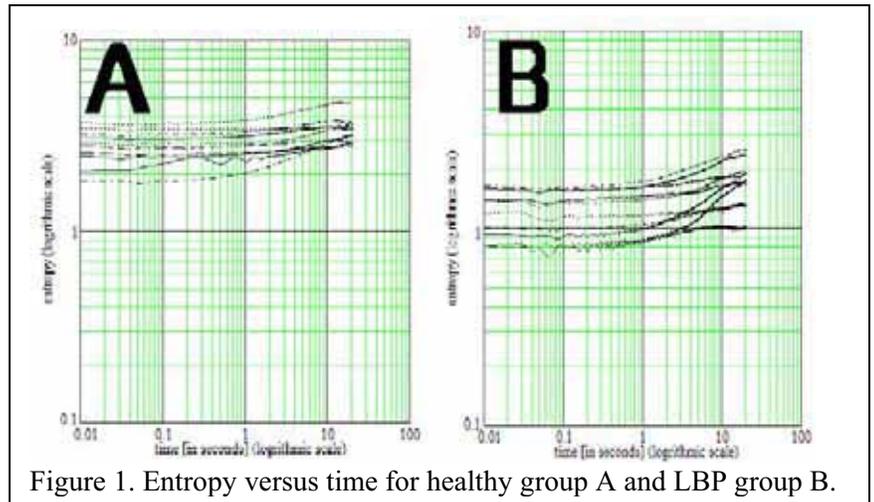

Figure 1. Entropy versus time for healthy group A and LBP group B.

### Conclusions

The mean-square displacement and entropy analysis are good diagnostic tools to diagnose LBP. The mean-square displacement versus time has a flat part, which reflects the presence of correlation in the EMG signal. In addition, the entropy values are larger for subjects without LBP than for those with LBP. Further study is required to understand the mechanism of action. The power spectrum seems to indicate a decrease in variability.

**DOES LOAD MAGNITUDE ALTER CUMULATIVE LOAD TOLERANCE? “WEIGHTING” FOR AN ANSWER**

<sup>1</sup> Robert J. Parkinson, and <sup>1</sup>Jack P. Callaghan

<sup>1</sup>University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1

<sup>1</sup>email:[callagha@healthy.uwaterloo.ca](mailto:callagha@healthy.uwaterloo.ca), web: [www.ahs.uwaterloo.ca/kin/people/faculty/callaghan.htm](http://www.ahs.uwaterloo.ca/kin/people/faculty/callaghan.htm)

**INTRODUCTION**

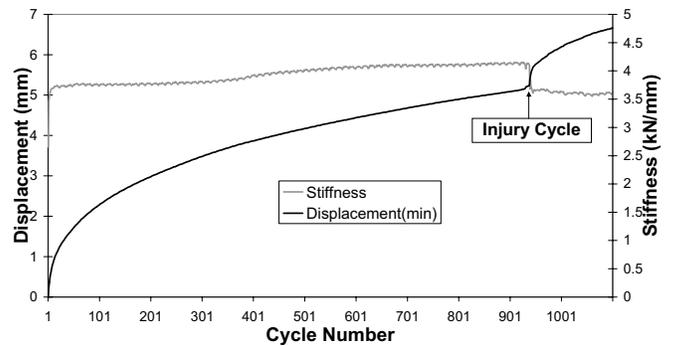

Previous research examining cumulative compression exposure in the low back has employed a linear summation of force-time magnitudes to obtain estimates of total exposure. More recently, force magnitudes have been weighted (square or tetra power) based on the idea that higher load magnitudes have a greater impact on the development of injury than do lower magnitudes [1,2]. Although researchers have indicated a need to adjust higher loading magnitudes for their role in cumulative injury development, the relationship between load magnitude and cumulative load tolerance has not been quantified. This study was performed to quantify this relationship and provide useable weighting factors to be employed when quantifying cumulative load exposure.

**METHODS**

40 porcine cervical spinal units were each randomly assigned to one of four loading groups, corresponding to 40, 50, 70, or 90% of the estimated compressive strength of the unit. The compressive tolerance of each spinal unit was estimated using a previously developed equation based on average endplate area [3]. Each spinal unit was mounted inside aluminum cups using non-exothermic dental plaster, mounted in a materials testing machine (8872, Instron Canada, Toronto, ON, Canada) and preloaded with 300N for 15 minutes. The inferior vertebral mounting of the spinal unit was placed on a bearing table to allow unconstrained translations in two directions and rotation about one axis. After preloading, specimens were cyclically compressed with a physiological loading profile at 0.5 Hz until failure occurred or a maximum of 21,600 cycles was reached. Failure was characterized by a distinct drop in stiffness and increase in displacement (figure 1). The relationship between load magnitude and cumulative load tolerance was mathematically characterized and used to generate weighting factors to adjust all loading magnitudes (1-100%) for their contribution to injury development.

**RESULTS AND DISCUSSION**

The average cumulative load tolerated in each group is provided in table 1. It was found that load magnitudes below 70% did not always induce failure prior to the cycle limit, as indicated in table 1. The measured relationship indicated that load magnitudes below 37.5% resulted in a minimal risk of injury and were therefore assigned a weighting factor of 1. Above this threshold value, equation 1 can be used to determine the necessary weighting factor. The square and tetra power approaches previously employed [1,2] are not supported by the current findings.

**Figure 1:** Displacement (mm) and stiffness (kN/mm) versus cycle number obtained from a specimen cycled to a peak load of 50% of the estimated compressive tolerance. Only the peak cycle displacement is plotted for clarity. Plots are overlaid to highlight the simultaneous decrease in stiffness and increase in displacement occurring at failure. The failure cycle is indicated.

## DIFFERENCES IN LOWER-LIMB NEUROMUSCULAR CONTROL BETWEEN SPORTS MOVEMENTS EXECUTED IN LABORATORY AND GAME SETTINGS

<sup>1</sup> Natalie Saunders, <sup>1</sup> Leonie Otago and <sup>2</sup> Scott McLean

<sup>1</sup> School of Human Movement & Sport Sciences, University of Ballarat, AUS: [n.saunders@ballarat.edu.au](mailto:n.saunders@ballarat.edu.au)

<sup>2</sup> The Cleveland Clinic, Cleveland, USA

### INTRODUCTION

Anterior cruciate ligament (ACL) injury is a common and traumatic sports injury. While the underlying mechanisms remain unclear, neuromuscular control elicited during high-risk sports movements has become increasingly viewed as a primary risk factor [2]. To date, neuromuscular predictors of ACL injury have typically arisen from lab-based assessments of these movements, as a means to counter the inherently random and unpredictable nature of the true game setting. It is possible however, that this approach excludes important components of actual game-play that contribute directly to the chosen movement response and resultant injury risk [4]. A game-based assessment of high-risk sports movements may thus afford more reliable neuromuscular injury predictors, and hence, more effective injury screening and prevention strategies. With this in mind, the purpose of the current investigation was to compare lab and game-based measures of lower limb neuromuscular control during high-risk sports movements.

### METHODS

Ten female subjects (age 24.3,  $\pm$  9.5 years) had lower limb EMG data recorded continuously during a fixtured netball game. At a subsequent session, occurring in the lab, EMG data was also recorded for 3 chosen conditions (as below). The movement chosen for investigation was a "leap" land, which is commonly employed in netball and involves taking off on a single leg and landing on the opposite leg. For each subject, bilateral EMG (Mespec 4000, MegaWin) data, sampled at 1000Hz, was first recorded telemetrically for rectus femoris (RF), biceps femoris (BF) and medial hamstring (MH) muscles throughout an entire game (4 x 10 min  $\frac{1}{4}$ 's). The game was also videotaped via a 50Hz Panasonic CCD camera, which enabled accurate detection of leap lands, surrounding factors eg. proximity of opposing players, and the moment of foot contact to be analysed in detail. During lab testing, video and bilateral EMG data were again recorded while subjects performed 5 leap land trials for each leg, for 3 specific movement conditions of increasing complexity, namely:

1. Run and leap land.
2. Run, leap land whilst catching a ball, pivot and pass to a team-mate in the same movement.
3. Break from a defender, run, leap land whilst catching a ball, pivot and pass to a team-mate in the same movement

Muscle EMG data obtained from the game movements were then matched to lab-based measures for the ensuing analyses. The point of initial contact (IC) of the land leg, for both the game and lab trials was first determined via the video camera recordings. EMG data were then analysed for each trial to

determine the moment at which each muscle turned 'on' relative to IC (onset to IC), and the resultant duration of the muscle activation burst that occurred concurrent with IC. Specifically, the onset level was defined as the point where muscle activation exceeded baseline levels by at least 1 SD for a minimum of 10 ms [3]. In addition to the landing leg, the same measures were also recorded 2 and 1 step prior to the land, being defined as the contralateral leg land (CL) and ipsilateral leg land (IL) respectively. All dependent measures were subsequently submitted to a 2-way ANOVA to determine for the main effects of test condition and leg.

### RESULTS AND DISCUSSION

Onset to IC for the RF and BF muscles was observed to be similar between the game and lab conditions for the landing, CL or IL leg ( $p > 0.6$ ). A significant difference ( $p = 0.008$ ) was observed however, for the MH of the land leg, with the onset of activation occurring much closer to IC during the game ( $73 \pm 19$ ms) compared to the lab ( $111 \pm 14$ ms) condition. Differences in MH activation were not observed for the IL or CL leg lands. Comparisons of muscle burst duration data also failed to yield significant results for all statistical comparisons. Previous lab-based investigations for the same sports movement have reported hamstring activation onset times relative to IC, and proposed that onset further from IC, as was found in females when compared to males, increased the likelihood of ACL injury due to an inability to effectively counter tibiofemoral anterior shear forces [1]. Current game observations however, suggest female onset times occur much closer to IC. Thus, the potential for female hamstring activation strategies to contribute to their increased ACL injury risk compared to males may be largely overstated. If this is the case, lab based screening and intervention strategies that focus on this predictor, may have limited success in reducing female ACL injury rates.

### CONCLUSIONS

Differences exist in female lower limb neuromuscular control between lab and game-based assessment of high-risk sports movements that may have a significant impact on the ultimate success of current screening and intervention strategies. Further work into this potentially important research disparity is warranted.

**EFFECTS OF STRESS DEPRIVATION ON BIOMECHANICAL PROPERTIES OF REGENERATED AND RESIDUAL TISSUES IN THE PATELLAR TENDON AFTER REMOVAL OF THE CENTRAL ONE-THIRD**

<sup>1</sup> Kozaburo Hayashi, <sup>2</sup>Hiroyuki Asanuma, <sup>3</sup>Eijiro Maeda, <sup>4</sup>Harukazu Tohyama and <sup>4</sup>Kazunori Yasuda  
<sup>1</sup>Osaka University and Okayama University of Science; email: yokohayasi23@yahoo.co.jp

**INTRODUCTION**

The central one-third of the patellar tendon (PT) is commonly used as a substitute for reconstruction of the anterior cruciate ligament. The defect made by the resection of the central portion is filled with regenerated fibrous tissue. We have observed in a rabbit model that the strength and elastic modulus of the residual tissue significantly decreased at an initial stage and then increased thereafter, and that those of the regenerated tissue progressively increased during healing [1]. Mechanical stress is considered to affect the remodeling phenomena in both tissues, because the strength and modulus of the normal PT are very rapidly and markedly decreased by the removal of the stress applied to it (stress shielding) [2]. Therefore, we hypothesized that stress shielding significantly affect the properties of both regenerated and residual tissues after the resection of the central one-third of the PT. The purpose of the present study was to test this hypothesis.

**MATERIALS AND METHOD**

Skeletally mature female Japanese white rabbits were used. After surgical exposure of the PT in each right knee, the PT was relaxed at all knee angles with a stainless steel wire hooked between the patella and the tibial tubercle, for the complete removal of stress [2]. Then, a full-thick, full-long (about 20 mm), rectangular defect, which had the width (about 3 mm) of one-third of the whole width of the PT, was made in the central portion of the PT. Postoperatively, all animals were applied no immobilization procedure, and were allowed unrestricted activities in cages.

At 3 or 6 wks after the operation, patella-tendon-tibia complexes were excised, and each complex was divided into the medial (residual PT tissue), central (regenerated tissue), and lateral (residual PT tissue) portions. Tensile testing was performed for each specimen in ? ? C saline solution at the rate of 20 mm/min; strain was determined at midsubstance with a video dimension analyzer.

The results from these completely stress-shielded tissues (CSS group) were compared with our previous results obtained from the animals which were made same defects in the PT but were applied no stress shielding treatment (NSS group) [3], and also with the results obtained from non-treated normal PTs (Control) [4].

**RESULTS AND DISCUSSION**

Fibrous tissues were regenerated in the PT defects already at 3 wks in both CSS and NSS groups, but their tensile strengths were very much lower compared to the control PT (Figure 1). The strength increased between 3 and 6 wks, although that at 6 wks was still significantly lower than control value. CSS group had significantly lower strength than NSS group at each period. The tensile strength of the residual PT tissue (average

for the medial and lateral tissues) was greatly decreased by the removal of the central portion in both groups, possibly due to overstress applied to the residual tissue [1], and the decrease was significantly larger in CSS than in NSS groups. The elastic modulus showed essentially similar results to the tensile strength in both groups. The strain to failure was significantly larger in CSS and NSS groups than in Control group regardless of experimental period, although there were no significant differences between CSS and NSS groups.

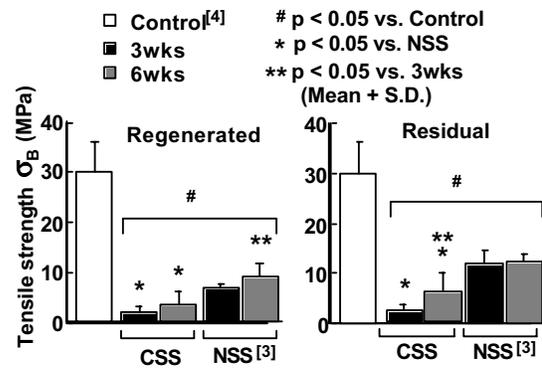

Figure 1 Tensile strength of regenerated and residual tissues after removal of the central one-third of the patellar tendon.

**CONCLUSION**

These results indicate that stress shielding induces adverse effects on the mechanical properties of the regenerated tissue and the unresected, residual tendon tissue after the removal of the central one-third portion of the PT as a substitute for ligament reconstruction. This fact implies that adequate stress is prerequisite for the healthy remodeling of not only residual tendon tissue but also newly regenerated fibrous tissue.

**INTRODUCTION**

Many runners suffer from tibial stress fractures. This may be a result of the repetitive loading applied to the tibia during running, as there is evidence of micro-damage in bone tissue after repetitive loading. Therefore, this study investigated 1) whether running-related loads are large enough to cause tibial stress fractures upon repeated application, and 2) whether muscle fatigue alters the potential for tibial stress fractures during running. The potential for tibial stress fractures was predicted, using an integrated experimental and mathematical modeling approach, by estimating the minimum number of loading cycles that would result in the failure of bone (Nfail).

**METHODS**

Ten male recreational runners with reflective markers attached to their left lower limb ran across a force plate for a total of 6 successful trials within the range of 3.5 – 4 m/s. Subjects then ran on a treadmill until muscle fatigue occurred, as indicated by a decrease of >25% in measured plantarflexion strength. Finally, the fatigued subjects performed 6 more running trials across the force plate within the same range of 3.5 – 4 m/s.

Inverse dynamics analysis was applied to the marker position and force data to estimate the joint reaction forces (JRF) and joint moments at the left ankle, knee, and hip. The forces acting in 21 muscles of the lower limb at each sample time were estimated from the joint moments through optimization, minimizing the sum of the cubed muscle stresses. From the JRF and the muscle forces, the 2-D bone contact forces at the distal end of tibia were computed. Stresses on the anterior and posterior faces of the tibia at 13.7 cm. from the distal end were then estimated from the bone contact forces, based on a beam model [1]. Finally, the tibial stresses were used to predict Nfail [2]. Nfail was log transformed for statistical analysis and a doubly multivariate was used to compare Ln(Nfail) before and after the onset of muscle fatigue.

**RESULTS AND DISCUSSION**

Compressive stresses were found at the posterior face of the tibia throughout stance, whereas both tensile and compressive stresses acted at the anterior face (Figure 1). This is consistent with strains that have been measured *in vivo* and *in vitro* [3,4]. The maximum compressive stress of  $-43.4 \pm 10.3$  MPa occurred at the posterior face of the tibia during mid stance

**Table 1:** The group mean  $\pm$  SD of Ln(Nfail) and the mean of Nfail at the posterior and anterior faces of the tibia.

	Before fatigue	After fatigue	P-value
<b>Ln(Nfail)</b>			
Posterior face	15.48 $\pm$ 2.56	16.07 $\pm$ 2.44	0.004
Anterior face	27.00 $\pm$ 4.95	27.94 $\pm$ 4.01	0.095
<b>Nfail (cycles)</b>			
Posterior face	5.28*10 <sup>6</sup>	9.53*10 <sup>6</sup>	–
Anterior face	5.32*10 <sup>11</sup>	1.36*10 <sup>12</sup>	–

and resulted in the minimum Nfail. Hence, the posterior face of the tibia was more prone to stress fractures, consistent with the results of a previous epidemiological study [5]. Although Nfail before fatigue averaged  $5.28 \times 10^6$  cycles, Nfail varied greatly between runners. The mean Nfails of two runners were only  $2.7 \times 10^4$  and  $2.7 \times 10^5$  cycles, suggesting that these two runners were at risk of a tibial stress fracture from running.

After muscle fatigue, tibial stresses tended to decrease (Figure 1), which led to a significant increase in Nfail (Table 1). This increase in Nfail implies that fatigue of the plantarflexors from prolonged running did not accelerate the onset of tibial stress fractures. Instead, changes in running technique with fatigue may have served to protect against tibial stress fracture. The results thus indicate that tibial stress fractures in runners result primarily from the repeated application of running-related loads in selected, at-risk individuals, and not from an increase in bone loading due to muscle fatigue.

## ARE THERE INHERENT DIFFERENCES IN HOW MALES AND FEMALES RESPOND TO LIFTING?

<sup>1</sup>Kermit Davis and <sup>2</sup>William Marras

<sup>1</sup>Low Back Biomechanics and Workplace Stress Laboratory, University of Cincinnati

<sup>2</sup>Biodynamics Laboratory, The Ohio State University

### INTRODUCTION

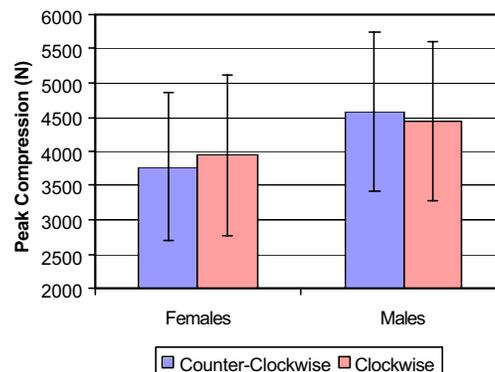

While the evidence is far from conclusive, males appear to be more susceptible to low cost low back injuries (mild low back pain) while females have higher rates of more costly injuries (severe low back pain) [1,2]. Although job requirements do not discriminate between genders, there is reason to expect that the biomechanical effect on the individual may differ as a function of gender. Males are significantly stronger than females [3,4]. Differences in strength and anthropometry between males and females may influence the trunk motions, muscle activities, and subsequent spine loads. Previous work evaluating how males and females respond biomechanically to similar lifting demands provides the evidence that females are not simply proportionally scaled down versions of males [5]. In other words, the differences in spine loading are not just a function of size. Overall, males have significantly greater three-dimensional spine forces than females when lifting. In addition to the differences in spine loading, males and females approached the lifting tasks differently with respect to trunk and hip kinematics as well as muscle recruitment. However, this previous study investigated gender differences but did not control for anthropometric differences. The *objective* of the current study was to evaluate males and females performing lifting tasks that were matched on height and body mass.

### METHODS

Nine females and nine males were selected from a larger study [6] based on matching anthropometry (within 5 kg and 5 cm). The average weight and height for males was 67.9 kg and 170.5 cm, respectively and for females was 67.5 kg and 168.9 cm, respectively. The experimental tasks consisted of asymmetric lifting of boxes to either a 90° clockwise or a 90° counter-clockwise shelf at two different lift rates—2 and 8 lifts/minute. Boxes weighing 6.8 and 11.4 kg were lifted from conveyor and placed on asymmetric shelf. The three-dimensional trunk kinematics as measured by the lumbar motion monitor, trunk kinetics measured by force platform system, and activity of the ten major trunk muscles were inputted into an EMG-assisted spine load model that predicted the three-dimensional spine loads—compression, lateral shear, and anterior-posterior shear forces. A repeated-measures split-plot analysis of variance was performed for all of the dependent variables with all significant effects being further analyzed using Tukey multiple pairwise comparisons.

### RESULTS AND DISCUSSION

Although males and females were virtually identical in body size, significant differences in spine loads still existed between the genders. Males were found to produce significantly greater compression forces—about 650 N than females. The direction of the task asymmetry also plays a role in the spine load responses. A small gender-asymmetry interaction effect was found to be significant for compression (Figure 1). In addition, males were found to have significantly greater lateral shear

**Figure 1:** Peak compression for males and females when lifting to counter-clockwise and clockwise shelves.

loads (130 N more) when lifting from the counter-clockwise shelf but significantly lower shear loads (about 70 N) when lifting from clockwise shelf. It is interesting to note that females had greater muscle activity in the right and left latissimus dorsi (about 22% MVC), right and left rectus abdominus (about 5% MVC), and left external oblique (about 11% MVC) muscles. Although this increase in muscle activity appears to be counter-intuitive, females lifted in a different way kinematically than the males, counteracting the muscle activity response. Many trunk kinematic differences were not significant but appear to be biomechanically important. Females were found to utilize their hips more (8° more and 10.5 °/sec faster) during lifting while males relied on more trunk motion (5° more and 6 °/sec faster). Together, the muscle responses and kinematic difference result in different spine load patterns between the genders.

### CONCLUSIONS

As with previous less controlled studies [5], the current study revealed that females are not scaled down versions of males. When exposed to the same lifting conditions, females respond with greater muscle coactivity but in a more neutral trunk posture by utilizing more hip motion. As a result, females minimize the loads on the spine during lifting. Thus, an inherent difference exists between males and females that cause the load pattern to be different.

## THE EFFECT OF PERIPHERAL ARTERIAL DISEASE ON GAIT

<sup>1</sup>Melissa M. Scott-Pandorf, <sup>2,3</sup>Iraklis I. Pipinos, <sup>2</sup>Leon Robinson, <sup>1</sup>Timothy Judkins, <sup>1</sup>Nick Stergiou

email:mmscott@mail.unomaha.edu, web: http://www.unocoe.unomaha.edu/hper/bio

### INTRODUCTION

Peripheral Arterial Disease (PAD) is the result of atherosclerotic occlusion of the leg arteries affecting more than 8.4 million people in US[1]. For PAD patients, walking is a difficult task because the increased metabolic demand of the leg muscles is not satisfied due to the decreased blood flow. The result is claudication, which is defined as pain in the leg muscles during ambulation. When ambulation stops, the muscle is reperfused and the pain subsides. Recent research has examined PAD and the associated claudication as a primary gait disability[2]. However, this work has performed evaluations using only temporal and spatial gait parameters, such as stride length and step time. As a result, these evaluations have been limited in their ability to describe in detail the true gait handicap of PAD patients[1]. For further advancement of the understanding of PAD, kinetics (i.e. ground reaction forces) and kinematics (i.e. joint angles) are warranted[3]. The purpose of this investigation is to examine the ambulatory dysfunction of the PAD claudicating, PAD healthy contralateral, and the healthy control legs using selected kinematic and kinetic parameters

### METHODS

Fifteen PAD patients and 5 age-matched (age 45-60 yrs) healthy controls walked through a 10m walkway while kinematic (60Hz) and kinetic (600Hz) data were collected both before and after the onset of claudication symptoms. The patients performed 5 trials at a self-selected pace with each leg while pain free (pre-pain), or with no claudication symptoms. Then patients were asked to walk on a treadmill at 1.5 mph (10% grade) until the onset of pain. After pain was induced, patients completed 5 more trials at a self-selected pace for each leg. The legs of the study participants were divided into 3 groups: PAD claudicating (CL, n=20), PAD healthy contralateral (CO, n=4), and control (HC, n=10). Statistics of selected measures were performed using 2x2 Mixed ANOVA (CL/CO vs HC, pre-pain vs post-pain) and 2x2 repeated measures ANOVA (CL vs CO, pre-pain vs post-pain).

### RESULTS AND DISCUSSION

The configuration of the vertical ground reaction force (VGRF) curve depicts a “flatter” configuration (Figure 1) for the CL and CO than the HC. Statistical analysis showed that the minimum values of VGRF ( $F_{min}$ ) for the CL ( $p=.02$ ) and CO ( $p=.03$ ) were significantly larger than the HC. The differences of the VGRF maximums to  $F_{min}$  ( $F1-F_{min}$ ,  $F2-F_{min}$ ) for CL ( $p=.04, p=.04$ ) and CO ( $p=.01, p=.01$ ) legs were significantly smaller than the HC. CO revealed larger braking impulse than the HC ( $p=.02$ ). For all legs, braking impulse significantly increased when comparisons included the CO legs from the pre-pain to the post-pain condition (HC: $p=0.01$ , CL: $p=0.02$ ). The stance time for CL ( $p=.01$ ) and

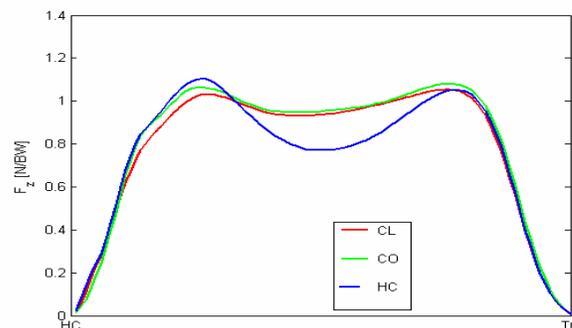

Figure 1. Mean VGRF for CL, CO, and HC legs.

CO ( $p=.04$ ) was found to be larger than the HC. Kinematic results indicated that CL had greater maximum plantar flexion at toe off ( $p=.033$ ) and ankle range of motion during stance than HC. At the knee, maximum flexion during stance decreased for CL from the pre-pain to the post-pain conditions while it increased for the HC ( $p=.02$ ). At the hip, CL had increased maximum hip extension during stance between the pain conditions while in CO decreased ( $p=.01$ ).

### CONCLUSIONS

The flatter configuration found in the VGRF curve may represent an attempt by the PAD patients to diminish any vertical fluctuations of the center of gravity and/or inability to accomplish proper knee extension during stance. This may offer a more stable gait to the PAD patient. The decreased knee flexion by CL and the slower walking pace (i.e. higher stance time) of the CL and CO may also indicate an effort toward a more stable gait pattern. In the majority of the patients, the most affected muscles reported were the foot plantarflexors. This may be the reason for the differences noted at the ankle. In addition, the decreased knee flexion observed may have resulted in the compensations found at the ankle. The increased braking impulse of the CO may be an adaptive pattern to slow the system early in stance phase in compensation for the CL. This is also evident by the changes in hip extension between conditions for the CL and CO legs. This again supports the idea of finding a more stable pattern as the gait of the patient slows down. In summary, PAD patients have altered their gait to (1) create a more stable gait and (2) to compensate for the pain induced during walking. Future directions for this investigation include examining stability directly via nonlinear tools.

## USE OF WAVELETS IN THE ANALYSES OF BIODYNAMIC RESPONSES

### INTRODUCTION

Biodynamic responses are usually transient, strongly localized in the time domain, and contaminated with noise, so that conventional statistical analysis, correlation analysis, or spectral analysis used for stationary signals may be neither appropriate nor efficient for the analyses of them. Wavelets, localized in both frequency and time domain, match the major characteristics of biodynamic responses. The use of wavelets in the analyses of biodynamic responses for various applications was investigated by the authors and is briefly described below.

### WAVELET/WAVELET PACKET DECOMPOSITIONS

A biodynamic response or signal  $S(t)$  can be decomposed on a wavelet basis [1]:

$$S = A_J + \sum_{j \leq J} D_j, \quad (1)$$

where the approximation  $A_J$  retains the lower frequency components of the original signal, and the details  $D_j$  contain high frequency components and often display vibrations and noises. In a wavelet packet basis, the decomposition of  $S(t)$  at level  $J$  can be expressed as [2]

$$S(t) = \sum_{n=0}^{2^J-1} \sum_k q_{Jnk} w_{Jn}(t-k), \quad (2)$$

where  $w_{Jn}(t)$  are wavelet packet atoms;  $q_{Jnk}$  are wavelet packet coefficients;  $n$  is the frequency index, and  $k$  is the position index. The wavelet transform allows for a view of biodynamic response in a time-frequency plane, and thus provides the information regarding when events take place.

### CORRELATION ANALYSIS

Decompose two signals  $x(t)$  and  $y(t)$  at a certain level using wavelets. The approximations  $x_a^l(t)$  and  $y_a^l(t)$  can be treated as deterministic signals, and the linear relationship or resemblance between them can be described by a classic correlation coefficient  $\rho_a^l(\tau)$  [3]. The time shift  $\tau$  is allowed to account for the phase shift between them. A quantity

$$\rho_{am}^l = \rho_a^l(\tau_m) = \max_{\tau} \{\rho_a^l(\tau)\}, \quad (3)$$

can be used to evaluate the agreement in the pulse shape, whereas  $\tau_m$  can be used to measure the time shift. As dyadic wavelet decomposition provides a multi-resolution analysis, the correlation analysis between the approximations at different levels describes the correlative relationship between the two original signals with different resolutions.

### SIGNAL ENERGY DISTRIBUTION ANALYSIS

If a signal is decomposed on an orthogonal wavelet packet basis using Eq. (2), in terms of the signal energy [3],

$$\|S\|^2 = \sum_{n=0}^{2^J-1} \sum_k q_{Jnk}^2. \quad (4)$$

The signal energy distribution can be defined in two ways:

- With respect to the frequency index  $n$ :

$$E_n = \sum_k q_{Jnk}^2; \quad (5)$$

- With respect to the time position  $k$  and the frequency index  $n$ :

$$E_{n,k} = q_{Jnk}^2. \quad (6)$$

### MODEL VALIDATION

The comparison of the energy distributions of a pair of biodynamic responses from a test and from the simulation shows the agreement or discrepancy in amplitudes between them; thus it can be used for the validation of bio-computational modeling. In order to compare the pulse shape and the peak timing between the two responses, the correlative relationship between the approximations can be used. Based on energy distributions and correlation analysis, several metrics were developed that can be used for quantitative validation. The comparison can be made at different levels so that details at different scales can be taken into account.

### PREDICTING HUMAN RESPONSE FROM ATD TESTS

The ATD (Anthropomorphic Test Device) response and human response are considered as the output of a black box system. Based on the decompositions of both responses on a wavelet packet basis, a mapping matrix is built after executing a procedure including de-noising, energy distribution analysis, correlation and regression analysis, and spectral coherence analysis and transfer function identification [4]. With the mapping matrix, an ATD response can be modified or reconstructed into the corresponding human response.

### CONCLUSIONS

Wavelet analysis is a useful and effective tool for the analyses of biodynamic responses in various applications.

<sup>2</sup>University of Iowa, Iowa City, IA; email: Ruth\_S\_Ochia@rush.edu

### INTRODUCTION

Spinal instability has been suggested as a potential cause of low back pain and axial rotational instability, in particular, has been implicated in its pathogenesis due to the presence of disc degeneration (DD) [1]. The use of radiographs has been under scrutiny in that it has been shown to be difficult to accurately measure vertebral translations and impractical to measure out of plane rotations with the 2D radiographic images [2, 3]. More precise techniques are generally invasive. The current study has expanded on a 3D non-invasive imaging technique to compare *in vivo* vertebral motions in human lumbar spines for healthy and chronic low back pain (LBP) subjects [3].

### METHODS

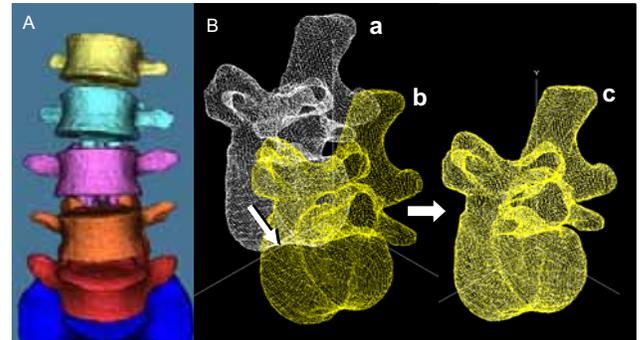

Using serial CT scans, a 3D computer model was developed to analyze lumbar segmental motion under axial torsion *in vivo* (Figure 1A). Male volunteers in their thirties (9 healthy (mean age:  $33.8 \pm 2.8$  years) and 5 LBP (mean age:  $33.0 \pm 3.5$  years)) were recruited to participate in this imaging study (IRB approved). The subjects were placed on a custom jig positioned in the CT scanner. The subjects were scanned in three positions: neutral (supine) and right and left rotated to  $50^\circ$  [4]. Reconstructed lumbar CT images were analyzed using the volume merge method, which virtually merged two 3D vertebrae models to calculate segmental motions in increments of 0.1mm and  $0.1^\circ$  (resolution:  $0.2^\circ$  and 0.1mm) (Figure 1B). Segmental rotations and translations between adjacent vertebral bodies were calculated in three major planes. All subjects were scanned using MRI for determination of disc degeneration using Thompson's grading system. Statistical analysis was conducted using unpaired t-tests with  $\alpha=0.05$ .

### RESULTS AND DISCUSSION

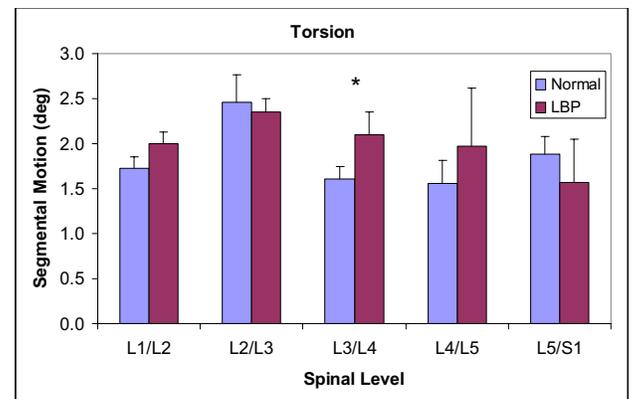

Segmental rotations were greatest in torsion with a trend for larger motion at L3/4 in LBP group ( $2.1^\circ$  vs  $1.6^\circ$ ,  $p<0.08$ ) (Figure 2). Lateral bending occurred in the direction opposite external rotation for upper vertebrae and with external rotation for the lower vertebrae, but these motions were not significantly different between groups. Segmental translations were negligible, except for the frontal plane with the greatest magnitudes in the upper vertebrae (range  $-6.0^\circ$  at L1/2 to  $1.4^\circ$  at L5/S1). In addition, the frontal plane translations showed significant differences between levels ( $p<0.01$ ) but not between groups ( $p>0.4$ ). There was a trend for greater degeneration in the LBP versus healthy group at L3/4 and L4/5 ( $p<0.1$  and  $p<0.09$ , respectively).

### CONCLUSIONS

Eventhough there was a relatively small sample size, some trends were determined. As expected there was greater level of degeneration in the LBP group, which also showed greater motion in torsion in the middle vertebrae. In addition, pure *in*

**Figure 1:** (A) 3D reconstruction of subject's lumbar spine from CT scans. (B) Vertebral body in the neutral position (a) was virtually rotated and translated toward the real rotated position (b) with  $0.1^\circ$  and 0.1mm increments, respectively, until the highest value of volume merge was calculated (c).

**Figure 2:** Comparison of torsional segmental motion between healthy and LBP subjects (mean  $\pm$  standard error of the mean). \*  $p<0.08$

*in vivo* torsion resulted in complex coupled motions with large lateral bending and frontal plane movements, especially in the upper lumbar vertebrae. Additional studies into segmental motion will be conducted in order to determine potential correlations with lumbar DD and LBP subjects' pain mapping.

## PRACTICE DISTRIBUTION AND THE ACQUISITION OF MAXIMAL ISOMETRIC ELBOW FLEXION STRENGTH

Kristina M. Calder and David A. Gabriel  
Raymond Nelson Reid Biomechanics Laboratory, Brock University  
Email: dgabriel@brocku.ca

### INTRODUCTION

Kroll [1] administered five maximal isometric wrist flexion strength trials, on each of three consecutive test days, and observed a significant increase across trials from the first to the last test session. There were then two retest sessions, two weeks and three months later. An 8-15% increase was observed between the first test and retest condition, and it was retained over the 3-month period until the second retest.

Kroll [2] later studied the effects of all contractions given on a single test day. There were three groups corresponding to 5, 10, and 15 maximal effort contractions. None of the three groups exhibited any increase in strength upon retest two weeks later. Thus, fifteen contractions distributed over 3 consecutive days enhanced muscular strength whereas fifteen contractions distributed on the same day did not. Kroll [2] theorized that the results of the two studies could be explained by the observed superiority of distributed versus massed practice in motor skill development. The present study tested Kroll's [2] hypothesis for the elbow flexors.

### METHODS

Twenty-six college-aged females were matched and randomly assigned to one of two groups. The massed group ( $n=13$ ) completed 15 maximal isometric elbow flexion strength trials in one session, while the distributed group ( $n=13$ ) performed five such contractions on three successive days. After a 2-week and 3 month rest interval, both groups returned to perform another five maximal isometric elbow flexion strength trials to assess retention of any potential strength gains.

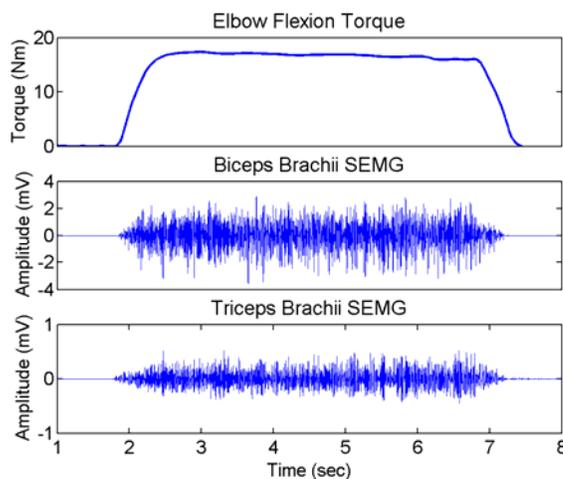

Surface electromyographic (SEMG) activity of the biceps and triceps brachii were monitored with bipolar electrodes (DE-2.1, Delsys Inc., Boston, MA). The signals were amplified (1000 $\times$ ), band-passed (20-450 Hz) filtered, before A/D conversion (BNC-2110, National Instruments) at 2048 Hz (DASYLab, DASYTEC National Instruments, Amherst, NH) on a Pentium III PC (Seanix Technology Inc., Blaine, WA). Force was monitored with a load cell (JR3 Inc., Woodland, CA). The force signal was low-passed (100 Hz) before being sampled in the same manner as the SEMG. Figure 1 depicts representative SEMG and force signals.

### RESULTS AND DISCUSSION

There was a significant ( $p<0.05$ ) increase in strength in both groups from Block 1 (first 5 contractions) to Block 2 (first retest) and from Block 1 to Block 3 (second retest). Both groups exhibited an increase ( $p<0.05$ ) in biceps root-mean-square (RMS) SEMG amplitude. A significant ( $p<0.05$ ) decrease in triceps RMS SEMG amplitude was found between

Block 1 and 2 for both groups. However, a significant ( $p<0.05$ ) increase was found between Blocks 2 and 3.

Both the massed and distributed groups exhibited a learning-related increase in maximal isometric elbow flexion torque that was retained over a three month period. The increase in neural drive to the agonist was also retained [3]. The reduction in antagonist coactivation was a short-term (2 weeks) training effect [4], dissipated over the longer rest interval (3-months). The subsequent increase in antagonist coactivation was necessary to increase joint stability in response to further increases in agonist muscle force output, observed during the last re-test session. The results of this study suggest that there is flexibility in how muscle contractions may be distributed. However, other aspects of motor learning theory should be explored further, such as the role of feedback. To subtract-out learning effects upon strength training studies, only one session is needed, as multiple sessions may be unnecessary.

**Figure 1.** Representative torque (top panel), biceps brachii agonist SEMG (middle panel), and triceps brachii antagonist SEMG (bottom panel) for one subject.

### INTRODUCTION

The interaction of a muscle and its attached tendon during dynamic activities such as locomotion is critical for both force production and economical movement. Sonomicrometry studies have revealed that compliant tendons can store and return elastic energy to change the timing and magnitude of muscular work and allow the contractile components to act nearly isometrically, despite substantial length changes in the muscle-tendon unit [1]. This produces higher forces and reduces the energetic requirements of the muscle fibres. Similar results have been reported for human muscle fibres using ultrasonography during slow walking [2].

Using a novel ultrasound probe and setup, we tested the hypotheses that –

1. the *medialis gastrocnemius* (GM) muscle undergoes a homogenous length and structure change across three sites along the length of the muscle (distal, middle and proximal) during walking and running;
2. the GM muscle fibres shorten more during running than during walking .
3. the elasticity of the Achilles tendon enhances GM muscle fibres efficiency under different locomotion conditions

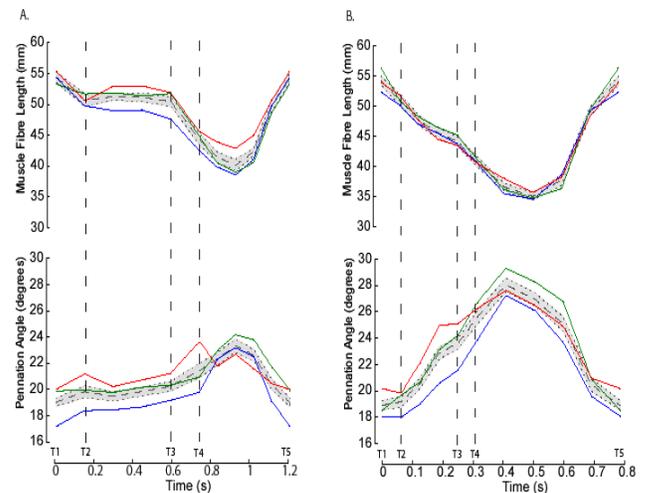

### METHODS

6 volunteers (3 male and 3 female) participated in the study. Participants walked and ran on a treadmill at speeds of 4.5km/h and 7.5 km/h respectively. A flat ultrasound probe was attached to the *gastrocnemius medialis* (GM) muscle such that it imaged a transverse section to the leg in the same plane as line of action of the muscle fibres at a rate of 25Hz. Measurements were made at three levels of the muscle; the midbelly and distally and proximally to this position. Muscle fibre length and pennation angle was measured throughout 3 complete gait cycles for each gait condition for each subject. Sagittal plane kinematics were recorded with an active LED motion analysis system (CODA, Charnwood Dynamics, England) and synchronised with the ultrasound data using a sonomicrometry crystal mounted on the ultrasound probe. Length changes of the *gastrocnemius medialis* (GM) muscle-tendon unit length were derived from joint angle data using the equations derived from Grieve *et al* (1978) [3]. Muscle fibre lengths and the pennation angle from the ultrasound images were used along with the whole muscle-tendon length to estimate the tendon elongation [2].

Identical measures were made with 6 male participants during walking (5km/h) at grades of -5,0 and 10% and also during running (10km/h) at grades of 0 and 10%.

### RESULTS AND DISCUSSION

The results of the study show that muscle fibres perform similar functions along the length of the human MG muscle during locomotion, regardless of speed or gait. However, they do not act totally homogeneously along the muscle lengths

**Figure 1:** Average length and pennation angle of muscle fibres across one complete stride (heel on to next heel on) during walking (A) and running (B) for each of three ultrasound sites (distal = blue; midbelly = green; proximal = red). The dashed line represents the average muscle fibre length and pennation angle across all three sites (shaded area is 95% confidence interval). The stride is divided up into the following specific events averaged from the kinematics: T1-Heel strike; T2 - Foot flat; T3 - Heel off; T4 - Toe off; T5 - Heel strike.

(Figure 1). The distal fibres tend to shorten more and act at greater pennation angles than the more proximal fibres. The fibres also shorten more during running compared to walking so that they can produce the forces required to support the body and propel it upwards and forwards. A tendon stretch of approximately 18mm and 25mm during walking and running respectively was estimated. The maximum shortening speed of the muscle tendon complex (6 muscle fibre lengths/s) occurs during the take-off phase of stance. However the muscle fibres never exceed a shortening velocity of above 1.5 lengths per second, even during running. This is a more optimal shortening speed for both power output and efficiency. With variations in grade, the stretch of the Achilles tendon and hence storage of elastic energy is modulated by a change in muscle fibre length. The muscle fibres respond to increases in work demands by activating in an efficient manner to produce the required power output.

## IN-VITRO TESTING OF KNEE JOINTS USING ROBOTICS: COMPUTER PROGRAMMING THEORY

### INTRODUCTION

The knee is the most used joint in the human body, and thus often succumbs to injury due to trauma and/or aging. Such trauma from accidents, and diseases commonly associated with aging, such as arthritis, can cause pain, inflammation and irregular function of the joint. Studying the knee allows for improved understanding of its injury mechanics as well as knowledge that can be used in improving chemical/surgical treatment of the injured joint and the design of knee prosthetics.

Using robots for *in-vitro* testing of the knee is less invasive than *in-vivo* research while still being able to apply physiologic conditions. The aim of this research is to develop the control theory for controlling a robot to apply physiologic load/motion to the cadaveric knee in order to determine the role and function of each of its structures.

### METHODS

An industrial parallel robot (Parallel Robotic Systems Corp., NH, USA) is used, while the knee is described using the floating axis system as described in [1,2,3]. The knee is manipulated by manipulating the tibia (secured to the robot) about the femur (secured to ground) (Figure 1). Local co-ordinate systems are defined through digitizing of the proximal tibia, distal femur, end-effector and load cell. Position and load control programs were then written in Matlab 7.0 to track the mathematical transformations between the systems in order to control the robot kinematics with respect to the knee kinematics and load cell kinetics [2,4]. These programs allow the user to specify either knee kinematic targets or knee kinetic targets respectively.

Both programs were verified using linkage systems that modeled the knee. The position control and load control programs were tested using artificial constructs.

### RESULTS AND DISCUSSION

The position control program can reach the target knee kinematics within  $0.1^\circ$  and 0.01mm. To incorporate the floating axis description of the knee, the program recalculates the position/orientation of the floating co-ordinate system after every  $0.2^\circ$  and 0.1mm increment of knee motion. This allows for a step-wise generated position path for the end-effector that can be saved and replayed in a more fluid fashion.

Currently, the load control program can reach the target knee kinetics within 3N and 0.5Nm. Kinetics read at the load cell (secured to the femur) are mathematically transformed to the knee co-ordinate system to represent the knee kinetics [4]. Target knee kinematics are then calculated using its kinetics

**Figure 1:** Testing set-up. Tibia is secured to the parallel robot (top) and the femur is grounded (bottom).

and a compliance matrix. When the knee reaches the desired kinematics, its kinetics are checked, the compliance matrix is updated; if necessary, new target knee kinematics are set and the process reiterates until the target kinetics are reached.

The position and load control programs are stepping stones for a hybrid control program that simultaneously controls both knee kinematics and kinetics to enable physiological joint loading. This program will allow the user to specify which degrees of freedom are controlled in load and which in position, and is currently being developed.

### CONCLUSIONS

Preliminary tests confirm that knee kinematics and kinetics can be controlled independently using the commercial robotic system. When hybrid control programming is complete, physical testing using cadaveric knees will begin.

**THE IMPACT OF USING DIFFERENT CALCULATION METHODS AND LOCAL COORDINATE SYSTEMS WHEN MEASURING 3D SCAPULAR ATTITUDES**

**INTRODUCTION**

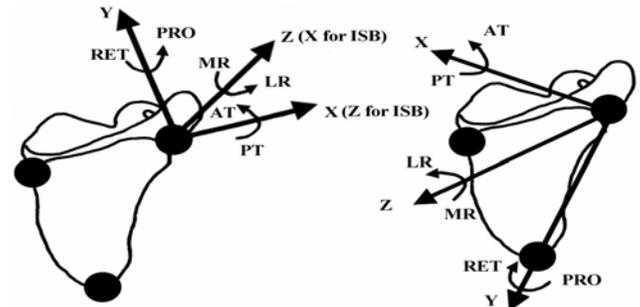

The normal range of scapular rotations during arm elevation of healthy subjects significantly varies from one study to another. Some factors suggested to explain this variation include differences between studies in the kinematic definition of scapular movements. For example, Karduna et al. have shown that, when calculating motion of the scapula, altering the sequence of rotations has a major impact on the magnitude of the estimated scapular motion in each plane [1].

The International Shoulder Group (ISG) has proposed standard definitions of the joint coordinate system for the reporting of shoulder motion to allow a better comparison of results between studies [2]. However, the impact of using different local coordinate reference systems and different methods of calculation when characterising scapular movements remains to be investigated. The objective of this study is to compare the 3D scapular attitudes (3DSA) obtained when using two different local coordinate systems and two different methods of calculation of relative movement.

**METHODS**

In a seated position, the 3DSA of both shoulders of 15 healthy subjects (mean age 37.8 ± 13.2 years) were measured in two shoulder positions: 70° of flexion and 90° of abduction. The 3DSA was calculated using the Optotrak Probing System (Northern Digital Inc., Waterloo, Ontario, Canada). For each trial, three non-collinear bony landmarks on the scapula (trigonum spinea, angulus inferior and angulus acromialis) and on the trunk (C7 spinous process and the right and left postero-superior iliac spines) were digitized.

Two methods of calculation of relative movement were used to determine the 3DSA. First, the 3DSA with the arm in elevation was calculated with respect to the position of the scapula with the arm at rest; and secondly, the 3DSA was calculated with respect to the trunk. 3DSA were also calculated using the local coordinate reference system proposed by the ISG [2] and by Hébert et al. [3] (Figure 1). The mean of the 3DSA of the 30 shoulders was used to compare the methods of calculation and reference systems. A *t-test* was performed to evaluate the differences.

**Figure 1:** Local coordinate reference system proposed by ISG (left) and Hébert et al. (right)

**RESULTS AND DISCUSSION**

Altering the method of calculation has the most significant impact on the magnitude of the scapular rotations calculated (Table 1A). This finding is not surprising since the two methods are so different. One method calculates the displacement of the scapula from its position at rest, while the other calculates the changes in the orientation of the scapula with respect to the trunk. When interpreting findings from different studies in which different methods of calculation were used, one must be careful to make comparisons.

Using different local reference systems has less impact on the 3DSA, except in medial-lateral rotation for the method with respect to the trunk (more than 45°) (Table 1B). In this latter plane of movement, the differences in the orientation of the y-axis seem to have brought important changes of attitudes.

These results support the ISG recommendations to adopt standards for joint coordinate systems and method of calculation to allow a better comparison and benchmarking between studies. However, as there is so much variability between methods and systems, the choice of standard parameters must be based on their capacity to best characterise normal and abnormal patterns of movement.

## NONLINEAR ANALYSIS OF POSTURAL CONTROL IN DIFFERENT POSITIONS AND VISION CONDITIONS

Kimberly Ryland, Clinton Wutzke, Nicholas Stergiou,  
University of Nebraska-Omaha, HPER Biomechanics Laboratory  
email: kryland@mail.unomaha.edu, web: www.unocoe.unomaha.edu/hper/bio/home.htm

### INTRODUCTION

Despite postural control being a multi-degree-of-freedom mechanical system with highly redundant actuators [1], recent research has demonstrated that postural sway fluctuations like fluctuations present in many other biological systems are not random but rather have order [2]. Unlike traditional linear measures which can mask patterns present during postural sway, nonlinear analysis measures can characterize this order. Quantifying these patterns could enable the pinpointing of the precise contributions of sensory input and the improvement of rehabilitation methods [3]. Our aim was to compare the ability of traditional linear measures to nonlinear measures in differentiating between sitting and standing in the presence or absence of visual information.

### METHODS

Eleven healthy young adults were asked to 1) stand quietly on a force platform (10 Hz) looking forward (STAND), 2) sit in a yoga style position directly on the force platform with their hands in their laps (SIT), and 3) sit upright on a stool (base 32x34 cm, height 75 cm) placed in the middle of the force platform with their arms to their sides and their feet not supported by the ground or the stool (SITSTOOL). Each position was maintained for five minutes and repeated three times with eyes open and three times with eyes closed. The coordinates of the center of pressure (COP) in the medial-lateral (ML) and anterior-posterior (AP) were calculated for each trial. Then, the unfiltered COP coordinates were analyzed using Chaos Data Analyzer Professional software to calculate four nonlinear measures (Correlation Dimension CoD, Lyapunov Exponent LyE, Hurst Exponent H, and the Lyapunov Exponent after the time series were surrogated SLyE) [2]. To calculate H, all data were first integrated. To calculate our nonlinear measures, we first reconstructed the state space by estimating the embedding dimensions (ED). ED is a measure of the number of dimensions needed to unfold a given attractor. This parameter was calculated with the Tools for Dynamics software [2]. We also calculated five linear measures (Root Mean Square RMS, Mean Distance MD, Total Excursion TE, Mean Velocity MV, and mean Total Excursion per second TEt) [5]. Statistical analysis was performed by either paired t-tests or ANOVA with further post hoc analysis when necessary.

### RESULTS AND DISCUSSION

No significant differences were found for ED (mean=4.83). Thus ED equal with 5 was used for all subsequent nonlinear calculations. Our results showed that postural sway fluctuations for all postures examined had deterministic nature (paired t-tests; mean LyE=0.245, SLyE=0.268,  $p<.0005$ ). A system is shown to have deterministic nature (orderly fluctuations), if the LyE is positive and is significantly different than SLyE [2]. We also found a mean  $H=1.005331$  with no significant differences between conditions or directions (paired t-tests). H is a measure of persistence (memory) of a given fluctuation in a time series. This H value suggests that the deterministic patterns in posture have long

range memory similar to the  $1/f$  noise found in heart rhythms [4]. We also found that nonlinear measures were able to better differentiate between sitting and standing. LyE (a measure of local stability, higher stability equals smaller LyE) in the ML and CoD (a measure of degrees of freedom) in ML and AP demonstrated significant differences between STAND and SIT ( $p=.002$ ,  $p=.002$ ,  $p=.003$ ) and STAND and SITSTOOL ( $p=.007$ ,  $p<.0005$ ,  $p=.003$ ). Significant differences were also found between STAND and SIT in the linear measures of TE, MV, and TEt in the AP ( $p=.034$ ,  $p=.034$ ,  $p=.034$ ) and TE, MV, TEt, and MD in the ML ( $p=.004$ ,  $p=.004$ ,  $p=.004$ ,  $p=.004$ ,  $p=.020$ ). In addition significant differences were exhibited between SIT and SITSTOOL for the linear measures TE, MV, and TEt in the AP ( $p=.001$ ,  $p=.001$ ,  $p=.001$ ) and ML ( $p=.002$ ,  $p=.002$ ,  $p=.002$ ). Curiously, no differences were found in the linear measures between STAND and SITSTOOL which suggests that it was the distance from the center of gravity to the force platform that influenced the linear measures, rather than characteristics of the COP time series itself. Also, while the linear measure values were different, they measured the same relationships (identical p values). However when differentiating between vision conditions the nonlinear measures performed poorly while the linear measures demonstrated some differences. Only RMS and TEt in the ML showed significant differences between eyes open and closed ( $p=.036$ ,  $p=.018$ ). However significant interactions were found in TE, MV, and TEt in both AP ( $p=.04$ ,  $p=.038$ ,  $p=.038$ ) and ML ( $p=.018$ ,  $p=.018$ ,  $p<.0005$ ) and LyE in ML ( $p=.027$ ). With the exception of TE and TEt in the AP, these interactions were the result of the eyes open values being larger than the eyes closed values during STAND, while the eyes open and eyes closed values were the same in both sitting conditions. This may be due to differing use of sensory information, while maintaining upright standing vs. sitting. There was also a discrepancy in the general trends found in the data. MD and RMS in AP, CoD and H in ML increased from eyes open to eyes closed, while TE, MV, LyE, CoD, and H in AP and RMS, MD, TE, MV, and LyE in ML decreased from eyes open to closed. This is not altogether surprising as Chiari et al. [5] found that while most subjects' sway increases with their eyes closed, there exists a second class of individuals who sway less with their eyes open. In conclusion, the results demonstrated that posture is deterministic and persistent and that nonlinear tools are able to pierce into the structure of posture. However, more work needs to be done to determine whether these tools can contribute to sensory understanding.

### INTRODUCTION

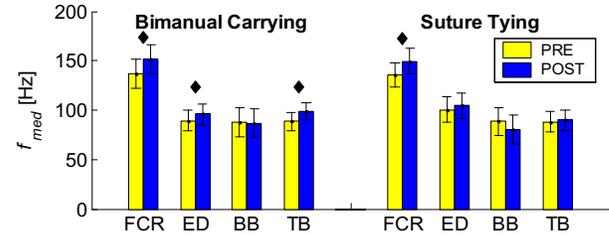

Laparoscopy, a form of minimally invasive surgery (MIS), has revolutionized the treatment of abdominal pathologies. The advent of robotic surgical systems, such as the da Vinci™ Surgical System (dVSS), have further improved MIS by adding three-dimensional viewing [1] and increasing dexterity [2]. However, it is necessary to train and evaluate surgeons on the usage of the robotic system. The current means of evaluating surgical performance, while using a robotic surgical system, are limited to task completion time and number of errors [2, 3] or subjective evaluations. To our knowledge, no studies have examined physiological measures of the surgeons during performance of robotic surgical techniques. Especially, how training affects such physiological measures is unknown. This study seeks to determine how physiological measures, in the form of electromyography, change during training with dVSS.

### METHODS

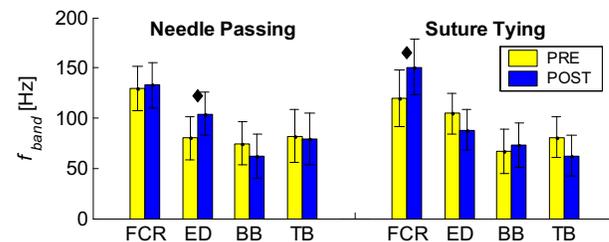

Fifteen right-handed novice dVSS users performed and/or practiced three tasks: bimanual carrying (BC), needle passing (NP), and suture tying (ST). BC required simultaneously picking up two rubber pieces and placing them 50 mm away. NP required passing a 26 mm surgical needle through 6 holes in a latex tube. ST required tying three intracorporeal knots with a surgical suture. All tasks mimicked actual laparoscopic tasks that require significant bimanual coordination. Subjects were randomly assigned to either a training (T) or a control (C) group. The experiment was performed over a period of four weeks and consisted of one pre-training test (PRE), 6 training sessions, and one post-training test (POST). Surface electromyography (EMG) was recorded (1000Hz) from 4 muscles: flexor carpi radialis (FCR), extensor digitorum (ED), biceps brachii (BB), and triceps brachii (TB). Frequency power spectrums for each muscle were calculated using Fast Fourier Transforms. Median frequency and bandwidth were compared using a mixed two-factor (group by testing session) ANOVA for each muscle and for each task.

### RESULTS AND DISCUSSION

Median frequency was larger for POST for three muscles (FCR, BB, and TB) during the BC task and for one muscle (FCR) during the ST task (Figure 1). This increase was independent of group. This is not surprising considering that our previous work has found that significant decreases in task completion time are possible even after one training session. Furthermore, the increase in median frequency may be due to a reduction in muscle fatigue, since it has been shown that decreases in EMG frequency are associated with muscle fatigue [4]. It was also found that when a significant difference in median frequency or bandwidth was found, it occurred in muscles that would predominately be used for the given task.

**Figure 1:** EMG Median Frequency grouped by PRE/POST training for Bimanual Carrying and Suture Tying tasks. A diamond indicates significance ( $p < 0.05$ ) between PRE and POST training.

**Figure 2:** EMG Bandwidth grouped by PRE/POST training for Needle Passing and Suture Tying tasks. A diamond indicates significance ( $p < 0.05$ ) between PRE and POST training.

During the BC task, median frequency increased for the muscles used for grasping (FCR) and arm movements (BB and TB). Likewise, the median frequency for the FCR increased POST-training during the ST task, a grasping intensive task. The EMG frequency content is also directly related to the conduction velocities of recruited motor units [5], i.e., the types of motor fibers that are recruited. Therefore, frequency bandwidth may be a representation of the range of motor units that are recruited. For the more complex tasks (NP and ST), we found that POST bandwidth increased for the muscles that are required to perform the respective tasks (ED for NP, FCR and BB for ST; Figure 2). It is likely that different motor units are recruited during different phases of the task depending on the complexity of each phase. In conclusion, an evaluation of the physiological demands of robotic laparoscopic surgery can provide us with a meaningful way to quantify performance and skill acquisition.

### INTRODUCTION

The triceps surae (TS) muscle group plays a key role during postural control and physical activities in humans. It is well known that disuse (e.g. spaceflight and bed rest) induces deconditioning of the TS muscle group. We demonstrated that the neuromuscular adaptation took place in the TS muscle group during fatigable exercise after 20-d bed rest [1]. However, it is not well known whether this adaptation may occur during moderate fatigable exercise in this muscle group. The purpose of this study, therefore, is to elucidate change of function in the TS muscle group during both moderate fatigable and fatigable exercises after disuse using muscle functional magnetic resonance imaging (mfMRI) and surface electromyography (EMG) techniques.

### METHODS

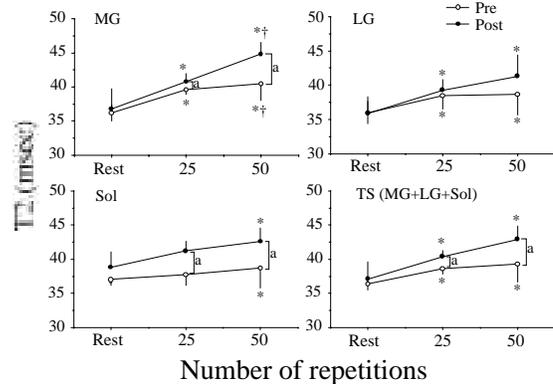

Five subjects participated in this study. The subjects were remained a 6 degree head-down tilted bed during 20 days, they were not permitted to be in any weight-bearing posture and all physical activities were kept to a minimum during this period. mfMRI (spin echo, TR 1500 ms, TE 25/70 ms) of the medial and lateral gastrocnemius (MG and LG, respectively), soleus (Sol) muscles was measured at rest and immediately after 25 repetitions (moderate fatigable, 25-rep Ex) and 50 repetitions (fatigable, 50-rep Ex) of unilateral calf-raising exercises [1]. Transverse relaxation time (T2) of the TS muscle group was measured as an index of neuromuscular properties. EMG activity (sampling rate: 1 kHz, band-pass filter: 20 to 450 Hz) was recorded from the MG, LG, Sol, and tibialis anterior (TA) muscles during 25-rep Ex and 50-rep Ex. Raw EMG signals was rectified and root mean squares was calculated. EMG activity was presented as the ratio of the last three repetitions to the first three repetitions. All data are presented as means and standard deviation. A one-way ANOVA and the Newman-Keuls was used for comparison.

### RESULTS AND DISCUSSION

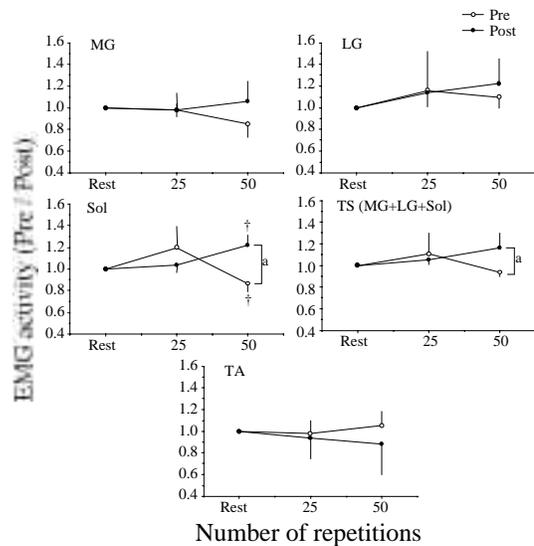

There was no significant change in resting T2 due to 20-d bed rest (Fig. 1). Overall, the T2 of the TS muscle group significantly increased with increase of the number of repetitions (Fig. 1). In the MG, Sol muscles, and TS muscle group, the T2 change was significantly higher after bed rest than before bed rest at 25-rep Ex and 50-rep Ex (both  $P < 0.05$ ), suggesting a greater number of muscle fibers were involved in performing during 25-rep Ex and 50-rep Ex under the same absolute load [1, 2].

EMG activity of the Sol muscle and TS muscle group during 50-rep Ex was significantly higher after bed rest than that of before (Fig. 2,  $P < 0.05$ ). No any significant changes of EMG activity were found in the MG, LG, and TA muscles.

We conclude that a short period of disuse affects on muscle function during moderate fatigable exercise as well as

**Figure 1:** T2 changes of the TS muscle group during unilateral calf-raising exercises before and after 20-d bed rest. \*:  $P < 0.05$  vs rest, †:  $P < 0.05$  vs 25-rep Ex, a:  $P < 0.05$  pre vs post.

**Figure 2:** EMG activity of the TS muscle group during unilateral calf-raising exercises before and after 20-d bed rest. †:  $P < 0.05$  vs 25-rep Ex, a:  $P < 0.05$  pre vs post.

fatigable exercise, and that the functional adaptation is muscle-specific in human calf.

#### INTRODUCTION

Delayed posttraumatic vertebral collapse (Kümmell's disease) is a rarely reported, poorly documented, and poorly understood phenomenon. Schmorl and Junghanns [1] and Resnick and Niwayama [2] supported and defined the delayed vertebral collapse as a form of vertebral osteonecrosis. Based on the Symptoms, radiographies, and MRI findings from 129 patients, classification of the Kümmell's disease has been studied by Li et al in 2004 [3]. Three stages of the disease were found. The object of this study is to understand the stress distribution of vertebral body with various levels of vertebral collapse. The comparison of stress distributed on the vertebral body can be a good reference to the development of three-stage classification system.

#### METHODS

A three-dimensional finite element model of the intact vertebra was developed. There were 5334 nodes and 25720 elements in this intact model. Four zones of materials, including cortex, cancellous bone, posterior elements and cleft element, were assigned. Various percentages of cancellous bone in other models were excavated to simulate different levels of vertebral collapse (Fig.1). Totally, twenty-two models with various sizes of intravertebral clefts, including 0% (intact), 1%, 2.5%, 5%, 10%, 15%, 20%, 25%, 30%, 35%, 40%, 45%, 50%, 55%, 60%, 65%, 70%, 75%, 80%, 85%, 90% and 95% clefts in vertebral height. Nodes under the inferior end plate of vertebral body were fixed as the boundary condition under loadings. A 1000 N compression was evenly loaded on the superior end plate. In addition to compression, flexion and extension condition were also simulated by loading a 5 N-m torque. The von Mises stress distribution on vertebra was compared among vertebral models with various collapses.

#### RESULTS AND DISCUSSION

In compression, the maximal von Mises stress in vertebra was much higher than intact and distributed at the bilateral corners of the intravertebral cleft inside the superior endplate (Fig. 2). Comparison among models with various sizes of clefts showed that there were three zones on the curve of maximal von Mises stress along increasing sizes of clefts (Fig. 3). Vertebral collapses with 10 % and 80 % clefts were two transitional points on this curve. In flexion and extension, curves with a similar trend were also found. On the other hand, high stress also concentrated at the posterior cortex behind the cleft.

Three-stage classification has been established by Li et al. The stage I was defined as when the plain x-rays or MRI revealed osteonecrosis signs in vertebral body. The stage II was that body collapsed with intact posterior cortex of body. The stage

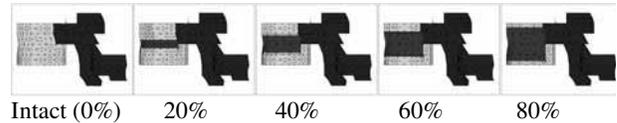

Figure 1: Models with various sizes of intravertebral clefts.

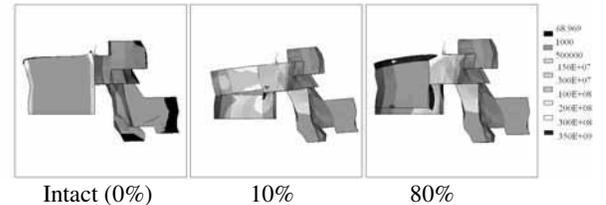

Figure 2: The von Mises stress distribution under flexion

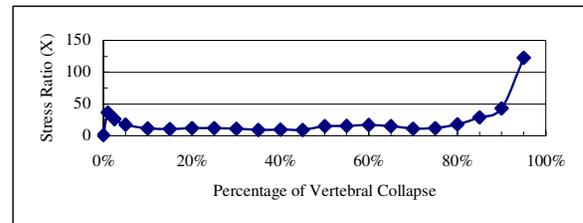

Figure 3: The ratio of maximal von Mises stress in vertebral body with various collapses to the intact under compression. The 0 % of vertebral collapse represents the intact.

III was that posterior body cortex collapsed with cord compression. Treatment for each stage was different. This finite element simulation has shown that the level of stress distributing on vertebral body depended on the size of the intravertebral cleft. Especially, there were three stages in the relation curve between the maximal stress and cleft's size. This becomes a biomechanical evidence to support the clinical finding of three-stage classification for the Kümmell's disease.

#### CONCLUSIONS

From view points of pathological and biomechanical progress, three-stage classification system is probably appropriate to the diagnosis of Kümmell's disease.

## LATERAL BALANCE IN A/K AMPUTEES AND HEALTHY CONTROLS

<sup>1,2</sup> At Hof, <sup>2</sup>Renske van Bockel and <sup>2</sup>Klaas Postema

### INTRODUCTION

In walking the human body is never in balance. Most of the time the trunk is supported by one leg and the center of mass (CoM) is never above some base of support. According to the inverted pendulum model, when support is on the left leg we should fall to the right, and vice versa [4].

Recently it has been shown [2] that in dynamical situations the velocity of the CoM should be acknowledged. The center of pressure (CoP) should be outside the 'extrapolated COM' (XcoM), where  $XcoM = CoM + \text{velocity of CoM} / \omega_0$ .

Parameter is  $\omega_0$ , the pendulum frequency,  $\omega_0 = \sqrt{g/l}$ . If this condition is not met, the CoM will traverse the CoP position and 'fall' to the wrong side, e.g. to the left of the left foot.

### METHODS

CoP position and temporal data were recorded by a treadmill with built-in force transducers [3]. Left-right CoM and XcoM position were computed by filtering the CoP data [1].

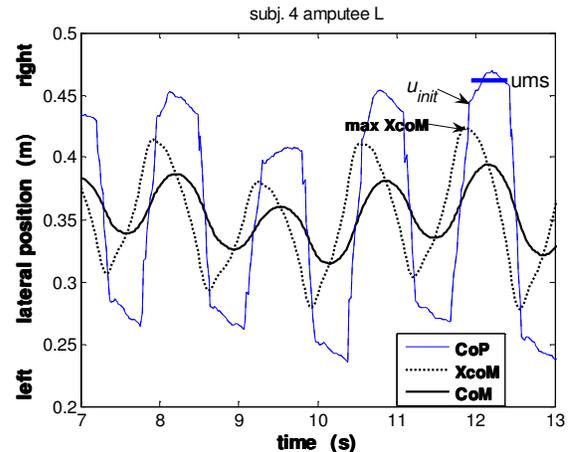

Subjects were six above-knee amputees, ages 32-50 yr, with prosthesis for 6-40 years, and six matched healthy controls. They walked at 1 m/s for 2 min.

### RESULTS AND DISCUSSION

Amputees showed asymmetric gait with shorter stance (60%) at the prosthetic side vs. 68% at the non-prosthetic side and a wider stride ( $13 \pm 4$  cm, mean  $\pm$ s.d.) compared to controls ( $8 \pm 3$  cm). At foot placement CoP was just outside of the XcoM, see Figure 1. The margin between average CoP and XcoM at foot contact was only  $1.6 \pm 0.7$  cm in controls. In amputees this margin was clearly different between the prosthetic side ( $2.7 \pm 0.5$ cm) and at the non-prosthetic side ( $1.9 \pm 0.6$ cm).

Next to this 'stepping strategy', CoP position was corrected after initial contact by modulating the lateral foot roll-off ('lateral ankle strategy') in non-prosthetic legs up to about 2 cm. Finally there are indications that in prosthetic walkers trunk movements also contribute to balance ('hip strategy').

The inverted pendulum model can explain that 1) a less precise foot placement (greater CoP-XcoM margin) results in a wider stride, and 2) a greater margin at one side, as with a leg prosthesis, should be compensated by a shorter stance duration to achieve a straight path.

**Figure 1** Detail of a recording of CoP, CoM and XcoM in walking at 1 m/s in a subject with a left A/K prosthesis. XcoM shows a maximum 'max. XcoM' when the right foot is initially positioned at  $u_{init}$ . After placement the normal right foot corrects itself to achieve an average CoP position  $ums$ , sufficiently far from the XcoM. Note stereotypical CoP patterns for left (prosthetic) foot, compared to right.

### CONCLUSIONS

Foot placement in walking should be remarkably precise to achieve a reasonably narrow and straight path, although some additional correction by ankle- and hip strategy is possible. In patients with a one-sided disability leading to less precise foot placement, as in prosthetic walkers but possibly also in stroke patients, this must be compensated by a shorter stance. Maybe in these patients symmetric gait should not be an aim of rehabilitation.

## PERTURBATION IN TRUNK MOTION OF LOW BACK PATIENTS

<sup>1,2</sup> Heydar Sadeghi, <sup>2</sup> Paul Allard, <sup>2</sup> Somayeh Sadeghi

<sup>1</sup>Department of Kinesiology, Tarbiat Moallem University, Ministry of Sciences, Research and Technology, Tehran, IRAN,  
<sup>2</sup>Research Center, Sainte-Justine Hospital, Montreal, PQ, Canada; email: sadeghih@yahoo.com

### INTRODUCTION

Analysis of trunk motion consists of a complementary test, which includes the diagnosis and follow-up of patients with low back pain [1,2]. The information provided by the analysis usually shows significant reduction in trunk mobility or functional compensatory behavior. Measuring three-dimensional spine motion in able-bodied subjects and patients with LBP, this study was undertaken to determine: a) if trunk motion and particularly coupling motions were perturbed in LBP patients, which trunk segments are mostly affected, and b) whether or not trunk rigidity was reduced after eight weeks of physiotherapy.

### METHODS

The fourteen subjects with low back pain who participated in this study had an age of  $33 \pm 7.3$  years, height of  $172 \pm 9$  cm and weight of  $70.9 \pm 15.6$  kg. The thirteen able-bodied subjects who participated in this study had an age of  $35.1 \pm 9$  years, height of  $175 \pm 10$  cm and weight of  $68.5 \pm 9.7$  kg. Data were collected using a four-camera high-resolution motion analysis video-based system while subjects were performing five principal movements, namely, right and left lateral bending and rotations as well as forward trunk flexion. The amplitude differences of the principal movements and the coupling motions of trunk and thoracic and lumbar segments of the able-bodied subjects and LBP patients were determined using ANOVA with a threshold of  $p < 0.05$ .

### RESULTS AND DISCUSSION

The absence of a difference in the principal motions leads us to believe that there is no limitation of movement because no significant difference was observed between the able-bodied subjects and the patients before and after treatment. Significant differences, however, were observed in the coupling motions between the control subjects and the group of the LBP subjects before treatment (Figure 1).

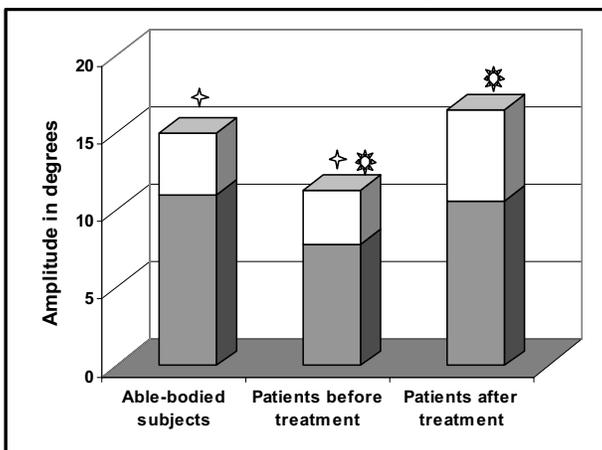

Figure 1: Maximum coupling in rotation for the lumbar segment during lateral bending of the trunk.

The difference for the coupling motions in rotation at the lumbar level during the principal movements of extension was 29% between the able-bodied subjects and LBP patients.

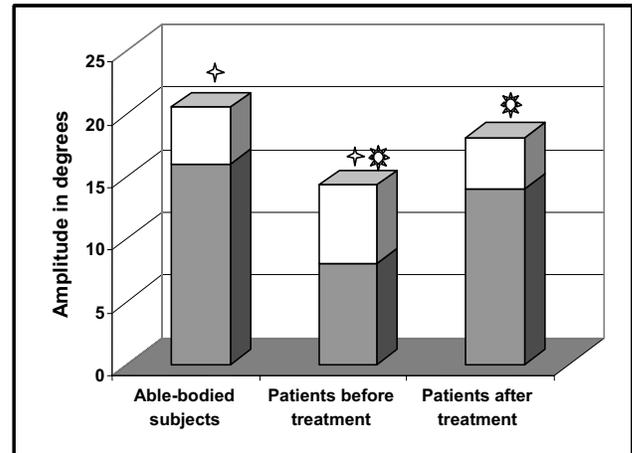

Figure 2: Maximum coupling in bending of the trunk during trunk rotation.

The significant differences in the coupling in lateral extension were recorded at the thoracic level for the principal rotation motion, as indicated in Figure 3. During lateral bending, the coupling rotation at the lumbar level was reduced by 27% in the patient group before treatment while the same group had a 50% reduction in the thoracic coupling bending motion.

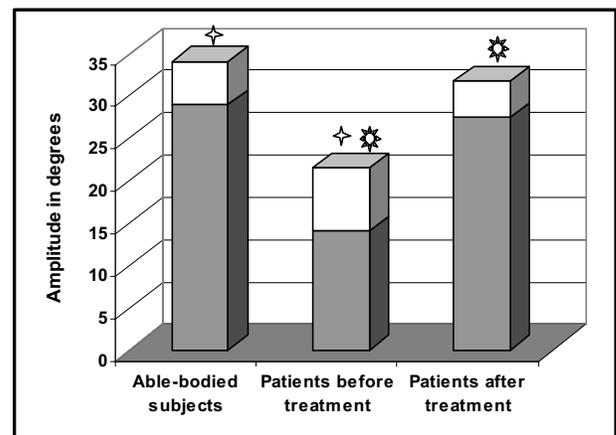

Figure 3: Maximum coupling in bending of the thoracic segment during trunk rotation.

### CONCLUSIONS

No indication appeared to locate trunk rigidity in patients with LBP. Reduction in the coupling motion can be expected for LBP patients before treatment. The rigidity might also be manifested for the coupling motions for the segments having the most mobility during the principal motions being executed.

## WHAT IS THE ACCURACY OF SURFACE MODELS CREATED FROM VISIBLE HUMAN MALE COMPUTED TOMOGRAPHY DATA?

<sup>1</sup>Schmidt J, <sup>1</sup>Eng J, <sup>2</sup>Viceconti M and <sup>1</sup>Ploeg H

<sup>1</sup>University of Wisconsin – Madison, WI, USA

e-mail: [jschmidt1@wisc.edu](mailto:jschmidt1@wisc.edu), web: <http://www.engr.wisc.edu/groups/BM/>

### INTRODUCTION

Three-dimensional (3D) finite element (FE) analysis is used to determine stress and strain distributions in bone in order to predict fracture risk and design orthopaedic implants. Many studies have used computed tomography (CT) data to supply data about geometry and material properties to FE models [1–5]. Both custom-built and commercial segmentation programs have been used to determine the complex bone shape. Yet, few studies have reported the geometric accuracy of the segmentation methods [6-7]. Therefore, the goal of the current study was to determine the accuracy of surfaces created from the visible human (VH) CT data using custom-made and commercial segmentation software programs.

### METHODS

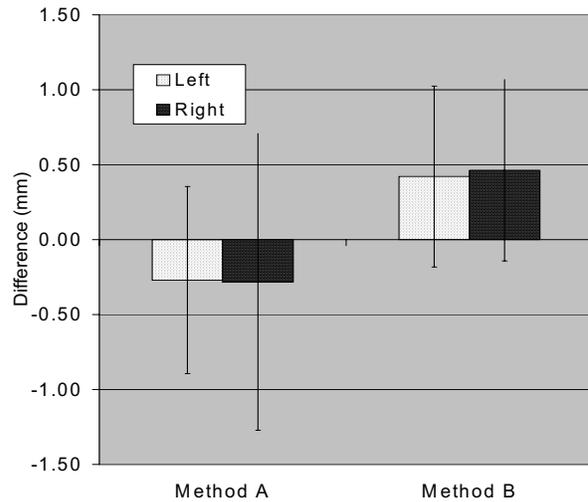

The National Library of Medicine's Visible Human (VH) male computed tomography (CT) and cryogenic standardized data sets were used in this study [8]. Two different methods were used to segment both the right (R) and left (L) femurs of the VH CT data. One method uses the custom-made border tracing algorithm, which was developed as part of the HIPCOM project [7], to segment the bones. This method extracts a closed contour as an object, which is an ordered sequence of adjacent pixels. Specifically, once a starting point and direction is located by the user the algorithm searches the eight neighboring points to determine the pixel with intensity greater than or equal to the current pixel. Polygonal surfaces are interpolated from the resulting stack of contour curves. This method is also used to segment the cryogenic VH data.

The second method uses the commercial software Mimics (Materialise, Ann Arbor, MI) to segment the bones. Within this software the primary segmentation command was 'Thresholding'. The 'Thresholding' feature allows the user to specify an upper and lower bound from a range of Hounsfield values, which is known to be related to density. Further processing is uses the 'Edit Masks' commands of 'Draw' and 'Erase'. These commands were only used when needed to fill holes or detach one mask from another.

Polyworks Inspector 8.0.8 software (InnovMetric, Sainte Foye, QC) was used to compare models. The perpendicular distance between points of the CT models and the surface of the cryogenic model was determined. These distances were then used to determine the mean, standard deviation, minimum, and maximum separation distances.

### RESULTS

Initial comparisons found no difference between the cryogenic STL and IGS models (L:  $0.02 \pm 0.11$  mm), therefore only the cryogenic STL models were used for the subsequent comparisons. For confidentiality, labels A and B are used to identify the segmentation methods. Method A created models smaller than the cryogenic models (R:  $-0.29 \pm 0.99$  mm; L:  $-0.37 \pm 0.62$  mm) (Figure 1). Method B created models larger than the cryogenic models (R:  $0.46 \pm 0.61$  mm; L:  $0.42 \pm 0.60$  mm) (Figure 1).

**Figure 1:** Mean distance and standard deviations between VH cryogenic and CT models created using custom-made and commercial segmentation software.

### CONCLUSIONS

The current study reported a smaller mean error (-0.3–0.5mm) compared to a previous study (0.6-0.9 mm) [6]. In addition, this study reported a higher range in standard deviation (0.6 – 1.0 mm) than a previous study ( $\pm 0.3$  mm), which also reported a peak error of 1.5 mm [7].

The current study reported the accuracy of two segmentation methods, while developing a protocol for validation of models created from CT data. This protocol determines the accuracy of a segmentation method using the internationally accessible VH CT data set. This study assumed that the segmented cryogenic VH data set was the gold standard for comparison. A similar method of validation can be used for solid geometry, mesh geometry, and FE deformations and stress. This protocol provides researchers with a method to accurately compare modeling methods created to predict fracture failure or to design orthopaedic implants.

## ASSIMILATING FULL BODY GAIT GRAPHS INTO SINGLE AREA PLOTS

Sam Augsburger, MSME, Hank White, MSPT, Chester Tylkowski, MD  
Shriners Hospitals For Children Lexington  
Email: saugsburger@shrinenet.org

### INTRODUCTION

Gait analysis offers detailed kinematic and kinetic assessments of multiple segments and joints. A single condition gait analysis report often includes over 60 graphs of individual segments and joints in multiple planes. The method presented assimilates all kinematic or kinetic gait data from one plane into a single area graph. Deviations from normal are assigned unique colors, creating multi-joint patterns. This visual integration of color patterns uniquely highlights pathologic data in a reproducible manner and facilitates accurate and relevant interpretations of gait analyses.

### METHODS

A retrospective review of subjects with a primary diagnosis of Cerebral Palsy resulted in 7 patients for whom bilateral hamstring lengthening only was recommended, and 4 patients for whom bilateral gastrocsoleus lengthening only was recommended. The deviations from normal of these two groups were calculated for each frame of data and each joint/segment in a fashion similar to Manal, et al [1]. The deviation ( $d$ ) was calculated from the pathological average ( $x_p$ ), the normal average ( $x_n$ ), and the normal standard deviation ( $sd_n$ ), using the equation  $d = (x_p - x_n) / sd_n$ .

The trunk and ankle data were plotted horizontally at the top and bottom of the area graphs. The pelvis, hip, and knee data were plotted horizontally with 20 vertical data points between them and adjacent joint data. A continuous gradient of deviations was calculated for the areas between joints. The deviation gradient ( $d_g$ ) was calculated for each frame using the inferior joint deviation ( $d_i$ ) and the superior joint deviation ( $d_s$ ) with the equation  $d_g = d_i + g*(d_s - d_i)/20$ , where  $g$  is the gradient position above the inferior joint (1 to 20).

Each deviation was assigned a color based on a gradient of 56 colors from red (+3 deviations) to violet (-3 deviations). Green was normal (0 deviations). Red was indicative of excessive anterior trunk/pelvic tilt, hip/knee flexion, and ankle dorsiflexion. Violet was indicative of excessive posterior trunk/pelvic tilt, hip/knee extension, and ankle plantar flexion. A total of 8500 data points were assigned colors (85 points high by 100 points wide).

### RESULTS AND DISCUSSION

In the hamstring-lengthening-only group (Figure 1a) the predominant patterns were excessive knee flexion at initial contact, excessive ankle dorsiflexion at weight acceptance, and excessive knee flexion during mid-stance. There was mild ankle plantar flexion during mid-stance and hyperextension of the knee during mid-swing.

In the gastrocsoleus-lengthening-only group (Figure 1b) the predominant patterns were excessive knee flexion at initial contact, excessive ankle plantar flexion during mid-stance, excessive knee extension during mid-swing, and excessive hip

flexion during late swing. There was a mild increase in ankle dorsiflexion during weight acceptance, and an increase in pelvic anterior tilt during mid-stance and early swing.

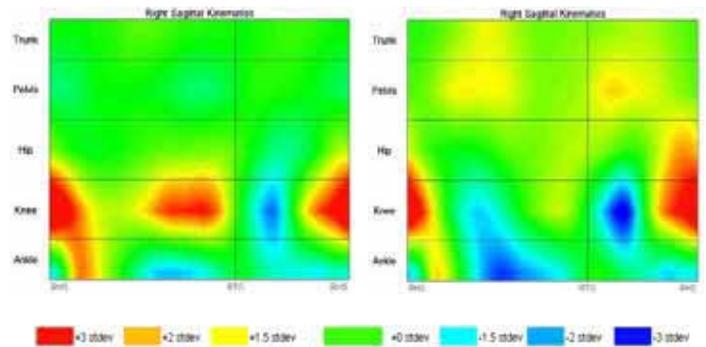

Figure 1: a) Hamstring Lengthening, b) Gastroc Lengthening

### CONCLUSIONS

This method of displaying gait analysis data has the advantage of displaying area patterns, which result from multi-joint as well as single joint deviations. The resulting shapes, as well as colors, are indicative of particular pathologies and corresponding interventions. The excessive knee flexion pattern during mid-stance in the hamstring lengthening group (Figure 1a) as well as the knee flexion at initial contact “pouring” into the ankle are characteristic patterns of this population. Likewise, the “chair-like” shape of the ankle plantar flexion/knee extension pattern during mid-stance in the gastrocsoleus lengthening population (Figure 1b) is both indicative and unique.

This method treats gait data as though they are “connected” from one joint to another, rather than disconnected line graphs. Interpretation and integration of the data is still required. However, the patterns assessed are not isolated to single joints and are typical of multi-joint pathologies.

Each clinician has his/her own preferred method of integrating and interpreting gait data. For those who find it difficult to integrate 5 graphs, let alone 60, this method offers an alternative presentation style of data for analysis. Having both color and shape in “zones” from the ankle to the trunk is a potentially useful alternative. The process of applying this method to individual subjects with combinations of pathologies has been enlightening. In doing so we have discovered combinations of the patterns discussed herein as well as new patterns that were not appreciated through more traditional presentation styles of gait data.

## NEUROMUSCULAR ADAPTATIONS IN GAIT WITH AGE AND MUSCULOSKELETAL PATHOLOGY

<sup>1</sup>Chris A. McGibbon, and <sup>2</sup>David E. Krebs

<sup>1</sup>Institute of Biomedical Engineering, University of New Brunswick, Fredericton NB, Canada,

<sup>2</sup>Massachusetts General Hospital, Biomotion Laboratory, Boston MA, USA; email: [cmcgibb@unb.ca](mailto:cmcgibb@unb.ca)

### INTRODUCTION

Arthritis and other chronic joint conditions are the leading cause of disability in older adults. Changes in locomotor patterns with age [1-3] and disability [4] may be caused by neuromuscular adaptations, which alter segmental kinematics and kinetics through reorganization of muscle firing patterns to compensate for primary mobility impairments. However, the underlying neuromuscular adaptations that arise from idiopathic, age-related impairment and musculoskeletal pathology are not well understood. The purpose of this study was to explore the underlying mechanisms of gait disorder among older adults, and determine which kinematic and kinetic variables best discriminate between young and old healthy adults, and between healthy and disabled elders.

### METHODS

Ankle, knee and hip peak angles, moments and powers in the sagittal plane were acquired during gait in 120 subjects: 45 healthy young (HY), 37 healthy elders (HE), and 38 disabled elders (DE) with functional limitations due to lower-extremity musculoskeletal pathology (primarily arthritis). MANCOVA with discriminate analysis, statistically controlled for gait speed, identified the variables that discriminate between young and old healthy adults, and between healthy and disabled elders. Correlation analysis was used to explore interrelationships among these variables within each group to identify possible mechanisms underlying gait dysfunction among older adults.

### RESULTS AND DISCUSSION

Eight variables strongly discriminated among groups (Figure 1). HE subjects were discriminated (sensitivity 76%, specificity 82%) from HY subjects via decreased late-stance ankle plantar flexion angle (AR2), and increased late-stance knee power absorption (KP4) and early-stance hip extensor power generation (HP1). DE subjects were discriminated (sensitivity 74%, specificity 73%) from HE subjects via decreased late-stance ankle plantar-flexor moment (AM2) and ankle plantar-flexor power generation (AP2), and increased early-stance ankle dorsi-flexor moment (AM1), late-stance hip flexor moment (HM2), and late-stance hip flexor power absorption (HP2). Among the eight variables, the number of significant ( $p < .005$ ) correlations increased with age and disability: there were 5 for HY, 7 for HE, and 13 for DE groups. For the DE group, late-stance hip flexor power absorption and hip flexor moment were more tightly coupled to other kinematic and kinetic variables than for healthy groups.

The data suggest that gait changes caused by lower extremity impairment, manifest differently than do gait changes from aging alone. Beyond age-related changes, elders with lower-

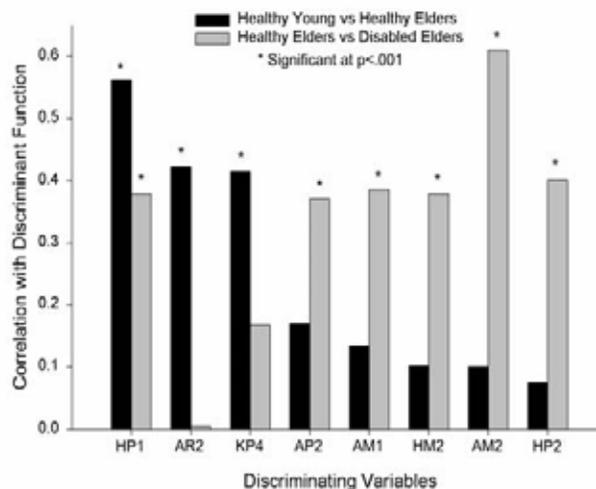

Figure 1. Strength of discriminate functions.

extremity dysfunction rely excessively on passive hip flexion torque to provide propulsion in late-stance, probably to assist with advancement of the swing leg, and ankle dorsi-flexors of the contralateral limb, probably to enhance trunk stability. This compensatory strategy probably increases hip joint stresses, leading to increase OA incidence [5] and promoting hip/trunk muscle overuse and thus fatigue. Furthermore, weak or fatigued ankle muscles could jeopardize control of the body center of mass, and increase risk of falling. Relationships among the biomechanical variables showed a higher degree of coupling for the DE subjects compared to the HY and HE subjects, suggesting reduced flexibility to alter motor strategies.

### CONCLUSIONS

This work supports a growing body of evidence that pathological gait changes from age and disability have a neuromuscular basis, which may be informative in a motor control framework for physical therapy interventions. Study of physical therapies, such as optimal functional training, ie, practicing more healthy and younger gait strategies, aimed at reducing the dynamic coupling among neuromuscular control parameters is warranted.

## MEASUREMENT OF NONLINEAR-ELASTIC PROPERTIES OF SKIN AND SUBCUTANEOUS TISSUES VIA UNCONFINED COMPRESSION TESTS

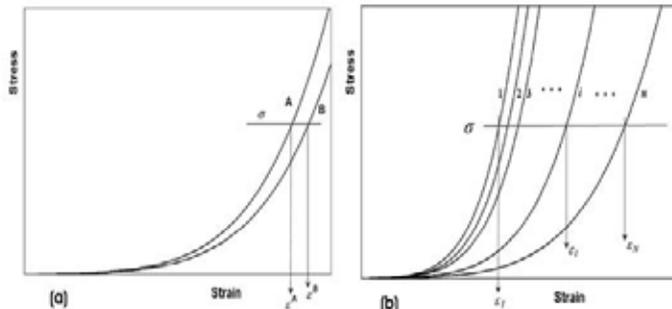

John Z. Wu, Robert G. Cutlip, and Ren G. Dong  
 National Institute for Occupational Safety and Health,  
 Morgantown, WV 26505, USA. email: jwu@cdc.gov

### INTRODUCTION

Knowledge of the nonlinear-elastic properties of soft tissues is essential for the development of reliable finite element models for biological systems. The compressive nonlinear-elastic properties of soft tissues are usually determined using unconfined compression tests. To determine the nonlinear-elastic behavior of skin and subcutaneous tissues using a conventional approach, the skin and subcutaneous tissues have to be separated before testing [1,2,3]. Using such an approach, measurement errors may be increased as a consequence of the reduced specimen dimensions and cumulative experimental errors. In the present study, we propose a novel method to determine the nonlinear-elastic behaviors of the skin and the subcutaneous tissues simultaneously using specimens of skin/subcutaneous composites.

### METHODS

If two unconfined compression tests (labeled A and B) are performed with specimens of different skin/subcutaneous tissue height ratios ( $\gamma_s$  and  $\gamma_f$ ), two different stress-strain relationships will be obtained (Fig. 1a). At the same stress

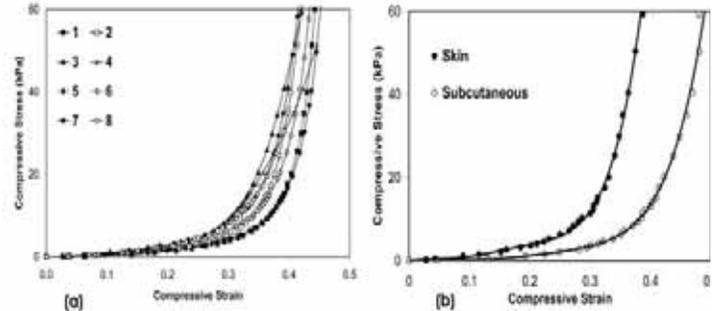

**Figure 1:** Schematics of the stress/strain relationships of soft tissue samples with different height ratios of skin and subcutaneous tissues. (a) Two samples; (b) Multiple samples

level, the total tissue strains can be obtained from these two distinct stress/strain relationships. Assuming that the tissue samples A and B are taken from two adjacent locations, the mechanical characteristics of the skin and subcutaneous tissues in specimen A should be similar to those in specimen B. Consequently, for a given stress, the strains in the skin ( $\epsilon_s$ ) and in the subcutaneous tissues ( $\epsilon_f$ ) for specimen A should be identical to those for specimen B. Therefore, the strains in the skin and subcutaneous tissues for a given stress can be solved from:

$$\epsilon^A = \gamma_s^A \epsilon_s + \gamma_f^A \epsilon_f, \quad \epsilon^B = \gamma_s^B \epsilon_s + \gamma_f^B \epsilon_f \quad (1)$$

Because of scattering of test data of soft tissues, multiple unconfined compression tests are to be performed using tissue

**Figure 2:** (a) The stress/strain curves of the eight unconfined compression tests using skin/subcutaneous composite specimens. (b) The stress/strain curves of the skin and subcutaneous tissues obtained using the proposed method.

samples with different skin/subcutaneous height ratios (as sketched in Fig. 1b). The stress/strain curves of skin and subcutaneous tissues are derived from stress/strain curves of the skin/subcutaneous composite soft tissue specimens using a least square method. In the present study, a total of eight samples of skin/subcutaneous composite were used. Tissue samples were collected from the palmar surface of the front feet of a pig (Landrace-Yorkshire-Duroc hybrid).

### RESULTS AND DISCUSSION

The stress/strain relationships for the eight unconfined compression tests were found to depend on the height ratio of skin/subcutaneous tissue – the specimens with a higher ratio of skin/subcutaneous tissue tend to produce a stiffer stress/strain curve (Fig. 2a). Using the proposed approach, the stress/strain relationships of skin and subcutaneous tissues were derived (Fig. 2b).

### CONCLUSIONS

Compared to conventional test procedures, our method offers the advantages that the skin and subcutaneous tissues do not need to be separated prior to testing, and that the soft tissue composite specimens reflect physiological loading conditions much more accurately than testing of isolated skin and subcutaneous tissues. Using the proposed approach, material properties of soft tissues can be obtained in a cost- and time-efficient manner, which simultaneously improves the physiological relevance.

## ESTIMATION OF VISCOUS PROPERTIES OF SKIN AND SUBCUTANEOUS TISSUES VIA UNIAXIAL STRESS RELAXATION TESTS

John Z. Wu, Robert G. Cutlip, and Ren G. Dong  
 National Institute for Occupational Safety and Health,  
 Morgantown, WV 26505, USA. email: jwu@cdc.gov

### INTRODUCTION

Using traditional experimental methodologies [1,2,3], the skin has to be separated from the subcutaneous tissues in order to determine the tissues' viscoelastic properties. Thus, the complex collagen fiber network in soft tissue could be damaged when the skin is separated from the subcutaneous tissue. Therefore, the viscoelastic properties of the skin and subcutaneous tissues measured using isolated samples may be different from those in physiological conditions. The purpose of the present study is to estimate the viscous behaviors of the skin and the subcutaneous tissues using composite tissue specimens.

### METHODS

In a creep test using a specimen of skin/subcutaneous tissue composite, dependence of the total tissue strain  $[\varepsilon(t)]$  on the strain contributions from skin and subcutaneous tissues is derived as:

$$\varepsilon(t) = \gamma_s \varepsilon_s(t) + \gamma_f \varepsilon_f(t) \quad (1)$$

where  $\gamma_s$  and  $\gamma_f$  are the skin and subcutaneous tissue thickness ratios, respectively. The corresponding normalized creep function of the tissue composite  $[j(t)]$  is related to those of skin and subcutaneous tissues  $[j_s(t)$  and  $j_f(t)]$  by:

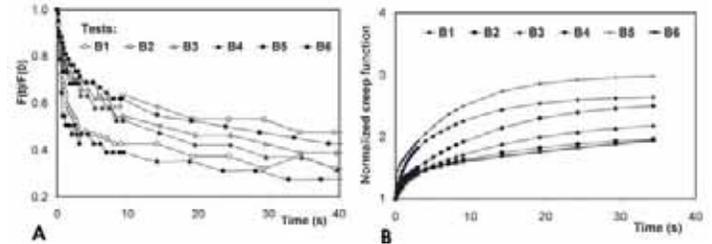

$$j(t) = \alpha j_s(t) + \beta j_f(t) \quad (2)$$

where  $\alpha$  and  $\beta$  are parameters depending on the thickness ratios and elastic stiffness of the skin and subcutaneous tissues. If two creep tests (A and B) are performed using specimens of different thickness ratios of the skin and subcutaneous tissues, they will result in two distinct creep curves. Assuming that these two tissue samples are taken from two locations close to each other from the same animal, the mechanical characteristics of the skin and subcutaneous tissues in specimen A should be similar to those in specimen B. Therefore, the normalized creep functions of the skin and subcutaneous tissues  $[j_s(t)$  and  $j_f(t)]$  can be solved from:

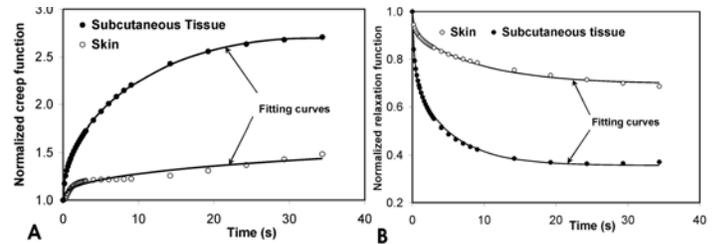

$$j(t)^A = \alpha_A j_s(t) + \beta_A j_f(t), \quad (3)$$

$$j(t)^B = \alpha_B j_s(t) + \beta_B j_f(t)$$

Because of scattering of test data of soft tissues, multiple tests are to be performed using tissue samples with different skin/subcutaneous thickness ratios and the equations are to be solved using a least square method. Viscoelastic properties of soft tissues in compression are usually obtained via stress relaxation tests, because the stress relaxation tests are, technically, much easier to perform than the creep tests. The proposed procedure is composed of four steps: (1) perform stress relaxation tests using skin/subcutaneous composite specimens, (2) convert the stress relaxation functions to the corresponding creep functions using Laplace transformations, (3) determine the creep functions of skin and subcutaneous tissue using the proposed method, and, finally, (4) convert the creep functions of the skin and subcutaneous tissues to their

**Figure 1:** A: The stress relaxations of skin/subcutaneous composite specimens. B: The corresponding normalized creep functions.

**Figure 2:** A: The normalized creep functions of the skin and subcutaneous tissues. B: The corresponding stress relaxations.

corresponding stress relaxation functions using inverse Laplace transformations. The proposed procedure has been applied to determine the viscous properties of the skin and subcutaneous tissues of pig. The tissue samples were collected from the palmar surface of the front feet of a pig (Landrace-Yorkshire-Duroc hybrid).

### RESULTS AND DISCUSSION

The six stress relaxation tests were conducted under unconfined compressions using tissue specimens of different skin/subcutaneous thickness ratios (Fig 1A). The stress-relaxation curves have been converted into their corresponding normalized creep functions (Fig. 1B). Using the proposed procedure, the creep and stress-relaxation curves of the skin and subcutaneous tissues were derived, as shown in Figs. 2A and B.

### CONCLUSIONS

Using the proposed test procedure, we can simultaneously estimate the viscous properties of the skin and subcutaneous tissues without separating them prior to testing, such that the soft tissue composite specimens reflect physiological loading conditions more reasonably than the specimens of isolated skin and subcutaneous tissues.

### INTRODUCTION

Injury to articular cartilage is thought to be one of the initiators of osteoarthritis. One possible mechanism of cartilage degeneration is that cells are killed due to impact. The resulting metabolic load on the remaining cells prevents them from properly maintaining the extracellular matrix, leading to matrix degeneration that further impairs the ability of the cartilage to support normal loads leading to further degeneration. Most impact models have used cartilage explants. The validity of taking cartilage out of its natural environment and testing isolated sections is suspect. The only other in vivo impact model in an intact joint has looked at mechanical properties of the cartilage after impact and not biological markers such as cell viability (Haut et al. 1995). The purpose of this study was to look at cartilage viability at different impactation energies in an in vivo rabbit model.

### METHODS

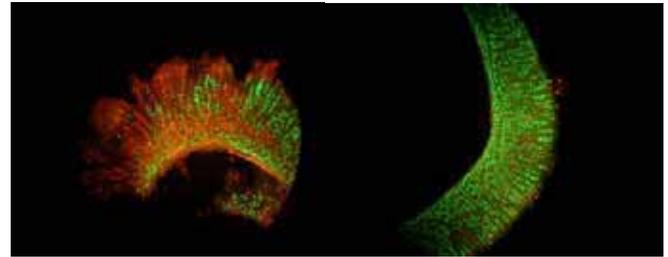

14 New Zealand white rabbits were used for this study. Rabbits were injected with acepromazine and then anaesthetized with isoflurane. They were mounted in a custom stereotaxic frame where their hips were pinned and experimental knee supported at approximately 90°. In 13 rabbits, the patella was subjected to either 0J, 2.5J, 5J or 7.5J impacts by dropping a weight from a specific distance. One rabbit knee was subjected to 10 >5J impacts. Cartilage from the patella and the loaded portion of the femoral groove was harvested 24 hours later and 50 µm full thickness sections were prepared with a vibratome. Slices were stained with Syto 13 and Ethidium Bromide and were then viewed under a fluorescent microscope and photographed with a digital camera. Live (green) and dead (red) cells were counted with a custom cell counting program.

**Figure 1:** Impact set-up showing impactor in approximation to the rabbit's patella.

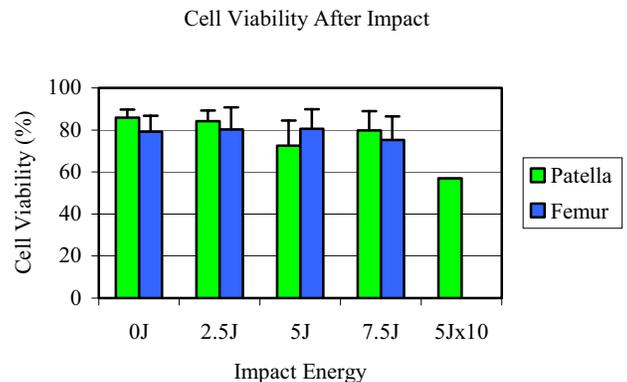

### RESULTS AND DISCUSSION

Cell viability in the first 13 rabbits ranged from 72 -86%. Ten impacts of the patella caused cell viability to drop to 57%. There was a trend that cell death was occurring more at the intermediate and middle layers than the superficial layer.

**Figure 2:** Two sample patella sections. The left section was subject to 10 impacts while the right section was a control (0J).

The cell viability protocol used was not sensitive enough to detect differences between the single impact conditions. This was due to high baseline cell death and variability in cell death in all samples including controls. Impact of the cartilage of one knee 10 times resulted in a much more consistent level of cell death throughout the samples.

**Figure 3:** Cell viability for each impact energy.

### CONCLUSIONS

Cell viability testing needs to be refined to reduce variability. Future studies will look at cell viability using a confocal microscope to minimize artefacts from cutting the tissue. Despite problems with variability, it appears that cartilage is much more robust in vivo than in vitro explants tests have suggested.

## EFFECT OF THE PREFABRICATED METALLIC POST LENGTH ON RESTORED TEETH: FRACTURE STRENGTH AND STRESS DISTRIBUTION

### INTRODUCTION

In order to restore devitalized teeth, modern restoring techniques in Dentistry use an external element, the intraradicular post, as a retention system for the material used in the tooth restoration to be carried out later.

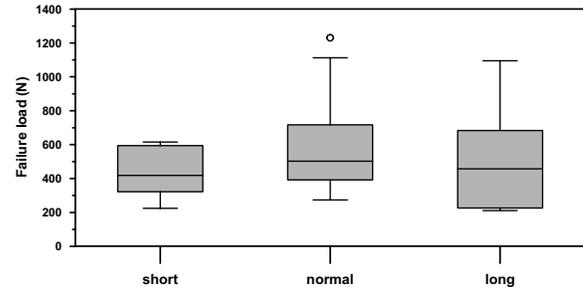

Although non-metallic posts are being increasingly used, metallic posts continue to be the standard for most situations because they have stood the test of time [1]. Different aspects of the post design have been studied [2,3,4], but the influence of the post length on the mechanical strength of the restored tooth is lacking. The aim of this work was to study how the prefabricated metallic post length affects the biomechanical performance of restored teeth.

### METHODS

A combined theoretical and experimental method was used to analyze the influence of post length (from 3 to 14 mm) for the ParaPost Stainless Steel (Coltène/Whaledent Inc, Ohio, USA).

First, an experimental fracture strength test was performed over thirty extracted human teeth. The purpose of this test was to analyze the differences in strength between the post systems with different post lengths. The teeth were decoronated, treated endodontically and restored with stainless steel posts. The specimens were placed in a retention device and mounted on the universal testing machine. This device allowed the teeth to be loaded on the palatal side at an angle of 30° to the radicular axis, in the vestibular direction. A controlled loading force was applied to the teeth at a rate of 5 N/s, until failure. Three group lengths were considered based on the post length to root length ratio: 'short' (<0.5), 'normal' (0.5 to 0.8) and 'long' (>0.8). The loading force (N) required to cause failure was recorded and the results for the groups were compared by using an ANOVA test.

Secondly, the finite element technique was used to develop a 3D model of the restored tooth. The model allowed us to study the stress distribution pattern on the restored tooth under external loads, for the different post lengths considered. The stress distribution pattern provided information about the fracture mechanism of the restored tooth. To generate the geometry, measurements were taken on 40 extracted human maxillary central incisors: cervico-apical height and mesio-distal and vestibulo-palatal diameters at both cervical and medial root heights were recorded. Mean values from these measurements defined the geometry of the tooth used for the study. Finally, the results from the fracture strength test were used to check the validity of the finite element model and the results from the simulations.

**Figure 1:** Box-whisker graphs showing spreads of failure load values for the groups of studied specimens.

### RESULTS AND DISCUSSION

From the experimental fracture strength test, no significant differences ( $p=0.3>0.05$ ) were observed between the failure loads of the different groups (short, normal and long) of teeth restored using stainless steel posts. Box-whisker graphs showing spreads of values in the data sets can be observed in Fig. 1. Restored teeth showed a fracture of the core along the juncture with the post, on the vestibular side.

The model of the restored tooth predicted similar stress distribution and peak stresses for the different post lengths considered, which agrees with the ANOVA test results. And a stress concentration was predicted along the interface of the post with the composite core, according to the failure mode experimentally observed.

### CONCLUSIONS

It has been experimentally proved that the biomechanical performance of teeth restored with stainless steel posts present a low dependency on post length. This is an important finding because the length of the post has a significant effect on its retention. The more apically the post is placed in the root canal, the more retentive it becomes [2,3]. However, it may not always be possible to use a long post, especially when the remaining root is short or curve.

The experimental results corroborated the estimations from the developed model, thus validating the model. The proposed model could be a useful tool for studying the influence that different post design variables have on the biomechanical performance of restored teeth, by means of simulations.

## HEAD REPOSITIONING ACCURACY IN PATIENTS WITH WHIPLASH-ASSOCIATED DISORDERS

<sup>1,2</sup>Veronique Feipel, <sup>1,2</sup>Patrick Salvia, <sup>1</sup>Helene Klein, <sup>1,2</sup>Marcel Rooze

<sup>1</sup> Department of Anatomy, Université Libre de Bruxelles, email: [vfeipel@ulb.ac.be](mailto:vfeipel@ulb.ac.be) web: [homepages.ulb.ac.be/~anatem](http://homepages.ulb.ac.be/~anatem)  
<sup>2</sup> Centre for Functional Evaluation, Université Libre de Bruxelles,

### INTRODUCTION

Head repositioning accuracy is commonly evaluated in patients with Whiplash-associated disorders (WAD). Most frequently, only neutral repositioning is assessed [1-4]. Only sparse data on repositioning in remote postures is available [5,8]. Similarly, only a few studies considered the components of HRE in all planes of space. Some bi-dimensional studies are available [1,3], but only one reported three-dimensional information [4] without comparing planes of motion.

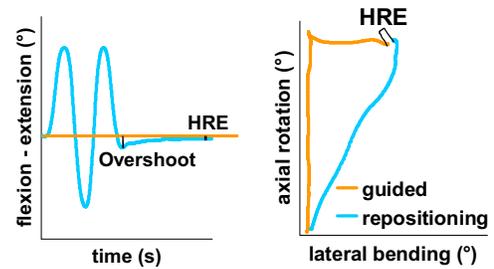

In this study head repositioning accuracy in patients with WAD was compared to that obtained in healthy controls. A comparison between different repositioning tasks is proposed.

### METHODS

29 patients suffering from WAD (age: 37, SD 14, years, 18 females) and 26 healthy subjects (control, age: 35, SD 11, years, 14 females) were recruited. Of the WAD patients, 71% had a grade III injury and 29% a moderate (grade I or II) injury [6].

Active head kinematics was sampled using a 3D-electrogoniometer (CA 6000 SMA, O.S.I., Union City, CA, USA) mounted using a harness at the level of Th1 and a helmet on top of the head [7]. The tasks consisted of neutral position repositioning tasks after maximal flexion-extension (FE) and of repositioning tasks in pure axial rotation (right and left of 50°) and complex postures (50° right or left axial rotation combined to a 20° ipsi-lateral bending). The former was carried out with eyes open (EO) and blindfolded (BF), the two latter only in blindfolded conditions. Four repetitions were requested for each condition. No feedback was given to the subject before the end of the entire test session.

For neutral repositioning tasks, head repositioning error (HRE) in each plane was computed as the absolute difference between initial head position and the final head position after stabilization (Figure 1a), and the maximal overshoot in each plane, not discussed here. For rotation and complex posture repositioning tasks, HRE in each plane was computed as the absolute difference between the end posture reached during the guided trial and that reached during repositioning trials (Figure 1b). A multiple-way repeated-measures ANOVA was used to compare tasks, motion components and groups.

**Figure 1:** Repositioning parameters for (a) neutral and (b) complex remote repositioning tasks

### RESULTS AND DISCUSSION

The HRE values found in the present study are comparable to those reported previously [4,6,7], although some authors found larger values [2,3,8]. These differences could be attributed to methodological differences. HRE was significantly increased ( $p=0.009$ ) in the WAD group as compared to controls (Table 1), confirming several previous studies [3-7], but not all [3,8].

The primary plane HRE was significantly larger than out-of-plane HRE both for neutral ( $p=7.1 \times 10^{-23}$ ) and remote ( $p=3.0 \times 10^{-23}$ ) repositioning tasks, confirming previous work [7,8]. Neutral repositioning tasks displayed better head repositioning accuracy than remote repositioning tasks ( $p=6.3 \times 10^{-18}$ ). The primary component HRE during neutral repositioning was of the same order of magnitude as the out-of-plane component HRE during remote repositioning in rotation. For neutral repositioning tasks, HRE was larger in blindfolded conditions ( $p=0.03$ ). A significant interaction between task complexity and component was obtained for remote repositioning tasks ( $p=1.1 \times 10^{-05}$ ). Specifically, lateral bending HRE was increased when task complexity was larger, probably due to task difficulty and to the fact that lateral bending is not an out-of-plane component in this task.

### INTRODUCTION

Deformability of red blood cells is an important parameter to maintain blood circulation, because cells have to deform to pass through capillary. Sublethal damage on red blood cells might occur through artificial blood pumps, before hemolysis [1].

### METHODS

A parallel-disk type of counter-rotating rheoscope system has been designed and manufactured. In the system, Couette-type shear field is induced in the fluid between two counter-rotating disks, which are made of transparent silica glass. The rotating speed was regulated with a stepping motor, which is controlled by a computer. The shear rate, which is calculated from the velocity difference between two disks, is constant regardless of the distance from the disk. A red blood cell can be observed under shear without translational movement, when it is suspended at the stationary plane in the middle part of the shear field.

A red blood cell deforms from biconcave to ellipsoid in Couette-type of shear field. Deformation of the red blood cell was quantified with an elongation index (E), which was calculated from dimensions of the major (L) and minor (W) axes by  $E=(L-W)/(L+W)$ . E becomes zero in a sphere ( $L=W$ ), and approaches to unity as the deformation advances ( $L \gg W$ ). The elongation index (E) was plotted as a function of shear stress (S), and the fitting exponential curve was calculated by  $E=C(1-\exp(-S/R))$ , where C is the critical elongation and R is the shear stress responsiveness. Both large C and small R indicate large deformability.

A concavo-convex Couette flow system has been designed to damage red blood cells under shear [2]. In the space between a stationary convex cone and a rotating concave cone, the sample blood was sheared in a uniform shear field, where the shear rate is constant regardless of the distance from the axes of rotation. Variation was made on shear rate with the rotational speed of the convex cone.

Human blood was drawn from volunteers with anticoagulant of ethylene-diaminetetraacetic acid and sheared for one hour at the shear rate of 640 per second at twenty degrees Celsius.

Before measurement of deformation, the cells were classified according to the density by a centrifugation method [3]. The

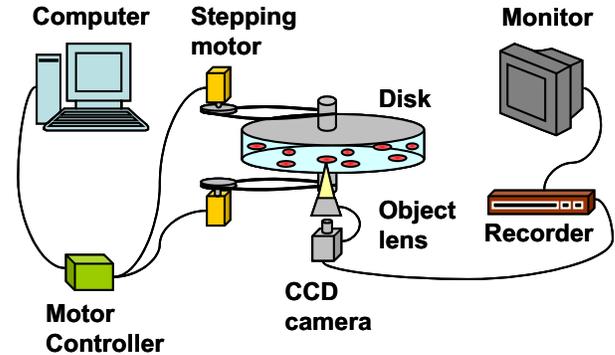

Figure 1: Pattern diagrams of system.

phthalate ester solution with controlled density was used as a separator. After separation, the red blood cells were suspended in a dextran aqueous solution to separate each other and exposed to the high shear stress (<6 Pa) field at low shear rate.

### RESULTS AND DISCUSSION

The experimental results shows, that the lighter cells are more compliant than heavier cells and that density of cells increased after exposure to shear fields, although cells of each density level keep their deformability.

One of the advantage of a parallel-disk type of counter-rotating rheoscope system is that a red blood cell deforms in the shear field without contact to the surface of wall, which gives effects to the deformation of the red blood cell.

### CONCLUSIONS

The designed system has enough sensitivity to detect sublethal damage of red blood cells with deformability.

## MYOFASCIAL FORCE TRANSMISSION IS MORE IMPORTANT AT LOW-FREQUENCY STIMULATION

H.J.M Meijer<sup>1</sup>, G. C. Baan<sup>1</sup> and P.A. Huijting<sup>1,2</sup>

<sup>1</sup> Instituut voor Fundamentele en Klinische Bewegingswetenschappen, Vrije Universiteit, Amsterdam, NL

<sup>2</sup> Integrated Biomechanical Engineering for Restoration of Human Function, Faculteit Construerende Technische Wetenschappen, Technische Universiteit Twente, NL

Email: [h.meijer@fbw.vu.nl](mailto:h.meijer@fbw.vu.nl)

### INTRODUCTION

In addition to myotendinous force transmission, force exerted by the sarcomeres can be transmitted between the muscle and surrounding inter- and extramuscular connective tissue, *i.e.* myofascial force transmission [1]. Proof of such epimuscular force transmission is a difference in force exerted at the origin and insertion of a muscle [2]. For fully activated muscle, myofascial force transmission has been shown to be important for muscle properties. However during *in vivo* motion, firing frequency may vary (in rat EDL muscle between 10 and 60 Hz [3]). Therefore, effects of submaximal stimulation frequencies on myofascial force transmission were investigated for fully recruited rat extensor digitorum muscle (EDL).

### METHODS

Male Wistar rats were anaesthetized and the anterior crural compartment was exposed. Proximal and distal tendons of the extensor digitorum muscle (EDL) and the tied distal tendons of the complex of tibialis anterior and extensor hallucis longus (TAEHL) were severed and connected to force transducers. Fully recruited EDL and TAEHL muscles were stimulated at 10, 20, 30 and 100 Hz. The TAEHL complex was kept at constant length, and length-force characteristics after distal lengthening of EDL were determined at the distal and proximal tendons.

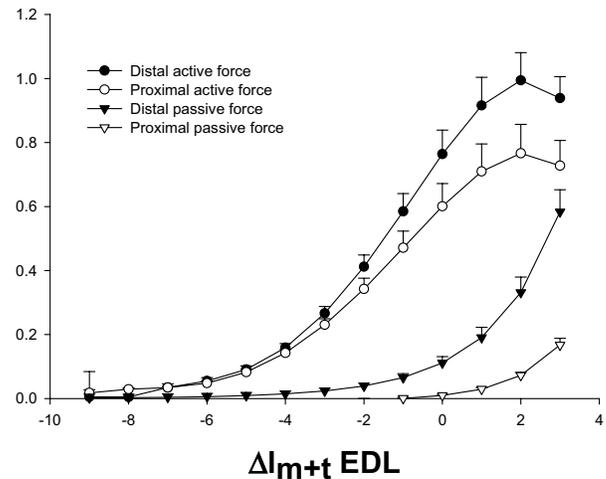

### RESULTS AND DISCUSSION

At lower firing frequencies, significant proximo-distal EDL force differences exist, indicating epimuscular force transmission (e.g. Fig. 1). Maximal absolute EDL proximo-distal active force differences were highest at 100 Hz ( $F_{\text{dist-prox}} = 0.4$  N). However, the percentual difference (Fig. 2) was highest at 10 Hz ( $F = 30\%F_{\text{dist}}$ ). Firing frequency dependent shifts of EDL optimum muscle length were found, although proximally and distally assessed effects of firing frequency differed quantitatively. After distal EDL lengthening, TAEHL distal isometric active force decreased progressively with a peak decrease at 100Hz ( $F_{\text{from initial}} = -0.25$  N). However, the highest percentual decrease was found for 10 Hz stimulation ( $F_{\text{from initial}} = -40\%$ ).

### CONCLUSIONS

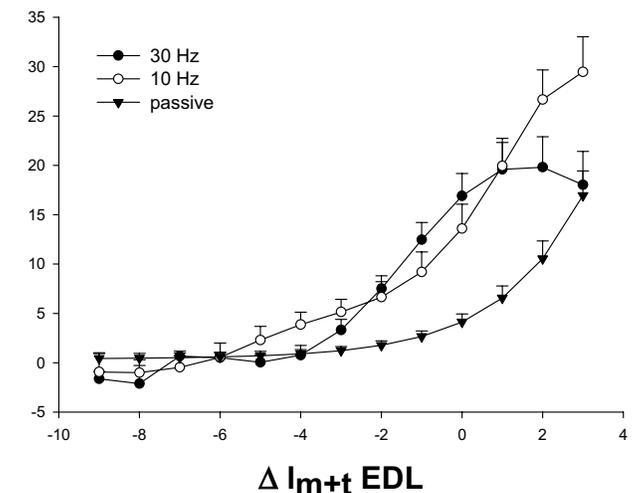

Myofascial force transmission becomes more important at lower submaximal firing frequencies: with a decreasing firing frequency, relatively more force is transmitted myofascially relative to the myotendinous path. Evidently, at progressively lower firing frequencies, the stiffness of epimuscular myofascial paths of force transmission decreases less than the stiffness of serial sarcomeres and myotendinous pathways. It is therefore concluded that low firing frequencies as encountered *in vivo*, enhance the relative importance of epimuscular myofascial force transmission with respect to the myotendinous force transmission.

### F<sub>m</sub> (N) EDL - 20 Hz

**Figure 1:** EDL proximal and distal length force characteristics at 20 Hz, as a function of EDL muscle-tendon complex length, increased by distal EDL lengthening ( $l_{m+t}$  EDL dist), expressed as deviation from 100 Hz distal optimum length. Error bars represent standard errors.

### ΔF (%F<sub>mao(f)</sub>)

**Figure 2:** Effects of firing frequency and EDL muscle-tendon complex length on the proximo-distal difference in active force, normalized for distal optimum active force ( $F_{\text{mao}(f)}$ ), and passive force (normalized for distal 100 Hz optimum force). Error bars represent standard errors.

## BIOMECHANICAL COMPARISON OF FIXATION TECHNIQUES FOR DOUBLE PARS FRACTURES

<sup>1</sup> Hsiang-Ho Chen, <sup>2</sup> Shih-Ting Huang and <sup>3</sup> Kung-Chia Li

<sup>1</sup> Dept. of Biomedical Engineering, I-Shou University, Kaohsiung, Taiwan; email: [hchen@isu.edu.tw](mailto:hchen@isu.edu.tw),

<sup>2</sup> Institute of Biomedical Engineering, National Yang Ming University, Taipei, Taiwan

<sup>3</sup> Dept. of Orthopedics Surgery, Chia-Yi Yang-Ming Hospital, Chia-Yi, Taiwan

### INTRODUCTION

Complete pars fracture is one of clinical conditions of spondylolysis and it can lead to spondylolisthesis or degenerative disc disease (DDD) [1]. Double pars fractures (DPF) commonly occur at L4-L5 due to traumatic in juvenile years, whilst occurring at L3-L4 in the elderly from degenerative change. Double pars fracture may decrease spinal stability and more so if complicated with DDD. Posterior instrumentation with cages may restore the biomechanical strength of the spine. Some studies biomechanically compared the spondylolysis fixation techniques [2, 3], but rare comprehensive biomechanical studies on DPF have been reported. The purpose of this study is to compare biomechanically the performance of fixation techniques for the repair of double spondylolytic defect in the pars interarticularis.

### METHODS

Eighteen fresh-frozen and thawed porcine lumbar L2-L6 spines were used for mechanical testing. In addition to the control group, DPF group was created by making 2-mm wide defects in the pars interarticularis bilaterally at L3 and L4 using a power saw. Disectomy in combination with the DPF procedure resulted in a DPF&DDD group. The TPS group used transpedicular screw system (TPS) to stabilize DPF defects. The D2TPS group used TPS system to stabilize the spine of DPF&DDD. The D2TPSC group used TPS and interbody cages to stabilize the spine of DPF&DDD. The biomechanical properties were estimated and compared amongst six groups (Fig. 1). Motion segments were mounted and tested on a MTS machine. A series of loadings, including flexion, extension, lateral bending, torsion, and compression, were applied, respectively. The axial stiffness test for this study was 0-250 N compression at the displacement rate of 25 mm/min. In other rotational testing, the torque was 2.5 N-m and the load rate was 25 mm/min [4].

### RESULTS AND DISCUSSION

In flexion, DPF had a significantly smaller stiffness ( $0.55 \pm 0.02$  N-m/deg) than the intact control group ( $0.68 \pm 0.03$  N-m/deg). With TPS fixation, the stiffness was increased significantly (Fig. 2). In extension, DPF had a significantly smaller stiffness than the intact group. With any kind of stabilization, stiffness was increased significantly. In lateral bending, DPF&DDD group had a less stiffness than controls. In compression, DPF and DPF&DDD gradually decreased the stiffness compared to controls. In torsion, DPF and DPF&DDD significantly reduced the intact stiffness. With fixation of TPS or cages, the stiffness was significantly greater than DPF group. In almost all testing, D2TPSC group had the higher stiffness than other groups.

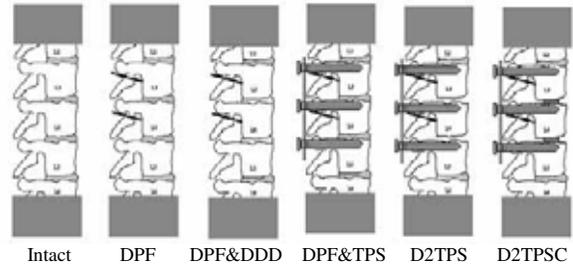

Figure 1: Diagram of 6 groups of device-spine constructs.

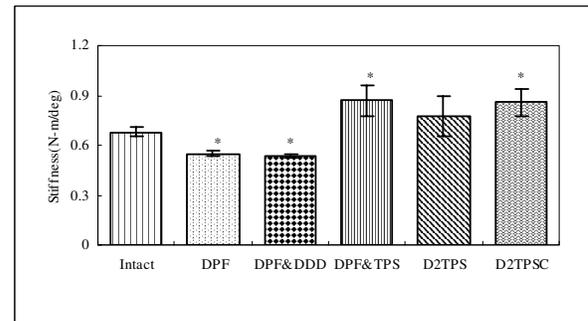

Figure 2: Comparison of flexion stiffness (N-m/deg).

\* significantly different from data of Intact group ( $p < 0.05$ )

Double pars fracture is occasionally found in clinical practice. The treatment depends on the symptoms if DDD and stenosis is severe, decompression and posterior instrumentation is indicated. This study focused on the degenerative situation. Therefore, the facet screw or hook-screw system is not included.

### CONCLUSIONS

Double pars fracture significantly reduced spinal stiffness. For spine with double pars fracture only, TPS could retain the intact stiffness. However, TPS seems not to stabilize spine with DPF and DDD. The cage possibly restored the stiffness decreased by the disc degenerative disease in all spinal motion.

### INTRODUCTION

The study concerns the regeneration of skeletal tissues (bone, cartilage, tendon, and ligament). It is possible to initiate, in vivo as well as in vitro, mesenchymal tissue regeneration, involving progenitor cells. This process recapitulates some cellular event of embryonic skeletal formation. If progenitor proliferation and differentiation pathways can be controlled, it is conceivable that a functional joint may be regenerated. The goal of this study is to analyse the mechanical factors regulating locally mesenchymal cell proliferation and differentiation pathways towards functional skeletal tissues production. This work is a first step to analyse undifferentiated cells as far as bone regenerated.

Experimental studies in vivo and in vitro are developed. This combined approach associating mechanical and biological analyse of the cellular events provides a powerful tool in understanding the regulation mechanisms of functional tissue engineering in vivo and in vitro.

### METHODS

Our in vivo experimental studies were coupled together with in vitro experimental studies to be used in numerical modelling. Very few authors have studied the mesenchymal tissue [1, 2] because it is very difficult to analyse this soft tissue before its maturity. A process of skeletal tissue regeneration was initiated by a vascularized periosteal flap transfer in New Zealand white rabbit. Time between the initiation of the regeneration process and the first explants are 7, 14 and 21 days (Figure 1). Fresh samples were preserved in the formaldehyde.

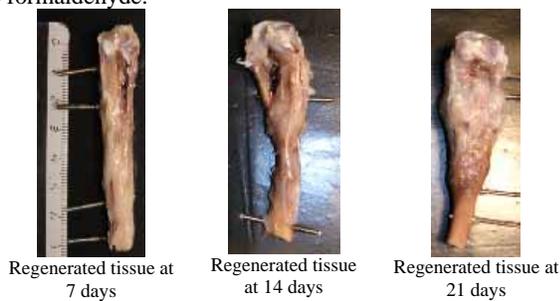

Figure 1: Regenerated tissue

We developed an experimental INSTRON device which was used to analyse the mechanical properties of bones and ligaments [3 and 4]. This device is adapted to analyse the behaviour of the regenerated tissues. Samples were attached by a cable. They were tested with tensile tests as far as failure in order to characterize their mechanical properties and include them in a numerical finite element model. The displacement of the lower traverse beam was measured using an LVDT sensor (Linear Variable Differential Transformer), attached to the machine frame. The tensile load was measured

by a strain gauge sensor with an uncertainty of measurement of 1% on the upper traverse beam.

### RESULTS AND DISCUSSION

From these results, the mechanical properties of compact bone were deduced where failure occurred. Force-displacement curve obtained for a 14 days sample (Figure 1) was divided into four parts.

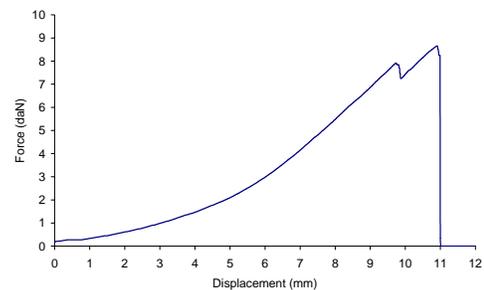

Figure 1

The first part of the curve corresponds to the setting in tension of the cables. On the second part of the curve the behaviour is linear elastic. On the third part, one could observe that the behaviour became non-linear, showing that the material was damaged ductile. In the final stage failure occurred. The damaging part of the bone behaviour is divided in two picks. The first one represents the failure of a first fibre networks constituted by a soft material comparable to a cartilage. The second one represents the failure of second fibre networks which is more mineralised.

### CONCLUSIONS

This study is a first step to analyze precisely the tissue regenerated by immature cells. The second step is to regenerate joint cartilaginous tissue because of the weak potential of spontaneous repairing of these tissues. The perspectives of this work concern the development of engineer processes tissue allowing the production of cartilage implants, and of biomaterials of joint resurfacing.

## NEURAL NETWORK ESTIMATION OF ISOKINETIC KNEE TORQUE

Michael E. Hahn

Movement Science Laboratory, Montana State University, Bozeman, MT, USA

email: [mhahn@montana.edu](mailto:mhahn@montana.edu)

### INTRODUCTION

Rectified, low-pass filtered electromyography (EMG) has been used with Hill-based musculoskeletal models to estimate muscle force and joint moments (Hof & Van Der Berg, 1981). However, it is rather difficult to find a set of neuromuscular activation signals that, when input into such models, produce coordinated movement simulation (Zajac, 1993). This may be due in part to a non-linear response of muscle tissue to activation. Recently, artificial neural network (ANN) models have been used effectively to estimate joint torque in the elbow (Luh et al., 1999; Wang & Buchanan, 2002), but no studies have utilized ANN theory in prediction of lower extremity torque. The purpose of this study was to develop an initial model to estimate isokinetic joint torque produced at the knee during concentric and eccentric contractions. It was hypothesized that ANN mapping would accurately estimate knee joint torque. Linear regression was performed for comparison.

### METHODS

Ten young adults (6 female / 4 male; 22.9yrs, 173.7cm, 72.3kg) were recruited for this study within the guidelines of the University I.R.B. All participants were determined to be free of neuromuscular or orthopedic pathologies.

Maximal strength data were collected using a KinCom dynamometer (Rehab World, Hixson, TN, USA). Isometric flexor/extensor maxima were measured at 45°. Isokinetic measures were taken through the knee's functional range of motion in a seated position at 30 and 60°/s. At each isokinetic speed, concentric and eccentric contractions were recorded (two each). Each subject was allowed two sub-maximal practice trials for each joint function. Four total cycles were collected for each direction and speed condition. Subjects were verbally encouraged during each trial to promote maximal motivation.

Joint position and velocity were recorded simultaneously with torque data, at 100Hz. Additionally, EMG signals were sampled at 1000Hz from the vastus lateralis and biceps femoris with passive bi-polar surface electrodes using the Myopac Jr. (Run Technologies, Inc., Mission Viejo, CA, USA). EMG signals were bandwidth filtered (10-1,000Hz), full wave rectified and smoothed with a 4<sup>th</sup> order Butterworth filter (low pass cutoff = 5Hz). Processed EMG signals were then normalized to the maximal isometric activation.

With all acceptable trials compiled, there were 308 total cases entered for analysis. Linear regression was conducted with age, gender, height, weight, EMG (agonist, antagonist), joint

position and velocity as independent variables, and joint torque as the dependent variable. The same inputs were entered into a three-layer back-propagation ANN, with the following settings: training proportion = 0.7, training error goal (E) = 0.1, and hidden units (H) = 5,10,15,20. A bootstrap re-sampling method (50 attempts) assessed each setting of hidden units. Model accuracies were compared using the R-values of each technique.

### RESULTS AND DISCUSSION

Linear regression resulted in an R-value of 0.75. Prediction accuracy for the ANN settings reached a maximum of 0.94 (ANN settings: E=0.1; H=10,15,20). Average R-values for those settings were 0.93 (SD, 0.01). The number of epochs needed for solution convergence at those settings averaged from 447.8 (H=20) to 620.2 (H=10). Prediction accuracy was not affected by the number of hidden units, however more hidden units required fewer epochs for convergence (Table 1).

Results indicate that ANN mapping provides a more accurate estimate of knee torque during maximal isokinetic (con/ecc) testing. Performance of the ANN with minimal training (E=0.1) indicates that prediction accuracy is likely without the risk of 'over-training'. Thus, the generality of this system would be more likely to provide accurate estimation for a separate sample of young adults.

### CONCLUSIONS

Findings from this initial development of a knee torque prediction model indicate that a more robust estimation of joint torque from muscle activation may be possible using ANN or similar techniques borrowed from the field of computational intelligence. Future efforts will focus on broadening the model to include sub-maximal torque production in more joints and developing adaptive algorithms for estimation of joint moments during locomotion.

## PARADOXICAL MUSCLE MOVEMENTS IN HUMAN STANDING

<sup>1</sup> Ian Loram, <sup>2</sup>Constantinos Maganaris and <sup>1</sup>Martin Lakie

<sup>1</sup>The University of Birmingham, UK, email: i.d.loram@bham.ac.uk

<sup>2</sup>Manchester Metropolitan University, UK; email: c.n.maganaris@mmu.ac.uk

**Figure 1:** Dynamic bias model. CE, contractile element. K, s.e.c.,  $\theta$  COM angle,  $\theta_0$  bias exerted on s.e.c. spring.

### INTRODUCTION

In human standing the calf muscles soleus and gastrocnemius actively prevent forward toppling about the ankles. It has been generally assumed that these postural muscles behave like springs with dynamic stiffness reflecting their mechanical properties, reflex gain including higher derivatives, and central control. We have used an ultrasound scanner and automated image analysis to record the tiny muscular movements occurring in normal standing and during large voluntary sways. This new, non-invasive technique resolves changes in muscle length as small as 10 microns without disturbing the standing process. This technical achievement has allowed us to test the long established mechano-reflex, muscle-spring hypothesis that contractile element length changes in a spring-like way during sway of the body.

### METHODS

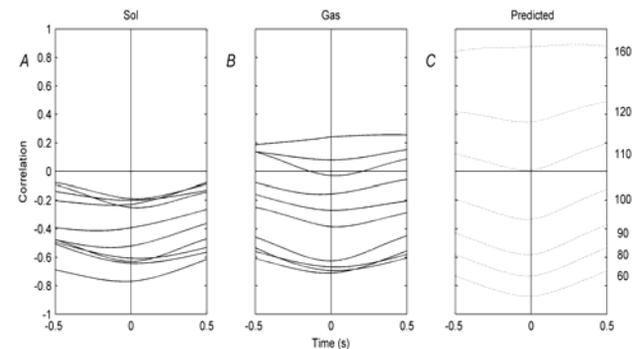

Ten subjects stood freely on a footplate that measured ankle torque. Ankle angle was recorded using a laser range finder reflected off the shin. Surface EMG were recorded from left soleus and gastrocnemius. An ultrasound scanner (Esaote Biomedica AU5) recorded 40 s (1000 frames) of sonographs focused on the distal aponeurosis of left soleus and gastrocnemius. Image markers were placed on the proximal and distal aponeurosis of the two muscles. Spatial cross correlation was used to track the changes in position of these markers throughout the 1200 frames. From the differential movement of these markers continuous changes in the length of the contractile element were calculated [1, 2].

Cross correlation was used to assess the relationship between changes in muscle length and changes in CoM angle. A simple model was constructed (Figure 1), incorporating a spring for the s.e.c. of the calf muscles, a contractile element for the muscles and a single mass for the body during standing sagittal sway. Using the model and measured values of ankle torque and CoM angle, we computed the predicted cross

correlation between muscle length and CoM angle for a variety of values of s.e.c. stiffness. By comparing the actual cross correlation with the predicted, we estimated the stiffness of the s.e.c.

### RESULTS AND DISCUSSION

The contractile elements are longest when the subject is closest to the vertical and shorten as the subject sways forwards (paradoxical movements). In quiet standing, muscle length fluctuates at approximately three times the frequency of body sway: on average, shortening during forward sway and lengthening during backwards sway (Figure 2). This counter-intuitive result is consistent with the fact that calf muscles generate tension through a series elastic component (s.e.c., Achilles tendon and foot, Figure 1) which limits maximal ankle stiffness to  $92\% \pm 20\%$  ( $\pm$  S.D) of that required to balance the body (Figure2). The higher frequency of muscle fluctuation is consistent with a central, impulsive controller [3].

**Figure 2** Cross correlation between **A** soleus, **B** gastrocnemius muscle length and centre of mass angle. Each line represents the mean of 6 trials for one subject. **C** shows the predicted correlation for a variety of values of s.e.c. stiffness expressed relative to the load stiffness.. The time lag is shown horizontally.

### CONCLUSIONS

The intrinsic length-tension relationship of the calf muscles partially stabilizes the human body in quiet standing while leaving the body mechanically unstable. Stability and balance is achieved by a higher level impulsive process that is poorly correlated with CoM angle.

## ELECTROMYOGRAPHY OF TRUNK MUSCLES DURING WHEELCHAIR PROPULSION

email: [akoontz@pitt.edu](mailto:akoontz@pitt.edu), web: [www.herlpitt.org](http://www.herlpitt.org)

### INTRODUCTION

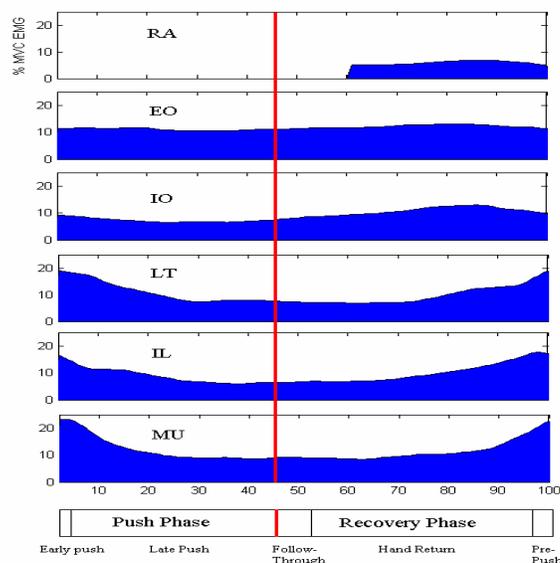

Paralysis of the primary trunk musculature likely contributes to ineffective force application during wheelchair propulsion [1]. Functional electrical stimulation (FES) as a modality to improve trunk posture, balance and propulsion efficiency in persons with spinal cord injury is currently under investigation. In order to implement an effective stimulation pattern during propulsion, an understanding of the muscle activation patterns of core trunk musculature is necessary. Therefore, the purpose of this study was to establish and describe muscle activation profiles of selected back and abdominal musculature during wheelchair propulsion using surface electromyography (EMG).

### METHODS

**Subjects:** Fourteen unimpaired subjects (12 male and 2 female) provided informed consent prior to participation in the study. The average age, weight and height were 24.7±3.6 years, 69.3±14.3 kilograms and 1.73±0.07 meters respectively.

**Experimental protocol:** Bipolar, surface electrodes (Noraxon Inc., Scottsdale, AZ) were placed over three abdominal muscles (rectus abdominis: RA, external oblique: EO and internal oblique: IO), and three back muscles (longissimus thoracis: LT, iliocostalis lumborum: IL, and multifidus: MU). Prior to the propulsion trials, ten seconds of maximum voluntary contraction (MVC) EMG data were recorded during maximal effort exercises for normalization purposes. Subjects were asked to propel at a steady-state speed of 1.8 m/s for 20 seconds using a test wheelchair which was fitted bilaterally with a SMART<sup>Wheel</sup> (Three Rivers Holdings, LLC., Mesa, AZ), and secured to a computer-controlled dynamometer with a four-point tie down system. Real-time propulsion speed was displayed on a computer screen in front of the subjects. A three-dimensional motion analysis system (Northern Digital Inc., Ontario, Canada) was synchronized with the SMART<sup>Wheel</sup> and EMG system to record kinematics of the upper limbs, propulsion forces and EMG activity during propulsion.

**Data analysis:** EMG data were sampled at 1000 Hz, full wave rectified and smoothed with a 10-Hz low pass filter. EMG voltages during propulsion were normalized as %MVC for each muscle. Significant EMG activity was defined as activity with an intensity of at least 5% MVC and for longer than 5% of the propulsion cycle (PC). In order to compare muscle activity across subjects, the time of the PC was normalized to 100% and the push phase to 45% of the cycle for each subject (mean push percentage for the groups). The push phase was further divided into early push (0%–2% of PC) and late push (2%–45% of PC), and recovery was separated into 3 subphases [2] of follow-through (45%–53% of PC), hand return (53%–97% of PC), and pre-push (97%–100% of PC) according to hand motion during an entire PC.

**Figure 1:** The mean EMG profile of trunk muscles during a propulsion cycle at speed of 1.8 m/sec

### RESULTS AND DISCUSSION

During pre-push and early push phases, abdominal muscles (RA, EO and IO), and back muscles (LT, IL, and MU) were active and contracted to provide stability for the trunk while delivering forces to the pushrim (Figure 1). While delivering forces to the rim during late push phase, back muscle activity declines allowing the trunk to lean forward in pushing. During recovery phase (follow-through/hand return), back muscle activity gradually increased to move the trunk upright and abdominal muscles activated to prepare for the next stroke in the late phase of hand return and pre-push.

### CONCLUSIONS

Our findings indicate that back and abdominal muscles both showed high activity levels during the pre-push and early push phase. This synchronized activation may provide trunk stability and prevent the trunk from moving in opposition to the arms when applying forces to the pushrim [3]. Researchers can use this profile of trunk muscle activation to develop a muscle stimulation pattern that will increase trunk stability and improve propulsion efficiency of manual wheelchair users with spinal cord injury.

## EFFECTS OF THE GRASPING FORCE MAGNITUDE ON THE INDIVIDUAL DIGIT FORCES DURING PREHENSION WITH FIVE DIGITS

Xun Niu, Mark L. Latash and Vladimir M. Zatsiorsky  
Department of Kinesiology, The Pennsylvania State University, email: [vxz1@psu.edu](mailto:vxz1@psu.edu)

### INTRODUCTION

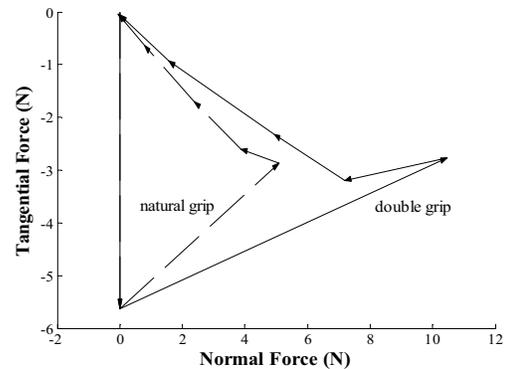

To control dextrous manipulation of mechanical 5-digit hands, the engineers should know the interrelations existing between the individual digit forces and moments during the performance [1]. The information obtained on humans can be useful in this case. When manipulating hand-held objects, people can grasp them with different forces. In this study, we address the following question: does the pattern of individual digit forces depend on the grip force magnitude? Subjects were asked to keep an instrumented handle with minimal effort and then double the grip force. The following questions are addressed: (a) Does doubling the total grip force double the individual digit forces? (b) Does the sharing percentage of normal forces among the fingers depend on the total force magnitude? (c) Does the percentage contribution of the normal and tangential forces into the total moment exerted on object depend on the grasping force magnitude?

### METHODS

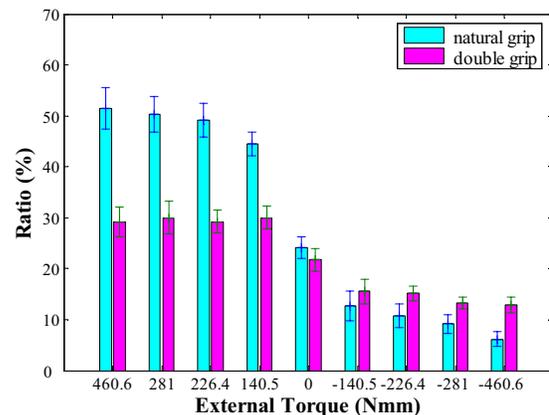

Seven right-hand-dominant subjects were required to stabilize in the air an instrumented handle (575 g) using prismatic grip (the tips of the fingers and thumb oppose each other). Four clockwise (negative) and four counterclockwise (positive) torques and one zero torque were applied to the handle. Five six-axis force-torque transducers (Nano-17, ATI Industrial Automation, Garner, N.C.) were mounted on the handle to measure the digit forces. The experiment had two phases. First, the subjects were instructed to hold the handle vertically with minimal normal (grip) force for 3 s. The computer recorded the force and then set a target force level at the double value. Visual feedback on the grip force and on the target force was provided on the computer screen. The subjects were instructed to squeeze the handle until the grip force matched the target. The second phase lasted 17 s.

### RESULTS AND DISCUSSION

The doubling of the grip force induced complex changes of the both normal and tangential digit forces (Figure 1). After grip force doubled, the percentages of the individual finger's contribution to the grip force at all torque values changed (Figure 2) although the changes were minimal at the zero torque. The contribution of antagonist fingers (fingers producing moments in the direction of the external torque) increased (e.g. during supination efforts of 460.6 Nmm, the contribution of the little finger changed from 6% to 13%, see Figure 2). The doubling of the grip force also affected the percentage contribution of the normal and tangential forces into the total moment production: the contribution of the moment of the tangential forces increased (e.g. during supination efforts of 460.6 Nmm, the contribution of the little finger changed from 38% to 55%).

**Figure 1:** Force polygons. The polygons are obtained by adding tail-to-head the individual forces. Starting from the upper left corner the following forces are shown: gravity, the thumb, index, middle, ring and little finger force. Ideally, in static conditions the polygon should close. Representative example: external torque is zero.

**Figure 2:** Exemplary little finger's contribution to grip force at different external torques before and after doubling the grip force. Error bars show standard errors.

### CONCLUSIONS

The increase of the grip force magnitude during prehension results in increased percentage contribution of (a) the normal forces of antagonist fingers into the total grip force and (b) the moment of the tangential forces into the total moment exerted on the object.

## THE BIODYNAMIC AND PHYSIOLOGICAL RESPONSES OF THE RAT TAIL TO A SINGLE BOUT OF VIBRATION EXPOSURE

Kristine Krajnak, Daniel Welcome, William G. Lindsley, and Ren G. Dong  
National Institute of Occupational Safety and Health, Morgantown, WV  
email: Kristine.Krajnak@cdc.gov

### INTRODUCTION

In humans, occupational use of vibrating hand tools leads to the development of neural and vascular damage. The goal of this study was to use the rat tail model to characterize the biodynamic response of the tail tissue to different vibration frequencies, and to determine what physiological changes occur in the vascular and neural systems of the tail after a single exposure to vibration.

### METHODS

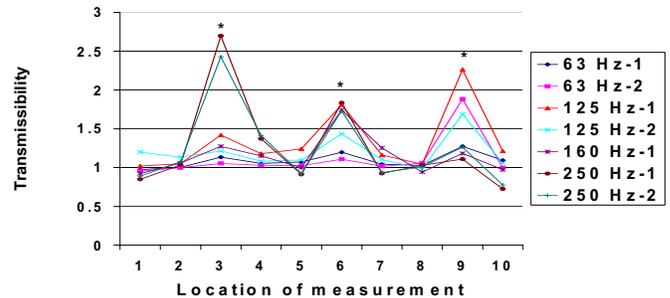

Male Sprague Dawley rats (6 weeks of age) were used for all experiments. Vibration exposures were performed by restraining rats in a Broome-style restrainer. Elastic straps (12 mm wide), located every 3 cm down the length of the tail, were used to hold the tail to a platform without compressing the tissue. The platform was attached to a shaker that produced a controlled, vertical vibration stimulus. The amplitudes of the tail and platform vibrations were measured down the length of the tail using a scanning laser vibrometer. The normalized magnitude (i.e., transmissibility) of the tail vibration was calculated by dividing the measured amplitude of the tissue vibration by the measured amplitude of the platform vibration. Measurements were made a number of frequencies (Figure 1).

The vascular and neural response of the tail to a single 4 h exposure to vibration (125 Hz, 49 m/sec<sup>2</sup> r.m.s.) was also measured to determine if the acute responses of the tail to vibration were similar to those of the human finger. The vascular responses assessed included tail temperature and luminal perimeter. The current perception threshold (CPT) procedure was used to assess the sensitivity of different nerve fiber types by measuring the response of the animals to electrical stimuli of different frequencies.

### RESULTS AND DISCUSSION

The magnitude of the tail vibration was greater than the magnitude of the platform vibration at 125-250 Hz (Figure 1). However, the amplified response of the tissue to vibration at these frequencies only occurred in the unrestrained portions of the tail. At 63 Hz, the amplitude of the tail vibration was approximately equivalent to the platform vibration at all locations.

The vascular response of the rat tail to acute vibration was similar to the effects that have been reported in humans. Immediately following the exposure, the tail temperature of both control and vibration exposed rats was reduced (mean  $\pm$  SEM, control pre 26.4  $\pm$  0.52 and post 22.4  $\pm$  0.33; vibrated pre 26.3  $\pm$  0.51 and post 22.3  $\pm$  0.02), suggesting that restraint caused a vasoconstriction in all rats. Tail temperatures in both groups of rats returned to pre-exposure levels 15 min

**Figure 1:** Normalized amplitude of the tail vibration vs. input frequency. The most proximal point on the tail is #1 on the x-axis and \* represent un-restrained regions of the tail (N = 2).

following the end of the exposure. However, the internal perimeter of the ventral tail artery was significantly smaller in rats exposed to vibration than in control rats (546.93  $\pm$  51.5 and 747.33  $\pm$  55.7  $\mu$ M). Therefore, even though skin temperatures recovered, there was a maintained constriction in the tail artery of rats exposed to vibration.

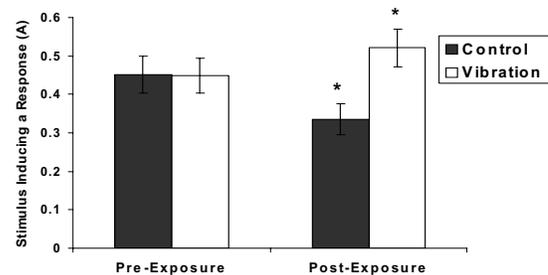

CPT measurements demonstrated that the sensitivity of the A $\beta$  fibers to 2000 Hz stimulation was significantly reduced (i.e. increased stimulus needed to induce a response) in rats exposed to vibration, but increased in the controls (Figure 2). The A $\beta$  fibers carry vibrotactile information from sensory organs to the nervous system. All rats demonstrated slight increases in sensitivity to stimulations of 250 Hz (A $\beta$  fibers) and 5 Hz (C fibers).

### CONCLUSIONS

The acute biodynamic and physiological responses of the rat tail to vibration are similar to the responses seen in human fingers (1-3). Future studies will use this model to understand the effects of repeated vibration on soft tissue damage.

## LANDING FORCES PRODUCED IN TAP DANCE

<sup>1</sup>Lester Mayers, <sup>2</sup>Sujani Agraharasamakulam, <sup>2</sup>Sheyi Ojofeitimi, and <sup>2</sup>Shaw Bronner

<sup>1</sup>Division of Sports Medicine, Pace University, Pleasantville, NY;

<sup>2</sup>Analysis of Dance and Movement (ADAM) Center, Long Island University, Brooklyn, NY;  
email: lmayers@services.pace.edu

### INTRODUCTION

We performed a retrospective survey among experienced tap dancers that suggested a relatively low injury prevalence and occurrence rate (0.31/1000 exposures) among the surveyed cohort.<sup>1</sup> A literature search revealed no information concerning biomechanical aspects of tap dance. To explain the findings of our injury survey, we hypothesized that tap dance might produce less musculoskeletal stress (forces and/or moments) than other dance and sporting activities and initiated a biomechanical analysis by measuring landing forces in a group of experienced tap performers.

### METHODS

Six experienced professional tap dancers (3 male and 3 female, mean age  $24.5 \pm 10.6$  years) were recruited. All subjects were injury-free, actively performing when tested, and signed an informed consent.

Four tap dance sequences (flaps, cramprolles, pullbacks, and a subject-selected virtuoso sequence) were repeated 4-8 times within each condition with both feet on the force platform. Three-D kinematic and kinetic data were acquired with a 5-camera motion analysis system (Vicon, Oxford Metrics Ltd, Oxford UK) at 120 Hz and force platform (AMTI, Advanced Mechanical Medical Technology, Inc., Watertown, MA) at 1080 Hz. A full body marker set, comprised of 39 reflective spherical markers 25 mm in diameter, was used to create an 11-segment model.

Peak amplitude Fx (sagittal plane), Fy (frontal plane) and Fz (vertical plane) forces (N) were calculated for each of the four conditions, and normalized to body weight (BW). Means for each kinetic variable were calculated for each subject to minimize intra-subject variability. Descriptive statistics were then calculated for each condition. Separate between-group (gender) t-tests were calculated for each condition ( $p < 0.05$ ).

### RESULTS AND DISCUSSION

Between-group t-tests were not significantly different for any condition, so results for all subjects were merged for analysis. Mean peak Fx and Fy for the six subjects were insignificant ( $< 1.0$  BW) for all conditions. For flaps, Fz ranged from 1.16 to 1.96 BW, (mean  $1.46 \pm 0.32$ ). For cramprolles, Fz ranged from 1.62 to 3.02 BW, (mean  $2.35 \pm 0.45$ ). For pullbacks, Fz ranged from 1.55 to 2.88 BW, (mean  $2.23 \pm 0.47$ ). For the optional or virtuoso steps chosen by each performer ( $n=5$ ), Fz ranged from 1.70 to 4.19, (mean  $2.52 \pm 0.99$ ). Mean Fz for all conditions and all subjects was 2.14.

Landing forces have been measured in numerous studies involving walking (1-1.4 BW), running (1.6-3.6), jumping (3.5-6.0 BW), gymnastics (9-14.5 BW), various sports activities (4.0-12.6 BW), aerobic dance (1.5-2.6 BW), and dance jump landings (1.4-2.8 BW). It is apparent that Fz forces occurring during tap dance are in the lower range of those reported for these various activities. Although this finding might appear to confirm our initial hypothesis and explain the apparent decreased injury risk for this dance form, there are additional factors to be considered.

### CONCLUSIONS

We conclude that the relatively small Fz forces measured during tap dance among experienced professional performers supports our hypothesis that the apparent lower injury occurrence rate among this group may reflect this finding. Nevertheless, the analysis is highly complex and involves many other factors remaining to be studied.

## INFLUENCE OF SKIN TEMPERATURE ON MECHANOMYOGRAM OF M. BICEPS BRACHII

<sup>1</sup> Kazuyuki Mito, <sup>2</sup> Takahiro Tamura, <sup>3</sup> Kenichi Kaneko, <sup>4</sup> Hitoshi Makabe, <sup>5</sup> Masto Takanokura and <sup>1</sup> Kazuyoshi Sakamoto

### INTRODUCTION

Mechanomyogram (MMG) is mechanical counterpart of myoelectric activity and it has gained considerable attention as a new noninvasive tool to investigate the muscular functions. The main mechanisms of MMG signal generation has been considered to be pressure waves generated by lateral expansion of the active muscle fiber [1].

It is well known that the changing of muscle temperature concerns the electrical and mechanical function (i.e., electromyogram: EMG and contraction torque, respectively) of the muscle [2,3]. The present study was therefore performed to examine the relation between the MMG properties and the muscle temperature.

### METHODS

Nine healthy male volunteers, aged from 21 to 26 years, participated in this study. The reference condition of skin temperature was attained in room air of 23-25 °C that resulted in the skin temperature of about 34 °C which was called "control" condition. The muscles of upper arm were cooled with over 20 minutes down to a skin temperature of 20 °C (i.e., "cold" condition). At some other day, the muscles were heated up to a 40 °C (i.e., "heat" condition). In each skin temperature, the EMG and MMG signals were measured on m. biceps brachii during isometric contraction. The maximum voluntary contraction (MVC) was measured in the "control" condition. The subjects maintained contraction level of 20%, 40%, and 60% MVC. The surface EMG signal was picked up by the bipolar Ag/AgCl electrodes (5mm pick-up diameter, 20 mm inter-electrode), placed over the muscle belly along the underlying muscle fiber. The MMG signal was detected by the piezo-electric accelerometer with weight of 2g (9G111BW, NEC Sanei Instruments Ltd.). The accelerometer was placed with double-sided adhesive tape at mid point between the EMG electrodes. The contraction torque, EMG and MMG signals were simultaneously and continuously stored into a personal computer through an A/D converter with 12-bits resolution and with sampling frequency 1-kHz. The root mean square amplitude (RMS) was computed from both signals of EMG and MMG. ANOVA was used to determine the EMG and MMG characteristics at three different temperatures (control, cold, and heat). Significances of individual differences were evaluated by using the Scheffé test if ANOVA was significant.

### RESULTS AND DISCUSSION

The mean  $\pm$  SD of MVC of nine subjects was  $22.9 \pm 3.6$  kg. The effect of skin temperature on the relation between the RMS of EMG and MMG and the contraction level was shown in Fig. 1. The RMS values of EMG and MMG were increased with increasing of the contraction level in all skin temperature. The RMS of EMG was not significantly influenced by the skin temperature. This was in good

agreement with the previous studies [2,3]. The RMS of MMG significantly increased with increasing the skin temperature at each contraction level. The present results might be related to the contraction time of muscle fibers and the viscosity of muscular tissue. These data can be extended to the notion that the MMG is a reliable method to investigate muscular function under a wide range of physiological conditions.

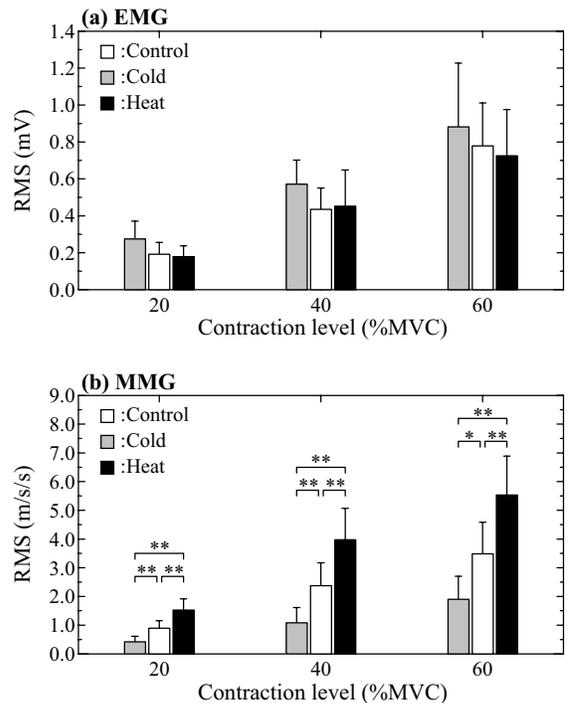

Fig. 1: The effect of skin temperature on the relation between (a) RMS of EMG and the contraction level and (b) RMS of MMG and the contraction level. The marks of \* and \*\* are  $p < 0.05$  and  $p < 0.01$ , respectively.

### CONCLUSIONS

The main purpose of this study is to examine whether or not the RMS of EMG and MMG could reflect the contraction properties of muscle during cooling and heating of the skin surface. The results were obtained as the following. (1) RMS of EMG was not almost influenced by the skin temperature. (2) RMS of MMG significantly increased with the increasing of skin temperature.

### INTRODUCTION

Slip-related falls have become a major cause of serious injuries, so that more and more researchers dedicate to this field. Grönqvist et al. [1] have indicated that the moment of heel contact is most dangerous for slip occurrence in a gait cycle. Cham et al. [2] have quantified the changes in gait biomechanics when people anticipate slippery environments. Buczek et al. [3] have suggested that the peak required coefficient of friction (RCOF<sub>peak</sub>) can be used to predict slip potentials in gait activities. However, little work has been carried out on the slip events of trans-femoral amputees. The aim of this study is to investigate the slips happening to trans-femoral amputees during level walking on normal and slippery path via the gait analysis.

### METHODS

Six male unilateral trans-femoral amputees and ten non-amputees participated in the current study. All of the amputated subjects were active and able to walk independently in daily life. In the experiment, the subjects were required to walk at a self-selected comfortable pace on the dry surface along a 5 m plastic walkway. Then five amputees and five non-amputees were required to walk on the oily surface. Two force plates (OR6-7, AMTI, MA), which were placed in the walkway, were employed to record the ground reaction forces (GRF). At the same time, the Qualysis Motion Capture System (Qualisys Medical AB, Sweden) were employed to record the kinematics data of each trail at 200 Hz synchronously.

The RCOF<sub>peak</sub> and the contribution ratio of F<sub>x</sub> to the RCOF (R<sub>Fx</sub>) were calculated using the following equations:

$$RCOF_{peak} = \frac{\sqrt{F_x^2 + F_y^2}}{F_z} \quad R_{Fx} = \frac{F_x^2}{F_x^2 + F_y^2}$$

Where F<sub>z</sub> represents the force in vertical direction; F<sub>y</sub> represents the force in forward direction; F<sub>x</sub> represents the force in lateral direction. A one way analysis of variance (ANOVA) was performed on RCOF<sub>peak</sub> and R<sub>Fx</sub>, respectively. Only values of P < 0.05 were considered significant.

### RESULTS AND DISCUSSION

The values of RCOF<sub>peak</sub> and R<sub>Fx</sub> are listed in Table 1 and Table 2. It is indicated from the comparison between the trans-femoral amputees and non-amputees that the RCOF<sub>peak</sub> and R<sub>Fx</sub> of amputees were significantly greater than that of non-amputees. And the comparison between sound side and prosthetic side shows that the value of R<sub>Fx</sub> of prosthetic side is much higher than that of sound side

while the R<sub>Fx</sub> of sound side is close to that of non-amputees.

**Table 1:** The comparison between the trans-femoral amputees and non-amputees

	RCOF <sub>peak</sub>	R <sub>Fx</sub>
Amputees	0.220 ± 0.071	0.183 ± 0.150
Non-amputees	0.165 ± 0.025	0.052 ± 0.059
P-value	0.007	0.008

**Table 2:** The comparison between the sound and prosthetic sides of trans-femoral amputees

	RCOF <sub>peak</sub>	R <sub>Fx</sub>
Sound Side	0.231 ± 0.094	0.071 ± 0.016
Prosthetic Side	0.209 ± 0.054	0.295 ± 0.137
P-value	0.707	0.017

The results come from the differences of ground reaction forces. The forces in lateral direction of prosthetic side F<sub>x</sub> are much greater than that of sound side and both F<sub>x</sub> and F<sub>y</sub> of sound side are greater than that of non-amputees.

The kinematic data also show the rationality of the results. When the subjects walking on the dry surface, there were obvious lateral swings in amputees' gait pattern. In the slip events the slip direction was completely different between prosthetic side and non-amputees including sound side. When the sound side of amputees or the non-amputees encountered slips, the foot slid mainly in the forward direction while that when slips occurred to the prosthetic side the foot slid mainly sideways.

### CONCLUSIONS

1) The large value of peak required coefficient of friction indicates that the trans-femoral amputees face a greater slip danger than normal people during level walking. 2) Swing in the lateral direction of amputees' gait pattern is the main cause of the increase of peak required coefficient of friction. 3) Sideway slip is the peculiar character of the prosthetic side of trans-femoral prosthesis user.

## HANDLING OF IMPACT FORCES IN INVERSE DYNAMICS IN LANDING AFTER A JUMP

<sup>1</sup>Rob Bisseling, <sup>1</sup>At Hof

<sup>1</sup>Center for Human Movement Sciences, University Medical Center Groningen, Groningen, The Netherlands  
email: r.w.bisseling@ppsw.rug.nl, web: www.ihms.nl

### INTRODUCTION

The relation between impact dynamics of a landing after a jump and the cause of chronic injuries, like patellar tendinopathy (jumper's knee), has been the focus for research for many years. During impacts, impact force produces a shock wave, which travels through the subject's extensor mechanism. Net joint moments are a measure of load of the extensor mechanism (patellar tendon).

The purpose of this study was to detect the real contribution of the ground reaction force (GRF) and segmental acceleration in the sagittal net knee moment during the first part of impact of a landing after a jump by comparing a standard inverse dynamic method (SM) with an accelerometer based inverse dynamic method (AM).

### METHODS

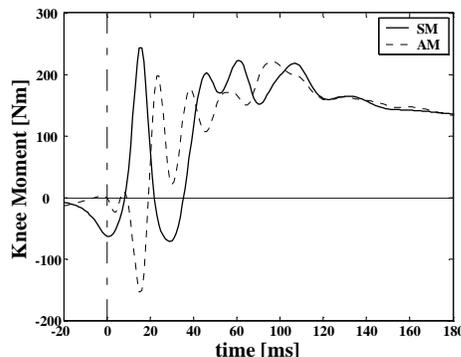

Seven healthy well trained male volleyball players participated in this study. The subjects were asked to perform a maximal counter movement jump, which was performed according to the subject's own preferred style.

Two different inverse dynamic based methods were compared to study the impact dynamics of landing: the SM, using accelerations from filtered (20 Hz) position data and GRF, and the AM, using accelerations from accelerometers and GRF. Measurements of both methods were applied to a three segment rigid body model of the right leg.

### RESULTS AND DISCUSSION

The net knee moment, calculated by the SM, showed major differences compared to the AM. These differences mainly took place during the first part of impact, from the time of touch down till approximately 35 ms later. SM showed an extension moment peak during impact, where the AM showed an oscillating effect: flexion moment peak, directly followed by an extension moment peak (figure 1). It turned out that this flexion peak was the result of an 'overestimation' of the moment caused by the horizontal accelerations.

Comparison of the segmental acceleration from position data used in the SM and from the AM showed good correspondence, indicating correctness of method and measurement data. The overshoot in horizontal accelerations can be explained by an underestimated correction factor [1] used to determine the linear acceleration of the centre of mass, using angular velocity and acceleration, which are calculated from position data. Furthermore, our rigid body model assumes that the foot is one rigid segment. Finally, we use a rigid body model without damping [2].

**Figure 1.** Net sagittal knee moment of a landing. Black line is the moment determined by the SM, and the dotted line is the moment determined by the AM

So, we can state that during impact the real contribution of GRF is for a great part neutralized by segmental acceleration of foot and shank, suggesting that the high impact peak moment shown by the widely used SM moment is be an artifact.

### CONCLUSION

Our results showed major differences during impact in sagittal knee moment between the SM and AM. The SM, used in this study, is a widely used method to determine biomechanical parameters. When estimating net joint moments during impact in activities like running and jumping one should take into consideration the inaccuracy of the net joint moment during impact when using rigid body models. To our opinion, adjustments to the widely used filter techniques can overcome artifacts in net impact joint moments, by using the same cutoff frequency for both kinematic and force data. Complementary, we recommend not to consider impact peaks as the source of chronic overuse injuries, like jumper's knee.

## FACTORS AFFECTING THE CEMENT PENETRATION OF A HIP RESURFACING IMPLANT: AN IN-VITRO STUDY

<sup>1</sup> Ralph Howald, <sup>2</sup> Uldis Kesteris, MD <sup>1</sup> Ralf Klabunde  
<sup>1</sup> Zimmer GmbH, Winterthur, Switzerland, email: ralph.howald@zimmer.com  
<sup>2</sup> University Hospital Lund, Sweden

### INTRODUCTION

Hip resurfacing is increasingly used in orthopedic arthroplasty. In order to plan and conduct the implantation properly, the operating surgeon needs to know how the cementing technique will influence the cement penetration. Breusch et al. [1] quantified the cement penetration in a conventional hip stem and Morberg et al. [2] investigated the cement-bone-interface histologically. However, no information could be found about cement penetration in hip resurfacing prostheses.

### OBJECTIVES

Determine the influence of the following parameters on cement penetration: use of jet lavage, type of cement, and the standing period of the cement.

### MATERIALS AND METHODS

The Durom™ Hip Resurfacing implant (Zimmer GmbH, Switzerland) and nine fresh frozen paired whole cadaver femora (mean 47 years, range 26 to 66 years) were used in this study. The standard case was the use of jet lavage for cleaning the prepared bone and Simplex® cement (Stryker Orthopaedics, USA) with a three minute standing time. The femora were divided into three paired groups: (A) compared the use of jet lavage to no jet lavage, (B) compared the two low viscosity cements SULCEM™-3 (Zimmer GmbH, Switzerland) and Simplex®, and (C) a 1.5 minute standing time was compared to a 3 minute standing time. All 18 implantations were conducted within a two day period by an experienced surgeon using the standard OR procedures.

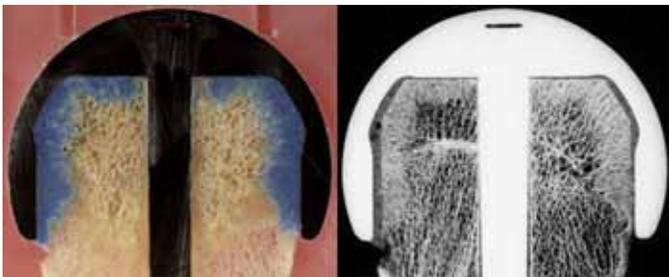

Fig. 1. Section cut of a femoral head (left) and contact x-ray image (right)

A single 2.6 mm thick slice was taken out of the center of each head using a precision diamond blade band saw. Contact x-ray images were then generated using a cabinet x-ray system (Fig. 1). After digitizing the images, computer based measurements were made using Matlab routines. The following measurements were taken: cement penetration *ratio* (penetration area divided by the bone area enclosed by the implant) and mean cement penetration *depth*. The results within each group were compared using a paired t-test. However, since the sample size was only three, the results only indicate tendencies.

### RESULTS AND DISCUSSION

Leaving out jet lavage decreased the mean cement penetration *ratio* by 62% ( $p = 0.018$ ), whereas the mean penetration *depth* decreased by 65% ( $p = 0.024$ ). No significant differences were seen between SULCEM-3 and Surgical Simplex when comparing the cement penetration *ratio* ( $p = 0.71$ ) and *depth* ( $p = 0.57$ ). Applying the cement after a standing time of 1.5 minutes instead of 3 minutes resulted in a lower penetration ratio and depth in all cases. However, the results were not significant ( $p = 0.15$ ,  $p = 0.16$ ) (Fig. 2).

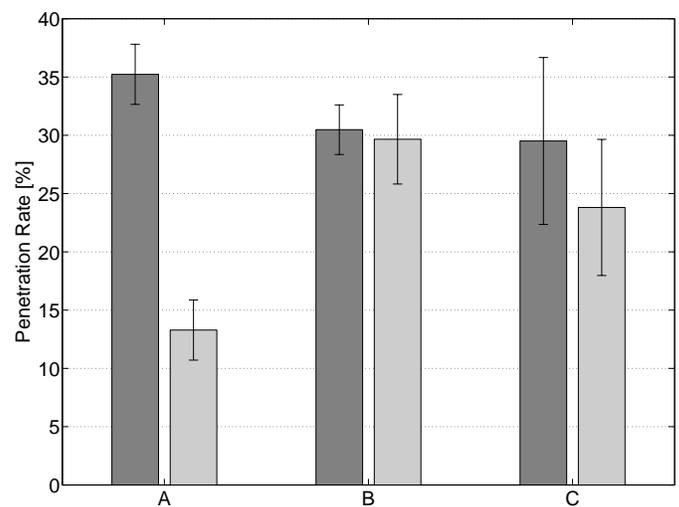

Fig. 2: Comparison of the penetration ratio: (A) Jet Lavage yes vs. no, (B) Simplex® vs. SULCEM™-3, (C) 3 min. vs. 1.5 min. standing period

### CONCLUSION

Using jet lavage or increasing the standing time of the cement to 3 min. has the tendency to increase the cement penetration, whereas no difference in cement penetration was found when different cement brands of comparable viscosity are used.

### INTRODUCTION

Activities of daily living (ADLs) involve smooth voluntary movements between joints that require a synchronized recruitment of relevant muscles. Motion is thus realized by a balance in directional preference of muscular activity. Upper motorneuron syndrome (UMNS) due to lesions in cortico-spinal pathways is common following a stroke or traumatic brain injury. UMNS manifests itself in the form of muscle under- or over-activity which consequently affects motor behavior [1]. An undesirable directional preference is imposed due to involuntary muscle activity thereby inducing spasticity and consequently impeding ADL performance. Muscle under-activity is apparent as weakness, loss of finger dexterity and selective control of muscles. Muscle over-activity is characterized by exaggerated tonic stretch reflexes and tendon jerks. This research is an attempt to identify and study patterns of hand motor dysfunction in ADL performance as a result of brain injury (BI).

### METHODS

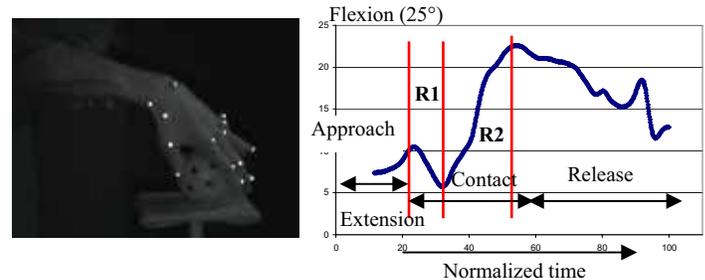

The research is an on-going study that uses a video-based motion analysis system to record hand activity during grasping. The activity involves grasping a spherical object. Subjects were instructed to reach for and wrap their fingers around the object, without lifting the object, and then gradually release the object. The protocol was set based on [2,3] in order to assess the degree of voluntary finger extension. Data were collected and analyzed to observe patterns of hand coordination during grasping in patients after brain injury.

Prior to data collection, the 3D SIMI motion analysis system was calibrated for spatial alignment and orientation. Reflective markers (5 mm in diameter) were placed on the metacarpal (MCP) and interphalangeal (IP) joints of the fingers and thumb, the base of the 3<sup>rd</sup> metacarpal and the styli of the ulna and radius (18 markers). Digital motion data was recorded at 60Hz for at least 8 secs. by three cameras. Spatial coordinate data were extracted from the motion clips of the grasping activity. These were used to calculate MCP and PIP joint angles. Passive range-of-motion for each finger joint and the wrist were also recorded. The abstract discusses a specific case and general observations.

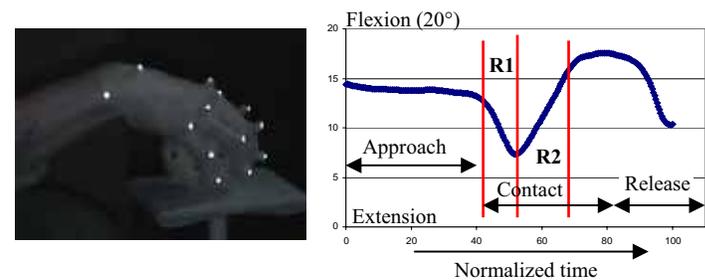

### RESULTS AND DISCUSSION

Figure 1 shows the MCP angle plot for the ring finger in the hand of a patient with bilateral hand motor dysfunction. The motion clips indicated that the patient initiated the dynamic phase of grasping by placing the fingers on the object, followed by lowering the wrist to stabilize the object in the palm. This is

observed in the MCP angle plot wherein region-1 (R1) shows increased MCP extension followed by R2 with increased flexion due to lowering of the wrist for object stabilization. The same regions are identified in the other hand of the same patient which exhibits relatively better hand motor function.

**Figure 1:** MCP angle plot of the patient's ring finger.

**Figure 2:** MCP angle plot of the ring finger in the other hand of the same patient.

The MCP and PIP angle plots were almost in phase in the controls, while the same was not the case in the brain injured patients. Table 1 lists the correlation values between the MCP and PIP angle plots of the fingers for the brain injured patients and age- and gender- matched controls.

### CONCLUSIONS

In this pilot, it was observed that hand motor dysfunction after BI severely affects the release mechanism of the fingers. Patients tend to use different strategies for stabilizing the object in their hand. Relatively low correlation was observed between the MCP and PIP angles in the brain-injured patients. Further research is required to get a more generalized stratification of hand motor dysfunction in BI.

## BEHAVIOR OF THE TRICEPS SURAE MUSCLE IN HOPPING

Sami Kuitunen, Masaki Ishikawa and Paavo V Komi  
Neuromuscular Research Center, Department of Biology of Physical Activity,  
University of Jyväskylä, Jyväskylä, Finland; email: [sami.kuitunen@sport.jyu.fi](mailto:sami.kuitunen@sport.jyu.fi)

### INTRODUCTION

Studies with ultrasonography (US) have revealed that muscle fascicle and tendon length changes may not follow the length changes of the whole muscle-tendon complex (MTC) in natural human movements [1]. In jumping, the gastrocnemius (Ga) muscle fascicles have been shown to shorten [2,3] during the ground contact, despite the lengthening-shortening action of the MTC. Fascicle behavior of the soleus (Sol) muscle in natural human movements has not yet been reported. However, modeling the triceps surae function in counter-movement jump indicates similar behavior of Ga and Sol muscle fibers [4]. The present study focused to explore fascicle behavior of the Ga and Sol muscles directly with US in natural stretch-shortening cycle (SSC) muscle action.

### METHODS

Eight male subjects performed bilateral hopping at low (LOW), medium (MED) and maximum (MAX) intensity. Ground reaction forces (GRFs) were collected simultaneously with high-speed video (200 Hz) recordings and real-time US (96 Hz) of Sol and medial Ga (GaM). Achilles tendon force (ATF) and MTC lengths of Sol and GaM were calculated.

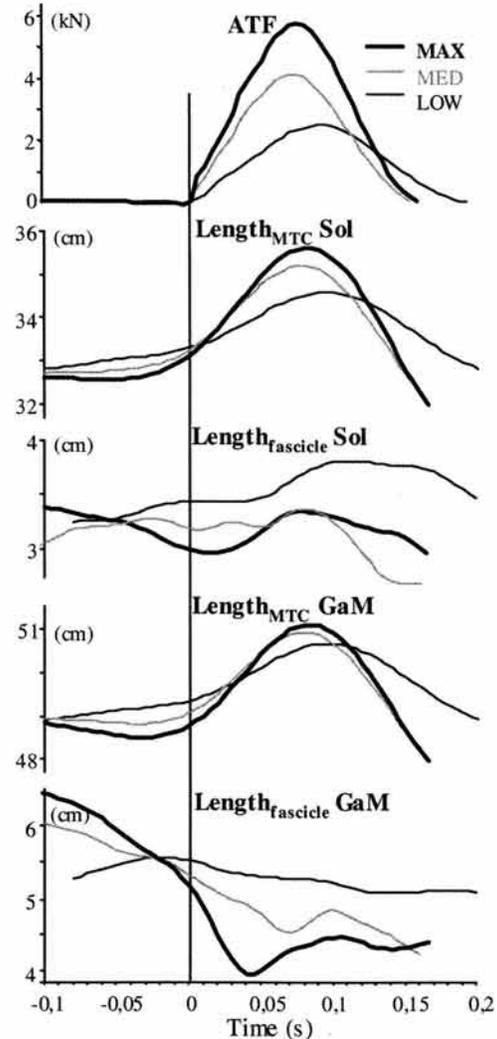

Ten jumps were selected and data was averaged from each subject for each hopping intensity excluding the US data, where two most representative jumps were chosen.

### RESULTS AND DISCUSSION

Fig. 1 represents a typical example of ATF and length changes of MTC and fascicles of Sol and GaM, respectively. Lengthening of MTC increased both in Sol and GaM with increasing loading (ATF). Despite the lengthening of MTC, fascicles of GaM shortened at the beginning of the ground contact. This shortening is similar to the earlier findings regarding counter-movement jumps [2] and drop jumps [3]. It may contribute to the storage of elastic energy by stretching the AT [1,2] and improving energy transfer of the proximal muscles to the ankle joint due to increased muscle stiffness [5]. On the other hand, SOL fascicles showed a lengthening-shortening behavior similarly to the MTC. Similar fascicle behavior has also been observed in the vastus lateralis muscle in drop jumps [3]. It may also be worth noting that the initial shortening of GaM fascicles was followed by a rapid lengthening at MED and MAX, which may imply cross-bridge detachment due to high loading. Similar yielding of GaM fascicles was also observed in the drop jumps [3].

### CONCLUSIONS

The novel finding of the present study was that Sol and GaM fascicles may behave differently in natural SSC muscle action. The Sol fascicles represented a lengthening-shortening behavior similarly to the MTC, whereas GaM mainly shortened during the contact phase in hopping. It is likely that

**Figure 1:** ATF and length-time curves of Sol and GaM MTCs and fascicles of one subject in hopping at different intensities. Vertical line denotes the onset of ground contact.

these differences in fascicle behavior between Sol and GaM are related to the suggested different roles of one- and two-joint muscles in human movements [5].

## MECHANICAL EFFICIENCY DURING WALKING AT DIFFERENT STRIDE RATES

<sup>1</sup>Brian R. Umberger and <sup>2</sup>Philip E. Martin

<sup>1</sup>Biodynamics Laboratory, University of Kentucky, Lexington, KY, USA

<sup>2</sup>Biomechanics Laboratory, The Pennsylvania State University, University Park, PA, USA

email: umberger@uky.edu web: www.coe.uky.edu/~brian

### INTRODUCTION

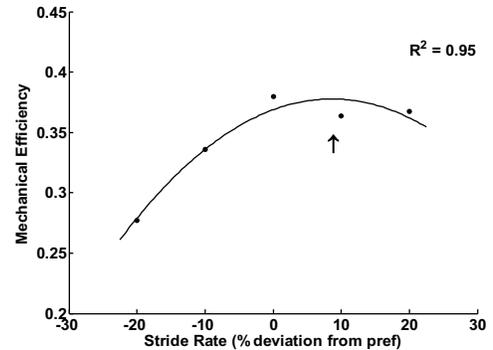

At any particular walking speed, the rate of metabolic energy expenditure in humans is minimized at the preferred, or self-selected, stride rate [6]. However, our understanding of the underlying factors that determine the global energy rate response, and that ultimately influence the preferred walking pattern, remains incomplete. Mechanical efficiency is a factor that is believed to be important in human locomotion [e.g., 5], but has not received much direct attention in regards to walking stride rate selection. The purpose of this study was to test the hypothesis that maximization of the mechanical efficiency of walking occurs at the preferred stride rate.

### METHODS

Six male and four female subjects ( $M_{\text{age}} = 26.7 \pm 3.6$  yr;  $M_{\text{ht}} = 173.9 \pm 9.6$  cm;  $M_{\text{mass}} = 67.9 \pm 11.9$  kg) walked at 1.3 m/s using five different stride rates (preferred,  $\pm 10\%$  of preferred, and  $\pm 20\%$  of preferred). Preferred stride rate was determined as subjects walked on a motorized treadmill, after which the subjects practiced walking at the experimental stride rates for at least 10 min. Following familiarization with the protocol, and after resting for at least 20 min, measurements were made of pulmonary gas exchange while subjects walked on the treadmill at the different stride rates. In a separate trial, ground reaction forces and body segment positions were monitored as subjects walked along a 12 m walkway across a force platform. Subjects matched their stride rates to a metronome for treadmill trials, and to marks placed on the floor for overground trials. For both trials subjects walked with arms folded across their chest, to minimize any influences from outside the lower limbs.

The net (walking minus resting) rate of metabolic energy expenditure ( $E_{\text{DOT}}$ ) was estimated from pulmonary gas exchange [3], and sagittal plane hip, knee, and ankle joint moments were calculated using inverse dynamics [4]. Joint powers were calculated from the net moments and joint angular velocities. Average positive ( $P_{\text{POS}}$ ) and negative ( $P_{\text{NEG}}$ ) power, summed over all three joints, was determined by integrating the instantaneous positive and negative powers over the gait cycle, and dividing by the cycle period.  $P_{\text{POS}}$  and  $P_{\text{NEG}}$  were doubled to approximate the power output of both legs. The mechanical efficiency of walking ( $\epsilon_{\text{W}}$ ) was estimated from  $P_{\text{POS}}$ ,  $P_{\text{NEG}}$ , and  $E_{\text{DOT}}$  as  $\epsilon_{\text{W}} = P_{\text{POS}} / (E_{\text{DOT}} + P_{\text{NEG}})$  [1].

Metabolic energy rate and mechanical efficiency data were fit with quadratic polynomials, and the stride rates corresponding to the respective minima and maxima were determined from the resulting equations. Differences between preferred stride rate and the stride rates optimizing energy expenditure and mechanical efficiency were detected using paired t-tests.

**Figure 1:** Mechanical efficiency of walking was predicted to be maximized at a stride rate 8.3% above the preferred.

### RESULTS AND DISCUSSION

Preferred stride rate (54.3 str/min) and the stride rate minimizing gross metabolic energy expenditure (55.6 str/min) were both similar to previous reports [6], and did not differ significantly ( $p > .05$ ). Mechanical efficiency (Figure 1) was maximized at a stride rate 8.3% higher than preferred (58.8 str/min;  $p < .01$ ). While this difference was statistically significant, the absolute deviation from preferred was modest (4.5 str/min). The present results, combined with earlier work [2] showing that mechanical demand (estimated from net joint moments) was minimized approximately 8.5% below the preferred rate, suggests that these two factors may combine to constrain normal walking stride rates to a narrow range centered around a stride rate of approximately 55 str/min.

### CONCLUSIONS

At a single speed, walking with stride rates lower than preferred results in decreased mechanical efficiency, while using stride rates higher than preferred leads to increased loading on the lower limb muscles. The self-selected stride rate in walking appears to represent the best compromise between these two competing factors.

## KINETIC ANALYSIS OF GAIT ON INCLINED SURFACES

<sup>1</sup>Robyn M. Wharf and <sup>1,2</sup>D. Gordon E. Robertson

<sup>1</sup>School of Human Kinetics, University of Ottawa, Ottawa, Ontario, Canada <sup>2</sup>[dger@uottawa.ca](mailto:dger@uottawa.ca)

### INTRODUCTION

Walking on a level surface usually takes minimal effort and is a daily occurrence. Access to areas on different levels, however, may become a barrier to the injured, elderly or disabled persons. Adding ramps or inclined surfaces is one means of permitting access to different levels of a building. Little data are available concerning the efforts required to negotiate different inclines. Prentice *et al.* [1] analyzed various inclines but only examined the swing phase while Post & Robertson [2], looked at ramp descent at one gradient. The purpose of this investigation was to quantify the moments of force and powers produced in the lower extremity during ascent of inclines of various gradients compared to those of level gait.

### METHODS

Twelve subjects (6 female, 6 male) between the ages of 20 and 30 volunteered. Sagittal plane kinematics from a 60 Hz video camera and ground reaction forces from a force platform placed on the ramp were collected. The participant's ascended four different ramp inclinations, five times each (level, 3-deg, 6-deg and 9-deg). The motion data were digitized using the APAS. Kinematic, inverse dynamic and power analyses were done with the Biomech Motion Analysis System [3].

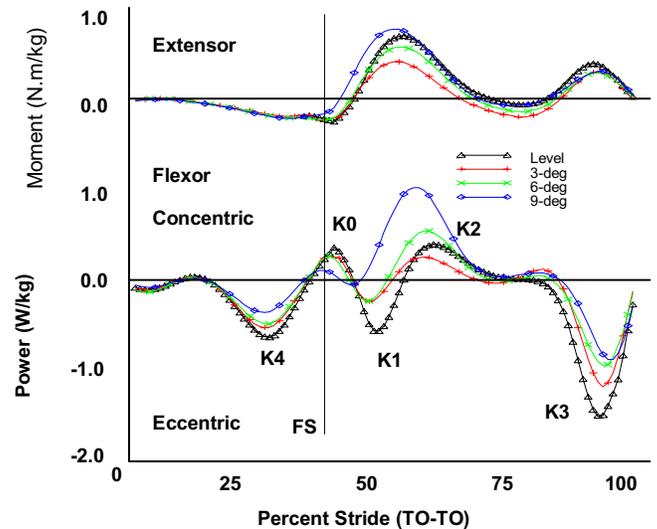

### RESULTS AND DISCUSSION

Ankle moments and powers were similar for the level and 3-deg inclined conditions. There were no significant differences in the peak moments of force for any of the four conditions but there was a steady increase in peak power between 3, 6, and 9 degrees of incline. There was a 21% increase in peak power between the 9-degree incline and then level and 3-degree incline (2.99 vs. 2.45 W/kg).

Figure 1 illustrates the average knee moments of force and moment powers for all four conditions. The power burst at K0 was equal for all the inclines excepting for 9-deg, which was significantly less. Other major differences with the 9-deg incline occurred after foot-strike (FS) at K1 where the knee extensors produced almost no negative work compared to the other grades and at K2 where substantially more work and power were required.

There were sequential reductions in the peak eccentric power bursts of the knee extensors at K3 prior to toe-off (TO) and by the knee flexors prior to FS (K4). Thus, the energy demands of ascending inclines are met by reducing the amounts of energy dissipated by knee eccentric muscle contractions.

The peak moments of force at the hip were not significantly different across the four gradients. The peak powers were also similar but there were differences in the extensor work done immediately after FS (H1). Here there was a gradual increase of 138% from level to 9-deg incline (0.29-0.69 W/kg).

**Figure 1:** Grand ensemble averages (n=12x5) of the knee moments of force (top) and their powers (bottom) for level, 3, 6 and 9-degree inclines normalized to body mass. Abscissa is percent of stride from toe-off to toe-off.

### CONCLUSIONS

There were few differences in the peak moment and power demands between level and 3-deg incline. The demands for 9-deg inclined ascent were significantly greater especially at the knee as compared to level and 3-deg of incline with the 6-deg incline being of intermediate demand.

## SKIN MOVEMENT ARTIFACT DURING GAIT AND CUTTING MOVEMENTS MEASURED IN VIVO

Daniel L Benoit<sup>1,2,\*</sup>, Dan K. Ramsey<sup>3,4</sup>, Mario Lamontagne<sup>5,6</sup>, Lanyi Xu<sup>6</sup>, Per Wretenberg<sup>2,4</sup>, Per Renström<sup>1,2</sup>

<sup>1</sup>Institution for Surgical Sciences, Section of Sports Medicine, Karolinska Institute, Stockholm, Sweden; <sup>2</sup>Department of Orthopaedics, Karolinska Hospital, Stockholm, Sweden; <sup>3</sup>Department of Physical Therapy, University of Delaware; <sup>4</sup>Institution for Surgical Sciences, Section of Orthopaedics, Karolinska Institute, Stockholm, Sweden; <sup>5</sup>School of Human Kinetics, University of Ottawa, Ottawa, Canada; <sup>6</sup>Department of Mechanical Engineering, University of Ottawa, Ottawa, Canada; dbenoit@magma.ca

### INTRODUCTION

Skin movement artifact limits the ability to accurately 3D tibio-femoral kinematics using non-invasive techniques. Previous investigations into the error associated with skin movement artifact have had few subjects and/or been measured under conditions that may not represent healthy populations. The purpose of this study is to measure the effect of skin movement artifact on the reporting of knee joint kinematics in a healthy population during gait and cutting, a movement believed to illicit non-sagittal plane rotations and translations.

### METHODS

Eight healthy male subjects participated in this study. Intra-cortical bone pins were transcutaneously implanted under local anaesthetic into the proximal tibia and distal femur. Three reflective markers were attached to each bone pin and four reflective markers were mounted on the skin of the tibia and thigh respectively. Roentgen-stereophotogrammetric analysis was used to determine the anatomical reference frame of the tibia and femur. Knee joint motion was recorded during walking and cutting using infra-red cameras at 120 Hz.

### RESULTS AND DISCUSSION

The kinematics derived from the bone-pin markers was compared with that of the skin markers. Rotational errors of up to 4.4 and 13.1 degrees and translation errors of up to 13.0 and 16.1 mm were noted for the walk and cut respectively (table 1).

Although the data was repeatable within subject the direction and magnitude of the error was not repeatable across subjects (figure 1). This suggests that repeatability of motion analysis data can not be used as an indication of accurate data.

### CONCLUSION

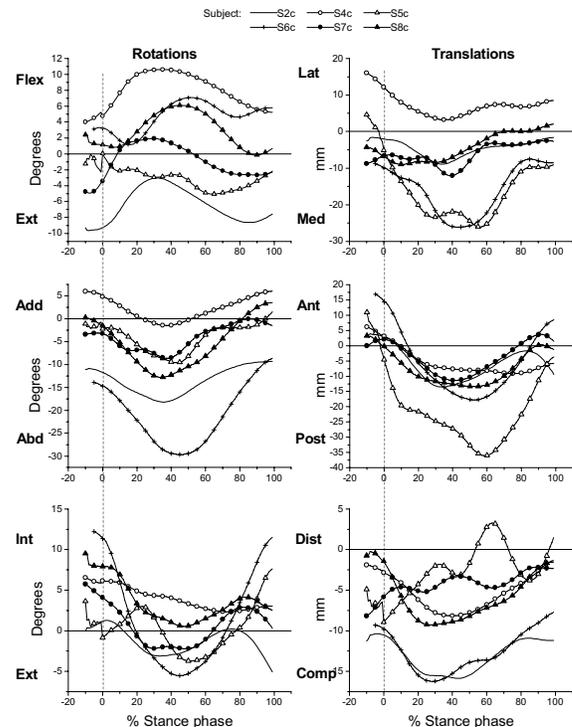

It was noted that although the skin marker derived kinematics could provide repeatable results this was not representative of the motion of the underlying bones. A standard error of measurement is proposed for the reporting of 3D knee joint kinematics.

**Table 1:** Absolute error values of skin-marker derived kinematics at three time points during walking and cutting of knee rotations and translations: flexion extension (Flex/ext), adduction-abduction (Add/abd), internal-external rotation (Int/ext); medio-lateral (Med/lat), anterior-posterior (Ant/post) and distraction-compression

(Dist/comp). Note: † denotes significant difference between skin and pin-marker data (2 tailed paired Students T-test, p<0.05)

		Rotations (degrees +/- StDev)			Translations (mm +/- StDev)

## IN VIVO FASCICLE LENGTH OF CAT MEDIAL GASTROCNEMIUS AND SOLEUS MUSCLES DURING SLOPE WALKING

Huub Maas, Boris I. Prilutsky and Robert J. Gregor

Center for Human Movement Studies, School of Applied Physiology, Georgia Institute of Technology, Atlanta, GA, USA  
 Email: huub.endemaas@ap.gatech.edu

### INTRODUCTION

By changing the slope of a walking surface, mechanical variables (e.g. muscle fascicle length, tendon force) related to proprioceptive feedback can be manipulated. It has been suggested that length-dependent feedback from muscle spindles is more important for limb control during downslope walking compared to level or upslope walking [1]. Such a conclusion is based on length changes of the whole muscle-tendon complex (MTC). However, muscle spindle strain is directly related to changes of muscle fascicle length ( $L_{fas}$ ).

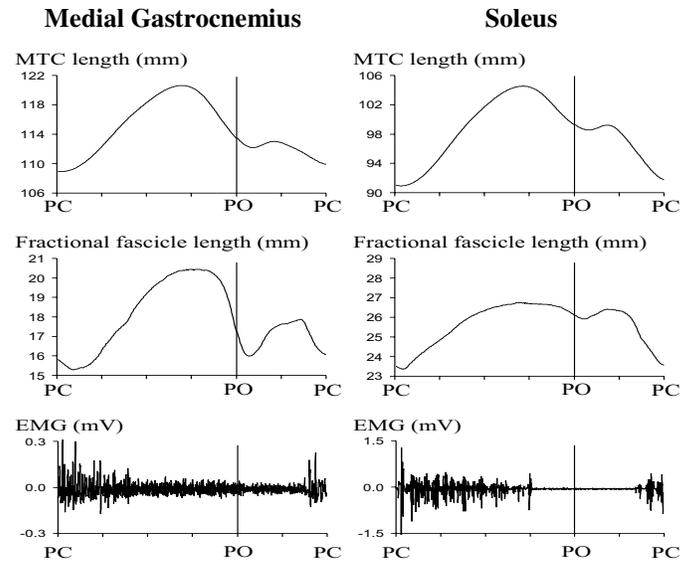

Fascicle length changes of medial gastrocnemius muscle (MG) have been reported for level walking as well as for modestly sloped surfaces only, i.e. 10% [2]. Therefore, the **aim** of this study was to quantify fascicle length changes of MG as well as soleus (SO) muscles during walking on a level surface as well as on substantially sloped surfaces (i.e. + and -50%, 26.6°).

### METHODS

Joint kinematics and kinetics of the hindlimbs, muscle activity patterns, MTC length and  $L_{fas}$  were assessed for three walking conditions in the cat: downslope, level and upslope. Four out of six cats were surgically implanted with EMG electrodes in SO and MG [3]. Selected muscles were also instrumented with sonomicrometry crystals to measure  $L_{fas}$ . The distance between the sonomicrometry electrodes (fractional  $L_{fas}$ ) was  $\approx 65\%$  and  $\approx 80\%$  of the total fascicle length of SO and MG, respectively. Resting fascicle [4] and MTC length, as calculated based on a geometrical model, at ankle and knee angles of 90° were used as reference lengths ( $L_{ref}$ ). For sonomicrometry, 6 step cycles were analyzed for level walking, 10 for the downslope and 13 for the upslope condition.

### RESULTS AND DISCUSSION

For all cats, biomechanical gait parameters as well as muscle activity patterns were similar. Significant ( $p < 0.05$ ) differences between changes of MTC length and total  $L_{fas}$  were found in early stance of all slope conditions (Figure 1, Table 1). During upslope walking, MTC lengthening of MG occurred in the presence of substantial  $L_{fas}$  shortening. For both muscles, fascicle lengthening in early stance during

**Figure 1:** Typical example of MTC and fractional fascicle length as well as EMG recordings during downslope walking.

downslope walking was significantly ( $p < 0.05$ ) higher than during level and upslope walking. This suggests a potentially higher contribution of length-dependent feedback for regulation of muscle activation, assuming constant activation of intrafusal fibers. Different muscle-tendon interactions ( $\Delta L_{fas} / \Delta L_{MTC}$ ) between muscles and slope conditions can be explained partially by the magnitude of muscle activity [3]:

- SO: EMG level < EMG downslope < EMG upslope
- MG: EMG downslope < EMG level < EMG upslope.

## ADAPTIVE CHANGES IN STEPPING UP ONTO Laterally-COMPLIANT STRUCTURES: AGE DIFFERENCE IN HEALTHY MALES

Bing-Shiang Yang and James A. Ashton-Miller

Department of Mechanical Engineering, University of Michigan, email: [bsyang@umich.edu](mailto:bsyang@umich.edu)

### INTRODUCTION

Falls from laterally-compliant structures, such as stepladders, cause injuries in industry and at home across the age spectrum; however, fall-related injuries become more frequent and more serious in older populations [1,2]. Healthy adults, especially the elderly, have been shown to take significantly more time to complete a single step-up movement onto a raised structure with unexpected structural compliance [3]. The purpose of this study was to investigate whether subjects demonstrate practice or learning effects in this behavior. We therefore tested the null hypotheses that there are (a) no significant practice effects in stepping up onto a laterally-compliant structure in repeated trials and (b) no age effects on this behavior between healthy young and older men.

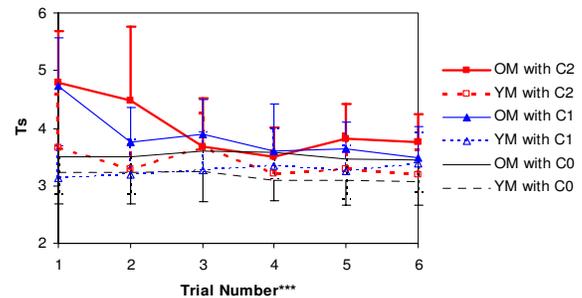

### METHODS

Twenty healthy male subjects, 10 young males (YM) aged  $26 \pm 3$  years and 10 older males aged  $72 \pm 3$  years, were asked to stand bare-foot on firm ground, and then step forward and up onto a 7" (0.178 m) -high structure at a self-selected comfortable speed. The mediolateral compliance of the structure could be covertly adjusted to one of three different values (measured at the structural top surface): rigid ( $C_0 < 10^{-5}$  m/N), smaller compliance ( $C_1 = 1 \times 10^{-4}$  m/N), and larger compliance ( $C_2 = 2 \times 10^{-4}$  m/N). Six stepping trials were performed with each compliance. Trial order was  $C_0$ ,  $C_1$ , and  $C_2$ , interspersed by different numbers of blocks of six  $C_0$  trials to prevent subjects knowing when a compliance change occurred. Adaptive changes in the stepping movements were examined by comparing data from the first to sixth trials in each compliance condition.

The primary parameter investigated was the total time each subject used to complete the step-up movement normalized by the time used from initiating weight transfer till the lead foot contacting the raised structure ( $T_s$ ). Kinematic and kinetic data were recorded and analyzed, but for brevity are not reported in this abstract. Repeated measure analyses of variance (rm-ANOVA) were performed to examine the effects of practice, structural compliance, and age on  $T_s$ . Post-hoc rm-ANOVA were used to examine the effects of structural compliance and age on stepping movements after practice (in the sixth trial). Additional post-hoc rm-ANOVA were performed to compare movement parameters of the first trial of YM with those of the sixth trial of OM.  $P < 0.05$  (with Bonferroni correction) was considered statistically significant unless otherwise noted.

### RESULTS AND DISCUSSION

Practice significantly ( $p < 0.001$ ) reduced the stepping duration ( $T_s$ ) needed for completing a single step-up movement, especially for older males stepping onto the laterally-compliant structures ( $C_1$  and  $C_2$ ) (Figure 1). The largest

**Figure 1:** Mean values (error bars: 1SD) of total duration ( $T_s$ ) of one stepping movement onto the raised structure with three values of structural compliance ( $C_0$ ,  $C_1$  and  $C_2$ ) in six consecutive trials each (\*\*\*:  $p < 0.001$ ). For six trials: age effect:  $p < 0.01$ ; interaction effect between age and practice:  $p < 0.01$ . In the sixth trial: compliance effect:  $p = 0.15$ ; age effect:  $p < 0.018$ .

practice effect appeared within the first three trials.  $T_s$  for OM decreased 21% from the first to second trials on  $C_1$  and 23% from the first to the third trials on  $C_2$ , while YM showed relatively smaller amounts of decrease (15%) in  $T_s$  from the first to sixth trials on  $C_2$ , but no significant changes on  $C_1$ . In contrast to results from the first trial only [3], after five repeated trials, the structural compliance did not affect the total duration of the stepping movements. Although the difference in stepping duration between the two age groups decreased over six consecutive trials, it remained significant, especially on the most compliant structure ( $T_s$  for OM was 18% longer than for YM on  $C_2$ ). By their sixth stepping trial, OM no longer differed significantly from YM in their first trial in either stepping duration or peak lateral structural displacement ( $p = 0.23$ ).

Within a small number of practice trials, healthy male adults (both young and older) were able to significantly adjust their stepping movements to adapt to the lateral structural compliance. Older males were able to compensate for the age difference after two or three practice trials.

### CONCLUSIONS

Elderly men require more time to adapt to the presence of unexpected lateral ladder compliance than do younger men.

## FORCE ENHANCEMENT IN SUB-MAXIMAL VOLUNTARY CONTRACTIONS

Mir Ali Eteraf Oskouei and Walter Herzog

Human Performance Laboratory, University of Calgary; email: oskouei@kin.ucalgary.ca

### INTRODUCTION

Force enhancement (FE) can be defined as an increase in steady-state isometric force after active muscle stretching [1,3,4]. Force enhancement has been observed in single fibers [3], isolated muscles [1], and intact muscles [2,4], and has been reported for maximal and sub-maximal electrical stimulation of muscles [1], as well as for maximal voluntary contraction (MVC) in humans [2,4]. However, it has not been studied for sub-maximal voluntary contractions. Therefore, it is not known if force enhancement occurs during normal everyday movements. The purpose of this study was to test whether force enhancement after stretching exists for sub-maximal voluntary muscle contraction

### METHODS

All procedures were identical to those described by Lee and Herzog [4] with two exceptions:

i) All contractions were performed at sub-maximal levels; that is, at either 30% of the maximal isometric voluntary force, or at an activation level (full wave rectified and smoothed EMG, AEMG) corresponding to the value obtained at 30% of MVC, and ii) Visual feedback was provided to the subjects so they could match either 30% of MVC, or the activation level corresponding to 30% of MVC.

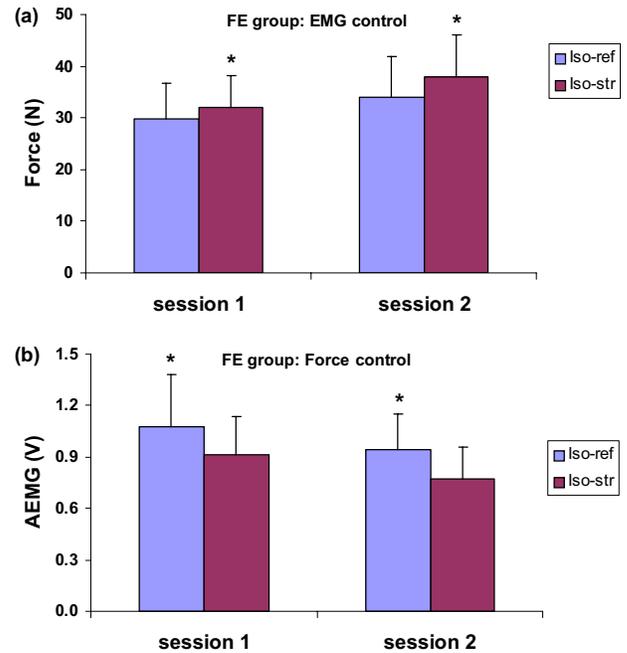

In this study, force enhancement was determined in two ways. Force enhancement in the force control protocol was defined as a decrease in steady-state isometric AEMG (activation deficit) in the stretch test contraction compared to the corresponding AEMG of the isometric reference contraction. Force enhancement in the activation control protocol was defined as an increase in steady-state isometric force in the stretch test contraction compared to the corresponding force obtained in the isometric reference contraction. The force enhancement experiment was performed with 17 volunteers.

### RESULTS AND DISCUSSION

Subjects fell into two groups showing distinctly different results. Eight of the 17 subjects had statistically significant force enhancement ( $9 \pm 5\%$ ) and activation deficit ( $15 \pm 7\%$ ) following adductor pollicis stretching (Fig 1, session 1). The remaining nine subjects showed no changes in force or activation after muscle stretching when compared to the corresponding reference contractions

In order to ensure the reliability of the force enhancement results, all force enhancement tests were repeated several weeks after the first testing session. Those subjects who had consistent force enhancement and EMG deficit in the first session also had force enhancement and EMG deficit in the second session (Fig 1, session 2), and subjects who showed no force enhancement in the first session also did not have force enhancement in the second session.

The primary results of this study were that there is force enhancement for voluntary, sub-maximal contractions in the

**Figure 1:** Mean (+1SD) isometric force and EMG during isometric reference contractions (Iso-ref) and following the stretching test (Iso-str) for activation control and the force enhancement group (a), force control and force enhancement group (b). Results for the initial session (session 1) and the repeat session (session 2) are shown. (\*  $p < 0.05$ )

adductor pollicis, and that this force enhancement is clearly and unequivocally apparent in about one half of the tested subjects, while there is not a hint of force enhancement in the remaining subjects. In order to explain these results, we performed a follow up study in which we showed that those subjects who exhibited force enhancement had greater post-activation potentiation and a smaller resistance to fatigue, suggesting that the group showing force enhancement might have had a greater percentage of fast twitch fibers than the group who showed no force enhancement. Therefore, the results suggest that force enhancement might occur exclusively (or to a greater extent) in fast twitch fibers than slow twitch fibers.

### CONCLUSIONS

Here we demonstrate for the first time that force enhancement exists for sub-maximal voluntary contractions, and we hypothesize that force enhancement might be associated primarily with fast twitch muscle fibers.

## LUMBAR EXTENSOR FATIGUE CHANGES POSTURAL RECOVERY STRATEGY

Erin Wilson, Michael Madigan, Bradley Davidson, and Maury Nussbaum

Virginia Tech, Musculoskeletal Biomechanics Lab; email: [mlm@vt.edu](mailto:mlm@vt.edu), web: [www.biomechanics.esm.vt.edu](http://www.biomechanics.esm.vt.edu)

### INTRODUCTION

Movements used to maintain standing balance in the sagittal plane following a postural perturbation have previously been described as a hip strategy, ankle strategy, or a combination of the two [1]. Numerous extrinsic and intrinsic factors affect which of these postural strategies are typically employed. To our knowledge, no studies have investigated fatigue in this regard. Therefore, the purpose of this study was to investigate the effect of lumbar extensor fatigue on postural recovery strategy in response to a balance perturbation.

### METHODS

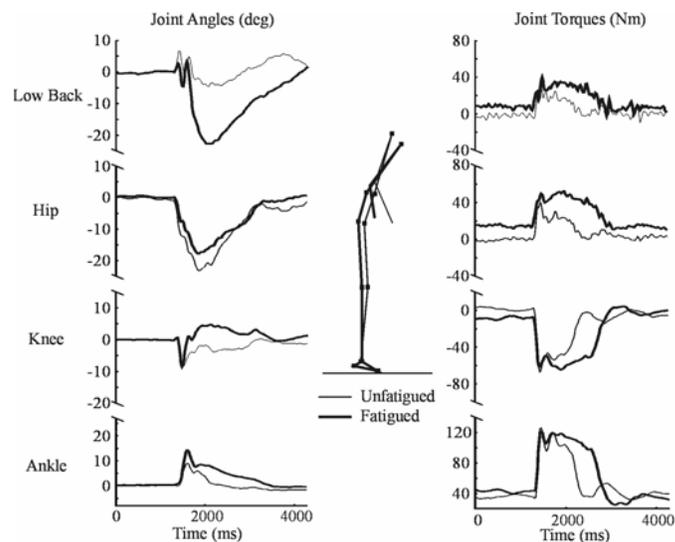

Twelve physically active males (20-22 years of age) participated in three experimental sessions, each consisting of four stages: warm-up, three unfatigued balance perturbations, fatiguing protocol, and a fatigued balance perturbation. The perturbation consisted of an anteriorly-directed impulse applied in the mid-sagittal plane at the level of the inferior margin of the scapulae. Typical perturbation characteristics were 170 N and 150 ms for the peak force and duration, respectively. Perturbations were designed to challenge the balance system while not eliciting a stepping response.

The fatiguing protocol consisted of multiple sets of back extensions and intermittent isometric maximum voluntary contractions (MVCs) to assess the level of fatigue [2]. The lumbar extensor muscles were fatigued over 14 minutes to 86%, 73%, and 60% of their unfatigued isometric MVC.

Triaxial ground reaction forces and body segment positions were collected from a force platform and a motion analysis system. Postural strategy was quantified using the trajectory of the center of pressure (COP) along with joint angles and joint torques for the ankle, knee, hip, and "low back" joints derived from inverse kinematics. A repeated-measures ANOVA was used to determine the effect of fatigue on recovery strategy.

### RESULTS AND DISCUSSION

Results showed both pre-perturbation and post-perturbation changes in postural strategy with fatigue. Pre-perturbation changes involved a slight anterior lean prior to the perturbation, as evidenced by a 1.1 cm shift in COP position. Post-perturbation changes of the joint angles and torques were consistent with a shift toward more of a hip strategy. Specifically, there was a 3.2 Nm decrease in plantar flexor torque, a 10.2 Nm increase in hip extensor torque, a 2.5° increase in ankle plantar flexion, and a 6.3° increase in low back flexion (Figure 1). Correlations between pre-perturbation COP position and post-perturbation joint angles/torques were low, indicating that the changes in post-perturbation recovery strategy were primarily due to fatigue and not the difference in pre-perturbation COP position.

**Figure 1:** Representative joint angle and joint torque data during unfatigued and fatigued postural recoveries. Positive values indicate extension movement and extensor torque.

Results also suggested that certain subjects, classified prior to fatigue as employing a hip strategy in response to the perturbation, were more affected by fatigue compared to subjects classified as using a combination of hip and ankle strategies prior to fatigue. Increasing fatigue level exaggerated some, but not all, of the changes in postural strategy following fatigue.

### CONCLUSIONS

Lumbar extensor fatigue elicited a change in postural strategy in response to a perturbation. Both pre- and post-perturbation postural compensations were identified and demonstrate a general shift toward increasing use of a hip strategy following lumbar extensor fatigue. These findings illustrate that neuromuscular fatigue can influence postural strategy similar to previously reported intrinsic factors.

## EFFECTS OF LUMBAR EXTENSOR FATIGUE AND CIRCUMFERENTIAL ANKLE PRESSURE ON ANKLE JOINT MOTION SENSE

Kevin Pline, Michael Madigan

Musculoskeletal Biomechanics Lab, Virginia Polytechnic Institute and State University; Blacksburg, VA

email: [kmpline@vt.edu](mailto:kmpline@vt.edu), web: [www.biomechanics.esm.vt.edu](http://www.biomechanics.esm.vt.edu)

### INTRODUCTION

Falls from heights are one of the three leading causes of occupational deaths in the United States, accounting for approximately 700 deaths annually [1]. Increases in postural sway, which suggests a degradation of balance, have been shown following lumbar extensor fatigue [2]. This could conceivably contribute to fall accidents because it is common in many occupational tasks. However it is unclear how lumbar extensor fatigue affects balance. Proprioception at the ankle is critical in maintaining balance and any loss of proprioception could cause increases in sway and contribute to falls. Therefore, the first objective of this study was to evaluate the effect of lumbar extensor fatigue on ankle proprioceptive acuity.

Circumferential Ankle Pressure (CAP) has been shown to improve ankle proprioceptive acuity in individuals with below average proprioceptive acuity [3]. If lumbar extensor fatigue degrades proprioceptive acuity at the ankle, it is possible that the application of circumferential ankle pressure could mitigate the deleterious effects of fatigue on ankle proprioceptive acuity. Therefore, the second objective of this study was to investigate the effect of CAP on ankle proprioceptive acuity both with and without lumbar extensor fatigue.

Proprioceptive acuity in this study was quantified as ankle joint motion sense (JMS) which is the angular displacement at a joint necessary to detect joint motion.

### METHODS

Fourteen healthy male subjects participated in the experiment with a mean (SD) age of 23.6 (2.9) years. To measure JMS, subjects were seated on a Biodex System 3 Pro, and the ankle was passively moved at 0.25 deg/sec in either plantar flexion or dorsiflexion until motion was detected by the subject and a hand held stop button pushed. During testing, subjects had their eyes closed and listened to music to prevent ancillary sensory cues of ankle motion. All subjects were tested with and without CAP both before and after a lumbar fatiguing protocol.

JMS was quantified as the angular displacement of the Biodex arm (in degrees) between the initial position and the final position after the subject stopped movement. Both directions were averaged together to give one JMS score for each condition. A square root transformation was used to obtain a normal distribution in the data. A two-way repeated measures ANOVA was used to test for the effect of fatigue on CAP on ankle JMS.

CAP was applied using a pediatric blood pressure cuff placed just above the talocrural joint and inflated to a pressure of 60 mmHg. Subjects were fatigued to 75% of their unfatigued maximum voluntary exertion (MVE) of the lumbar extensors by performing multiple sets of back extensions on a Roman Chair over 14 minutes [2].

### RESULTS AND DISCUSSION

Subjects were fatigued to 68.3 (7.2)% of their unfatigued lumbar extensor MVE. Both fatigue and CAP impaired JMS scores (Figure 1). Fatigue induced a 6 (10) % increase in the JMS scores

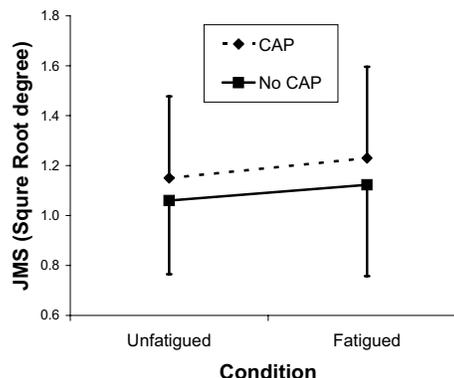

Figure 1: Mean (SD) averaged JMS scores (deg) after square root transformation for unfatigued and fatigued condition with and without CAP

( $p=0.031$ ). CAP induced a 7.7 (10) % increase in the JMS scores ( $p=0.016$ ). The ANOVA performed on the JMS scores revealed no significant interaction between fatigue and CAP ( $p=0.868$ ).

The explanation for lumbar extensor fatigue impairing proprioception at the ankle joint is not intuitive. One possible explanation is that the general body fatigue, induced by the lumbar extensor fatiguing protocol, hindered joint proprioception at the ankle due to the deficiency of central processing of proprioceptive signals. A number of central changes occur during fatigue and affect, among other things, proprioception [5]. Contrary to previous reports, CAP had a negative effect on ankle proprioception, which may be explained by difference in experimental methods.

### CONCLUSIONS

Muscle fatigue of the lumbar extensors decreased ankle JMS. Our results also indicated that the application of CAP decreased ankle JMS. Although this provides a convenient explanation for the previously reported increase in postural sway with lumbar extensor fatigue, this is likely only one contributing factor. Future studies are needed to further understand the relationship between muscle fatigue, JMS, and balance.

### INTRODUCTION

It has been shown that backwards walking is metabolically more demanding than forward walking at the same speed, in part due to the change in quadriceps activity [1]. During forward walking the quadriceps contract eccentrically in early stance, while during backward walking the eccentric activity is replaced by concentric activity, which has a higher energy cost. This increased demand may contribute to improvements in cardiovascular fitness when backward walking is included in a training program [2]. Reduced joint stresses, in addition to the increased demand also make backward walking beneficial as a rehabilitation strategy for those suffering from knee injuries. Changing the grade of the walking surface may further increase the demands on the muscles and therefore increase the benefits of backward walking for rehabilitation [3]. The purpose of this study was to investigate the knee joint kinetics of backward upslope walking, compared to forward upslope walking, as a means of assessing its functionality as a rehabilitation exercise. [4].

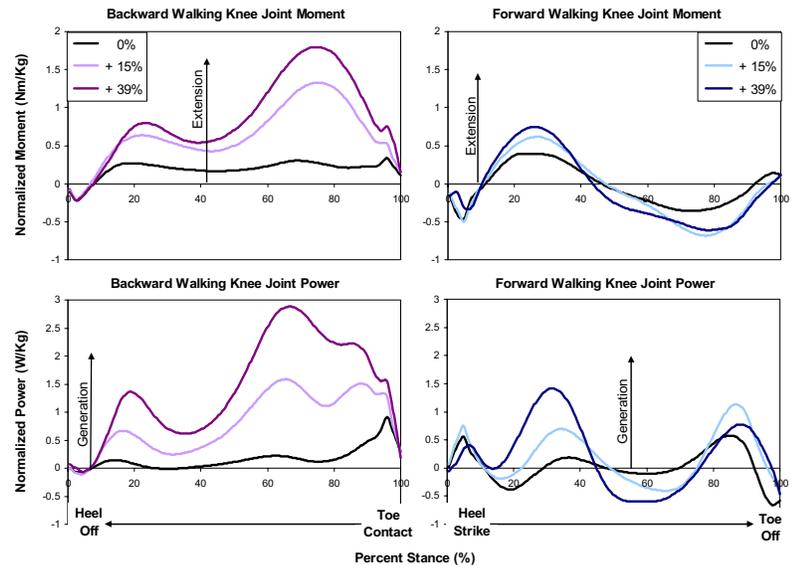

### METHODS

Nine healthy adult volunteers (5M, 4F, mean age = 24 yrs) each read and signed an informed consent statement approved by the IRB at Georgia Tech. Participants were then fitted with fifteen retroreflective markers (Helen Hayes system) and performed sixteen walking trials (8 forward, 8 backward) at each of three different grades (0%, +15%, +39%) on a custom ramped walkway [5]. Starting positions were adjusted so each subject struck the force plate with their self-selected limb (8R, 1L). Each participant started at 0% and walked at a self-selected pace; for all subsequent forward trials the stance time was constrained to  $\pm 5\%$  of his/her 0% average stance time.

Ground reaction forces (GRF) were sampled at 1200 Hz from a Bertec force platform concealed flush with the walkway surface. Kinematic data were captured at 60 Hz using a six camera Peak 3D Optical Capture system. GRF and kinematic data were exported to in-house software for inverse dynamics calculations. Joint moment and power data were normalized to 300 points over the stride (200 stance, 100 swing) and then ensemble averaged across all subjects for each grade.

### RESULTS AND DISCUSSION

The joint moments and powers at the knee joint during backward and forward upslope walking are presented in Figure 1. The knee joint moment during the second half of stance in backward walking is dominated by a large extension moment that is not present in forward walking. The joint power data indicates that the knee extensors act concentrically during the entire stance phase of backward walking. During

**Figure 1:** Backward (time-reversed such that the tasks are kinematically similar in time) and forward upslope walking joint moments and powers, ensemble averaged across subjects.

forward upslope walking the eccentric knee extensor activity also decreases from that at level forward walking, but the demands are much lower than during backward upslope walking. In both activities, the decrease in (or lack of) eccentric quadriceps activity may reduce the patellofemoral joint stresses that are often associated with anterior knee pain [3]. In addition, the large increases in the activity of the knee extensors during backward upslope walking may be useful for strengthening these muscles, a frequent goal in knee rehabilitation. Backward upslope walking also utilizes a greater range of knee joint motion (another common rehab goal) compared to forward upslope walking. In conclusion, backward upslope walking may be a more effective exercise than forward upslope walking for knee rehabilitation, although it is a more difficult task and may not be appropriate for all patient populations.

## MEASUREMENT OF TURBULENCE IN GLOTTAL FLOW

Fariborz Alipour and Ronald C Scherer  
University of Iowa, Iowa City, IA 52242  
alipour@blue.weeg.uiowa.edu

### INTRODUCTION

Glottal flow during phonation exits the glottis as a pulsatile jet that has both a repetitive quasi-periodic portion (called the *deterministic signal*), as well as a more random *turbulence ripple* [1]. Studies have suggested that the glottal jet between the vocal folds typically is laminar before the glottal exit, with transitions to turbulence within a short distance of the glottis [2].

This report discusses three different methods of analyzing the velocity signal of the air exiting the glottis into the deterministic (nearly repetitive) signal and the turbulence residual velocities: smoothing, wavelet de-noising, and ensemble averaging. These will be described following discussion of the excised larynx set-up.

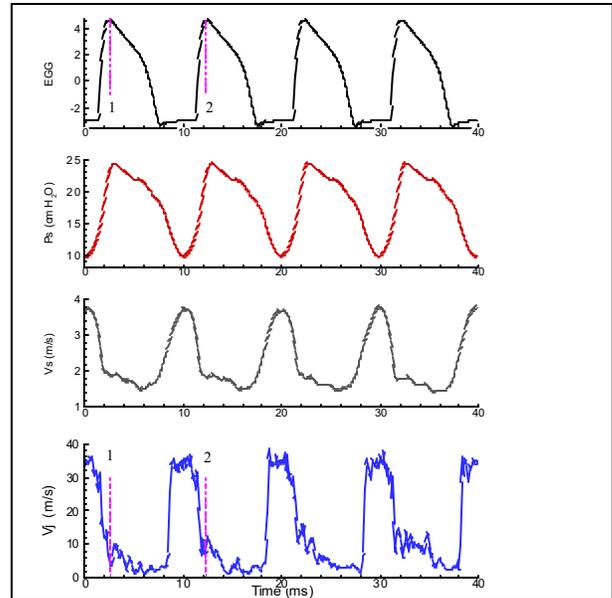

### METHODS

Canine larynx was mounted on an air tube with a hot-wire probe placed above the glottis outlet. Airflow was passed through a heater and humidifier to achieve 37°C and 100% humidification. The use of sutures, micrometers, and shims controlled glottal length and adduction. The jet velocity above the glottis was measured with hot-wire or hot film sensors using a constant-temperature anemometer system (Dantec 56C01). Analog signals from the hot-wire probe, EGG, and pressure transducer were monitored on a digital oscilloscope and simultaneously recorded on a DAT recorder. The signals were digitized later at a minimum of 10 kHz per channel for 1 to 5 seconds. **Figure 1** shows typically recorded data, including from top to bottom the following signals: EGG, subglottal pressure (Ps), tracheal velocity (Vs), and glottal exit jet velocity (Vj).

In the interest of flow analysis, it is important to separate the turbulence from the velocity. Thus, by time averaging the instantaneous velocity over time, one can find the mean or time-averaged velocity, and by subtraction, an estimate of the turbulence. This works easily in steady flows where time-averaged velocity becomes time independent. However, in pulsatile glottal flow, simple averaging does not work and other ways of separating turbulence are needed. Once the turbulence is separated, the remaining velocity is still time dependent and is called deterministic velocity.

### SUMMARY OF RESULTS

The existence of flow turbulence in the glottal jet flow has been shown to be highly likely. The importance of the turbulence has not been well established, although it may appear obvious that it is part of the noise creation for breathy voicing, whisper, and perhaps secondary dipole sound. Thus, it is important to establish methods to measure turbulence associated with phonation. Turbulence intensity is the conventional measure of choice. But what methods should be

**Fig. 1 – Typical waveforms of recorded data**

used to extract the turbulence from velocity signals? This study attempted to examine three different methods, ensemble averaging, smoothing, and wavelet de-noising.

The results suggest that the ensemble averaging is inadequate because it gives the worst representation of the deterministic signal and the lowest cross-correlation between the deterministic signal and the original velocity. It takes away cycle “individuality” by making them all the same (for the chosen group with which to calculate the deterministic signal). The wavelet de-noising scheme would appear to be highly applicable, but the requirement to make a choice of which level of analysis to make lends flexibility for which there is an absence of knowledge. That is, the actual turbulence intensity is unknown, and therefore the level of analysis is not determinable. The smoothing method appears to be a reasonable compromise at this time because of its reasonable calculation of both the deterministic signal and the turbulence intensity, and because of its simplicity.

## BILATERAL SYMMETRY IN SINGLE LEG LANDINGS

Barbara Bentley, Peter Milburn, Stephan Milosavljevic and Allan Carman  
School of Physiotherapy, University of Otago, Dunedin, New Zealand  
email: peter.milburn@otago.ac.nz

### INTRODUCTION

Landing on one foot from a jump is a complex task that is required during many sporting activities. An athlete uses muscular energy in an attempt to dissipate these forces with the contractile and articular structures about the knee playing a significant role as a shock absorber [1,2]. It is argued that the high mechanical demand on the knee joint on initial impact and during the landing phase makes it vulnerable to injury [2,3]. Therefore, variations in landing technique and knee movement patterns could contribute to the risk of injury by both increasing the amount of force as well as altering the direction of the load transmitted to the passive structures of the knee [4]. Significant asymmetries have been identified in bipedal landings [5] but there is no information comparing landing strategies of lower limbs in single leg landings. The aim of this project was identify differences in kinematics of the knee joint of the dominant and non-dominant legs during a single leg landing task.

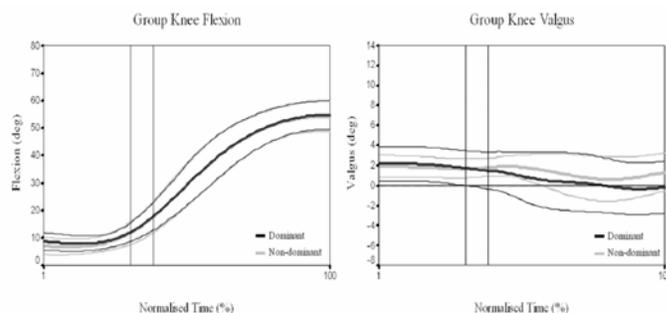

### METHODS

Five male and five female healthy university students performed 10 single leg landings on each leg from a fixed height of 37.5 cm. A 12 camera (Eagle™, EGL-500RT) motion analysis system (EvaRT™, Motion Analysis Corporation™, USA) was used to collect 3D kinematic data. Data were captured for three seconds at a sampling rate of 200 Hz and synchronised with the force plate (BP2436, Advanced Medical Technologies Inc™, USA) sampling at 1000 Hz. Calibration markers placed over the medial and lateral malleoli and knee joint lines, and the ASIS and PSIS on each lower extremity established the thigh and shank body fixed coordinate systems and allowed the local coordinates of segment markers to be determined relative to their respective local axes. Seventeen markers per limb allowed a least squared reconstruction of segment trajectory paths for the thigh and shank [6]. These trajectory data were then used to determine the kinematic variables of motion acting at the knee joint prior to foot contact to maximum knee flexion. These data were then filtered with a 6 Hz low pass Butterworth filter and exported into an Excel™ database for further analysis. A one way ANOVA was also used to consider the effect of gender on these kinematic parameters.

### RESULTS AND DISCUSSION

While comparisons between the dominant and non-dominant legs demonstrated minimal differences in the sagittal plane knee kinematics, the movement patterns and sampled variables revealed considerable variability both between and

within-subjects. However, the presence and formation of these movement pattern asymmetries appeared to occur independently of both limb dominance and gender. In contrast, and consistent with previous research, male to female differences were observed for the discrete variables of both flexion and valgus initial contact and maximum displacement. Importantly when the data were pooled and the leg dominance groups compared, these individual differences were concealed, highlighting the potential error of drawing conclusions regarding individual performance on the basis of group characteristics.

**Figure 1:** Sagittal and frontal plane knee kinematic patterns of the group means and confidence intervals for the dominant and non-dominant legs. Vertical lines represent the 95% confidence interval for initial contact.

### CONCLUSIONS

These findings not only add to our understanding of the kinematics of landing performance and possible risk factors for non-contact ACL injuries, but should also guide methodology and interpretation of results in future research on single leg landings in sports tasks. The results question the reliability of pooling data to make conclusions about individual subjects. Further investigations including other biomechanical and neuromuscular parameters are needed to allow a more comprehensive comparison of the dominant and non-dominant legs during landings, which will then provide a clearer illustration of the clinical implications for non-contact ACL injuries.

## MEASURING CONTINUOUS CHANGES IN HUMAN MUSCLE LENGTH, IN VIVO, USING ULTRASOUND

<sup>1</sup> Ian Loram, <sup>2</sup>Constantinos Maganaris and <sup>1</sup>Martin Lakie

<sup>1</sup>The University of Birmingham, UK, email: i.d.loram@bham.ac.uk

<sup>2</sup>Manchester Metropolitan University, UK; email: c.n.maganaris@mmu.ac.uk

### INTRODUCTION

Muscle length is a key variable in the understanding and modeling of musculoskeletal dynamics. Direct, continuous measurement of changes in muscle length has traditionally been achieved using animal preparations and invasive methods (e.g. microsonography) in which the muscle and tendon are exposed. There has been no technique for measuring continuous changes in muscle length in humans or animals *in vivo* in a non-invasive manner. Ultrasonography has been used for several years to measure discrete changes in tendon length and aponeurosis length. We have recently developed this technique to continuously track naturally occurring changes in muscle length as small as ten microns [1, 2]. Here we use externally applied perturbations to investigate the spatial and temporal resolution of the technique.

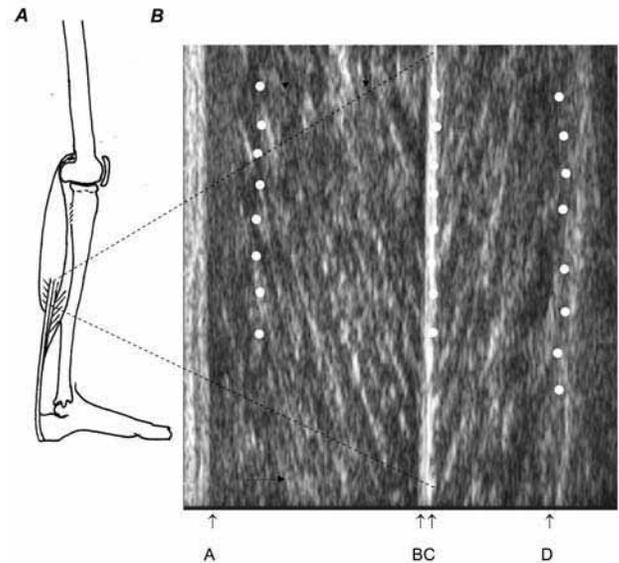

### METHODS

Six subjects stood on a footplate that independently measures left and right ankle torque. The subjects were strapped to a vertical back board while they maintained a low, constant level of ankle torque (~ 5 Nm). Every 1.3 s a pneumatic actuator applied a rapid, square pulse, dorsiflexing ankle rotation of defined magnitude and 0.2 s duration to the left ankle joint.

An ultrasound scanner (DIASUS, UK) recorded 40 s (1200 frames, 29 rotations) of sonographs focused on the distal aponeurosis of soleus and gastrocnemius medialis (Figure 1). In subsequent analysis, image markers were placed on the proximal and distal aponeurosis of the two muscles. Spatial cross correlation was used to track the changes in position of these markers throughout the 1200 frames. From the movement of these markers continuous changes in the length of the muscle were calculated from the differential movement between proximal and distal markers along the line of the central, distal aponeuroses [1]. All 29 rotations were averaged and the step changes in footplate angle and muscle length were measured.

### RESULTS AND DISCUSSION

The applied ankle rotation and corresponding step increases in muscle length are recorded in Table 1. The ankle rotations are several tenths of a degree which is comparable with the size of rotations that occur naturally during human standing. Changes in gastrocnemius muscle length range from 8 to 300 microns

**Figure 1:** A Postural muscles soleus and gastrocnemius, B Sonograph showing marker positions (white dots) used for tracking changes in length of the contractile element. A, D proximal aponeuroses of gastrocnemius and soleus. B, C distal aponeuroses which are continuous with the Achilles tendon

and increase systematically with the size of the ankle rotation. The temporal and magnitude agreement between the measured changes in muscle length and the applied ankle rotations is evidence that the ultrasound tracking technique is recording real changes in contractile element length.

### CONCLUSIONS

This technique is non invasive and can measure changes in muscle length with high spatial and temporal resolution. It promises new insights into the study of muscle activity that is difficult to assess using surface EMG where muscles are close together or are relatively deep, or where tendon compliance and motion across multiple joints complicates knowledge of the changes in muscle length.

## THE STRESS LEVEL ANALYSIS FOR DYNAMIC CASES AT HUMAN HIP JOINT

<sup>1</sup>Wang XiShi, <sup>1</sup>Jiang FuChuan and <sup>2</sup>Duan YiXiang

<sup>1</sup>Dept of Mathematics and Physics, QingDao Technological University, No.11, FuShun Rd., QingDao, 266033\_P.R.China;

<sup>2</sup>Dept of Orthopaedics, QingDao Hospital, No.1, Jiaozhou Rd., QingDao, 266011\_P.R.China; email: [wang\\_xishi@hotmail.com](mailto:wang_xishi@hotmail.com)

### INTRODUCTION

The estimation of hip joint stress level is very useful for both preoperative planning and postoperative rehabilitation. Since 1980's, Bergmann and his research group have been pursuing the instrumented hip implants with telemetric data transmission. Their collected gait data were recorded in HIP98, and updated in 2001[1]. So far it is unique gait database of the human hip contact force simultaneously measured in vivo. It is well recognized, however, that intrinsic pathomechanical changes in articular cartilage depends upon local stress levels rather than upon global joint loading, and the abnormal mechanical stress upon hip joint cartilage is one of the main causes of osteoarthritis. In this paper, based on the Hertzian elasticity contact theory[2] and the hip dynamic measured data in vivo for the human various daily activities[1], such as walking slowly, walking normal, walking fast, going up stairs, going down stairs, standing up, sitting down and knee bending, a realistic stress level analysis for dynamic cases at the human hip joint are presented.

### METHODS

#### 1 Coordinate Systems

The three coordinate systems are established for the purpose of describing relationships between the hip motion and resultant load. They are, respectively,  $X, Y, Z$  system,  $X_C, Y_C, Z_C$  system and a spherical coordinate system  $\rho, \theta, \varphi$ , as shown in Figure 1.

#### 2 Stress Distributions on the Hip

The Hertzian theory for the elastic contact of two bodies with nonconforming geometrical shapes, which is suitable to the specific case of a sphere contacting inside a sphere, is employed to calculate the stress distributions on the hip[2]. The formulas are given in the following:

$$\sigma_t(\theta, \varphi) = \frac{3F(t)}{2\pi r^2(t)} \left[ 1 - \frac{d_t^2(\theta, \varphi)}{r^2(t)} \right]^{1/2} \quad (1)$$

where 
$$r(t) = \left[ \frac{3\pi}{8} F(t) \left( \frac{1-\nu_H^2}{\pi E_H} - \frac{1-\nu_C^2}{\pi E_C} \right) \left( \frac{1}{D_H} - \frac{1}{D_C} \right) \right]^{-1/3} \quad (2)$$

$$d_t(\theta, \varphi) = \frac{D_C}{2} \sin \left\{ \cos^{-1} \left[ \sin \theta \sin \theta_p(t) \cos(\varphi - \varphi_p(t)) + \cos \theta \cos \theta_p(t) \right] \right\} \quad (3)$$

#### 3 Gait Data in vivo for Routine Activities

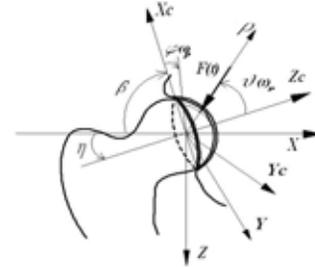

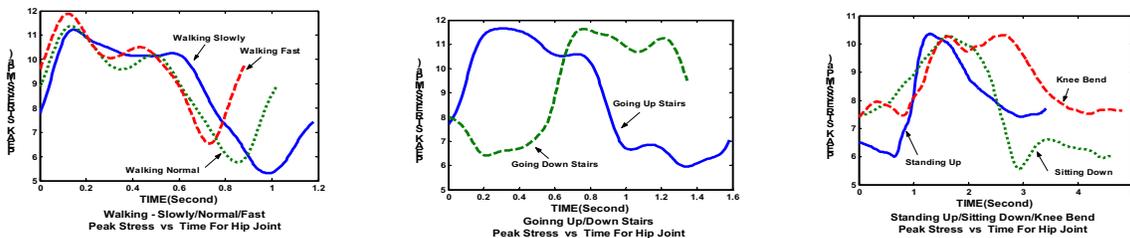

Figure 1: Coordinate System for the peak stress analysis

In 2000 version of HIP 98[1], the gait data in vivo for nine different human routine activities were collected, in which it is assumed to cause high hip joint loads and occur frequently in daily living. In this study, the gait data is taken from the patient H. Sonke[2]. The parameter values for peak stress evaluation are given as following:  $p=860N$ ,  $\eta=4^\circ$ ,  $\beta=56.9^\circ$ ,  $D_c=28.2mm$ ,  $D_h=28mm$ ,  $E_c=900MPa$ ,  $\nu_c=0.4$ ,  $E_h=206GPa$ ,  $\nu_h=0.3$ .

### RESULTS AND DISCUSSION

In Figure 1, the comparisons for the peak stress curve in the human eight routine activities are given. The three types of walking cases, the two types of going up/down stairs cases and three types of standing up/sitting down/knee bend cases are, respectively, given in Figure 1(a), 1(b), 1(c). The results show that the higher peak stress level at the human hip joint in the walking fast case is existed. This is probably due to the fact with the higher contact force and with the larger inertia in walking fast case. This may reveals that the hip injury would be more probable when the human walks at the fast speed.

### INTRODUCTION

Skeletal muscles generate low-frequency sounds when they contract. These sounds originate from resonant vibrations of muscle fibers and their frequency is related to fiber length and tension. Although more than 2 decades have passed since acoustic myography (AMG) was first described, clinical applications have been limited to neuromuscular junction monitoring during anesthesia [1, 2]. With few exceptions, AMG has provided little more information than surface electromyography (EMG).

Recent improvements in ultrasonic Doppler technology have made it possible to detect sub-micron displacements. Indeed, the measurement of heart sounds propagating in myocardial tissue has been reported [3]. We hypothesize that a similar technique can be used to detect and possibly image skeletal muscle vibrations. This could lead to a biomechanical analog of needle EMG and could provide a noninvasive alternative.

### METHODS

As many different terms appear in the literature, we will refer to the *phenomenon* of muscle fiber vibration as AMG, the recording of AMG signals at the skin surface as phonomyography (PMG) and the recording of AMG using Doppler ultrasound as Doppler myography (DMG).

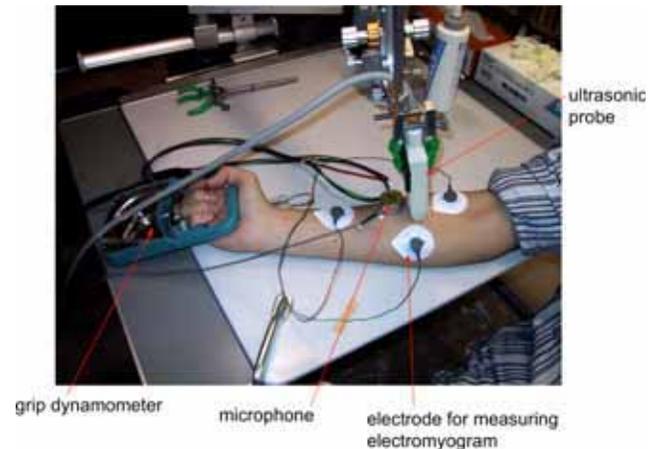

We conducted a single subject exploration of DMG by placing an ultrasound transducer over the flexor forearm group. Doppler signals were obtained during active grasp and the range gate was adjusted to be within the flexor digitorum superficialis (FDS). Surface EMG and PMG signals were simultaneously recorded. Grip strength was measured using a grip dynamometer (Figure 1).

### RESULTS AND DISCUSSION

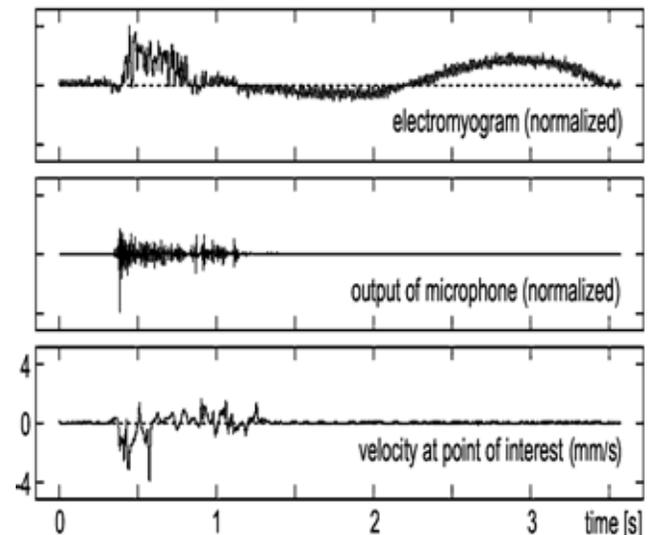

Simultaneous recordings were obtained for a variety of grip strengths. Vibrations are evident in the DMG recordings, however, translational motion was also observed (Figure 2). As with EMG, it is likely that filters will need to be implemented to remove unwanted components from the DMG signal. Additional experiments will be required to determine the optimum ultrasound parameters and configuration. Still, we believe that this is an important first step and that, with additional research, DMG could become a clinically useful test. The addition of real-time imaging capabilities could lead to a powerful new diagnostic tool.

**ANISOTROPIC ELASTICITY & VISCOSITY DEDUCED FROM SUPERSONIC SHEAR IMAGING IN MUSCLE**

<sup>1</sup>Stephen F. Levinson, <sup>2</sup>Stefan Catheline and <sup>2</sup>Mathias Fink

<sup>1</sup>University of Rochester Department of Orthopaedics, Rochester, NY, <sup>2</sup>Laboratoire Onde et Acoustique, Ecole Supérieure de Physique et de Chimie Industrielles, Paris, France; email: [levinson@ece.rochester.edu](mailto:levinson@ece.rochester.edu)

**INTRODUCTION**

Although the role of viscoelasticity in muscle mechanics is well recognized, methods for measurement *in situ* are limited. Recent advances in elastography have made possible the imaging of viscoelastic moduli within individual muscles [1, 2]. We have investigated a new approach, supersonic shear imaging (SSI), which combines high frame-rate (5kHz) ultrasound with acoustic radiation force induction of shear plane waves transients [3]. The elastic moduli can then be deduced from the propagation of these waves, and the viscous moduli from their attenuation.

**METHODS**

We applied SSI elastography in a single subject. With the subject seated comfortably, ultrasound image sequences were obtained from the right (dominant) biceps during sustained contractions. With the elbow held at 90°, various loads were applied by having the subject hold known weights. In addition, data were collected with the forearm supported (unweighted,) and unloaded (limb weight only). Image sequences were obtained and tissue displacements calculated using frame-to-frame cross-correlation.

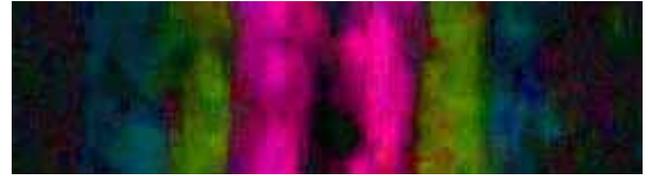

**RESULTS AND DISCUSSION**

Displacement image sequences (e.g. Figure 1) were used to reconstruct speed of sound maps (Figure 2) in both the transverse and axial (longitudinal fiber orientation) directions. Average shear elastic moduli were obtained from these (Table 1) Propagation could not be observed in the transverse direction for loads greater than 0.8 kg. It is evident that the axial elastic moduli are significantly greater than their transverse counterparts, and that both increase with load.

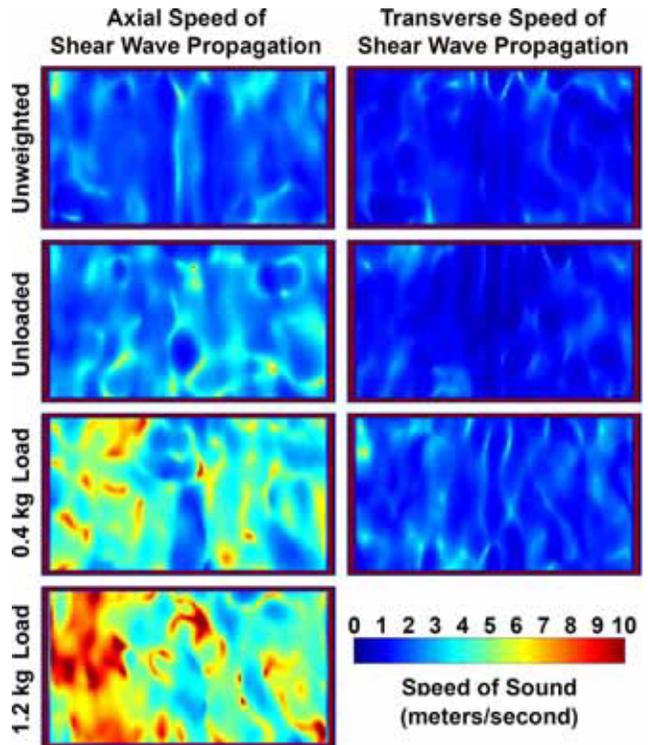

Although we currently lack a direct means of calculating viscosity, it is evident from the observed attenuation of the induced waves that transverse viscosity is significantly greater than axial viscosity and that transverse viscosity increases dramatically with load to the point that propagation is suppressed entirely at greater loads. Whereas the significance of these results is not clear, we anticipate that knowledge of anisotropic and dynamic viscosity could have a significant impact on the field of Biomechanics.

## KINETIC ANALYSIS OF GAIT INITIATION

<sup>1</sup>D. Gordon E. Robertson, <sup>2</sup>Richard Smith and <sup>2</sup>Nick O'Dwyer

<sup>1</sup>School of Human Kinetics, U. of Ottawa, Canada, <sup>2</sup>School of Exercise and Sport Science, U. of Sydney, Australia

### INTRODUCTION

Walking from quiet stance has been analyzed kinematically and kinetically, [2,4] yet little research has been conducted involving inverse dynamics. To understand how gait begins, electromyographic analyses [1,3] have also been carried out to identify the responsible muscles. Although ground reaction forces have often been recorded [1,2,4], net moments and powers were not computed. The purpose of this study was to determine the mechanical causes of gait initiation based on the moments and powers produced in the lower extremities.

### METHODS

Subjects were required to stand on two force platforms (9281, Kistler) and then after a signal, begin walking briskly across two additional force platforms (9287, Kistler). Forty-two markers identified thirteen segments in three dimensions. Ten high-speed cameras (Eagle, Motion Analysis) filming at 200 Hz recorded the motion simultaneously with the force signals (EVART 4.2). These data were exported to Visual3D for computations of inverse dynamics and moment powers.

### RESULTS AND DISCUSSION

Only data for the one-second period immediately before toe-off (TO) of the trailing leg will be presented because the following two steps produced patterns similar to those seen in other walking studies. During these two steps, the subjects accelerated but the moment and power histories had similar shapes to constant-speed gait [5].

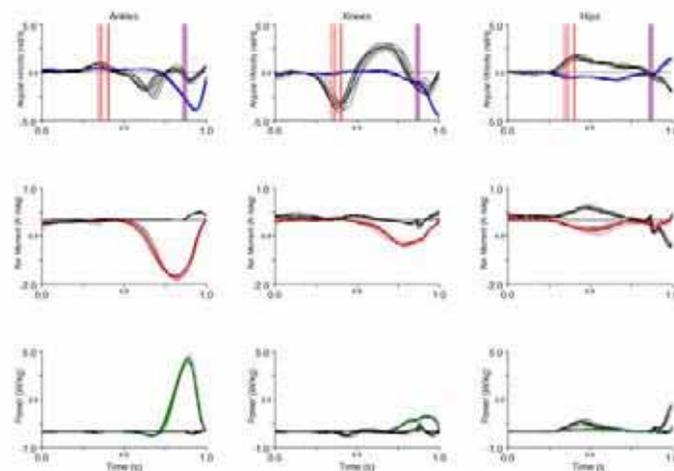

**Leading leg, stance phase.** The moments of force of the leading leg did little work despite the relatively large ground reaction forces. At the hip, flexors initially acted isometrically but before TO and through early swing began hip and consequently knee flexion. Ankle plantar flexors produced small amounts of negative work to control dorsiflexion. Similarly, the knee extensors dominated the stance and early swing phases to control knee flexion. This suggests that initiation of gait began with active hip flexion and a simultaneous controlled collapse of the lead knee and ankle.

**Leading leg, swing phase.** The ankle moments of force were nearly zero throughout the swing phase doing virtually no work. The knee moments of force were initially extensor until midswing and then became flexor. The knee extensors first worked eccentrically to limit the amount of flexion and then concentrically to extend the knee slightly. Similarly, the knee flexors after midswing acted eccentrically to slow the extending knee (and foot) prior to foot-strike (FS). They then began a concentric phase that continued after FS. During the swing phase, the hip flexors performed positive work to elevate the thigh and thereby enable a longer stride. Like walking, this activity started before TO continuing throughout swing with its peak power occurring early in swing and reducing to zero before FS.

**Trailing leg, stance phase (see Figure 1).** The hip extensor moment of force was the first lower extremity moment to

provide work during the stance phase of the trailing leg. It did the smallest amount of work of the three moments and was essentially inactive before TO. After TO, the hip flexors acted to flex the trail leg and enable swing.

The ankle moment of force did no work until after the leading leg passed midswing, after which it performed largest amount of positive work to provide the body with forward propulsion. At this point, the line of gravity was medial to the trail leg and just past the toes. Similarly, the knee moment was essentially inactive through most of the stance phase doing no work until midswing of the leading leg. At this point, the flexors acted to perform positive work to flex the knee and assist with elevation and forward motion of the foot. The amount of work done by the knee flexors was greater than for the hip extensors but much less than that of the ankle plantar flexors.

**Figure 1:** Five trials of one subject showing joint angular velocities (top), moments (middle) and powers (bottom). First column is ankle, second is knee and third is hip. Coloured curves are from the trailing leg--black curves from the leading leg. Data begin one second before toe-off of the trailing leg.

### CONCLUSIONS

Initiation of gait begins with the hip flexors of the leading leg and a controlled collapse at the knee and ankle. The trailing leg's moments of force do no work until after the leading leg is midswing. Then the lead leg's hip extensors have a minor role at midswing preceding both the ankle and knee moments performing positive work. The trailing legs' ankle plantar flexors provided the main source of energy during push-off supplemented by work done by the knee flexors.

## EFFECT OF BILATERAL REACHING ON AFFECTED ARM MOTOR CONTROL IN STROKE — WITH AND WITHOUT LOADING ON UNAFFECTED ARM

<sup>1</sup> Wen-Lin Tung, <sup>1</sup> Fong-Chin Su and <sup>1,2</sup> Jyh-Jong Chang

<sup>1</sup> Institute of Biomedical Engineering, National Cheng Kung University, Tainan, Taiwan,

 email: minlynn@seed.net.tw, web: <http://www.bme.ncku.edu.tw/>

### INTRODUCTION

Bilateral movements are often used to facilitate symmetrical and smoother movements of the hemiparetic arm in stroke patients. Previous research has shown that bilateral movements with inertial loading on unaffected arm may increase interlimb coupling. The goal of this present study is to investigate the effect of bilateral reaching, with/without inertial loading on the unaffected arm, on hemiparetic arm motor control in stroke.

### METHODS

Recruited were twenty unilateral stroke patients (17 males, 3 females), aged between 37 to 75 years (mean  $\pm$  standard deviation, 56.00  $\pm$  10.54 years). All subjects scored at least 30 on the upper extremity subtest of the Fugl-Meyer Motor Function Assessment (total score: 66). Taking the difference of upper extremity function level into consideration, we split the subjects into two groups according to the score of FMA. Thirteen subjects in group 1 scored between 50 and 66, indicating a mild motor deficit, and seven subjects in group 2 scored between 30 and 49, indicating a moderate motor deficit. A three-dimensional kinematics analysis equipment (Visualeyez™ Hardware, Canada) was used to collect the movement trajectory data of the hemiparetic arm during performing the experimental tasks. Subjects were asked to perform four movement tasks as quickly as possible: (1) reaching forward with the affected limb only (Uni); (2) reaching forward with both limbs simultaneously (Bil); (3) reaching forward with both limbs while adding a load of 25% upper limb inertia to the unaffected limb (Bil+25%). Kinematic parameters were utilized to quantify the reaching performance of the affected arm.

### RESULTS AND DISCUSSION

No matter if loading was applied on the unaffected arm, bilateral reaching task did not significantly facilitate smoother and faster movement. Furthermore, during bilateral reaching with loading on unaffected arm, stroke patients showed slower movement, smaller maximal movement velocity, and less smooth movement in affected arm than bilateral reaching without loading. The greatest proximal active upper extremity range of motion was found during bilateral reaching without unaffected arm loading. More trunk movement was adapted during bilateral reaching either with or without loading on unaffected arm. Patients with moderate upper extremity motor impairment level performed more discontinues and less active elbow range of motion than those with mild upper extremity motor impairment level during performing reaching tasks.

### CONCLUSIONS

Bilateral reaching tasks with/without loading on unaffected arm could be considered as adding costs and challenges during motor control. Training with bilateral arm movements may be considered as a treatment strategy and can be incorporated in stroke rehabilitation to facilitate greater active movement and improve motor control performance in affected arm.

### INTRODUCTION

One motion of any part of the human body includes the movement of many joints and axes of the whole body. When one part of our body moves, our whole body moves simultaneously. It enables us to perform such body movement ranging from the fine motions used in manual labor to the dynamic motions utilized in sport. When a factor exists that disturbs any part of this series of movements in any part of our body, then the whole motion loses its smoothness and thus causes such symptoms as pain. A new diagnostic method for acupuncture treatment which evaluates motion-induced pain<sup>1)</sup> now makes it possible to identify a location that actually causes pain. This method can identify an affected meridian which thus enables us to select an appropriate acupuncture point to reduce pain based on the concept of meridians. The appropriate stimulation of the acupuncture point may help a patient to correct an abnormal motion<sup>2)</sup>. In addition, the effect of a selected acupuncture point is identified by observing that the motion-induced pain decreases after stimulating the acupuncture point. This is a very simple but effective method for identifying the affected meridians and confirming the effect of the selected acupuncture point. To popularize this method, we have developed a web-based decision support system for this method by expressing the loads of movement, which therefore make it possible to precisely identify the exact location that causes a specific pain, using a 3-D computer graphic model for selecting the appropriate acupuncture points.

### METHODS

A three-dimensional motion analysis device (Motion Analysis Expert Vision HiRES system) and high-speed camera (FALCON CAMERA) are used to accurately capture an optical motion on film. Next, 32 reflector markers are attached to the parietal region, the cervical vertebra, the lumbar vertebrae and other joints of the subject. Thereafter, the subject is asked to perform the movements similar to those done during orthopedic and neurological tests. Eight high-speed camera takes pictures of these movements which consist of 30 different kinds of movement; the extension of the neck, upper extremities, lower extremities and trunk.

The photographs taken with a high-speed camera are then developed into animation data which are then combined with human body modeling data. Next, such data are run on a human body modeling program using three dimensional computer graphics (hereafter, called 3DCG).

In addition, we also take photographs of all 36 acupuncture points which are each composed of twelve acupuncture points which are suitable for restoring the restriction of extension on

either the front, the back or the side of the human body, respectively. We then established a home page in which 30 kinds of movement are connected with the photographs in order to indicate the appropriate acupuncture locations.

### RESULTS AND DISCUSSION

The movements consist of the motions which extend from the front, back and side of our body. A total of thirty such movements are considered to exist when performing a physical assessment similar to those performed during orthopedic and neurological tests. Each individual motion influences the 14 meridians of the body. When a specific movement induces pain, then an affected meridian can be found. Next, the optimal acupuncture points to reduce such pain can then be selected based on the concept of meridians. The newly developed home page can show us how to follow such movements based on 3DCG modeling, thus allowing therapists to select the appropriate acupuncture points to reduce pain. When you click on any of the movements shown on screen, then the acupuncture points that need to be stimulated are shown. This tool greatly supports the therapist. Moreover, this system may also be utilized as a self-care tool of pain because it can show the appropriate points to reduce pain which can thus be performed by the patient himself. This system also provides new insight into Oriental Medicine. Further similar research on the motion-induced fluctuation of pulse waves<sup>3)</sup> may therefore eventually lead to the compilation of scientific evidence supporting the theory of a pulse diagnosis in Oriental Medicine.

### CONCLUSIONS

A newly developed homepage has been established as a support system for performing effective acupuncture treatment by therapists and also as a tool for self-care, since this homepage is able to clearly demonstrate the movements and thereby can help in selecting the most appropriate acupuncture points.

### INTRODUCTION

Manual wheelchair propulsion is the primary source of mobility for many persons with disabilities. The user's position relative to the drive wheel has been recognized as an important factor affecting propulsion efficiency [1, 2]. Currently, many wheelchairs provide the ability to adjust the position of the drive-wheel. To justify the effectiveness of this design feature, it is necessary to document the relationship between a user's propulsion performance and the axis position. Therefore, the purpose of this study was to investigate wheelchair users' shoulder and elbow joint workspace associated with various wheel axis positions.

### METHODS

Ten persons with disabilities who use manual wheelchairs voluntarily served as subjects for this study. Detailed data for the subjects are presented in Table 1. A wheelchair with adjustable axis positions was used. Six positions including various vertical and horizontal positions were tested (Figure 1). A Zebris ultrasonic motion analysis system was used to measure each subject's upper extremity motion. ANOVA with post-hoc multiple comparisons were used to examine the differences of upper extremity motion among the six positions.

### RESULTS AND DISCUSSION

The results showed that different axle position did not significantly affect ( $P>0.05$ ) temporal parameters of push time and recovery time. High and backward axle positions resulted in increasing shoulder initial extension angle. In comparison with low axle positions, high axle positions produced significantly larger shoulder and elbow joint ranges of motion

( $p<0.05$ ). High axle positions also produced larger efficient joint workspace than lower axle positions (Table 2).

Thigh length; cm	42.71	3.19

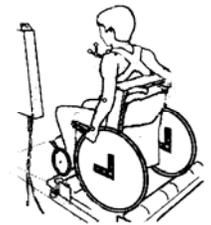

Figure 1. Experimental configuration

### CONCLUSIONS

The location of the drive-wheel axis determined performance of manual propulsion [3, 4]. This finding provides valuable information for guiding adjustments of the wheel-axis position relative to a user's upper body. An initial shoulder extension angle of 45 degrees and larger shoulder and elbow advantageous joint workspace could be considered adjustment principles. Adjusting the axis upwards and backwards might increase shoulder initial extension angle. Furthermore, adjusting axis height might increase efficient joint workspace.

### INTRODUCTION

In competitive rowing, a large amount of mechanical power is produced. However, only the fraction of power that contributes to average velocity will determine the performance. In this study the previously established power equation of rowing [1] is used to analyze rowing performance. Mechanical power is lost by moving water with the blades. Power is lost to water friction on the hull which is related to velocity cubed. Those power losses are higher when there are larger fluctuations in velocity. Due to the intermittency of propulsion, and due to impulse exchange between the rower and the hull, these fluctuations are substantial. Stroke rate is an important aspect of rowing technique. In this study the effect of stroke rate on the power flow in rowing was investigated.

### METHODS

Nine subjects participated in this study. Subjects were instructed to row a minimum of 10 constant strokes at rates of 20, 24, 28, 32 and 36 strokes per minute with maximal intensity. Subjects rowed 5 trials at each prescribed stroke rate.

Forces on the pin were measured using piezoelectric transducers (Kistler, Switzerland). Oar angle in the horizontal plane was measured using servopotentiometers (Radiospares). Boat velocity was measured using a trailing turbine with embedded magnets (Nielsen Kellermann). Data was transmitted to the shore using telemetry (ROWSYS, Australia).

Steady state rowing was assumed to be perfectly periodic. In this situation, the average power production during the stroke cycle ( $\bar{P}_{\text{rower}}$ ) equals the average power losses to drag ( $\bar{P}_{\text{drag}}$ ) and moving water with the blades ( $\bar{P}_{\text{blade}}$ ).

Propelling efficiency ( $e_{\text{propelling}}$ ) was calculated as the fraction of  $\bar{P}_{\text{rower}}$  not lost to the blades. Velocity efficiency ( $e_{\text{velocity}}$ ) was calculated as the fraction of  $\bar{P}_{\text{rower}}$  not lost to velocity fluctuations. From these two terms, the fraction of  $\bar{P}_{\text{rower}}$  contributing to average velocity ( $\bar{v}_{\text{boat}}$ ), defined as total efficiency ( $e_{\text{total}}$ ) was calculated.

A repeated measures ANOVA was used to analyze the data. Pearson's correlation coefficient was also calculated.

### RESULTS AND DISCUSSION

A significant main effect of stroke rate was found for  $\bar{P}_{\text{rower}}$ ,  $e_{\text{propelling}}$ ,  $e_{\text{velocity}}$ ,  $e_{\text{total}}$  and  $\bar{v}_{\text{boat}}$  (all  $p < 0.0001$ ). The correlation of these variables with stroke rate were 0.98, 0.82, -0.72, 0.73 and 0.96 respectively, indicating strong linear relationships (correlation coefficients are averaged over subjects). In table 1 the mean values are presented.

The increase of velocity at higher stroke rates was mainly caused by the increase in  $\bar{P}_{\text{rower}}$ . However, rowers are probably not able to maintain the values found for  $\bar{P}_{\text{rower}}$  throughout a typical 2000m rowing race.

The decrease of  $e_{\text{velocity}}$  at increasing stroke rate was expected and is caused by a higher  $\bar{v}_{\text{boat}}$  and larger accelerations and decelerations by the rower itself. However,  $e_{\text{total}}$  increases at increasing stroke rate, caused by a substantial increase of  $e_{\text{propelling}}$ . While the mechanical work of the rower remains relatively constant with increasing stroke rate, the energy lost at the blades actually *decreases*. This is most likely related to the finding that at higher stroke rate the blade travels less in the direction opposite the propulsion, thus less water is being moved.

### CONCLUSIONS

This study shows the power equation to be an adequate conceptual model to analyze rowing performance. Results indicate that stroke rate not only affects the power output of the rower, but also affects the power loss at the blades and the power loss associated with velocity fluctuations. When similar results become available regarding the effect of other technique-related factors, it may become possible to understand the optimal technique as the optimal compromise between generation of power by the rower and power loss to terms not contributing to average velocity.

## BONE REMODELING MODEL OF A BASIC MULTICELLULAR UNIT

Sylvie Wendling-Mansuy, Emmanuel Rixrath, Jean Louis Milan and Patrick Chabrand  
 Laboratoire d'Aérodynamique et Biomécanique du Mouvement, CNRS USR 2164,  
 Université de la Méditerranée, Marseille, France. email: wendling@morille.univ-mrs.fr

### INTRODUCTION

The bone tissue adapts itself to the mechanical and physiological environment and involves cellular processes of mechanotransduction and remodeling. In fact, bone remodeling results from closely coupled resorption and apposition processes of organized cellular units called Basic Multicellular Units (BMUs) which are controlled by local mechanical signals. Recent studies revealed that osteocytes which are the most abundant cells in bone play a fundamental role as mechanosensors in the early stage of bone remodeling [1]. Moreover it has been shown that osteocyte apoptosis induces bone resorption and appears at very high or very low strains level. However mechanotransduction, biological and biochemical processes involved in the resorption/formation coupling are complex and not yet clearly identified.

The idea of the present study is to develop a model to mechanically simulate the resorption/apposition processes of a BMU taking into account high and low strain energy, microcracks, osteocyte apoptosis, fluid flow effects as well as biochemical factors. The present mechanical model is based on thermodynamic approaches following Silva and Ulm [2] resorption model.

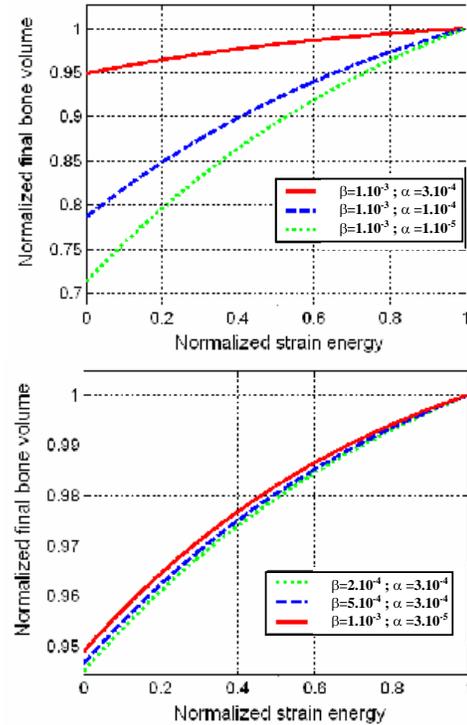

### METHODS

The present bone remodeling model is applied to one isolated trabeculae of spongy bone considered as a homogenous isotropic and elastic cylinder containing a network of canaliculae with osteocytes. The biochemical activities of the osteoclasts to dissolve bone matrix and the osteoblasts to synthesize collagenous matrix are translated into energetic quantities which transformations are studied using the two thermodynamical principles. During the resorption phase, the dissolution potential of the cell is balanced by the strain energy of the trabeculae and a chemical energy due to the osteocyte apoptosis. During the apposition phase, the chemical potential of the cell to synthesize collagen is balanced by the trabeculae strain energy through the adherent surface and a chemical energy of the factors released during the resorption phase. Two scenarios of bone remodeling are simulated considering a low strain energy which is defined by *understress* conditions and a high strain energy which is defined by *overstress* conditions.

### RESULTS AND DISCUSSION

The numerical results show the variation of the final bone volume (after remodeling) normalized by the initial volume as a function of the strain energy normalized by reference strain energy in two stress conditions (*understress* and *overstress*). Figure 1 shows that the final bone volume obtained after remodeling tends to a non zero minima (i.e. for no stress applied;  $W^*=0$ ). Two parameters have been introduced in the model: the coupling parameter  $\alpha$  represents the chemical

energy of factors and proteins released in the medium during the resorption phase which might stimulate the recruitment and the differentiation of the osteoblasts.

**Figure 1:** Final bone volume normalized as a function of the applied normalized strain energy in *understress* conditions.

The parameter  $\beta$  represents the mechanical sensibility of the osteoblasts during the apposition phase. It appears that in *understress* conditions, the new bone volume seems to be regulated mainly by chemical factors (the coupling parameter  $\alpha$ ) because the increase of the mechanical sensibility of the osteoblasts has no effect on the final bone volume (see Figure 1). By contrast, in *overstress* conditions, the numerical results show that increasing  $\beta$  increases the new bone volume more than the coupling parameter  $\alpha$ . Since this model could contribute to understanding bone remodeling related to cellular activity and more particularly in pathologic cases (osteoporosis), further studies are needed to validate this model and to identify the parameters introduced in the model.

## TRUNK AND SHOULDER MUSCLE RESPONSE COMPARING ONE REPETITION MAXIMUM BENCH AND STANDING CABLE PRESS

<sup>1</sup>Francisco J. Vera-Garcia, <sup>2</sup>Juan Carlos Santana, <sup>1</sup>John R. Gray and <sup>1</sup>Stuart M. McGill.

### INTRODUCTION

With the current interest in core and functional training, the use of cables and pulleys in standing positions to train the whole body while emphasizing pressing or pulling motions is becoming more popular [1]. Little is known about the effects of these cable exercises on trunk muscle activity. The purpose of this study was to compare the amplitude of the electromyography (EMG) and the coactivation patterns of the trunk muscles during the single arm staggered stance cable press and the traditional bench press.

### METHODS

Fourteen recreationally trained men (age =  $28.14 \pm 8.33$  yr, height =  $1.78 \pm 0.05$  m, mass =  $77.78 \pm 10.41$  kg) were recruited from the university population. All subjects were right-handed and healthy, without current back or shoulder pain. Superficial EMG was recorded bilaterally from rectus abdominis (RA), external oblique (EO), internal oblique (IO), latissimus dorsi (LD) and erector spinae at T9, L3 and L5 (EST9, ESL3, ESL5). EMG was also collected on the right side from pectoralis major (PM) and anterior deltoid (AD).

After warming-up, subjects performed bench and standing press exercises. Resistance was progressively increased until reaching the participant's one repetition maximum (1RM). Rest periods of 2-5 minutes between exercises were utilized in order to avoid muscular fatigue.

The EMG was A/D converted at 12 bit resolution at 1024Hz. Signals were full wave rectified and low pass filtered (single pass Butterworth) at 2.5 Hz, and then normalized to maximal voluntary contraction (MVC) amplitudes. The normalized muscle activity corresponding to the pushing phase of the 1RM was averaged for each press exercise. Differences in average normalized activity for each muscle between exercises and between muscles during each exercise was assessed using a two-way ANOVA (muscle/exercise) with Tukey correction ( $\alpha = 0.05$ ).

### RESULTS AND DISCUSSION

1RM bench press performance resulted in an averaged load ( $74.2 \pm 17.6$  kg) significantly higher than 1RM single arm standing press ( $26.0 \pm 4.4$  kg). Pressing from a standing position imposes greater demands on the motor control system to stabilize and balance the body – this reduces the capacity to push heavy weights.

The significant differences among exercises are shown in Figure 1. EMG amplitudes of the erector muscles (EST9, ESL3, ESL5) and pectoralis major (PM) were larger for the 1RM bench press. However, the pressure of the trunk on the back electrodes when supine on a bench could modify the EMG amplitudes. On the other hand, the activation levels of left abdominal muscles (LRA, LEO, LIO) and left latissimus dorsi (LLD) were higher for the right arm cable press.

Statistically significant differences in normalized EMG amplitudes were found among muscle sites within each exercise. For the 1RM bench press, anterior deltoid (AD) and pectoralis major (PM) were more activated than the most of the trunk muscles, although this exercise produced important mean levels of trunk muscle activation (Figure 1). In contrast, for the 1RM standing cable press, the left internal oblique (LIO) and left latissimus dorsi (LLD) activities were similar to the anterior deltoid activity (AD) and higher than the pectoralis major activation (PM).

### CONCLUSIONS

The traditional bench press emphasizes the activation of the shoulder and chest muscles and challenges the ability to develop great shoulder torques. Whereas, a single arm standing press principally activates the contralateral abdominal and latissimus dorsi muscles and challenges the ability to produce smaller forces but in more functional horizontal plane. Coaches and fitness professionals should consider these differences when prescribing exercises to develop pushing or pressing abilities.

## AGE-RELATED JOINT TORQUE ANALYSIS DURING SUPPORT PHASE OF SINGLE STEP RECOVERY

Kathleen Bieryla, Michael Madigan, and Emily Lloyd  
Virginia Tech, Musculoskeletal Biomechanics Laboratory; email: [kbieryla@vt.edu](mailto:kbieryla@vt.edu)

### INTRODUCTION

Unintentional falls were the leading cause of non-fatal injury in every age group except for 15 -24 year olds for the year 2002 [1]. In 1995, \$64 billion dollars was spent on medical costs stemming from 14 million injurious falls [2]. Falls in the elderly can lead to many health problems including hip fractures or even death. Previous studies have shown that older adults have a reduced ability to recover from a forward fall than younger adults. The purpose of this study was to investigate age-related differences in joint torques during the support phase of recovery from a forward fall.

### METHODS

Twenty healthy male subjects, 10 young ( $20.6 \pm 1.3$  years) and 10 older ( $74.0 \pm 6.5$  years) participated in the study. A forward fall was simulated by releasing subjects from a forward leaning posture. Subjects stood with each foot on a force plate with their weight evenly distributed. Once the cable was released, participants recovered by taking one step with the right leg onto an oversized forceplate. The degree of the lean was measured by the percent body weight on the cable as determined by a load cell. Initial lean was 12% body weight (BW) and increased by 4% BW after successful recoveries. The data collection ended when two unsuccessful attempts at one lean magnitude occurred. Failure to recover was defined as: 1) more than one step was taken by the right leg, 2) greater than 30% BW applied to the harness during the trial, and 3) a step of the left foot greater than 30% of body height. To prevent a fall from occurring, participants wore a full body harness.

A 2-D model of 4 rigid segments (foot, thigh, shank, head-arms-trunk) was used for torque estimation. Peak extensor torques were calculated for the support phase of balance recovery (SPBR). Body segment data was sampled at 200 Hz with an Optotrak optoelectric motion analysis system. Force plate and load cell data were sampled at 1000 Hz.

A repeated measures analysis of covariance was run on the dependent measures of peak extensor torques at the hip, knee and ankle with the independent variables being lean

angle and age. Height and weight were used as the covariates. Directional hypotheses based on previous studies of observed age related differences in joint torques were used to improve statistical power [3].

### RESULTS AND DISCUSSION

Young subjects were able to recover from a significantly larger lean angle than the older participants ( $29.9 \pm 4.0^\circ$  vs  $20.5 \pm 4.0^\circ$ ,  $p < .001$ ). During the SPBR, joint torques of the hip, knee, and ankle were predominately extensor (or plantar flexor) dominant. The order for which the peak torque extensor occurred was the hip followed by the knee and finally the ankle. Peak extensor torque significantly increased with increasing lean angle at the hip, knee, and ankle. Older subjects had a significantly lower peak knee extensor torque during SPBR compared to young subjects. There was no significant age related increase in the hip extensor ( $p=0.084$ ) or decrease ankle plantar flexor torque ( $p=.909$ ) but a trend of larger torques in older adults was seen (fig 1).

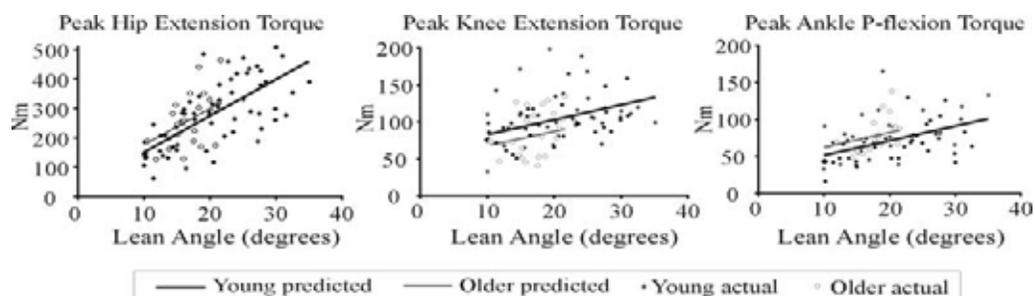

Although the general pattern of joint torques is similar for young and older adults, the peak extensor torque values suggest a possible difference in strategy across age groups during the SPBR of single step recoveries. The extensor torques helped decelerate the body rotation about the obstacle and assisted in resisting the buckling of the stepping leg. A post-hoc power analysis was performed and showed a small increase in sample size, 5 for the hip and 6 for the ankle, would have shown significance.

### CONCLUSIONS

Age related differences and trends seen in the joint torques is believed to be a combination of age related reduction in muscle strength along with neuromuscular adaptation to lessen the effects of muscle strength loss on physical performance capabilities [3].

**INTRODUCTION**

This study designed an arm movement trainer, called bilateral resistance-induced arm movement trainer, for stroke arm motor rehabilitation. The arm movement trainer integrated robot-aided therapy with bilateral arm movement and arm strength training strategies (Figure 1). The purpose of this study was to analyze the effects of bilateral resistance-induced arm movement training on arm motor recovery in chronic strokes.

**METHODS**

Twenty unilateral chronic strokes, length of onset over 6 months, were recruited in this study. Each subject received 8 weeks' arm trainer training program and followed up for 8 weeks. The pretest, posttest and follow-up measures of clinical arm motor function and reaching kinematics were compared and analyzed. Data analysis was performed by using repeated ANOVA and post hoc analysis.

**RESULTS AND DISCUSSION**

After comparing the pretest and posttest of arm motor function and reaching kinematics, We found that arm motor function were significantly improved in total arm strength, grip strength, Fugl-Meyer upper limb scale (Table 1). Reaching kinematics was significantly improved in movement time, normalized jerk score, pick velocity, and percent time to pick velocity (Table 2). There were not significant differences between posttest and follow-up measures in arm motor function and reaching kinematics. Findings from this study might provide evidence that robot-aided therapy combined with bilateral resistance movement training would promote inter-hemispheric disinhibition likely to allow reorganization by sharing of normal movement commands from the undamaged hemisphere. Such "overflow" effect may be more marked under movement with resistance. It is suggested that effect of bilateral resistance-induced arm movement training may also promote a balancing effect on between-hemisphere cortical motor excitability that is associated with brain reorganization and finally contribute to motor recovery.

**CONCLUSIONS**

Bilateral resistance-induced arm movement trainer might enhance arm motor recovery for chronic strokes. Such simple

robot-assisted devices will be more feasible in clinical application for stroke arm rehabilitation.

## LEG LENGTH AND LEG TORSION MEASUREMENT WITH ULTRASOUND IN CHILDREN DURING ONE YEAR – FIRST RESULTS

Kerstin Bosch, Dieter Rosenbaum

Movement Analysis Lab - Orthopaedic Department - University Hospital Muenster - Germany

email: [boschk@uni-muenster.de](mailto:boschk@uni-muenster.de) , web: [www.motionlab-muenster.de](http://www.motionlab-muenster.de)

### INTRODUCTION

The growth of the lower extremity and the shape changes of leg in infants often lead to uncertainty in parents. The infant's leg can develop from a typical bow leg via a knock-knee to a normal "straight" leg. The reasons for the knock-kneed gait of the infants are the antetorsion of the femur associated with a valgus position of the knee. The reduction of the femoral antetorsion occurs during growth and is pronounced during two phases of detorsion [1]. The aim of the present longitudinal investigation was to quantify the development of leg geometry in children over the course of one year by means of an ultrasound measurement system.

### METHODS

33 healthy children (18 male; 15 female) aged 3.5 to 5.2 years were measured during 3 times within one year (every 6 months). To determine leg geometry a sonographic system (Sonoline Prima, Siemens) coupled with a 2.5-dimensional ultrasound measurement system (CMS70P4-K Zebris, Germany) was used. Defined bony landmarks of hip, knee and ankle joint were sonographically displayed. The bony outlines were marked with circles, points and/or vectors. With use of dedicated software (MedMess 2.0, Zebris) the femur, tibia and total leg length as well as femoral and tibial torsion and the mechanical axis were calculated.

For statistical analysis an ANOVA for repeated measurements with  $p < 0.05$  and Scheffé test for paired comparison was used.

### RESULTS AND DISCUSSION

In the one-year observation period, a significant increase of the total leg length of 9.4% from 437mm to 477mm could be detected. The femur length increased significantly by 9.4% and the tibia length by 8.7% which confirms the literature [1]. Femoral torsion changed significantly from  $-31.1^\circ$  to  $-28.8^\circ$  during 1 year but significant changes of tibia torsion were not established. After 6 months a significant decrease of the mechanical axis was detected [Tab. 1].

The significant change of femur torsion can be attributed to the natural decrease of antetorsion during growth. The decrease of  $0.7^\circ$  of mechanical axis can also confirm the development of antetorsion but this low value has no clinical relevance.

Furthermore, it is important to note that the defined bony structures in this age group are not completely ossified. This can lead to complications during the measurement and following calculation.

### CONCLUSIONS

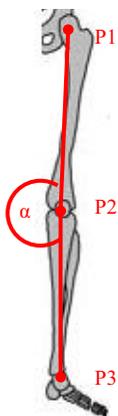

Due to the lack exposure to harmful radiation, the ultrasound based measurement system is an adequate medium for determining leg geometry not only in children but also in adults and for follow-up investigations. The degree of ossification of the bony landmarks of children in the demonstrated age group can be problematic and should not be compared with that of adults. Therefore, the results have to be considered and used with caution.

## INCREASE IN AMPLITUDE OF PARASPINAL MUSCLE REFLEXES FOLLOWING LUMBAR EXTENSOR FATIGUE

Christine M. Herrmann<sup>1</sup>, Michael L. Madigan Ph.D., Bradley S. Davidson, Kevin P. Granata Ph.D.  
Virginia Tech, Musculoskeletal Biomechanics Laboratory  
<sup>1</sup>email: [herrmacm@vt.edu](mailto:herrmacm@vt.edu)

### INTRODUCTION

Low back disorders (LBDs) are one of the most prevalent and costly musculoskeletal problems in the United States. Abnormal paraspinal reflexes have been linked to low-back pain [1,2] and neuromuscular fatigue has been shown to affect reflexes in multiple muscle groups [3]. Therefore, the purpose of this study was to investigate the effect of lumbar extensor fatigue on paraspinal reflexes.

### METHODS

Ten physically active males (20-22 years of age) participated in the experiment. During each experimental session, paraspinal muscle reflexes were measured both before and after a lumbar extensor fatiguing protocol. Reflexes were elicited in response to an anteriorly-directed perturbation applied at the inferior margin of the scapulae while the subjects stood quietly. Perturbation force was recorded using a load cell, and EMG was recorded from the paraspinal muscles (4cm lateral from L4). The fatiguing protocol consisted of multiple sets of back extensions and intermittent isometric MVCs on the Roman chair [4] for a period of 14 minutes to fatigue participants to 60% of their unfatigued lumbar extensor MVC. The reflex measurement began within fifteen seconds of the completion of the fatiguing protocol.

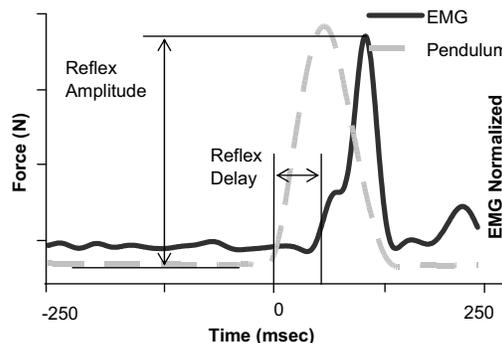

Preparatory muscle activity was computed from 250 msec of data prior to each force impact. Any reflex response after 120 msec was considered voluntary motion and not included in the analysis. Reflex delay was calculated as the time delay from the perturbation onset to the reflex onset, and reflex amplitude was calculated as the peak amplitude of the paraspinal EMG (Figure 1). A paired t-test with a significance level of  $p \leq 0.05$  was used for all statistical tests.

### RESULTS AND DISCUSSION

Perturbation characteristics differed between fatigue conditions with peak amplitude decreasing an average of  $5.8 \pm 4.9\%$  with fatigue. Reflexes occurred in 92% of all perturbations. The mean reflex delay was  $60 \pm 18$  msec, and was not affected by fatigue ( $p=0.278$ ); however, reflex amplitude significantly increased  $36 \pm 32\%$  with fatigue ( $p=0.017$ ).

The aim of this study was to examine the effects of lumbar extensor fatigue on paraspinal muscle reflex in response to a sudden perturbation. The results showed fatigue was associated with an increase in reflex amplitude but no

significant influence in response delay. Three aspects of the methodology warrant discussion. First, the quantified paraspinal reflexes during a task involved no external constraints on trunk angle and/or response to the perturbation. However, similar conditions have been used in other studies. In addition, analyses of conditions prior to the unfatigued and fatigued perturbation showed that preparatory EMG levels and lumbar flexion angle were not affected by fatigue. Secondly, the perturbation amplitude was not consistent across unfatigued and fatigued conditions which we feel may be due to a decrease in lumbar extensor stiffness with fatigue.

**Figure 1:** EMG reflex delay and amplitude after pendulum perturbation.

Third, the increase in reflex amplitude may not solely be attributed to fatigue. Dynamic fatiguing can elicit strain in paraspinal tissue in addition to fatigue. Despite this, a dynamic fatigue exercise more closely represents an occupational task.

### CONCLUSIONS

Spinal stability is primarily controlled by muscle recruitment, muscle stiffness, and reflex response. Trunk fatigue has been shown to alter trunk muscle recruitment patterns and decrease the force producing capacity of muscle. The increase in reflex amplitude found here may reflect an attempt to compensate for losses in muscle force capacity with fatigue in order to maintain sufficient spinal stability.

**USING THE EIGENVECTOR APPROACH TO LOCATE SPINAL INSTABILITY**

**Samuel J. Howarth and Stuart M. McGill**

**Department of Kinesiology, University of Waterloo, Waterloo, Canada**

**INTRODUCTION**

Models have been developed in the past to evaluate stability of the lumbar spine. One approach to quantify the stability index is to determine the smallest eigenvalue associated with a Hessian matrix comprised of all second partial derivatives from a potential energy function [1]. The system is deemed to be unstable whenever the smallest eigenvalue is less than zero. Clinically the location of potential instability is necessary for developing the buttressing motor patterns to prevent instability. Since eigenvectors associated with particular eigenvalues indicate the buckled configurations, this work proposes a particular form of the eigenvector that would enable investigators to determine the location of spinal instability.

**METHODS**

The lumbar spine model used here includes six vertebral joints (Pelvis/L5-Ribcage/L1) and three axes (flexion/extension, lateral bend, axial rotation) for a total of eighteen degrees of freedom [2]. Each joint is assigned a passive rotational stiffness component. Instability occurs when the stiffness at a joint is compromised along a particular axis. This study compromised the stiffness at various vertebral levels, and particular axes to investigate the plausibility of the proposed eigenvector format.

As a proof of principle, a theoretical trial of a 25 kg load applied to the upright spine was considered. The rotational stiffness parameters [3] for each joint and axis were made to be identical. This forced the rotational stiffness at each joint to be identical. Lastly, we reduced the rotational stiffness at the L3-L4 joint and lateral bend axis to obtain a compromised joint and axis. Thus, the primary instability will occur at the L3-L4 joint and in the lateral bend axis. Subsequently, the known location of the instability can be checked with the proposed form of the eigenvector described below.

**RESULTS & DISCUSSION**

The Hessian matrix used for the analysis of spinal stability is a symmetric 18 x 18 matrix whose individual entries are second partial derivatives of a potential energy function taken with respect to generalized coordinates at each lumbar joint and

axis. The symmetric nature of the Hessian matrix admits the following relationship between the eigenvalues and eigenvectors of the Hessian matrix:

$$VDV^T = H \quad (1)$$

This is where H is the Hessian matrix, D is a diagonal matrix that contains the eigenvalues along its main diagonal, and V is a matrix whose columns are the eigenvectors associated with a particular eigenvalue. V, D, and H are all 18 x 18 matrices. The individual entries of each eigenvector represent a particular vertebral level and axis (Table 1). Consequently, the joint and axis of buckling is indicated by the largest component of the eigenvector associated with the smallest eigenvalue.

The smallest eigenvalue from the example indicated that an instability had occurred ( $\lambda_{\min} = -18.7231$ ). The largest entry of the eigenvector associated with the smallest eigenvalue occurred along the lateral bend axis of the L3-L4 joint (Table 1). This is precisely the joint and axis with compromised rotational stiffness.

Interestingly, the eigenvector also has large components along the lateral bend axis for all joints above L3-L4. These components are all smaller than the component at L3-L4 along the lateral bend axis, and decrease as the segmental level reaches the top of the spine. This suggests that the entries of the eigenvector demonstrate a deflection of the vertebral joint from some reference orientation.

**CONCLUSIONS**

The example illustrates the plausibility of the proposed form for an eigenvector in the solution of spinal instability when such instability occurs. This interpretation of the eigenvector allows investigators to develop efficient motor patterns that will buttress instability.

## A FINITE ELEMENT ANALYSIS ON THE EFFECT OF SOFT TISSUE THICKNESS ON PLANTAR PRESSURES IN SUBJECTS WITH DIABETES AND PERIPHERAL NEUROPATHY

<sup>1</sup> Michael J. Mueller, <sup>2</sup>Ricardo L. Actis, <sup>2</sup>Liliana B. Ventura, <sup>2,3</sup>Barna A. Szabo,

<sup>1</sup>Program in Physical Therapy, Washington University School of Medicine; email muellerm@wustl.edu

<sup>2</sup>Engineering Software Research and Development, Inc, <sup>3</sup>Center for Computational Mechanics, Washington University

### INTRODUCTION

Excessive localized peak plantar pressures (PPP) are known to contribute to skin breakdown in people with diabetes (DM) and peripheral neuropathy (PN). Previous work has shown a correlation between plantar soft tissue thickness (STT) under the metatarsal heads (where most ulcers occur) and PPP in subjects with DM and PN [1,2]. The purpose of this study was to use a validated finite element analysis (FEA) model to determine the effect of reducing STT on PPP in subjects with DM and PN and a history of plantar ulcers.

### METHODS

Data were collected on 4 males with DM & PN. Mean age was 53±26 years, mean BMI was 34±9, and mean duration of DM was 19±9 years. All subjects had dense PN (unable to sense 6.10 Semmes Weinstein monofilament) and a history of a plantar neuropathic ulcer.

The 3D internal structure was determined using data from SXCT [3], the reference pressure distribution was measured using the F-Scan system [3], and soft tissue properties were estimated using an indenter testing device and confirmed with values in the literature for each foot.

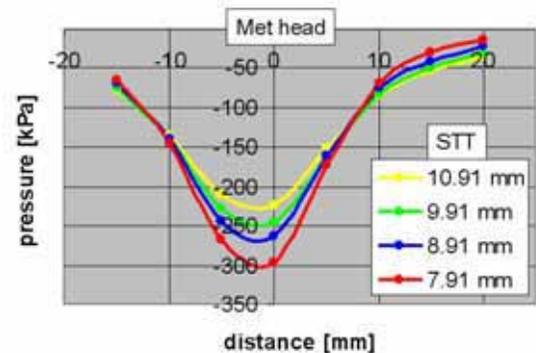

Individual two-dimensional FEA models in the sagittal plane were developed for metatarsals 2 and 3 using the p-version FEA program StressCheck with the foot in a push-off position for each subject. Bones included a support bone (tibia, talus, calcaneus, navicular, cuneiform), metatarsal and 3 phalanges. Cartilage with linear elastic material properties was included between the bones to simulate the composite stiffness between bones. Fascia and the long flexor tendon were included and the properties were assumed to be linearly elastic. Material properties of bone, fascia, and tendon were obtained from the literature.

The model's ability to predict plantar pressure distribution was tested against measured pressure distribution and found to be good, as reported elsewhere [4]. The effect of reducing STT under the metatarsal head was accomplished by translating the bones, tendon, and fascia vertically downward in 1 mm increments within the soft tissue envelop and keeping the skin outline and boundary conditions unchanged.

### RESULTS AND DISCUSSION

Initial STT, PPP, and the % increase in PPP with 1-3 mm reduction in STT for the 2<sup>nd</sup> and 3<sup>rd</sup> metatarsal heads are contained in Table 1. Figure 1 shows the change in plantar pressure distribution for a specific subject (D07). There was a strong inverse relationship ( $r=-0.99$ ) between the reduction in

STT and the increase in PPP. According to the model, PPP will increase 14 to 24% under met heads 2 & 3 with a 3 mm reduction in STT depending upon other factors such as the shape and position of the metatarsal head.

**Figure 1:** Change in pressure distribution 15 mm proximal to 20 mm distal 3rd met head with changes in STT (3mm).

Although this model is limited by being static and 2D, the results are robust and underlying assumptions for this application seem reasonable, but the effect of reducing STT on PPP may be even greater in reality. Methods currently are underway to establish a 3D model.

### CONCLUSIONS

The results have important implications for understanding the factors contributing to skin breakdown in patients with DM and PN. STT has been correlated with PPP [1,2], and these results indicate a reduction in STT is highly correlated to an increase in PPP. Therefore, specific reductions in STT at a localized area, perhaps as a result of previous skin breakdown, could result in higher PPP at that site making it more susceptible to future skin breakdown. We plan to expand the FEA model further to develop strategies to evenly distribute pressures across the plantar foot.

## THUMB MUSCLE FORCES IN JAR OPENING

<sup>1</sup>Fong-Chin Su, <sup>1</sup>Kun-Yueh Ho, <sup>1,2</sup>Jer-Hao Chang

<sup>1</sup>Institute of Biomedical Engineering, <sup>2</sup>School of Occupational Therapy, National Cheng Kung University

### INTRODUCTION

Twisting activities such as jar turning and door opening are common functional activities in our daily living. It is a big challenge for the patients with arthritis or after hand injuries. The literature in understanding the muscle contribution of the thumb during jar turning still lacks [1,2]. It is interesting to understand how the muscles of the thumb play their roles in mobility and joint stability. The purpose of this study was to establish a biomechanical model to predict the muscle forces in the thumb and to understand their roles during jar opening.

### METHODS

The jar simulator was equipped with one torque sensor (Transducer Techniques, CA,  $\pm 22.6N\cdot m$ ) and a six-axis force transducer (Nano25, ATI Industrial Automation, NC,  $F_x, F_y = \pm 111N; F_z = \pm 445N; T_x, T_y, T_z = \pm 2.8N\cdot m$ ). The single-axis torque sensor set inside the jar center was for recording the total torque of the hand and the six-axis force transducer mounted under the tap was for the applied forces and moments of the thumb while jar opening. In addition, three-dimensional kinematical data were captured by a motion analysis system (Motion Analysis Corp., CA). Thirteen 4 mm diameter retro-reflective markers were attached on the dorsal surface of the thumb to define the local coordination system of the thumb and three other markers were on the jar simulator to define its coordination system (Figure 1). The IP joint was represented by a hinge joint with one degree of freedom and three constraint forces ( $C_x, C_y, C_z$ ) and two constraint moments ( $M_x, M_y$ ). The MCP joint was regarded as a universal joint with two degrees of freedom and three constraint forces and one constraint moment. The CMC joint was also regarded as a universal joint. According to the mechanical equilibrium at each joint, the optimization technique was used to solve the redundant system. The objective function minimizing overall muscle stress was selected.

$$\text{Min } \sum (F_i^M / PCSA)^2$$

$$0 \leq F_i^M \leq PCSA * \sigma_{\max} \quad i = 1, m$$

where  $PCSA_i$  and  $F_i^M$  were cross section area and forces generated in the  $i$ th muscle or tendon.  $\sigma_{\max} = 35.3 N/cm^2$  was the maximum which a thumb muscle could bear. Eight female and two male volunteers without hand impairment took part in this study. They were all right handed and asked to grip the base of this jar simulator by left hand in a comfortable position. The right hand held the lid of the jar simulator and put the thumb pad on the six-axis force transducer. The subject then turned the jar lid counter-clockwise three times at maximal effort by both power grip and precision handling.

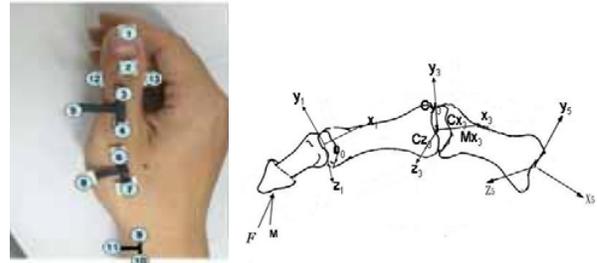

Figure 1: Markers setting and coordination system

### RESULTS AND DISCUSSION

Figure 2 shows the muscle forces of the thumb in jar opening. The major active muscles were FPL, FPB, APB, ADP and OPP. The forces of extensor muscles (EPL, EPB, APL) not larger than flexor muscles were average 15N and were about 6 % of total muscle forces. Total muscle forces in precision handling were 5.6 times the applied forces of thumb but that in power grip were 4.7 times. It indicated that power grip was more effective than precision handling. To compare with previous researches, this study adopted measured data instead of assumed value as Cooney et al. and Giurintano et al. did. They measured the moment arms of cadaver muscles by X-ray and CT images. The muscle loads thus varied. This new apparatus here presented a proper method to measure the actual load in jar opening activity and the biomechanical model developed contributed to the prediction of the muscle forces of the thumb during such activity.

## MUSCLE DYSFUNCTION DURING WALKING IN CHILDREN WITH CEREBRAL PALSY

<sup>1,2</sup> James Wakeling, <sup>2</sup>Roisin Delaney and <sup>2</sup>Israel Dudkiewicz

<sup>1</sup>The Royal Veterinary College, UK ,

<sup>2</sup>The Royal National Orthopaedic Hospital, UK; email: [jwakeling@rvc.ac.uk](mailto:jwakeling@rvc.ac.uk)

### INTRODUCTION

Cerebral palsy (CP) is a disorder of movement or posture due to a lesion in the immature brain [1]. Release of the gamma system from higher inhibitory control results in the muscles being hyperexcitable [2], and they exhibit elevated muscle tone and excessive co-contraction during walking [3].

CP is typically assessed using gross measures of gait (e.g. walking velocity), or overall motor function and sometimes by the joint kinetics. However, none of these measures are direct measures of the muscle dysfunction.

The purpose of this study was to quantify the differences in the myoelectric activity between children with CP, and healthy controls, in order to determine the extent of the muscle dysfunction during walking.

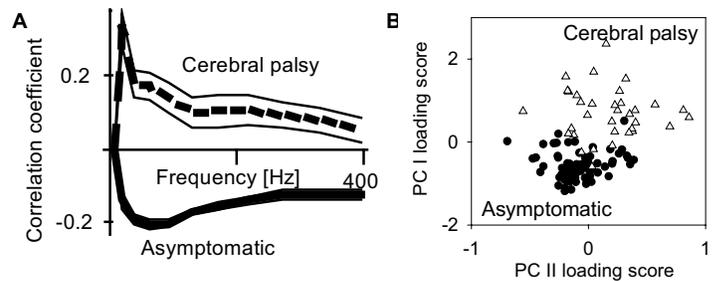

### METHODS

Surface electromyography (EMG) was performed bilaterally on the rectus femoris, semimembranosus, medial gastrocnemius and tibialis anterior from 36 healthy children and young adults (age range 3.1 – 21.0 years) and 17 children and young adults with CP (4.8 – 21.5 years). Each child walked along a walkway at their preferred velocity. Segmental kinematics were used to determine the time of foot-contact with the ground, and thus to window the walking into stance phase, swing phase, or the entire stride cycles. Data were analyzed from 5-15 strides per individual.

The EMG was resolved into its intensity (a correlate of the power of the signal) in time-frequency space using wavelet techniques [4]. The intensities (at each frequency-band analyzed) were correlated between antagonistic muscles. Correlations were thus calculated across a range of frequencies to make a spectrum. The correlation spectra were used as a measure of the co-contraction. Correlation spectra between the asymptomatic and cerebral-palsied conditions were compared using principal component techniques [5].

### RESULTS AND DISCUSSION

Intensity spectra showed that the cerebral-palsied condition had systematically higher mean EMG frequencies than the asymptomatic controls. The extensor muscles (rectus femoris and medial gastrocnemius) showed higher intensities, but the tibialis anterior intensity was less than the asymptomatic condition (Table 1). The results show that the muscle is either activated in a different way, or that the muscle structure is

**Figure 1:** [A] Correlation spectra (mean  $\pm$  s.e.) and [B] principal component (PC) loading scores for co-contractions for all subjects between the tibialis anterior and medial gastrocnemius during walking

different in the children with CP. This type of analysis can direct future research questions.

The correlation spectra showed that the cerebral-palsied condition has different (but not always greater) patterns of co-contraction (Fig. 1A). Co-contractions in the cerebral-palsied muscles were always greater in the low-frequency range (<100 Hz) of the myoelectric spectra, and may indicate a greater involvement of the slower motor units for co-contractions [5]. The principal components of the co-contraction could be distinguished between the cerebral-palsied and asymptomatic conditions, and were most different for the more distal muscles (Fig. 1B).

### CONCLUSIONS

The EMG signals during walking are markedly different between children with cerebral palsy and asymptomatic controls. Time-frequency analysis of the spectra and the co-contractions provide direct measures of the muscle dysfunction and have an application for quantifying the severity of the condition or the efficacy of treatment.

## JOINT LOAD OF THE THUMB IN JAR OPENING

<sup>1,2</sup>Jer-Hao Chang, <sup>1</sup>Kun-Yueh Ho, <sup>1</sup>Fong-Chin Su

<sup>1</sup>Institute of Biomedical Engineering, <sup>2</sup>School of Occupational Therapy, National Cheng Kung University  
 email: [fcsu@mail.ncku.edu.tw](mailto:fcsu@mail.ncku.edu.tw)

### INTRODUCTION

The thumb plays an important role in daily activity because of its opposition characteristics. Jar opening is a common but challenging task for those who could not provide the sufficient twisting torque. Some researchers had developed the biomechanical model of the finger or thumb by means of the hypothetical loads [1,2,3]. This study aimed to develop a novel device to measure the actual three-dimensional loads of the thumb during jar opening and to establish a biomechanical model to reveal the joint loads of the thumb in such activity.

### METHODS

The jar simulator was equipped with one torque sensor (Transducer Techniques, CA,  $\pm 22.6N\cdot m$ ) and a 6-axis force transducer (Nano25, ATI Industrial Automation, NC,  $F_x, F_y = \pm 111N$ ;  $F_z = \pm 445N$ ;  $T_x, T_y, T_z = \pm 2.8N\cdot m$ ). The single-axis torque sensor set inside the jar center was for recording the total torque of the hand and the six-axis force transducer mounted under the tap was for the applied forces and moments of the thumb while jar opening. These data recorded by the jar simulator were used to calculate the normal forces ( $F_n$ ), tangent forces ( $F_t$ ), and the torque contribution ( $C$ ) of the thumb applied to the jar lid. In addition, three-dimensional kinematical data were acquired by a motion analysis system (Motion Analysis Corp., CA). Thirteen 4 mm diameter retro-reflective markers were attached on the dorsal surface of the thumb to define the local coordination system of the thumb and three other markers were on the jar simulator to define its coordination system (Figure 1). The IP joint was represented by a hinge joint with one degree of freedom and three constraint forces ( $C_x, C_y, C_z$ ) and two constraint moments ( $M_x, M_y$ ). The MCP joint was regarded as a universal joint with two degrees of freedom and three constraint forces and one constraint moment. The CMC joint was also regarded as a universal joint. According to the mechanical equilibrium at each joint ( $\sum F=0, \sum M=0$ ), the resultant forces and moments of three thumb joints were computed. Eight female and two male volunteers without hand impairment took part in this study. They were all right handed and asked to grip the base of this jar simulator by left hand and put the right thumb on the 6-axis force transducer of the lid then did jar opening at maximal effort by both power grip and precision handling.

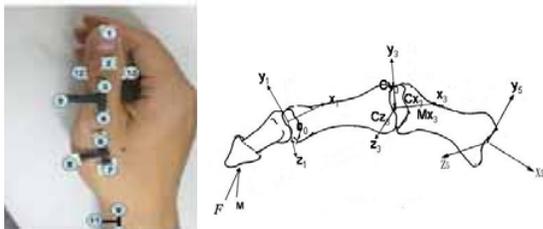

Figure 1: Markers setting and coordination system

### RESULTS AND DISCUSSION

The normal force applied by the thumb to the lid was averaged about 45N and the tangent forces were averaged about 15N. The twisting torque contribution of the thumb was averaged about 32.5%. The joint constraint forces and moments of the thumb were calculated and also normalized with respect to applied thumb tip load. The joint contact forces were mainly applied at normal direction ( $C_x$ ) of each articular surface. The CMC joint bore the largest dorsal and lateral shear forces among three joint. Figure 2 shows the joint resultant forces per unit external applied forces during jar opening. There were 221.5N at the CMC joint, 153N at the MCP joint, and 69N at the IP joint. They were respectively 4.8, 3.3 and 1.5 times the applied forces of the thumb. The external forces and the muscle forces were the major factors to influence the joint constraint forces and moments.

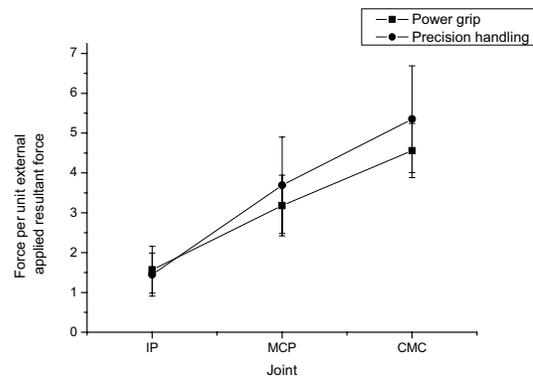

Figure 2: Joint resultant forces per unit external applied force

### CONCLUSIONS

This study contributed to the measurement of the biomechanical express and calculation of the joint loads of the thumb in jar opening activity. The new apparatus provides a proper method for measuring the three dimensional load during the activities. The biomechanical analysis model would help to discover more information about the muscle and joint load in other twisting activities by further application.

## PHASE TRANSITION OF FORCE DURING RAMP STRETCH OF MUSCLE FIBERS WITH BDM

Dilson E. Rassier and Walter Herzog  
Human Performance Laboratory, Faculty of Kinesiology  
University of Calgary (AB), Canada; email:rassier@kin.ucalgary.ca

### INTRODUCTION

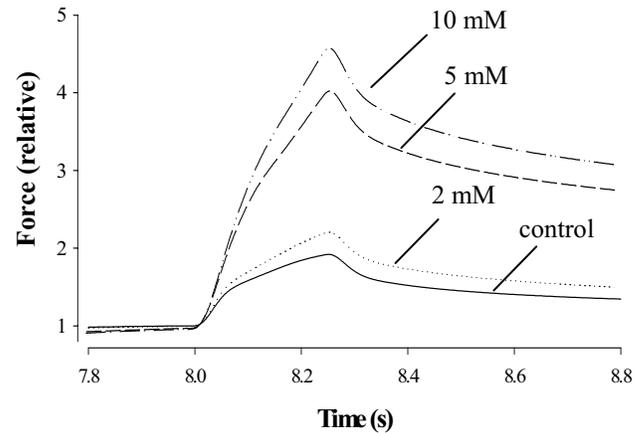

When muscle fibers are stretched while activated, force increases in two phases: a fast steep increase, and a slow increase. It has been proposed that the breakpoint between phases and the increase in force is due to weakly-bound cross-bridges [1], that do not produce substantial isometric force, but contribute significantly to force when stretched. We tested this hypothesis by stretching muscle fibers while biasing cross-bridges towards a weakly-bound state. If the hypothesis was correct, stretch forces would increase relative to the isometric forces when cross-bridges are biased into a weakly-bound state.

### METHODS

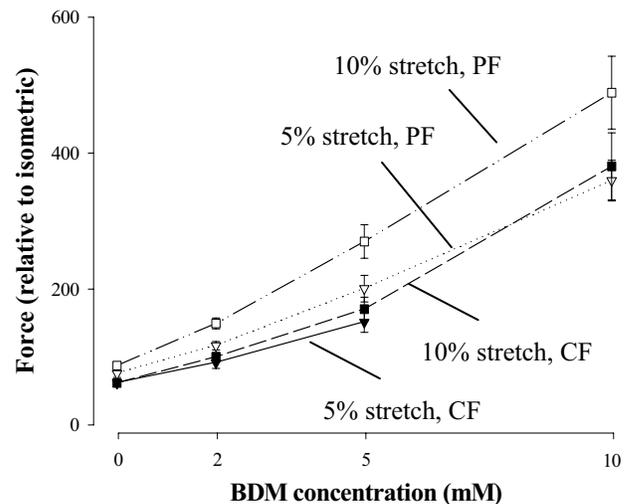

Single fibers were dissected from lumbrical muscles of the frog and suspended between a force transducer and a motor arm in an experimental chamber. Fibers were stimulated to produce maximal isometric force, and stretched 5% and 10% of optimal fiber length ( $L_0$ ) at different velocities, starting at a length 20% above  $L_0$ . Experiments were performed at 9°C in Ringer solution, and with 2, 5 and 10 mM of 2,3 Butanodione-monoxime (BDM). BDM is known to bias cross-bridges into a weakly-bound state [2], preceding phosphate release and the power stroke. Force values were evaluated before and at the end of stretch (peak forces), as well as at the point of transition between the fast and the slow phases of force increase during stretch (critical forces).

### RESULTS AND DISCUSSION

When active muscle fibers were stretched while fully activated, force increased significantly. This increase could be divided into a fast rise and a slow rise in force (Fig 1). Increasing concentrations of BDM significantly decreased the isometric force, the absolute forces measured at the end of stretch, and the force at the transition between the fast and the slow phases of force increase. However, BDM significantly increased the peak force and the force at the transition point relative to the isometric force before stretch (Fig. 1). This result was confirmed statistically in 10 fibers, with 5 and 10% fiber length stretches (Fig. 2). Since BDM places a large proportion of cross-bridges in a weakly-bound state [2], we conclude that the force obtained during stretch is caused by weakly- and strongly-bound cross-bridges, while the isometric force is produced only by strongly-bound cross-bridges.

**Figure 1:** Force during stretch without (control), and with 2, 5 and 10 mM BDM.

**Figure 1:** Peak forces (PF) and critical forces obtained at the transition between the fast and the slow phases of force increase during stretch (CF) during stretch, without (control), and with 2, 5 and 10 mM BDM

## MODULATION OF PASSIVE FORCE IN SKELETAL MUSCLE FIBERS

Eun-Jeong Lee, Dilson E. Rassier and Walter Herzog  
Human Performance Laboratory, Faculty of Kinesiology  
University of Calgary (AB), Canada; email:walter@kin.ucalgary.ca

### INTRODUCTION

When skeletal muscle is stretched while activated, the passive force following deactivation is higher than that produced by passive stretches with the same characteristics (amplitude, initial length), and following isometric contractions at the corresponding lengths [1]. The mechanism behind this phenomenon, referred to as “passive force enhancement”, is unknown. Recent evidence shows that increasing  $Ca^{2+}$  concentration enhances the force produced by titin [2], suggesting that the passive force enhancement may be caused by modulation of titin upon muscle activation. If that was true, the entire passive force-length relationship would be affected by activation. In this study, we evaluated if the passive force-sarcomere length relationship following active stretches was different from that following isometric contractions and following passive stretches.

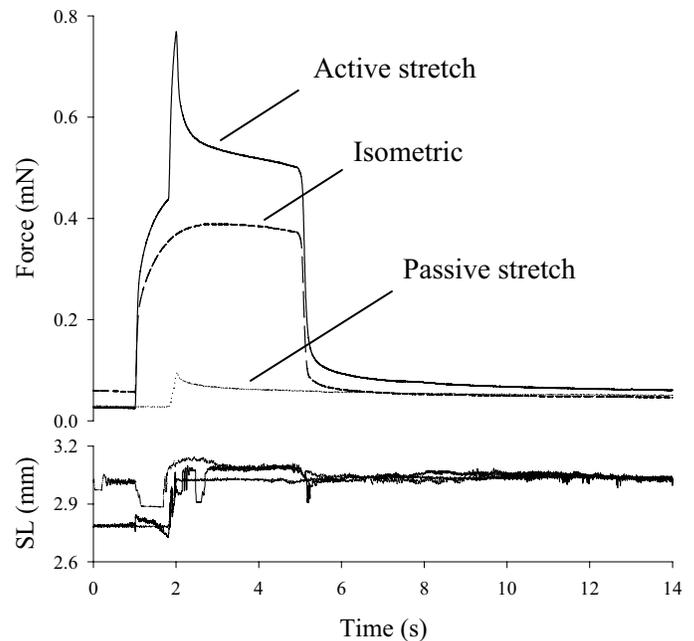

### METHODS

Single fibers ( $n = 6$ ) were dissected from lumbrical muscles of the frog (*R. Pipiens*) and suspended between a motor arm and a force transducer inside an experimental chamber (temperature:  $9^{\circ}C$ ). Sarcomere length was measured using the laser diffraction technique, with a He-Ne laser beam (633nm wavelength) projected perpendicular to the axis of the fiber. Fibers were pre-stretched to different sarcomere lengths along the descending limb of the force-length relationship, activated and stretched  $\sim 0.22 \mu m$  per sarcomere. Passive stretches were performed with similar characteristics, and isometric contractions were performed at the corresponding final lengths. Experiments were performed in Ringer solution (pH=7.5), and with the addition of 5 and 20 mM of BDM, which inhibits active force production [3].

### RESULTS AND DISCUSSION

Passive force measured after stretch of activated fibers was higher than the force measured after passive stretches, and higher than the passive force measured after an isometric contraction at the corresponding length (Figure 1). This result was confirmed statistically in all fibers investigated in this study. The passive force enhancement was length-dependent, as it increased with increasing sarcomere lengths, causing an upwards shift in the passive force-sarcomere length relationship along the Y-axis. Adding BDM to the Ringer solution did not decrease the degree of passive force enhancement after stretches. Therefore, it seems that the increase in passive force observed during an active stretch is not due to cross-bridge kinetics, but due to the engagement of

a passive element upon activation and stretch. Based on previous studies [2], we suggest that this passive element is titin, which would be activated by  $Ca^{2+}$  when muscle contraction starts.

**Figure 1:** Typical experiment performed with a single fiber in Ringer solution. Force-time traces (top) and sarcomere length-time traces (bottom) are shown for an isometric contraction, an active stretch and a passive stretch. Note that the sarcomere lengths after contractions are similar, but forces following an active stretch are higher than those in the other conditions.

### CONCLUSIONS

The passive force-length relationship is shifted upwards along the force axis when fibers are stretched while simultaneously activated. These results might account for the passive force enhancement observed recently in skeletal muscles.

## DEVELOPMENT OF A BIOMECHANICALLY VALIDATED TURF TESTING RIG

Steven Blackburn<sup>1</sup>, Alexander Nicol<sup>1</sup> and Colin Walker<sup>2</sup>

<sup>1</sup>Bioengineering Unit, University of Strathclyde, Glasgow, Scotland. <sup>2</sup>Department of Mechanical Engineering, University of Strathclyde, Glasgow, Scotland. Email: steve\_blackburn1@yahoo.com

### INTRODUCTION

Many sports are increasing the use of artificial turf, especially with the development of 3rd generation turf. FIFA has decreed that any artificial surface that meets its performance criteria can be used for competitive soccer games [1]. However, it has been suggested that the applied loads in current testing procedures do not reflect the loading actions that occur during actual sporting movements [2,3]. The aim of this study was to develop an artificial turf testing rig that applied biomechanically validated vertical, shear and torque loads to the surface. Results of initial testing on 3<sup>rd</sup> generation artificial turf and natural grass soccer pitches are presented.

### METHODS

The Strathclyde turf testing rig (Fig. 1) was designed to be portable, so that surfaces can be tested *in situ*. The rig was based on a drop-mass/spring/mass system. The basic operation of the test rig involved the use of two weighted pendulum systems to apply loads in a vertical, horizontal and rotational direction. Electromagnets were triggered to release the pendulums at the same time. Loads were applied to a test foot with a pimped rubber or studded tread design to allow testing on different types of surfaces. A force transducer/accelerometer complex, positioned just above the test foot provided a measurement of the applied impact loads and accelerations.

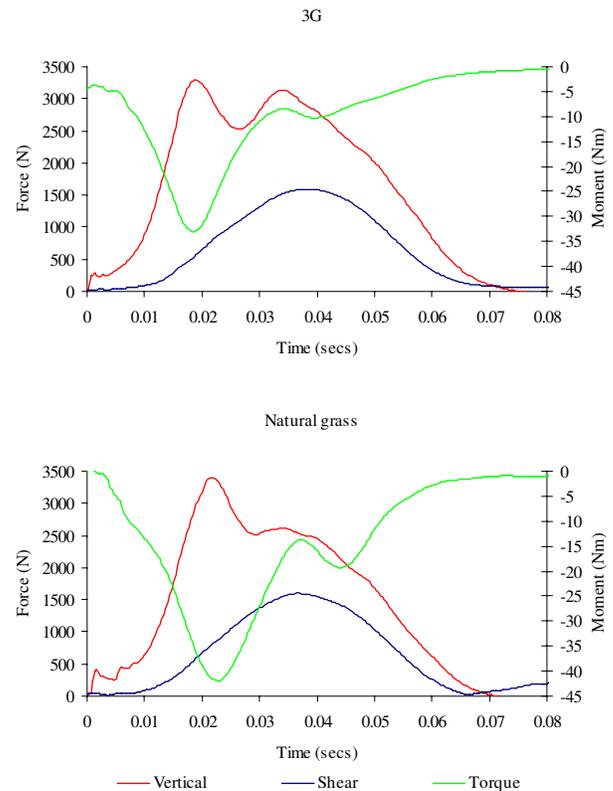

**Figure 1:** Strathclyde turf testing rig

A battery of tests was developed to characterize sports turfs. This included an assessment of linear traction (with a static and dynamic vertical load), rotational traction, vertical impact and a combined vertical, shear and torque impact test. Five trials of each test were conducted on five areas of each pitch.

### RESULTS

Table 1 indicates that the traction coefficient and the peak torque measured on the 3G surface were generally lower than the natural grass pitch. The peak vertical forces were similar. The variability in the results reflects the different areas of the

pitch tested. The combined impact test (Fig. 2) produced similar loading profiles on both surfaces, although a greater resistance to torque was measured on the natural, dry grass surface.

**Figure 2:** Vertical, shear and torque loads applied during combined impact test on 3G and natural grass surfaces

### DISCUSSION

The appropriate loading profiles applied by the test rig were derived from a biomechanical assessment of the player/surface interaction [4].

The operation of the rig is flexible so that different loads can be applied unidirectional or multidirectional in one impact action. This study demonstrated the potential of a new, portable rig to mechanically characterize artificial and natural turfs used in competitive sport.

## KNEE JOINT MOMENTS DURING SPORTS ACTIVITIES ON ARTIFICIAL TURF

Steven Blackburn<sup>1</sup>, Alexander Nicol<sup>1</sup>, Colin Walker<sup>2</sup> and Philippe Brachet<sup>1</sup>

<sup>1</sup>Bioengineering Unit, University of Strathclyde, Glasgow, Scotland. <sup>2</sup>Department of Mechanical Engineering, University of Strathclyde, Glasgow, Scotland. Email: steve\_blackburn1@yahoo.com

### INTRODUCTION

In team sports, the knee joint is especially susceptible to non-contact injury. With the increased use of artificial turf in sports, there is little evidence regarding the effect of these surfaces on knee joint loading. The aim of this study was to quantify the three-dimensional knee joints moments during different sports movements performed on artificial turf.

### METHODS

Ten subjects (ages: 28.2±9.7 years) took part in the study. All subjects played professionally or at a high level of competition and had no history of significant lower extremity injury. Each subject performed three movements on two types of artificial turf. One surface was a short pile, sand-infilled turf and the other was a third generation, long pile, sand/rubber infill turf (3G). The three movements consisted of a straight-line sprint (RUN), a one-stride stopping action during a sprint (STOP) and a 45°-cutting turn to the right (45R). The laboratory was laid out with each turf to provide an area large enough to perform the movements fully. The subjects performed each movement three times on each surface. The players wore their own preferred footwear and were instructed to perform each running movement as fast as possible.

Three dimensional motion analysis was performed using an 8-camer, 120Hz Vicon Motion System. Markers were attached to the body to allow the identification of bony landmarks. Ground reaction forces were measured using a Kistler force plate which was synchronized with the Vicon data. Knee moments were calculated using inverse dynamics and normalized to body weight.

During the stance phase, Peak moments were measured during a weight acceptance (WA) period (0-20% of stance phase) and during a propulsion (PP) period (21-100% of stance phase) for the RUN and 45R. A propulsion period was not defined for the STOP movement, except for moments in the sagittal plane. Moments in this paper are reported as moments that must be generated by the internal musculature.

### RESULTS AND DISCUSSION

The magnitudes of the knee joint moments are comparable with published data [1,2]. Internal knee flexor moments of approximately 1-1.5N/kg were applied to the knee during the WA phase of all three movements. These were slightly lower on the 3G turf. Large extensor moments were measured during the propulsion phase, especially in the 45R movements.

Frontal and transverse moments were more variable between subjects, especially during the STOP. During WA, there was an abductor knee moment during the RUN, whereas a larger adductor moment was applied during the 45R. During PP, the RUN produced higher abductor moments than the 45R, with values slightly reduced on the 3G turf. In the WA phase, internal/external moments during the 45R and STOP were much higher than the RUN.

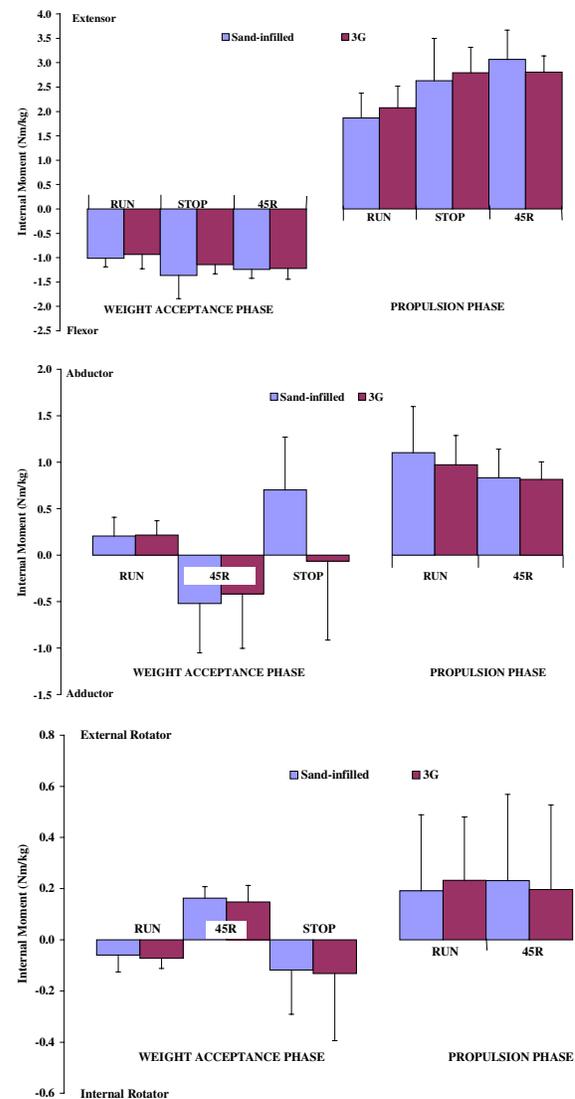

Figure 1 Knee joint moments in transverse, frontal and transverse planes

### CONCLUSIONS

Movements that involve rapid deceleration and/or a change in direction produce large knee moments. The high moments observed have the potential to significantly load the knee ligaments, increasing the risk of injury.

It is indicated that the sagittal plane loading of the knee during initial impact is generally reduced on third generation turf.

## PREHENSION SYNERGIES: EFFECTS OF FRICTION

Tomoko Aoki, Mark L. Latash and Vladimir M. Zatsiorsky  
Department of Kinesiology, The Pennsylvania State University  
email: [vxzl@psu.edu](mailto:vxzl@psu.edu)

### INTRODUCTION

Friction at the digit-object interface is a critical factor for the central nervous system to adjust digit forces applied to a manipulated object. In two-digit grasps, force normal to the surface becomes greater for an object with a more slippery surface, resulting in a higher normal/tangential force ratio, but the safety margin to prevent slippage is normally kept relatively constant [1]. In multi-digit holding tasks the effects of surface friction have been investigated only for tripod grasps [2]. We therefore investigated these effects in a five-digit object grasping task in relation to changes in the torque acting on the object.

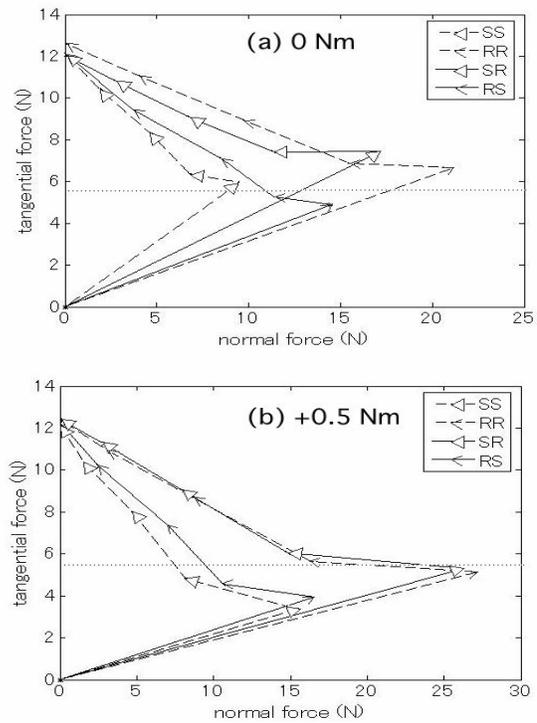

### METHODS

Six right-handed healthy young males held an aluminum handle equipped with five six-component force/moment transducers and a level. The level was used to visually guide the subjects to keep the vertical handle orientation. The external torques (-0.5, -0.25, 0, +0.25 and +0.5 Nm) were applied by changing the location of a suspended weight. The total weight of the apparatus was 11.5 N. Sandpaper (S) and rayon (R) materials were used to change friction at the sensor-fingertip interface. There were four surface conditions classified as symmetric — namely SS (all surfaces are S) and RR (all are R) — and asymmetric, SR (S for the thumb and R for the others) and RS (the reverse of SR). Data were collected for each of these conditions while torques were changed (20 trials per subject). Signals were recorded for 3 s after reaching a steady holding condition. In a separate trial for the SS and RR, a hold-to-drop task was performed to measure the minimum normal force to hold the handle, from which we estimated coefficient of static friction ( $\mu$ ),  $0.6 \pm 0.2$  for R and  $1.8 \pm 0.3$  for S. Forces normal ( $F_n$ ) and tangential ( $F_t$ ) to the grip surface were analyzed for each digit. Safety margin (SM) was evaluated based on the following equation,  $SM = ((F_n)_i - |(F_t)_i|) / \mu$ .

### RESULTS AND DISCUSSION

As expected, both  $F_n$  and  $F_t$  of all digits were largely influenced by surface condition (Figure). In the symmetric tasks, the  $F_n$  was larger in the RR conditions. The effect of friction on  $F_n$  was larger than the torque effects: even the smallest value of the  $F_n$  for the thumb and virtual finger (VF: an imaginable finger that generates the same mechanical effect of four actual fingers) in the zero torque task was larger than any  $F_n$  value in the SS task. There was an equal sharing of the  $F_t$  by the thumb and VF for the zero torque condition.

In the asymmetric tasks, force vectors of the thumb and VF differed substantially: the digit force vectors were torque dependent (Figure a). In the zero torque conditions the  $F_n$  of the thumb and VF were larger than in the SS and smaller than in RR tasks. At a zero torque, the thumb and VF exerted

**Figure:** Mean force vectors for different surface conditions across all subjects. The force polygons have been obtained by adding tail-to-head the individual force vectors. Vectors represent the forces of the thumb, index, middle, ring and little fingers, respectively, in a counterclockwise sequence (starting from the bottom left corner).

unequal  $F_t$ . Such an unequal sharing of  $F_t$  generated a moment of the tangential force that had to be negated by the moment of the normal forces. In the non-zero torque tasks when the torque production required an exertion of a tangential force at the more slippery side, the  $F_n$  were as large as in the RR condition (Figure b). The SM values at the zero torque were similar for the thumb and VF for SS and RR, while for the SR and RS tasks they were larger for the S side than the R side.

### SUMMARY

In the asymmetric tasks the subject decrease the  $F_t$  production at the places of low friction. Such a strategy results in changes of  $F_n$  and the moments produced by the normal and tangential forces (chain effects).

## STATIONARY VISUAL CUES REDUCED CENTRE OF PRESSURE DISPLACEMENT IN A DYNAMIC ENVIRONMENT FOR EXPERIENCED ROOFERS

<sup>1</sup>Shirley Rietdyk, <sup>1</sup>Steven R. Torgerud, <sup>2</sup>James D. McGlothlin, <sup>2</sup>Mark J. Knezovich  
<sup>1</sup>Health and Kinesiology Department, <sup>2</sup>School of Health Sciences, Purdue University  
 email: srietdyk@purdue.edu

### INTRODUCTION

A worker's postural stability can be compromised by the worksite, work experience and age. Roofers are chronically exposed to a challenging environment: dynamic visual fields, various roof pitch angles and frictional surfaces, gusting winds and handling loads. Recent research has shown that job-specific skills are maintained despite age [1, 2]. These observations might extend to enhanced balance control in roofers due to the challenging environment. Changes to the worksite may improve balance: visual references reduced centre of pressure (COP) displacement in a static lab environment, both at height and on a deformable surface [3].

The purpose of this research was to determine if stationary visual references would reduce COP displacement in a dynamic visual environment, and if the amount of reduction was dependent on work experience and age.

### METHODS

Four groups (n = 10 in each group) were examined: younger (26.3 ± 3.1 yrs) and older roofers (50.6 ± 4.2 yrs), younger (26.2 ± 3.7 yrs) and older controls (55.1 ± 4.5 yrs). Roofers had a minimum of two years experience. All subjects were male, healthy and free from any neurologic or otologic disorder. Participants stood on a forceplate (AMTI), either outside (quiet standing) or inside a visual surround (1.2 x 1.2 x 2.3 m), which translated 13 cm in a sinusoidal manner at 0.24 Hz. Six conditions of visual stimuli were examined: (1) 'normal' visual field, (2) static visual field (quiet standing inside stationary surround); the remaining conditions were dynamic visual fields with the following stationary references, (3) no references, (4) two foreground references (inside the moving room), (5) two background references (outside the room) and (6) both foreground and background references. The COP was filtered at 10 Hz with a dual-pass zero-phase-shift fourth-order Butterworth digital filter and quantified by the root mean square (RMS). Statistical analyses were a three factor ANOVA (visual stimuli x age x work experience).

### RESULTS AND DISCUSSION

The three way interaction was not significant (p=0.38). The effect of visual stimulus on COP RMS was dependent on work experience (p=0.035). Post hoc analyses revealed that the

RMS of the roofers was not different from the controls for four of the six conditions: the quiet standing conditions and the moving room conditions without references or with foreground references (Fig. 1). When background stationary references were present, the COP RMS of the roofers was significantly lower than the controls. When both foreground and background stationary references were present, the COP RMS was reduced compared to the no reference condition, but only for the roofer group. In fact, with both foreground and background references, the response was not different from quiet standing without references. The control group did not reduce the COP RMS with the visual references. Therefore, work experience in a challenging environment did not result in reduced COP RMS either during quiet standing or in a dynamic environment without stationary visual cues in the background. Stationary references in the background did reduce COP displacement, but only for experienced roofers.

The age effect was not dependent on work experience (p=0.17). The roofers had significantly lower COP RMS (p<0.001), and both groups showed similar increases in COP RMS with age (p<0.001). It was interesting to find that the COP RMS of the older roofer was not different from the younger control. Therefore, work experience did not mitigate the age-related changes on COP RMS, but the older roofer had similar postural stability as the younger control.

### CONCLUSIONS

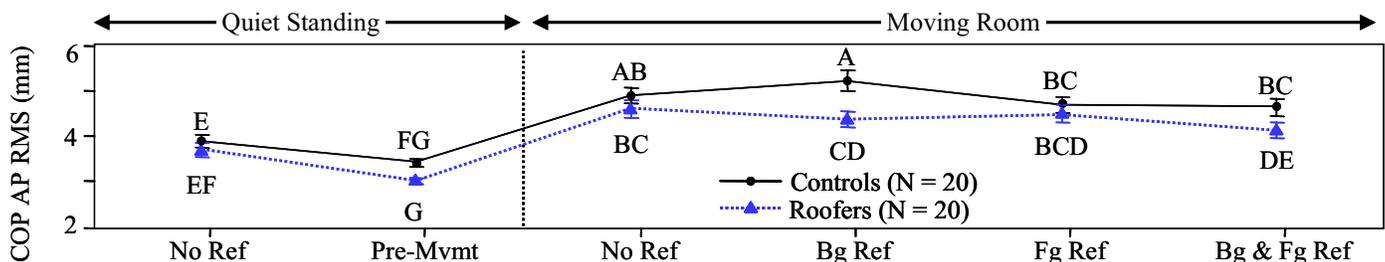

Stationary references at the dynamic worksite would only be beneficial for experienced roofers, and need to be in the background. Those at greatest risk of instability due to increased COP displacement, the older, inexperienced roofer, would not benefit from stationary references added to a dynamic worksite.

### INTRODUCTION

Stress-strain relationships for materials have been traditionally established through direct phenomenological modeling based upon experimental observations. However, it is widely accepted that the material stress-strain behavior critically depends upon the underlying mechanisms that occur at scales smaller than the material sample scale. Modeling methodologies that account for the underlying mechanisms governing the material behavior and explicitly model material microstructure are expected to provide better insight to the material stress-strain behavior and bridge the scale between continuum and discrete representations. For instance, micromechanical models considering particle interactions have been successfully used for describing stress-strain behavior of granular materials [1]. The objectives of this work are: (1) to develop a micromechanical model that relates the anisotropic elastic properties to the microstructure of dentin using a virtual bond idealization, and (2) to study the average force constants and anisotropy parameters utilizing the developed model in order to understand how the dentin elasticity is affected by the presence of water.

Along this approach, we consider the material-scale to be composed of nano-scale grains (representing molecular bonds) whose centroids represent material points. Similar granular or discrete microstructure models have been considered in the past for developing constitutive relations, such as the virtual internal bond model developed by Gao and Klein [2], the higher order constitutive relationships developed by Chang and co-workers (see among other publications [3]), and the micromechanics models [1,4]. In analogy with atomistic-scale interactions, these nano-scale grains are viewed as interacting with each other through pseudo-bonds.

### METHODS

The underlying material microstructure is conceptualized as a collection of interacting grains modeled by virtual bonds. With the view of bridging behavior at nano and micro-scales, the virtual bond force-displacement relationships are formulated taking inspiration from atomic-bond interactions. The force-displacement relationships are formulated for both central and non-central interactions, denoted by the force constants  $K_n$  and  $K_w$ , respectively. The dentin microstructure is characterized by a virtual bond directional distribution function modeled by first-term of the spherical harmonic expansion denoted by anisotropy parameter  $a_{20}$ . Considering the kinematic assumption that the bond displacement is linearly related to the overall strain, the pseudo-bond force-

displacement relationships may be combined with its orientation to derive the incremental stress and stiffness tensors. Alternatively, utilizing a static assumption that relates the virtual-bond force to the stress tensor, the pseudo-bond force-displacement relationships may be combined with its orientation to derive the incremental strain and compliance tensors.

### RESULTS AND DISCUSSION

Closed form expressions of the transverse isotropic stiffness tensor are obtained for the case of linear inter-granular interactions. These expressions are utilized to compute the stiffness and anisotropy parameters for dry and wet dentin [5] utilizing an optimization method. The stiffness parameters are defined as follows:  $A_I = L_o^2 N_p K_n$  and  $C_I = L_o^2 N_p K_w$ , where  $L_o$  is the bond length, and  $N_p$  is the bond density per unit volume. The stiffness parameters  $A_I$  and  $C_I$ , (in GPa) respectively are as follows: 183.2, 0.0 (dry dentin), 199.7, 0.0 (wet dentin) based upon kinematic approach, and 196.5, 45.7 (dry dentin), 243.2, 38.3 (wet dentin) based upon static approach. The anisotropy parameter  $a_{20}$  are as follows 0.0 (dry dentin), -0.234 (wet dentin) based upon kinematic approach, and 0.0 (dry dentin), -0.218 (wet dentin) based upon static approach. Measured elastic moduli for dry dentin are isotropic, while those for wet dentin are transversely isotropic with the isotropy plane perpendicular to the tubule direction being stiffer. Consequently, the anisotropy parameter  $a_{20}$  vanishes for dry dentin and takes a negative value for wet dentin.

### CONCLUSIONS

The force constant for wet dentin is higher than that of dry dentin indicating that the presence of water results in the stiffening of bonds that contribute to the mechanical stiffness at the sample scale. Moreover, the anisotropy parameter of wet dentin indicates that the bond density becomes higher in the isotropy plane in the presence of water.

## FORCE PROFILE COMPARISON OF ROWING ON A STATIONARY AND DYNAMIC ERGOMETER

<sup>1</sup>Aaron Benson and <sup>2</sup>Julianne Abendroth-Smith

<sup>1</sup>Ithaca College, Ithaca, NY; email: benson\_aaron@hotmail.com

<sup>2</sup>Willamette University, Salem, OR; email: jabendro@willamette.edu

### INTRODUCTION

Recently developed dynamic rowing ergometers enable part or all of the machine to move back and forth inversely with the rower, akin to the response of a boat. A common dynamic design incorporates a wheeled base beneath a normally stationary machine. Such a setup conserves mechanical energy and enables higher stroke rates, thus better simulating on-water rowing [3]. Comparisons of “fixed” and “floating” conditions using the RowPerfect (a truly dynamic ergometer) have found similar results, as well as decreased work per stroke in the dynamic condition [1,2].

Concept 2 has designed “Slides” to allow dynamic rowing, but research involving this popular equipment is minimal. This study compares the use of a Concept 2 ergometer alone and with Slides, through force profile evaluation.

### METHODS

Varsity and novice rowers from the Ithaca College Crew volunteered; 21 women (ht.  $1.71 \pm 0.08$  m, mass  $67.4 \pm 7.6$  kg) and 16 men (ht.  $1.82 \pm 0.08$  m, mass  $80 \pm 11.4$  kg) participated. IRB approval and informed consent were obtained.

Subjects completed two 1000-meter trials on a Concept 2 Model C ergometer. The ergometer was alternately stationary or dynamic (counterbalanced). Subjects rowed at their self-selected race pace, maintaining a constant workload within and between trials. All subjects were allowed to warm-up, rest, and familiarize with equipment as needed.

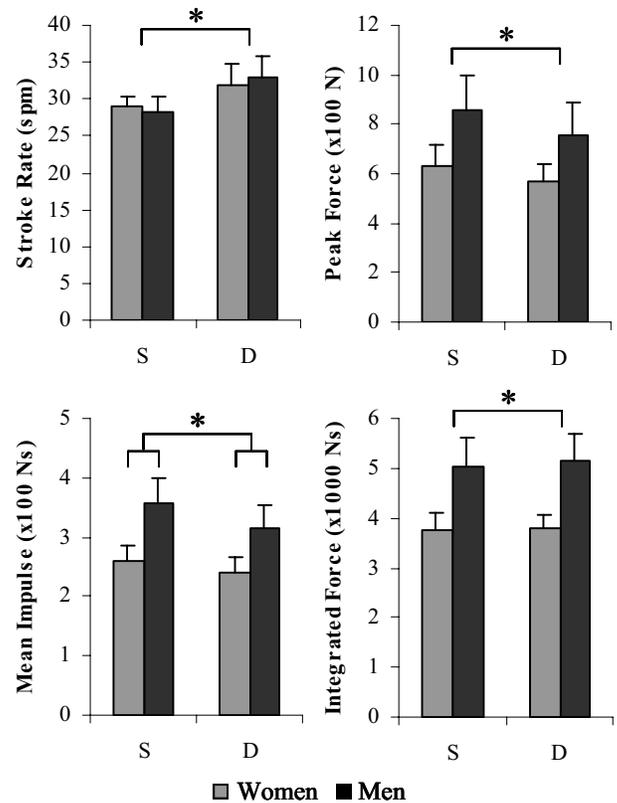

A load cell (Bertec, 2200 N) mounted between the handle and chain provided stroke rate, peak force, mean impulse, and total integrated force (representing work) for the final 30 seconds of each trial. Differences by condition and sex were located with a 2x2 repeated measures ANOVA ( $\alpha=0.05$ ).

### RESULTS AND DISCUSSION

Rowers displayed significantly higher stroke rate and total integrated force, and significantly lower peak force and mean impulse in the dynamic condition than in the stationary (Figure 1). Men exhibited significantly greater peak force, impulse, and integrated force than women. An interaction occurred whereby men decreased impulse on the dynamic ergometer more than women.

The statistical difference in integrated force implies that more work was performed on the dynamic ergometer. Although this is contrary to the literature [1], the small effect size (0.09) indicates minimal practical difference. Measurement over the entire bout could clarify this discrepancy.

These results support the suggestion that dynamic ergometers might reduce injury risk [1], given that the body is subjected

**Figure 1:** Mean (+SD) stroke rate, peak force, impulse per stroke, and total integrated force on the stationary (S) and dynamic (D) ergometer for women and men. An asterisk indicates a statistically significant difference by condition.

to lower peak forces and load (impulse) during each stroke. It is likely that the reduced musculoskeletal stress is paired with greater cardiovascular stress, in the form of higher stroke rate.

### CONCLUSIONS

The dynamic ergometer appears to be more useful for training rowers during the sprinting season, when high stroke rates are desired. Training for strength and endurance might be more effective with the stationary ergometer, providing sufficient overload for muscle and connective tissue development.

## Accuracy of Three Mathematical Models vs. Human Trained Paralyzed Muscle

Laura A. Frey Law and Richard K. Shields

Graduate Program in Physical Therapy & Rehabilitation Science, The University of Iowa  
 1-252 MEB, Iowa City, IA 52242 USA; email: [laura-freylaw@uiowa.edu](mailto:laura-freylaw@uiowa.edu)

### INTRODUCTION

Paralysis due to chronic spinal cord injury dramatically decreases physical function, can induce transformation towards fast fatigable muscle fibers [1], and can result in life threatening musculoskeletal deterioration (e.g. pressure ulcers, osteoporosis). Electrical stimulation may be able to improve function of paralyzed muscle and isometric muscle training may attenuate various neuromuscular and skeletal adaptations. Previous work has demonstrated that several mathematical muscle models can represent chronically paralyzed human muscle (untrained) to assist in the development of optimal activation strategies for specific muscle force doses [2]. However, no previous studies have evaluated the ability of mathematical muscle models to represent altered muscle contractile properties resulting from repetitive activation (training) in paralyzed muscle. The purpose of this study was to compare the force predictions of three available muscle models (one linear and two nonlinear) versus human trained (> 1 year) paralyzed muscle.

### METHODS

Isometric soleus forces were obtained from 4 individuals with complete spinal cord injury (SCI, 1.5 to 4.2 yrs) who had been continually training their left soleus muscles since the acute injury stage (~6 weeks post injury). Three models of varying complexity, a Hill based nonlinear (Hill NL, [3]), a 2<sup>nd</sup> order nonlinear (2nd Ord NL, [4]), and a simple 2<sup>nd</sup> order linear model (Linear), were parameterized using a single force train resulting from a variable ramp of increasing and decreasing stimulation frequencies [4]. The optimal parameter values were then used to predict forces for 9 trains (5, 10, and 20 Hz constant, CT, doublet, DT, and dual doublet, DDT, trains) for each model. Model errors were determined relative to the experimental results for each subject (Matlab 6.0) as an overall error (% error) and specific force property errors: peak force (PF), force time integral (FTI), time to peak tension (TPT), half-relaxation time (HRT), relative fusion index (RFI), and doublet difference (DDiff) to estimate the “catch-like” property of muscle. Model comparisons were made using repeated measures ANOVA, alpha = 0.05, with follow-up tests using Bonferroni correction for multiple comparisons.

The simplest model was the Linear model (3 parameters), followed by the 2<sup>nd</sup> Ord NL model (6 parameters) and the

most complex was the Hill NL model (6 parameters). The Hill NL model was more complex than the 2<sup>nd</sup> Ord NL model because one of its differential equations had no analytical solution. Numerical analysis techniques (e.g. Runge-Kutta) were required adding to the computational complexity and processing time necessary for optimal convergence.

### RESULTS AND DISCUSSION

All three models provided reasonable estimates of force (< 20% mean error), but to varying degrees. Overall, human trained soleus muscle forces were best predicted by the Hill NL, followed by the 2<sup>nd</sup> Ord NL, and lastly the Linear model (Table 1). However, the 2<sup>nd</sup> Ord NL model often produced similar errors (p > 0.05) as the Hill NL model (e.g. PF, FTI, and DDiff). The 2<sup>nd</sup> Ord NL model had the greatest difficulty predicting TPT accurately, consistently under predicting contraction times. The simplest Linear model produced the greatest overall error, but had similar errors as the NL models for unfused constant frequencies (5 Hz CT). The relative degree of force fusion (RFI) was best predicted by the nonlinear models, but the Linear model provided reasonable predictions. All three models had difficulty predicting the “catch-like” property of muscle.

### CONCLUSIONS

The 2<sup>nd</sup> Ord NL model produced nearly equivalent force predictions as the Hill NL model, but with less model complexity. Further, the Linear model was the simplest model, producing reasonable force predictions for select force trains. These three models can provide reasonable estimates of human trained paralyzed muscle force, but the 2<sup>nd</sup> Ord NL model produced the best estimates most simply.

### INTRODUCTION

Physiological tremor is invisible mechanical vibration of body part. Finger and upper limb have been studied, but the other body parts like lower limb has not reported. The purpose of the study is to elucidate the function no knee joint by physiological tremor under various conditions.

### METHODS

Measurement system of physiological tremor of lower leg is shown in Fig.1. The knee angle  $\theta$  was hold by gazing on the marker connected to ankle with string. The ankle was fixed with use of equipment fastened the ankle (AFO). Tremor was detected by accelerometer (9G111BW, NEC Sanei) glued with both sides adhesive tape on the middle point between knee joint and ankle joint. Tremor was evaluated by total of power spectrum (TP) in frequency range from 0.5 to 50 Hz. The frequency range also divided into two frequency bands, lower band of 0.5 to 5 Hz and higher band of 5 to 50 Hz. The former and the latter showed reflex nervous component and central nervous component, respectively [1, 2]. Three kinds of experiments were performed: (1) Experiment of holding posture of lower leg in knee angle from 10 to 90 degrees, (2) Experiment of weight load of 5% to 40% MVC (Maximum Voluntary Contraction). (3) Experiment of muscular fatigue. The measurement time was 35 seconds for all the experiments. The subjects were ten aged 21 to 24 years old.

### RESULTS AND DISCUSSION

Results of (1) experiment of holding posture were presented in Fig. 2. The amplitude of the tremor shown in total power increased linearly as the knee angle  $\theta$  decreased and the change in lower band was larger than the higher one, but the peak frequencies for various angle remained constant. The function of reflex component was dominant in holding posture. The results of (2) experiment under weight load revealed the contribution of higher band when weight load was more than 20 % MVC. The peak frequency decreased significantly at the load more than 20% MVC. The results meant that the central nervous

component predominated under higher load. The results of (3) are shown in Fig.3. The relative total powers in both frequency bands after all out increased significantly compared with the value before the load. And the value of higher band was significantly larger than that of lower band. Just after the all-out state, the tremor holding posture was controlled by higher band component. The result revealed that the fatigue of central nervous was recognized predominantly.

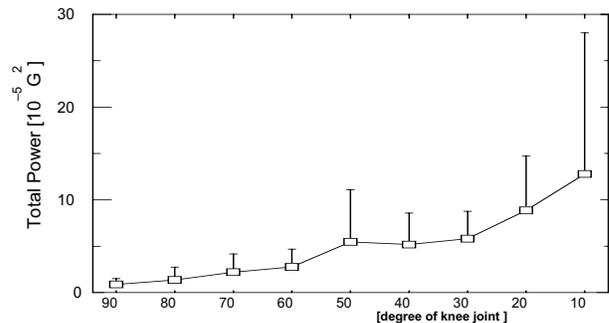

Figure 2: Total power (TP) in full frequency band (0-50Hz) for knee joint angle  $\theta$ .

### CONCLUSIONS

Characteristics of tremor of lower leg under the conditions of knee angle and weight load were obtained. Fatigue of knee joint was evaluated by the total power of the tremor. It was recognized that these results could be applied to the function of knee joint for disease person of knee joint as compared with the fundamental data evaluated in the study.

### INTRODUCTION

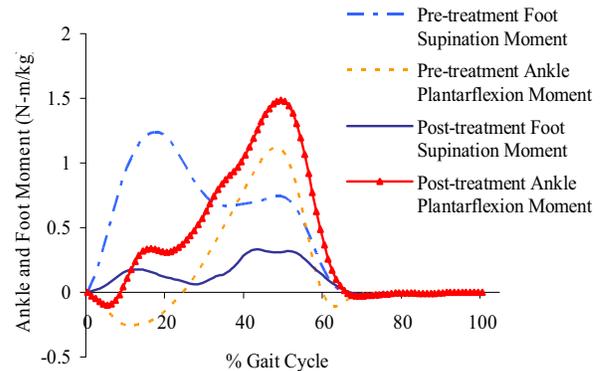

Myofascial pain syndrome (MPS) is a common clinical problem of muscle pain caused by myofascial trigger points (MTrPs). MTrP has been defined as the hyperirritable spot in a taut band of skeletal muscle fibers [1]. The majority of researches concerning the myofascial pain have been related to pain condition and the areas of head, neck, upper extremities, as well as back, but the lower extremity problems were generally overlooked. The purposes of this study were to investigate the influence of the chronic calf muscle tightness caused by myofascial pain syndrome on gait performance and the treatment effect in order to inform the clinical management of patients with inflexibility of calf muscles.

### METHODS

A female subject suffered from chronic knee and ankle pain for five years as a result of calf muscles myofascial pain syndrome. The pain intensity (Visual Analog Pain Scale), ranges of motion on ankle joints, and gait analysis were evaluated before and after myofascial pain therapy. The Expert Vision HiRes motion analysis system (Motion Analysis Corporation, CA, USA) equipped with 6 CCD cameras were synchronized with ground reaction forces measured by two forceplates (Kistler Instrument Corporation, NY, USA) and used to capture the subject's motion at 60 Hz sample rate. The 8-week calf myofascial treatment programs included manual techniques (deep myofascial release, deep friction massage, and proprioceptive neuromuscular facilitation stretching) and home program (self-stretching exercises).

### RESULTS AND DISCUSSION

There were significant improvements in the ankle-dorsiflexion ROMs of the affected leg after treatment ( $p < 0.01$ ). A trend of moderate improvement in pain conditions were recorded both in resting and after work. Although the kinematic data of gait analysis were quite similar across treatments except for improved knee flexion angles, the kinetic findings revealed significant effectiveness of myofascial treatments. The significantly decreased peak ground reaction forces ( $p < 0.001$ ), and significantly improved peak joint moments of ankle dorsiflexion ( $p = 0.008$ ), foot supination ( $p = 0.002$ ), and knee extension ( $p = 0.009$ ) were demonstrated during walking. This case study demonstrated the biomechanical abnormality of gait due to chronic myofascial pain in the calf muscles. This greater and prolonged dorsiflexion moment could be due to

**Figure 1:** The joint moments of ankle and foot across treatments throughout the gait cycle. (positive values: ankle plantarflexion and foot supination; negative values: ankle dorsiflexion and foot pronation).

greater demands of dorsiflexor muscles to maintain an appropriate heel strike as the result of the tightness of calf muscle. The significantly greater moments of foot supination in the stance phase before treatment may indicate that more supinator efforts to prevent excessive pronated foot that usually compensated for insufficient dorsiflexion flexibility [2]. The significantly greater knee extension moments caused the increase muscle loading of knee extensors and could be the result of excessive knee flexion angles during walking. The excessive knee flexion angles were the obligatory compensation for tight calf muscles in order to have a nearly normal ankle-foot motion. The myofascial treatments improved the clinical symptoms and kinetics of gait.

### CONCLUSIONS

The chronic muscle tightness caused by myofascial pain syndrome is a factor influencing the joint motion and easily ignored by clinicians. The quantitative gait analysis is valuable and necessary to clarify the influence of the chronic calf muscles tightness on ankle and knee joints and the effectiveness of myofascial treatments.

## BIOMECHANICAL EFFECTS OF PLANTAR FASCIA RELEASE AND POSTERIOR TIBIAL TENDON DYSFUNCTION- A FINITE ELEMENT AND CADAVERIC FOOT SIMULATION

<sup>1</sup>Jason Tak-Man Cheung, <sup>1</sup>Ming Zhang and <sup>2</sup>Kai-Nan An

<sup>1</sup>Rehabilitation Engineering Centre, The Hong Kong Polytechnic University, Hong Kong, China,

<sup>2</sup>Biomechanics Laboratory, Department of Orthopedic Surgery, Mayo Clinic, Rochester, Minnesota, USA;

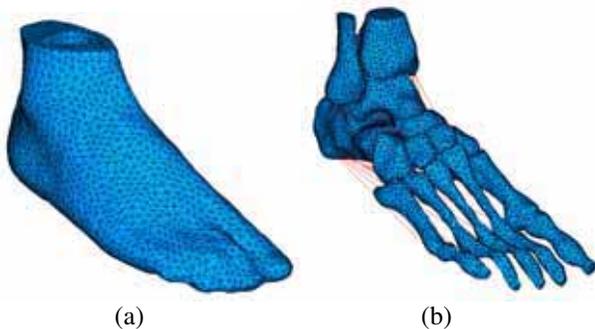

email: [jason.cheung@polyu.edu.hk](mailto:jason.cheung@polyu.edu.hk)

### INTRODUCTION

The plantar aponeurosis and the posterior tibial tendon are important for maintaining the normal foot arch. Failure or dissection of these structures may lead to arch instability and increase the load bearing of surrounding structures of the foot such as the interlocking tarsal joints, joint capsules and plantar ligaments. In this study, a finite element (FE) and cadaveric foot simulation was done to investigate the biomechanical effects of plantar fascia release (PFR) and posterior tibial tendon dysfunction (PTTD).

### METHODS

A geometrical accurate FE model of the human foot and ankle was developed from 3D reconstruction of 2mm coronal MR images from the right foot of a normal male subject in the neutral unloaded position [1]. The FE model (Figures 1) consisted of 28 bony segments embedded in a volume of encapsulated soft tissue. A total number of 72 ligaments and the plantar fascia were included and defined by connecting the corresponding attachment points on the bones.

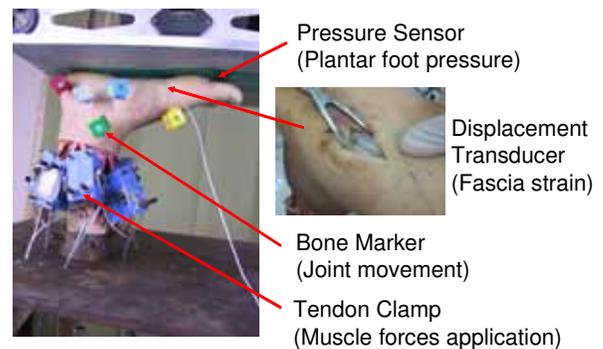

**Figure 1:** The FE meshes of the (a) encapsulated soft tissue, (b) bony and ligamentous structures.

A hyperelastic material model was adopted to represent the nonlinear and incompressible nature of the encapsulated soft tissue. Other tissues were idealized as homogeneous, isotropic and linearly elastic. The interactions among the bones were defined as contact surfaces to allow relative bone movements. Nonlinear contact stiffness was defined to simulate the contact behavior between the articulating surfaces. A horizontal ground support inclined at 10 degrees relative to the plantar foot was used to establish the frictional contact interaction of the foot-ground interfaces during midstance.

The superior surface of the soft tissue, distal tibia and fibula was fixed throughout the analysis. The ground support was constrained to move in the same direction of ground reaction force vector, which was applied perpendicularly at the inferior ground support. The extrinsic muscles forces during midstance

were estimated from muscles cross-sectional area and EMG data with a linear EMG-force assumption [2]. Musculotendon forces were applied at their corresponding points of insertion by defining contraction forces via axial connector elements. Simulation of PFR and PTTD were done by removing the plantar aponeurosis and the tendon forces from the FE model.

The FE predicted results were validated with experimental measurements on six cadaveric foot specimens under similar loading and boundary conditions. Quasi-static foot simulation was done to measure the relative bone rotation, plantar pressure and strain of the plantar fascia (Figure 2).

**Figure 2:** Experimental setup of cadaveric foot simulation.

### RESULTS AND DISCUSSION

Both PFR and PTTD decreased the arch height with the former having a greater effect. The reduction of arch height intensified with a combination of PFR and PTTD but did not cause total collapse of foot arch. Both PFR and PTTD increased the strains of the plantar ligaments. The effect of PTTD on the metatarsal stress distribution is minimal while PFR induced medial shift of peak von Mises stress from the third to the second metatarsal. The lack of foot arch support with PFR and PTTD may lead to attenuation of surrounding soft tissue structures and elongation of foot arch, resulting in a progressive acquired flatfoot deformity.

## ACTIVATION PATTERNS OF TRUNK MUSCLES DURING CYCLIC FLEXION-EXTENSION

Michael W. Olson and Li Li

Department of Kinesiology, Louisiana State University, Baton Rouge, Louisiana, USA

Email: molson2@lsu.edu

### INTRODUCTION

A high incidence of low back injuries has been reported in individuals employed in labor intensive work environments [1]. The interactions between the active and passive tissues of the lumbar spine are important factors to consider when identifying the etiology of these injuries [2]. Behavior of the lumbar muscles is affected by the changing mechanical properties of both active and passive tissues.

In healthy individuals the myoelectric activity of the lumbar muscles decreases during deep trunk flexion [3]. This event has been termed the flexion-relaxation phenomenon [4]. Mechanical load-sharing and neural mechanisms have been used to explain this event [4]. However, compensatory mechanisms must be initiated in order to offset the flexion moment applied at the lumbar spine.

The purpose of this study was to explore the behavior of the trunk muscles to identify mechanisms used to compensate for decreased lumbar muscle activity.

### METHODS

Data were collected from 13 asymptomatic males [age mean 20 ( $\pm$  SD 1) yrs., height 1.77 ( $\pm$  0.06) m, body mass 82 ( $\pm$  11) kg] who performed five separate cycles of trunk flexion-extension. Cycle duration was 10 sec and controlled with the tempo of a metronome. Once collected, the time series of each cycle was normalized to a percentage of the cycle.

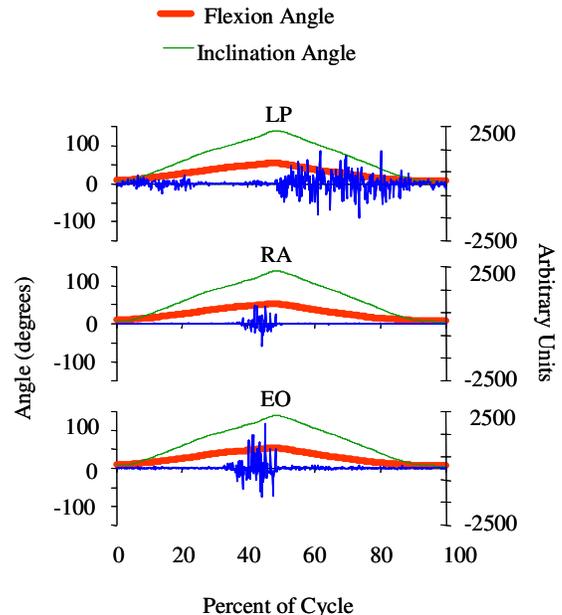

EMG signals were collected on the right side by pre-gelled Ag-AgCl electrode pairs. The muscles analyzed were the lumbar paraspinal (LP) at the L3-L4 level, the rectus abdominis (RA), and external oblique (EO). The inter-electrode distance was 2.5 cm from center to center.

Reflexive spheres, 2.5 cm in diameter, were taped onto the skin on the left side at the lateral edge of the twelfth rib, lateral midline of the iliac crest, and greater trochanter. These markers were used to represent trunk inclination and lumbar flexion angles. Kinematic and EMG data were temporally synchronized.

One-way ANOVA with repeated measures was used to evaluate the changes of each variable between trials. The alpha level was set at 0.05.

### RESULTS AND DISCUSSION

No trial effects were observed in the data, only means and sd are presented in here as a percentage of the cycle. The LP flexion-relaxation phenomenon occurred in all participants (cessation at  $34\pm 7\%$  and re-initiation at  $57\pm 7\%$ ). The EMG activity of the abdominal muscles, RA (n = 5) and EO (n = 7), were detected (initiation at  $42\pm 4\%$  and  $39\pm 5\%$ , cessation at  $54\pm 5\%$  and  $57\pm 5\%$ , respectively) at the deepest trunk inclination and lumbar flexion angles in about half of the

**Figure 1:** Exemplar EMG pattern of lumbar paraspinal (LP), rectus abdominis (RA), and external oblique (EO) muscles from one participant during a single trial of trunk flexion-extension.

participants (Figure 1). EMG activity of both RA and EO muscles was observed in four individuals. One individual had only RA activity and three had only EO activity detected during this time period.

The activation of the RA and EO muscles may serve to increase the intra-abdominal pressure (IAP). The IAP may also assist with the extension moment at the lumbar region. The involvement of the abdominal muscles leads to increased IAP support for the abdominal cavity. Elevated IAP results in a complementary reinforcement of the integrity of the lumbar vertebrae [5,6].

### CONCLUSIONS

Mechanisms responsible for the flexion-relaxation phenomenon need further examination. Likewise, compensatory mechanisms that respond to this myoelectric silent period also require additional attention.

## Measures of Postural Stability During Quiet Stance.

Geoff Walmsley, Alan Walmsley  
Massey University, Wellington, New Zealand  
email: [G.M.G.Walmsley@massey.ac.nz](mailto:G.M.G.Walmsley@massey.ac.nz)

### INTRODUCTION

The control of balance and postural stability has been studied extensively by biomechanists and roboticists, with many interesting results. Postural sway is inherent in all humans during both bipedal and unipedal stance. Time series data of the Center of Pressure (CoP) of a subject on a force plate are most commonly used to analyze postural sway. In this paper we will outline how the time series data may be manipulated to discover what types of process are active, and describe measures that distinguish each series. We follow Zatsiorsky's rambling/trembling concept introduced in [3,4], with particular emphasis given to comparative tests of stability in the elderly. The focus of this paper is to describe the random stochastic movements contained in the tremble component of Zatsiorsky's framework.

### METHODS

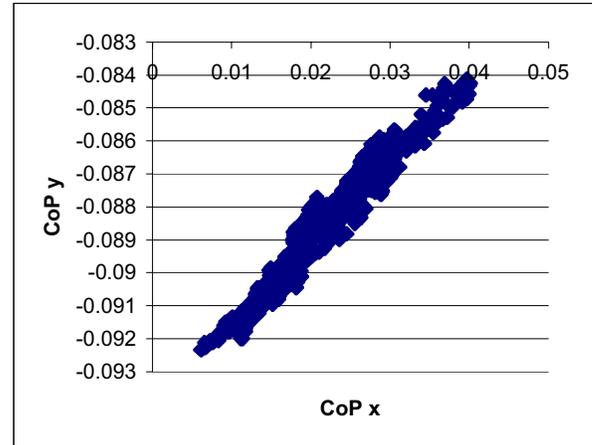

Force plate data were collected at 50Hz from 12 healthy subjects aged over 60. The data were processed to give (x, y)-coordinates of the CoP. After normalization and mean drift removal, we calculated the distribution of CoP movement in both anterior-posterior (AP) and medial-lateral (ML) directions.

We decided to model the migration of the CoP as a random walk in two dimensions, which is analogous to a particle undergoing diffusion. Inspection of the data revealed that the distribution of particle jump sizes was not Gaussian, and in fact, followed a stable distribution. Denoting the probability of finding the CoP at position  $x$  at time  $t$  by  $P(x, t)$ , then the fractional diffusion equation, which has the class of stable distributions as solutions, is given by

$$\frac{\partial P(x,t)}{\partial t} = -D \frac{\partial^\alpha P(x,t)}{\partial x^\alpha}, \quad (1)$$

where  $0 < \alpha \leq 2$ . In the case  $\alpha=2$ , the system is Gaussian, and we observe Brownian motion. This equation can be manipulated into an arbitrary dimensionality, with different  $\alpha$ 's in different directions [2]. The main feature of equation (1) is that the random walk described by this equation has large but infrequent particle jumps that drive the system.

Finally, a method was developed to calculate an individual measure of postural stability, based on existing theory in fractional calculus. For this, the multiscaling fractional advection-dispersion equation, examined thoroughly in [2] was used. Although heavily mathematical, the theory allows simple computation on data sets to obtain a measure of stability based on the exponent  $\alpha$  in both the AP and ML directions.

### RESULTS AND DISCUSSION

In the data analyzed to date, estimated  $\alpha$  values were reduced when subjects moved from bipedal to unipedal stance. There was a further reduction of  $\alpha$  when subjects closed their eyes. Figure 1 shows the change in CoP coordinates between consecutive samples for a subject in unipedal stance with eyes closed. Clearly the graph is suggestive of a high correlation between AP and ML movements. Using the multiscaling fractional advection-dispersion equation, we can use this correlation to find the real value of  $\alpha$  in each direction.

### CONCLUSIONS

From the data collected so far, it is clear that the rambling/trembling framework provides an excellent starting point for describing postural sway. Using the Lambda Model of [1] to describe the main cyclic component of sway combined with the random behavior observed, it is possible to come up with a measure of stability for each subject akin to the concept of Value at Risk (VaR) for a stock portfolio. VaR measures the risk in holding a correlated portfolio of stocks. This would provide a method of indexing subjects according to their relative stability with a minimum amount of a data collection required, which may prove particularly helpful in analyzing changes in stability over time.

### INTRODUCTION

Nowadays, tennis players are looking to try anything to gain a slight edge over an opponent. Tennis coaches and players are continually searching for ways to improve performance. Past review studies have discussed about the angle at which a ball rebounds from the ground on different types of court surfaces. When a ball bounces on the court, its horizontal speed is usually reduced somewhat by its interaction with the court surface. There are only two characteristics of a court surface that influence what the ball does when it bounces. These are the coefficient of restitution (COR) and the coefficient of friction (COF) between the ball and the surface (Brody, 1987). Brody who derived mathematical relationships between the angles and speeds of a ball before and after the bounce had carried out a theoretical analysis of the bounce process earlier. He distinguished two types of bounce – a low angle high speed bounce (such as the service) when the ball slides along the bounce contact without rolling. At higher angles and lower speeds, such as lobs, volleys etc, the ball rolls during the bounce contact with the surface and the characteristics of the bounce are quite different from the sliding bounce. The purpose of this study was to investigate the effects of the slice backhand with different ball speeds on the bounce angle.

### METHODS

Three male tennis players, who rank in the top five domestically, were used as subjects of this study. The court surface was an indoor hard-court with various acrylic types. A ball projector was positioned on the service line. The projector ejected balls without appreciable spin at muzzle speed of 35 miles/ hrs. The high-speed video camera was positioned on the ground and about 6m at a distance from the center of the target area. Three male tennis players were asked to stand on the baseline and strike slice backhand for measurements on two different ball speeds – a fast ball (above 50 miles/ hrs) and a slow ball (below 45 miles/ hrs). From these 40 sliced backhand strikes (20 fast balls and 20 slow balls) were subsequently analyzed. The speed gun captured the maximum speed of the ball after being struck by the tennis racquet and direct reading ball speed. The ball trajectory was recorded on a high-speed video camera to determine the bounce angle. Each ball was filmed with 60 frames per second (fps). The frames of each selected slice backhand were stored using a PC and re-digitized and analyzed with a Peak Performance System. The press mouse button was pressed for marking the ball trajectory and court surface when the frame was displayed. We then, printed out the ball trajectory chart from PC. The incident angle and the rebound angle were calculated using a protractor. Mean, standard deviation as well as ball speed, incident angle, rebound angle and the angle difference were determined.

Statistically relevant differences were assessed using the dependent T-test.

### RESULTS AND DISCUSSION

There is significant difference between the fast ball and slow ball with backspin in incident angle, rebound angle and the angle difference. Both fast ball and slow ball, rebound angle was larger than incident angle. Furthermore, the results showed that there was a significant negative correlation found between the ball speed and incident angle, the ball speed and rebound angle. ( $p < 0.01$ ). It showed that the slice backhand with a faster ball speed had less incident angle, rebound angle. Groppe (1984) showed that, due to frictional factors and the coefficient of restitution between the ball and tennis court, however, the angle of rebound was almost always greater than the approach angle. Bill Murphy and Chet Murphy (1987) indicate that the fast ball with backspin travels in a low trajectory; the ball will skid and remain low as it bounces. As for the slow ball with backspin, High- speed film analyses demonstrate that a soft, lazy ground stroke hit with backspin will cause the shot to sit up and give the opponent a chance for an easy return (Groppe, 1992). Tennis players cannot obtain the ball speed if players hitting the ball without forward motivation. If players chop at the ball, the ball just has spin without forward power (Tony Trabert, 1996). Therefore, a nice slice backhand not only with the fast ball speed but also it has less incident angle and rebound angle.

### CONCLUSIONS

Elite tennis players take advantage of a short ball with a slice backhand and hit the ball deep and advance to the net behind the shot. When a under spin shot is hit with a high speed, its incident angle to the court will be low causing it to skid and remain low after the bounce. This forces the opponent to hit upward on the ball so it will clear the net, thus allowing ample time to reach a good volleying position. According to these results, tennis coaches should integrate special training for forearm action as standard practice.

**The Correlation between Energy Absorption Ratio and Pain Score of the Upper Extremity  
 under Different Fall Heights**

You-Li Chou<sup>1</sup>, Pei-Hsi Chou<sup>2</sup>, Hung-Yu Chen<sup>1</sup>, Shen-Kai Chen<sup>2</sup>,

<sup>1</sup> Center of General Education, Chang Jung Christian University, Tainan, Taiwan

**INTRODUCTION**

A fall onto the outstretched hand is the most common cause of upper extremity injury, including approximately 90% of fractures at the distal radius, humeral neck, and supracondylar region of the elbow. In the study by Chou et al. [1] found if the elbow flexed instead of outstretched after impact would decrease the ground reaction forces. They suggested the elbow-flexed motion represents the effects of damper and spring. In the whole, the total dissipation energy produced by shoulder moment is larger than dissipation energy produced by elbow moment; this means that the shock-absorption effect of shoulder is stronger than that of elbow. Since elbow joint and shoulder joint play important roles to absorb impact energy during falls. The purpose of this study is to find the best joint energy distribution between elbow joint and shoulder joint.

**METHODS**

The ExpertVison motion system (Motion Analysis Corp., Santa Rosa, CA, USA) with six 120 Hz cameras and two 1000 Hz Kistler force-plates (Type 9281B, Kistler Instrument Corp., Winterthur, Switzerland) was used to measure relative joint positions and ground reaction forces.

The subjects were dropped from a height of 10 cm and 20 cm (i.e. distance between the outstretched hand and the force plate), and fell onto two hands. The angle between the trunk and the upper arm is maintained at 60° forward flexion of the shoulder. A questionnaire was also designed to record each subject's sensation of pain or uncomfortable index during the impact. The index ranged from 0 to 10, and higher score means more uncomfortable.

**RESULTS AND DISCUSSION**

Table 1. is the grouping result of all subjects when h=10 cm.

Table 1. energy absorption ratio (h=10 cm)

	comfortable	moderate	uncomfortable
1	1.45	1.50	1.62
2	1.41	1.57	1.60
3	1.69	2.00	2.29
4	1.28	1.38	1.57
5	1.84	1.85	2.08
6	1.53	1.79	2.13
7	1.51	1.55	1.73
8	2.02	2.18	2.45
9	1.66	1.69	1.79
10	1.61	1.69	1.71

Table 2. is the result of the subjects when h=20 cm.

Table 2. energy absorption ratio (h=20 cm)

	comfortable	moderate	uncomfortable
1	1.59	1.67	1.76
2	1.63	1.76	1.89
3	2.00	2.28	2.35
4	1.47	1.57	1.64
5	1.99	2.16	2.17
6	1.71	2.24	2.34
7	1.73	1.73	2.01
8	2.14	2.44	2.63
9	1.78	1.79	2.10
10	1.78	1.85	1.90

Different energy absorption distribution between shoulder joint and elbow joint makes different kind of feeling to the subject. The most comfortable group has the smallest energy absorption ratio since the most uncomfortable group has the highest ratio. In the other words, the most comfortable group has the best energy distribution. In this experiment, all the energy absorption ratios are bigger than 1. So shoulder joint plays the important role during the impact. But smaller ratio makes subjects feel better. If elbow joint can help to share the energy absorption, it is the better way to prevent subjects from injury. Otherwise, when the falling height is higher, the ratio is getting bigger and bigger. That means that we normal people used to use our shoulder to absorb the impact energy. It is not a good way during the impact.

**CONCLUSIONS**

In this study, different energy absorption ratio really makes subjects feel different. Smaller energy absorption ratio makes subjects feel better. If we can use our elbow joint to help absorbing more energy, it is the better way for us to prevent from injury.

## PREHENSION SYNERGIES: TRIAL-TO-TRIAL VARIABILITY AND PRINCIPLE OF SUPERPOSITION DURING STATIC PREHENSION IN THREE DIMENSIONS

<sup>1,2</sup>Jae Kun Shim, <sup>1</sup>Mark Latash and <sup>1</sup>Vladimir Zatsiorsky  
<sup>1</sup>The Pennsylvania State University and <sup>2</sup>University of Maryland

### INTRODUCTION

Multi-digit prehension is performed by a redundant system (the hand) which exerts numerous combinations of digit forces and moments to produce a required output of a hand-held object. The human central nervous system (CNS), confronts a choice of selecting a solution of digit forces and moments from an apparently infinite set (Bernstein 1967).

According to the principle of superposition suggested in robotics (Arimoto et al. 2001), some actions can be split in several subtasks that can be controlled by independent control processes. In two dimensions, both simulations of a two-digit robot grasping and experiments with multi-digit human grasping (Shim et al. 2003a; Zatsiorsky et al. 2004) have confirmed the principle of superposition showing the existence of two decoupled subgroups of elemental variables (digit forces and moments): one related to adjustments of the grasping forces, ‘*grasp control*’ and the other associated with control of rotational equilibrium of the hand-held object, ‘*torque control*’. In the current study, we tested the principle of superposition during multi-digit human prehension in three dimensions (3D).

### METHODS

Subjects held a customized handle statically twenty-five times under each of seven external torques (ranged from -0.7 to 0.7 Nm) about a horizontal axis (*X*-axis) in a plane passing through the centers of all five digit force sensors (the grasp plane; Shim et al 2004). *Y*- and *Z*-axes were respectively defined as a vertical axis and an axis perpendicular to *X*- and *Y*-axes. Three force and moment components in 3D were recorded from each sensor.

Regression analysis and principal component analysis (PCA) with varimax rotation and Kaiser criterion were performed on elemental variables (forces and moments) of the thumb and virtual finger (VF: an imagined finger producing a wrench equal to wrenches generated by individual fingers; McKenzie and Iberall 1994; Shim et al. 2004).

### RESULTS

PCA performed on all thumb and VF forces and moments under each external torque condition generated three PCs (PC1 to PC3) which accounted for 94.80±0.65 % of the total variance (average ± SD across external torque conditions after the results were averaged across the subjects for each external torque condition). Among the three PCs, one PC had large loadings of thumb and VF grasping forces ( $F_Z^{vf}$  and  $F_Z^{th}$ ), Table 1. The rest two PCs had large loadings on the moments about *X*- and *Y*-axes, respectively. Therefore, the ‘*grasp control*’ variables ( $F_Z^{vf}$  and  $F_Z^{th}$ ) were decoupled from the ‘*torque control*’ variables (all of moment variables). These

findings were true for all external torque conditions in each subject.

Table 1. Loadings of principal components (PC1, PC2, and PC3) in all elemental variables under -0.70 Nm external torque condition of a representative subject.

Variable	PC1	PC2	PC3
$M_X^{vf(Y)}$	<b>0.89</b>	0.00	-0.27
$M_X^{vf(Z)}$	<b>-0.92</b>	0.02	0.26
$M_X^{th(Y)}$	<b>0.90</b>	0.03	-0.27
$M_Y^{vf(Z)}$	0.01	<b>-0.99</b>	0.07
$M_Y^{th(X)}$	0.00	<b>0.97</b>	-0.04
$M_Y^{th(Z)}$	-0.02	<b>-0.99</b>	0.06
$F_Z^{vf}$	-0.25	-0.10	<b>0.97</b>
$F_Z^{th}$	0.26	0.07	<b>-0.96</b>

$F_Z^{vf}$  and  $F_Z^{th}$  are VF and thumb forces along *Z*-axis (grasping forces).  $M_X^{vf(Y)}$  is a moment of  $F_Y^{vf}$  about *X*-axis and similar nomenclatures are applied to the other moment variables. The loadings with large magnitudes are shown in **italics**. Variables without significant loadings according to the Kaiser criterion are not included in the table.

### CONCLUSIONS AND DISCUSSION

The grasping control (the slipping prevention) is realized separately from other subtasks (e.g. maintaining the rotational equilibrium of the object about each axis in 3D) that have to be solved by the CNS during multi-digit prehension. The changes of the grasping forces ( $F_Z^{vf}$  and  $F_Z^{th}$ ) being perfectly matched to each other do not immediately affect the other variables. Therefore, we conclude that the principle of superposition is supported in a 3D static prehension.

### INTRODUCTION

The anterior cruciate ligament (ACL) injury is a common sports injury in basketball athletes [1]. It needs specific functional task for rehabilitation to assist athletes return to sports [1-4]. Enhance, understanding the safety and adequacy of those specific functional tasks is priority work. Therefore, the purpose of this study was to understand the muscle activation pattern of lower extremity muscles during performing specific functional basketball tasks.

### METHODS

Sixteen high school basketball players voluntarily participated this study (mean age: 18.25±2.78; mean height: 184.50±5.35; mean weight: 74.19±6.43). Four specific basketball tasks including sudden stop, jump shot, twist, and cross over movement were investigated in this study. Four channels of electronic signals were measured in this study. Quadriceps and hamstrings were measured by 2 EMG channels. The other channel was used to measure knee joint motion by electrogoniometer. The last channel was used to measure the foot-to-ground contact by self-designed foot switch. All signals were simultaneously collected with sampling 1000Hz. One-way ANOVA was used to examine the differences among four tasks' EMG activities. Scheffe's multiple comparisons were used to examine the difference between each test group.

### RESULTS AND DISCUSSION

The results showed that quadriceps and hamstring EMG intensities during sudden stop and jump shot were significantly higher ( $p<.05$ ) than cross over and twist. However, the hamstrings to quadriceps EMG ration showed that sudden stop and jump shot were significantly ( $p<.05$ ) less than cross over and twist.

Table 1 Parameters of four basketball tasks

Parameters		Sudden Stop		Jump Shot		Twist		Cross over	
		Mean	SD	Mean	SD	Mean	SD	Mean	SD

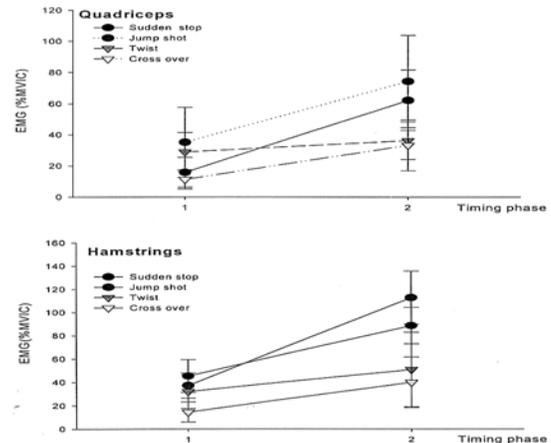

Figure 1: The EMG activation of lower extremities. 1 means pre-airing phase; 2 means landing phase.

### CONCLUSIONS

In order to protect a basketball athlete with ACL injury, the clinician and coach have to understand the safety priority among basketball tasks. Based on present study findings, we believed that the sudden stop and stop shot were more dangerous than cross over and twist. These findings can be implicated in knee rehabilitation program, especially in the return-to-sports phase [2-4]. The results suggest that exercise program of sudden stop and jump shot should be described on the last phase of knee rehabilitation program.

## BIOMECHANICAL ANALYSIS OF FOUR-WHEELED WALKER FOR AN ELDERLY PERSON

<sup>1</sup>Masato Takanokura, <sup>1</sup>Toshihiro Yamauchi

<sup>1</sup>Dept. of Industrial Engineering and Management, Kanagawa University, Japan; email: takanokura@ic.kanagawa-u.ac.jp

### INTRODUCTION

Japan goes toward a superannuated society. According to the population projects of National Institute of Population and Social Security Research in Japan, the percentage of the aged population of 65 years and up will reach 25.0% in 2017 [1]. To deal with the superannuated society, the activities of daily living (ADL) have attracted an attention in Japan. Walking is the most important in ADL because a fall of the elderly persons during walking leads to a high possibility of the disuse syndrome. A four-wheeled walker for an elderly person without some disease is a product to assist walking, to carry a baggage, and to take a rest on a street. We analyze the biomechanics of steady walking and step mounting using walkers by an articular angle and torque of a lower limb estimated by a video-based motion-analysis system.

### METHODS

The subject was five male students aged 20 to 23 years because we intended developing an analytical method for the biomechanics of elder walking using walkers. Although we used three kinds of walkers as shown in Figure 1 (Mutsumi Medical), we modified the rear wheels to avoid getting them and feet on a force plate by lengthening the wheel axes.

An angle and torque at a hip, a knee, and an ankle joint in a sagittal plane were analyzed by the motion-analysis system (Frame-DIASII, DKH). Reflective markers were attached to ten anatomical landmarks: shoulders, greater trochanters, knees, ankles, and toes. The marker position was estimated by using the DLT method from images filmed by four digital-video cameras of 60 fps (GR-DV5000, Victor). The angle was estimated from the marker positions. Ground reaction force was measured by force plates (9286A, Kistler) and charge amplifiers (9865E1Y28, Kistler). Torque was estimated by the inverse dynamics from the marker positions and ground reaction force.

We formed a floor of 3.6m by a force plate and aluminum floorboards for steady walking. The subject walked at a natural speed with the walker on the floor. We formed a step of 17cm by two force plates, floorboards, and a curb for step mounting. The subject first lifted up front wheels onto the step and then mounted the step along with the walker by lifting up rear wheels. He mounted with a load of 5kg on a basket of the walker and without a load.

Figure 1: Four-wheeled walkers for elderly person.

### RESULTS AND DISCUSSION

Figure 2 illustrates flexion torque at hip during steady walking. The ANOVA demonstrated that the main effect of the walker was significant ( $F(3,12)=10.67$ ,  $P<0.01$ ). *Post hoc* analysis showed that the walkers reduced flexion torque at hip ( $P<0.01$ ). Extension torque was not varied. Torque at knee showed similar results. The walkers reduced plantarflexion torque at ankle. The subject supports the body weight not only by the lower limb but by the upper limb through the handgrip of the walker. Articular torque of the lower limb did not depend on the structure of the walker because it went forward at a constant speed during steady walking. Walking using the walkers caused a smaller extension angle at hip, a larger flexion angle at hip, and a larger dorsiflexion angle at ankle.

Figure 3 shows flexion torque at hip during step mounting. The ANOVA demonstrated that the main effects of the walker ( $F(2,8)=10.62$ ,  $P<0.01$ ) and the load ( $F(1,8)=12.10$ ,  $P<0.01$ ) were significant. *Post hoc* analysis showed that the walker "Careman" with a load of 5kg caused larger torque. Torque to hip extension, to knee flexion and extension showed similar results. The handgrip of Careman is positioned just above the rear wheels. The larger moment caused by force to push down the handgrip is necessary to lift up the front wheels because the moment arm is shorter than the other walkers.

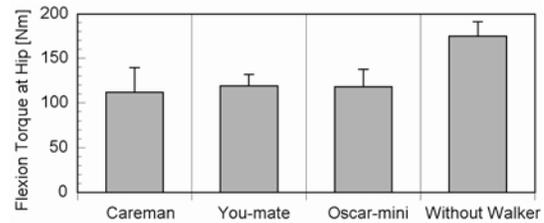

Figure 2: Flexion torque at hip during steady walking.

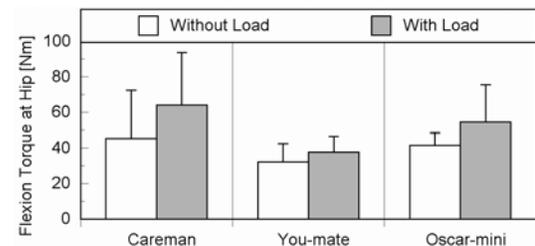

Figure 3: Flexion torque at hip during step mounting.

### CONCLUSIONS

During steady walking, the walkers reduce articular torque of the lower limb. During step mounting, torque depends on the structure of the walker and the load on the basket.

## A VIRTUAL TOOL FOR THE CLINICAL PLANNING OF THE ULNAR PALSY TREATMENT

<sup>1</sup>J.L. Sancho-Bru, <sup>1</sup>P.J. Rodríguez-Cervantes, <sup>2</sup>D.J. Giurintano, <sup>1</sup>A. Pérez-González and <sup>1</sup>M. Vergara-Monedero  
<sup>1</sup>Departament de Tecnologia. Universitat Jaume I, Castelló (Spain); correspondence email: [cervante@tec.uji.es](mailto:cervante@tec.uji.es)  
<sup>2</sup>National Hansen's Disease Programs, Baton Rouge (Louisiana)

### INTRODUCTION

Mechanical efficiency of the hand can be reduced because of different pathologies. One of these pathologies is ulnar palsy. Ulnar palsy is common in Hansen's disease patients. *Mycobacterium leprae* bacteria attack the ulnar nerve at the elbow level, which reduces the motor capability of the intrinsic muscles of the hand. This paralysis results in the *claw hand* deformity. It occurs because of the loss of the balance between the intrinsic and extrinsic muscles that power the hand [1].

Mathematical models of the finger have been used in the past to study different aspects of hand function. In this work, the use of a 3D model of the index finger for the clinical planning of the ulnar palsy treatment is investigated.

### METHODS

A biomechanical model of the finger previously developed by the researchers [2] was used to simulate the ulnar palsy and a tendon transfer for the restoration of the hand function.

The biomechanical model considered the finger as a skeletal open chain of 4 rigid bodies (the bones) connected to the carpus through different joints that characterize the kinematic behavior of the chain. The DIP and PIP joints were modeled as 1 degree of freedom joints capable of flexion-extension movements, while MCP joint is modeled as a 2 degree of freedom joint capable of flexion-extension and abduction-adduction movements with respect to a fixed metacarpal bone. The data for the location and orientation of the rotation axes came from An et al [3] and Brand and Hollister [1]. Muscles, tendons and ligaments control the movement of the chains. A total of 7 muscles (FP, FS, LU, DI, VI, EC and EI) were considered using a Hill's 3 component model that takes into account the muscle activation level and the force-length and force-velocity relationships, as well as the different index of architecture of muscles. Muscles transmit force to the tendons, which finally insert into the bones. To model the effect of tendons crossing the joints, straight lines connecting 2 points were considered, except for the extensors, for which Landsmeer's model I was used. Appropriate force balances were considered in the connecting points of this deformable tendon net, where tendon excursions were calculated by combining the excursions at each joint according to the tendon net configuration. Because tendons were assumed inextensible, tendon excursion defined the change in muscle length. Tendon paths came from the literature [3]. The collateral ligaments of the MCP joint were modeled as non-linear elastic elements.

First, the model was used to simulate the ulnar palsy. The paralysis of the ulnar nerve was modeled by reducing the PCSA of the intrinsic muscles (DI, VI and LU) proportionally

to the severity of the palsy. With this model, a search for feasible postures of the finger with ulnar palsy was performed. Moreover, the grasp capabilities of the normal and injured finger were compared for two different grasps (Table 1).

**Table 1:** Postures defining the grasps that have been analyzed.

Grasps	MCP flex	MCP abd	PIP flex	DIP flex
Wide	60°	0°	60°	45°
Narrow	30°	0°	45°	45°

Second, the model was used to simulate the tendon transfer of the PL muscle to restore hand function. This transfer was modeled by introducing the transferred tendon path in the model, which affected the MCP flexion-extension and abduction-adduction balances. With this model, a new search for feasible postures of the restored finger was performed, as well as the evaluation of grasp capability achieved after the restoration.

### RESULTS AND DISCUSSION

From the search for feasible postures performed with the ulnar palsy model, only feasible postures were found for a combination of MCP flexion angles smaller than 20° and PIP flexion angles greater than 90°, i.e. the model predicts that only clawing postures are possible when an ulnar injury occurs. On the other hand, the model predicted a greater reduction of the grasp capability for an 80% injured hand for wide grasp (81%), than for narrow grasp (51%), which agrees with literature [1]. Both results validate the model.

The model for the restored finger predicted feasible non-clawing postures, in contrast with the results of the injured finger model. On the other hand, the restored finger model predicted a 73% improvement of grasp capability for wide grasp and a 38% improvement for narrow grasp.

### CONCLUSIONS

Biomechanical models of the hand could be used as virtual tools to investigate the consequences of pathologies such as ulnar palsy and to check the advantages and disadvantages of the different clinical techniques that could be used to restore hand function.

## COMPUTER AIDED PRE-OPERATIVE PLANNING OF FRACTURE REDUCTION AND DEFORMITY CORRECTION IN TIBIA WITH HEXAPOD EXTERNAL FIXATOR

Sang Min Joo and Yoon Hyuk Kim  
School of Advanced Engineering, Kyung Hee University, Korea  
email: yoonhkim@khu.ac.kr

### INTRODUCTION

When the Ilizarov external fixator is used for fracture reduction and deformity correction, the planning for correction of 3-D multiple deformities is difficult due to the lack of information on required joint rotations and translations in order to correct the deformities [1]. In addition, if the rotational axis is not placed exactly with respect to axis of the deformity, the rotation may generate the unwanted translational shift at the fracture site [1, 2]. Hexapod external fixator, which is also known as the Taylor spatial frame, has an advantage to kinematically calculate the necessary translations of the telescopic struts in order to correct any 3-D deformities at the fracture site. The purpose of this study was to perform computer aided pre-operative planning of fracture reduction and deformity correction in tibia with single or double hexapod fixator system and to compare the results with the clinical ones.

### METHODS

Our procedure consisted of four steps (Figure 1). The 3-mm CT data of a tibia in pseudoachondro-plasia was digitized and transformed to the graphic model using the custom made program. Radiographic examination was performed to check the AP and lateral deformities at the proximal and distal bone segments before and after the deformity correction. We used conventional hexapod fixators or modified ones to a double hexapod system, which consists of three rings of 170 mm diameter and twelve telescopic struts of 90 mm length. We developed the CAD model of the fixator system using the CAD software, Solid Works®(Solidworks, USA). The necessary positions of six or twelve telescopic struts to correct given deformities were calculated using the program developed by the authors based on the forward kinematics of parallel manipulators [2-4]. From the calculated values of the telescopic struts, the computer graphic simulation of correction process was performed by simultaneous change of the struts based on simulation software, RecurDyn™ (FunctionBay, Inc, Korea). Finally, the results of planning were compared with clinical outcomes to evaluate the developed analysis and simulation techniques.

### RESULTS AND DISCUSSION

A fracture case with 15° of deformity in the AP plane and 15° of deformity in the lateral plane and a deformity correction case with 49° of proximal and 39° of distal deformities in the AP plane and 12° of proximal and 9° of distal deformities in the capital plane were corrected by the pre-operative planning. The graphic simulation could visualize the fracture reduction and deformity correction process by adjusting the telescopic struts simultaneously and showed possible clinical problems such as ring collision and excessive soft tissue distractions (Figure 2).

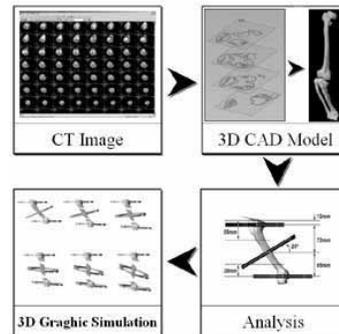

Figure 1: Procedure of computer aided pre-operative planning with double hexapod external fixator system

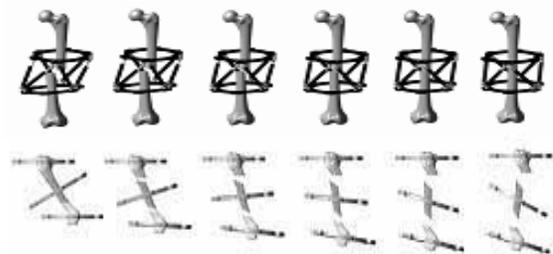

Figure 2: Graphic simulation of sequential adjustment for the fracture reduction (a) and the deformity correction (b)

Pre-op planning for correction of complex multiple deformities is often unavoidable and very difficult. The main reason for this difficulty is the six deformity parameters, which are three translations and three rotations, are coupled. The computer modeling and simulation techniques presented in this study could successfully perform the pre-op planning of tibia with hexapod fixators based on the kinematics analysis. The results showed that the computer simulation could visualize the fracture reduction and deformity correction procedure and check any surgical problems. This results support the feasibility of the computer-aided planning of fracture reduction and deformity correction.

## INCREASE OF LUMBAR SPINAL STABILITY UNDER FOLLOWER LOAD IN SAGITTAL PLANE

Kyungsoo Kim and Yoon Hyuk Kim  
School of Advanced Engineering, Kyung Hee University, Korea  
email: yoonhkim@khu.ac.kr

### INTRODUCTION

There has been a discrepancy between in vivo and in vitro experiments investigating the load carrying capacity of human lumbar spine. A follower load concept was introduced to explain this discrepancy [1]. A follower load is a compressive load applied along a path that approximates the tangent to the curve of the column. The trunk muscles are supposed to generate the follower load in vivo, but it is still difficult to assess the muscle contraction forces by experimental techniques. Hence a musculoskeletal modeling of the spine and trunk muscles is indispensable. The purpose of this study is to show that there is muscle activations generating the follower load and the lumbar spine is more stable under the follower load using the finite element model of the lumbar spine and trunk muscles in the sagittal plane.

### METHODS

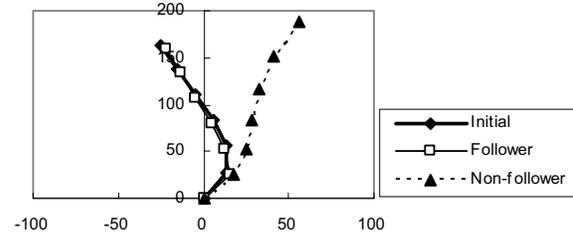

A two-dimensional finite element model of a human lumbar spine (T12-S1) and 66 pairs of trunk muscles was developed in the sagittal plane. Each motion segments were assumed to beam elements with elastic stiffness properties in [2], and the muscles were assumed to act statically. A follower load path was defined as having a direction parallel to the bisection of two adjacent segments at each node. At each node, the resultant joint force could be decomposed into two perpendicular force components, follower force in the follower load path direction and shear force.

The forces and moments used in the analysis consist of muscle forces and moments derived by muscle forces, motion segment forces and moments by the stiffness property, and applied external forces and moments. Since the number of unknowns including muscle forces and displacements exceed that of equations describing the equilibrium state of the lumbar spine model, the optimization technique was used. The cost function was the summation of squared muscle stresses and it was minimized in order to decrease the efforts of muscles. The follower load was represented by restricting the shear forces to zero at all vertebral body centers while the non-follower load was unconstrained at all about the shear force. The physiologic limits were assumed as in [2, 3].

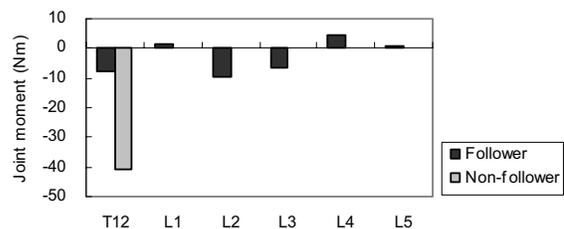

In this paper, the deformed shapes of the model and the muscle force combination were examined under the follower load and the non-follower load respectively when 410N of vertical load and 41Nm of moment were applied at T12. The corresponding resultant joint forces (the follower forces and the shear forces) and moments at all nodes were investigated

### RESULTS AND DISCUSSION

The patterns of muscle activity on the lumbar spine model generating the follower loads could be estimated under the given external load: 31 pairs of muscles were activated while no muscle acted on the lumbar spine under the non-follower load.

**Figure 1:** The initial posture of the spine model and the deformed shapes under the follower load and the non-follower load when the external load of 400N and 41Nm applied at T12

**Figure 2:** The joint moments at all vertebral body centers under the follower load and the non-follower load when the external load of 400N and 41Nm applied at T12

The deformed shape of the lumbar spine for the follower load was very similar to the initial posture of lumbar spine model in contrast to that for the non-follower load which assumed no muscle activation (Figure 1). The follower forces at all vertebrae under the follower load were around 1000N and there were no shear forces. In contrast, the magnitudes of shear forces were over 100N under the non-follower load though the follower forces were far below those under the follower load. The joint moments under the follower load were smaller than 10Nm while the external moment 41Nm was preserved at T12 under the non-follower load (Figure 2).

It was proved that the follower load could be successfully generated by trunk muscles from the observation that the shear forces were eliminated at all vertebral body centers in contrast with the non-follower load. Also, it was confirmed that the spinal stability under the follower load is much higher since the deformation of posture and the resultant joint moments were much smaller than those under the non-follower load. In addition, the validity of the investigated results is obtained by comparing with the previous studies [1-3].

## THE ROLE OF THE FEMORAL STEM IN THE STABILITY OF A METAL ON METAL HIP RESURFACING IMPLANT. AN RSA STUDY

<sup>1</sup> Itayem Raed, <sup>1,2</sup>Arndt Anton, <sup>3</sup>Derek McMinn, <sup>3</sup>Joseph Daniels and <sup>1</sup>Lundberg Arne  
<sup>1</sup>Karolinska University Hospital, Stockholm, Sweden

<sup>3</sup>Nuffield Hospital, Birmingham, United Kingdom  
email: itayem\_r@hotmail.com

### INTRODUCTION

The advantage with the minimal resectioning concept is that natural anatomy is more closely replicated than with traditional total hip replacement devices.

Today, the Birmingham Hip Resurfacing (BHR) metal on metal resurfacing implant is the golden standard. It has a narrow, strait femoral stem which requires good bone stock. In many cases, bone stock of the femoral head does not allow resurfacing arthroplasty such as in BHR. A short-stemmed device has been developed with a more robust, curved femoral stem. The load pattern of this type of device is expected to be different than that described in BHR [1] and the different lever arms resulting from the curved design of the stem may result in greater retroversion problems. Will this contribute to a different migration pattern and early loosening as a result?

### METHODS

For most joint implants, migration is known to correlate to loosening. Radiostereometric analysis (RSA) was used to measure migration, as this method has been proven to be superior to conventional radiography. This is an ongoing study, which at present includes 9 patients (8 male, 1 female; mean age 51.2, range: 33-62) with data up to 12-months post-operatively. All patients are physically active. Three 0.8 mm tantalum markers were attached on the tip and sides of the short stem implant and 5 – 8 markers were placed in the greater and lesser trochanters at the time of the hip arthroplasty. RSA evaluation was performed post operatively and at 2, 6 and 12 months follow-up. The first patients are expected for the 24-month follow-up this year.

The implant head centre was estimated from the acetabular cup circumference at the post-operative examination and calculated from femoral component markers in subsequent examinations. Standard RSA calculations were used to determine proximal/distal and anterior/posterior translation and implant rotation relative to the femur. The results were compared with the 2 years follow up of the BHR [1].

### RESULTS AND DISCUSSION

Migration values for the BHR were very small up to 2 years follow up. The pattern of migration over time indicated limited subsidence. The mean of the BHR migration is presented as a strait line in the figures of the individual results of each migration parameter of the short stem device.

*Short stem proximal translation:* Values were small. However 2 slightly higher individual distal translation values were seen at 6 and 12 months follow up.

*Short stem anterior translation:* 2 values were greater in the anterior and 1 value in the posterior direction. No consistent pattern was seen, fig. 1.

*Short stem Y rotation:* Small values were measured. However individual outliers were seen, fig.2.

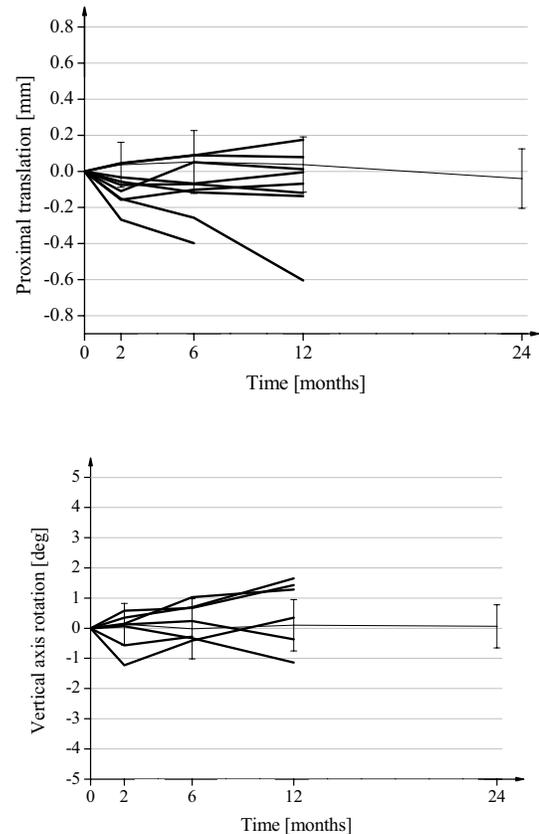

Figure 1. Proximal translation and vertical rotation of individual patients with the short stem hip resurfacing implant. The mean ( $\pm$  SD) of the BHR results is provided as a comparison.

### CONCLUSIONS

We found a tendency towards a greater distribution in vertical migration in comparison to the BHR design. A large variation and no clear pattern in anterior migration and individual outliers in rotation could be described. At the 12-month stage no migrations exceeding those expected for conventional hip replacements were found. A follow-up of 20 patients for 2 years will provide final results.

## NECK MUSCLE ACTIVITY DURING SHORT DURATION IMPACTS

Joseph Pellettiere, Mary Ann Sanders, and Erica Doczy  
AFRL/HEPA  
Wright-Patterson AFB, OH

### INTRODUCTION

Helmet-mounted systems, such as night vision goggles and helmet-mounted displays, are designed to enhance pilot performance; however, they may also affect pilot safety during ejection due to the change in helmet inertial properties. The effects of variable helmet weight and bracing ability on subject response during impact are unknown. A useful tool for investigating the mechanics of bracing and the relationships to helmet weight and impact acceleration is electromyography (EMG). In addition, EMG can be used to establish the relationship between the potential for neck injury and the force exerted by the neck muscles due to bracing. Two recent studies were conducted at Wright Patterson Air Force Base (WPAFB) to investigate the effect of helmet weight and subject bracing on human response during impact. A better understanding of the relationship between bracing and injury potential can be used to develop detailed instructions for pilots during their training to reduce their injury potential through proper positioning and bracing in the event of an ejection.

### METHODS

The methodology for collecting EMG data during short duration acceleration experiments was developed during a -Gx (frontal) impact study on the Horizontal Impulse Accelerator (HIA) at WPAFB. Male and female volunteer subjects, 10 of whom were instrumented with EMG sensors, participated with the approval of an Institutional Review Board (IRB). The MyoMonitor Portable EMG system from DelSys recorded the data separately from the rest of the response measurements, which included head and chest acceleration, belt loads and seat loads. Helmet weights ranged from 0 lb (no helmet) to 4.5 lbs, and acceleration levels were 6, 7, 8 and 10 g. The muscles of interest were those that play a major role in neck position and stability: the upper trapezius and sternocleidomastoid (SCM). Phillips et al. examined the characteristic changes in the EMG data from these muscles that was associated with isometric muscle fatigue [1]. Past research, however, does not quantify timing and level of muscular activation during short-duration impact events. The sensors were placed on the right and left upper trapezius and SCM, over the belly of the muscles.

The collection of EMG data continued during a study that examined neck muscle strength and response during vertical impact with a variable weighted helmet. Male and female volunteer subjects participated in this study on the Vertical Deceleration Tower (VDT), also located at WPAFB. Anatomical landmarks were used for consistency of sensor placement, on the right and left upper trapezius and SCM. An on-board data acquisition system was employed to easily record and synchronize the EMG data with other acceleration and load data. Maximum Voluntary Contractions (MVC) data were collected for each subject before the experiment. Helmet

weights were 3.0, 4.0 and 5.0 lbs, with acceleration levels of 6, 8 and 10g.

### RESULTS AND DISCUSSION

EMG data were collected for 29 of the HIA tests. Root Mean Squared (RMS) time histories of the EMG voltage were calculated for each successful data collection. RMS amplitude analysis indicated that, in general, the muscular strain increased with increasing -Gx acceleration levels. Activity of both muscle groups was synchronized, by their RMS values, with head and neck motion. It was demonstrated that in fact the neck muscles can respond quickly to the short-duration impacts. Furthermore, the EMG system was able to collect these changes during the impact.

No muscle activity was observed in the SCMs during the -Gx pre-impact bracing period, while measurable muscle activation occurred in the trapezius. This was to be expected since the bracing required of the subjects is that of an isometric extension action and the SCMs primarily act in flexion. The neck muscle activation level generally increased when heavier helmets were worn (Figure 1). This was expected since the bracing levels were similar and the heavier helmet would require higher activation levels to keep the head stable and prevent head rotation during impact.

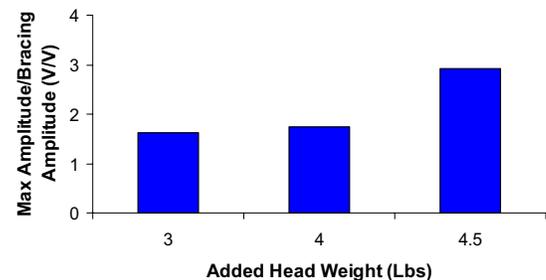

Figure 1. Increase of Trapezius activity with change in helmet weight during 8b impacts

### CONCLUSIONS

A method of collecting neck muscle activity data from the trapezius and SCM during short-duration impact experiments was successfully developed. EMG can be used to determine the activation timing of the muscles and to estimate the force produced by the muscles in a dynamic environment. This study showed that the muscles in the neck can and do react during the short time of these impacts. Because of these facts and this unique research, further studies are warranted to establish a relationship between potential for neck injury and muscle force.

### INTRODUCTION

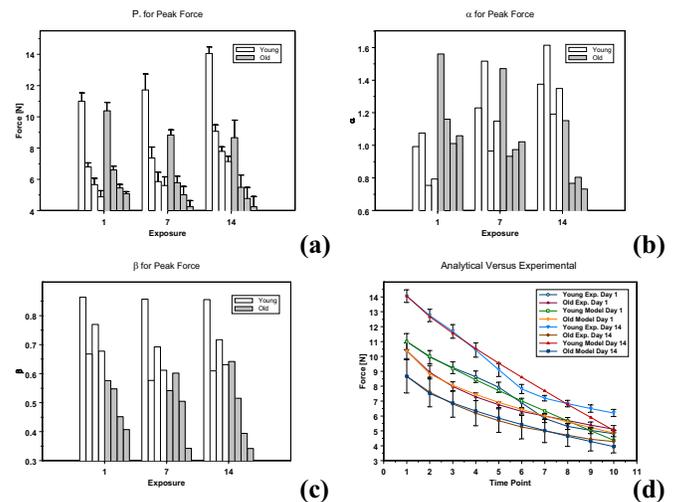

The 55-64 year old demographic comprises the fastest growing sector of the labor force in the United States. However, the effects of age on muscle response and injury resulting from repetitive exposures to mechanical loading have not been studied extensively. It is clear that susceptibility to contraction-induced injury increases with age in both humans [1], and animals [2]. The purpose of this research was to investigate if aging affects the ability of skeletal muscle to adapt to repetitive exposures of stretch-shortening cycles (SSCs). Skeletal muscle adaptation was assessed by characterizing changes in eccentric performance longitudinally during the chronic exposure period. We tested the specific hypothesis that young animals can adapt to repetitive mechanical loading of potentially injurious SSCs while older animals will not be able to adapt. Adaptation was defined by a maintenance or increase in eccentric muscle performance as a result of the repetitive exposures, while mal-adaptation was defined as a decrease in eccentric muscle performance as a result of the exposures.

### METHODS

Male F344 x BN F1 rats (N = 11) were obtained from the National Institutes on Aging colony. Young adult (N=6, 330g ± 28 g SD, 12 weeks of age) and old (N= 5, 588g ± 32 g SD, 30 months) rats were housed in an AAALAC accredited animal quarters. The dorsiflexor muscles were tested on a custom-built rodent dynamometer. The dynamometer provides precise control over the muscle length and muscle force output parameters to be studied. Rats were anesthetized with 2% isoflurane gas and placed supine on the heated x-y positioning table of the rodent dynamometer, with an anesthetic mask placed over its nose and mouth. The knee was secured in flexion (at 90 deg) with a knee holder. The young and old age groups were exposed to 80 total SSCs. The SSCs were administered in 8 sets of 10 repetitions each with 2 minute intervals between each set. Within each set, there was a rest of 2 s between each SSC. For each repetition, the muscles were activated for 100 ms and the SSC was initiated with a movement velocity of 60 deg/s over the prescribed range of motion of 90 deg to 140 deg ankle angle. The dorsiflexor muscles were then deactivated 300 ms later. Total stimulation time per repetition was 2.06 s. The exposure protocol and performance tests were administered three times per week for a total of 14 exposures over a 4.5 week period. The eccentric force response was modeled by identifying the peak force from each SSC, and then mathematically characterizing the change in those forces within each set of 10 repetitions and between set using a power law:  $T_i = f(t) = P_0 - \alpha \cdot t^\beta$

**RESULTS AND DISCUSSION** The peak eccentric force of the young and old age groups responded differently during the chronic exposure ( $p = 0.03$ ). The young and old groups were

not statistically different at the start of the protocol ( $p = 0.196$ ), but the young group produced statistically greater eccentric force by the 7<sup>th</sup> exposure ( $p = 0.0002$ ), and continued through the 14<sup>th</sup> exposure ( $p = 0.0001$ , Figure 1a). Model parameters ( $\alpha$  and  $\beta$ ) were quantified (Figs 1b and 1c) and the analytical model fit well to the experimental data for all sets throughout the exposure period (1<sup>st</sup>, 7<sup>th</sup>, and 14<sup>th</sup> exposures shown, Fig 1d).

**Figure 1:** (a) The peak eccentric force of the old and young groups for sets 1-8 of the first, seventh and fourteenth exposures. (b) Parameter ( $\alpha$ ) of the old and young groups for sets 1-8 of the first, seventh and fourteenth exposures. (c) Parameter ( $\beta$ ) of the old and young groups for sets 1-8 of the first, seventh and fourteenth exposures. (d) Analytical versus experimental response for 1<sup>st</sup>, 7<sup>th</sup>, and 14<sup>th</sup> exposures.

### CONCLUSIONS

Age negatively affects the ability to adapt to repetitive exposures of SSCs as evidenced by a significant increase in peak eccentric force in the young group as compared with the old group. Also, there was a statistically greater decline in peak eccentric force during each exposure in the old group as compared with the young group. The power law accurately characterizes the changes in eccentric force within each session, and across sequential sessions, and quantifies the difference in dynamic response between age groups during the 4.5 week exposure.

### INTRODUCTION

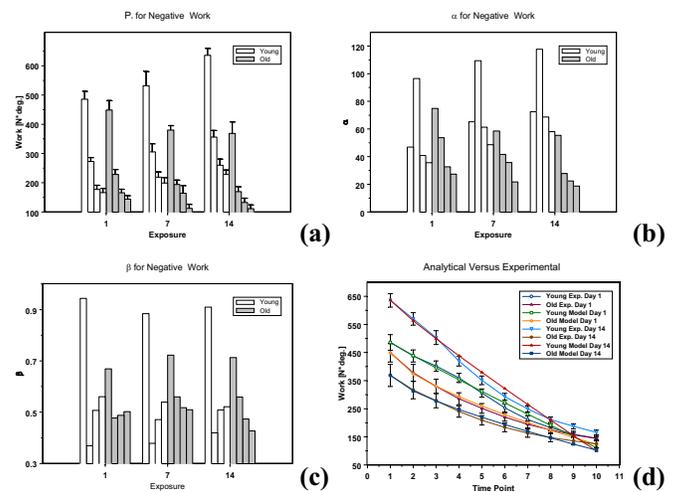

Musculo-skeletal injury in aged workers has been identified as an important research focus by The National Occupational Research Agenda [1]. However, the effect of age on skeletal muscle adaptation from repetitive mechanical loading has not been studied extensively. It is clear that susceptibility to contraction-induced injury increases with age [2]. The purpose of this research was to investigate if aging affects the ability of skeletal muscle to adapt to repetitive exposures of stretch-shortening cycles (SSCs). Skeletal muscle adaptation was assessed by characterizing changes in dynamic performance longitudinally during the chronic exposure period. We tested the specific hypothesis that young animals can adapt to repetitive mechanical loading of potentially injurious SSCs while older animals will not be able to adapt. Adaptation was defined by a maintenance or increase in eccentric (negative) work as a result of the repetitive exposures, while mal-adaptation was defined as a decrease in negative work as a result of the exposures.

### METHODS

Male F344 x BN F1 rats (N = 11) were obtained from the National Institutes on Aging colony. Young adult (N=6, 330g ± 28 g SD, 12 weeks of age) and old (N= 5, 588g ± 32 g SD, 30 months) rats were housed in an AAALAC accredited animal quarters. The dorsiflexor muscles were tested on a custom-built rodent dynamometer. The dynamometer provides precise control over the muscle length and muscle force output parameters to be studied. Rats were anesthetized with 2% isoflurane gas and placed supine on the heated x-y positioning table of the rodent dynamometer, with an anesthetic mask placed over its nose and mouth. The knee was secured in flexion (at 90 deg) with a knee holder. The young and old age groups were exposed to 80 total SSCs. The SSCs were administered in 8 sets of 10 repetitions each with 2 minute intervals between each set. Within each set, there was a rest of 2 s between each SSC. For each repetition, the muscles were activated for 100 ms and the SSC was initiated with a movement velocity of 60 deg/s over the prescribed range of motion of 90 to 140 deg ankle angle. The dorsiflexor muscles were then deactivated 300 ms later. Total stimulation time per repetition was 2.06 s. The exposure protocol and performance tests were administered three times per week for a total of 14 exposures over a 4.5 week period. The dynamic force response was modeled by calculating the negative work from each SSC, and then mathematically characterizing the change in negative work within each set of 10 repetitions and between set using a power law:  $T_i = f(t) = P_0 - \alpha \cdot t^\beta$

**RESULTS AND DISCUSSION** The ability to absorb negative work differed between age groups with subsequent exposures during the chronic exposure period (p = 0.011).

Negative work increased in the young group for sets 1-8 during the chronic exposure period, but remained static in the old group (Fig 1a). Negative work was not different with age at the 1<sup>st</sup> exposure, but was statistically higher in the young group by the 7<sup>th</sup> exposure (p = 0.001) and the trend continued at the 14<sup>th</sup> exposure (p < 0.0001, Fig 1a). Model parameters ( $\alpha$  and  $\beta$ ) were quantified (Figs 1b and 1c) and the analytical model fit well to the experimental data for all sets throughout the exposure period (1<sup>st</sup>, 7<sup>th</sup>, and 14<sup>th</sup> exposures shown, Fig 1d).

**Figure 1:** (a) The negative work of the old and young groups for sets 1-8 of the 1<sup>st</sup>, 7<sup>th</sup>, and 14<sup>th</sup> exposures. (b) Parameter ( $\alpha$ ) of the old and young groups for sets 1-8 of the 1<sup>st</sup>, 7<sup>th</sup> and 14<sup>th</sup> exposures. (c) Parameter ( $\beta$ ) of the old and young groups for sets 1-8 of the 1<sup>st</sup>, 7<sup>th</sup>, and 14<sup>th</sup> exposures. (d) Analytical versus experimental response for 1<sup>st</sup>, 7<sup>th</sup>, and 14<sup>th</sup> exposures.

### CONCLUSIONS

Age negatively affects the ability to adapt to repetitive exposures of SSCs as evidenced by a significant increase in negative work in the young group as compared with the old group. Also, there was a statistically greater decline in negative work during each exposure in the old group as compared with the young group. The power law accurately characterizes the changes in negative work within each session, and across sequential sessions, and quantifies the difference in dynamic response between age groups during the 4.5 week exposure.

### INTRODUCTION

Short-leg walking boots have gained popularity in clinical uses [1, 2] due to several advantages over traditional casts: ease of removal for examination and cleaning, edema treatment, less expensive, and a lesser adverse effect on kinematic and kinetic gait patterns than a synthetic walking cast [1]. They are commonly used in treatment of acute and chronic injuries, and post surgical interventions [3, 4]. Limited information is available on gait biomechanics while walking in these walking boots (walker) [1]. To the knowledge of the authors, no ground reaction force (GRF) profiles of walkers were documented in the literature. Therefore, the objective of this study was to examine the ground reaction force characteristics and lower extremity three-dimensional (3D) kinematics during walking wearing two different short-leg walking boots.

### METHODS

Eleven (5 females and 6 males) subjects (Age:  $27.4 \pm 7.8$  years, Body mass:  $72.0 \pm 13.4$  kg, Height:  $1.76 \pm 0.08$  m) participated in the study. The subject performed five level walking trials in each of three randomized conditions: two short-leg walking boots of Gait Walker (DeRoyal Industries, Inc.) and Equalizer (Royce Medical Co.) and one pair of lab shoes. A force platform (1080 Hz, AMTI) and a 6-camera motion analysis system (120 Hz, Vicon) were used to collect GRF and 3D kinematic data simultaneously during the testing session. A pair of photocells was used to determine and monitor the preferred walking speed during testing.

Kinematic and GRF data were smoothed at 6 and 20 Hz respectively, using a fourth-order Butterworth low-pass filter. The 3D kinematic variables were computed using Visual3D software suite (C-Motion, Inc.) in conjunction with a customized computer program. A one-way repeated measures of analysis of variance (ANOVA) was used to evaluate selected GRF and kinematic variables and post hoc comparisons were conducted with an alpha level ( $p < 0.05$ ) adjusted for multiple comparisons through a Bonferroni procedure.

### RESULTS AND DISCUSSION

In addition to two normal vertical GRF peaks associated with

**Table 1.** Average vertical GRF peaks (N/kg).

Condition	Max1	Max2	Max3
Shoe	--	$10.77 \pm 0.59$	$10.68 \pm 0.41$
DeRoyal	$8.91 \pm 1.49$	$10.27 \pm 0.72$	$10.47 \pm 0.59$
Royce	$7.37 \pm 2.74$	$10.72 \pm 0.61$	$10.43 \pm 0.44$

--: No apparent peak observed

the loading response (Max 2) and terminal stance (Max 3) in normal walking, one earlier peak (Max 1) occurs before the peak of loading response in the two walker conditions (Table 1). This peak was mostly absent in the shoe walking trials. The statistical comparisons showed no significant differences for the three peaks. Even though the first GRF peaks for the two walkers were below one body weight, it poses loading that may be detrimental to the injured foot/leg structure(s). This risen peak is related to the outsole material and the heel design of the walkers.

The ANOVA comparisons of joint kinematics suggested that the subtalar eversion range of motion (ROM) was greater for the DeRoyal compared to the no walker condition (Table 2). In addition, the hip abduction ROM for the DeRoyal and Royce walkers were significantly smaller than those for the shoes. These data suggest that both walkers restrict motions of the subtalar and hip joints in the frontal plane. Our data basically agreed with the findings of Pollo et al. [1] except for the maximum knee flexion in the earlier stance for the DeRoyal walker, which was greater than walking in the shoes. This may be related to the slight different ground reaction force profile for the condition.

### CONCLUSIONS

This study showed both short-leg walking boots, DeRoyal's Intuition Gait Walker and Royce's Equalizer, were effective in minimizing motion of subtalar eversion and hip adduction. Both walkers did not increase the two peak ground reaction forces observed in normal walking in shoes. However, they did impose a small initial peak (less than one BW) in early stance phase.

## STEPPING ON AN OBSTACLE WITH THE MEDIAL FOREFOOT: USE OF A 3D DYNAMIC CONTROL MODEL TO SIMULATE AGE AND NEUROPATHY

### INTRODUCTION

Approximately 24% of falls in the elderly occur while walking on irregular surfaces [1]. Irregular surfaces are known to increase the step width variability in the elderly, particularly those with peripheral neuropathy [2]. Bilateral ankle braces generally decrease this variability [3].

A previous study in healthy young women showed that unexpectedly stepping on a 15 mm-high object with the medial forefoot shifts the center of pressure (COP) medially, thereby decreasing the ankle eversion moment and increasing inversional stance foot acceleration [4]. Increased inversional foot acceleration has been associated with a narrowed recovery step, and sometimes even a crossover step [4].

Our goal was to develop a model to 1) simulate stance leg single support phase dynamics during a sudden medial shift in COP progression during gait, and 2) provide insights in how age, neuropathy, and attachment of an ankle brace might affect maximum inversional stance foot acceleration.

### METHODS

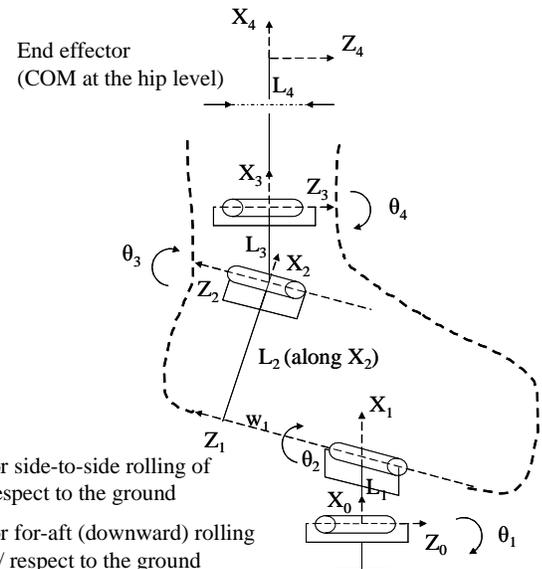

A 3D dynamic control model of the stance leg was developed to simulate an unexpected sudden medial shift in COP during the stance phase and to correctly reproduce angular dynamics comparable to those obtained from experimental studies (Figure 1). The equations of motion were implemented in a Matlab Simulink control model with anatomic joint torques under feedback control. The model was then 'aged' through a) reduction of the maximum torque inputs [5], b) adjustment of joint stiffness [6], and c) increased feedback delays [7]. Furthermore, the effect of neuropathic nerve conduction delays on inversional foot acceleration was investigated. Finally, attachment of an ankle brace was simulated by increasing the model's ankle stiffness [8].

### RESULTS AND DISCUSSION

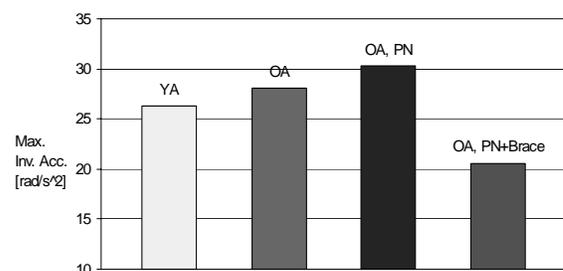

Aging the model resulted in increased maximum inversional foot acceleration in presence of a medial shift of the COP (Figure 2). Adjusting feedback delays to those of a neuropathic patient further increased inversional foot acceleration (Figure 2). However, simulating attachment of an ankle brace by increasing ankle stiffness resulted in decreased inversional foot acceleration (Figure 2).

### CONCLUSIONS

We conclude that the increased neural latencies and decreased muscle strength associated with old age and neuropathy act to increase maximum inversional stance foot acceleration following an unexpected medial COP shift. Bilateral use of ankle braces help reduce this effect.

**Figure 1:** Model schematic according to Denavit-Hartenberg convention: 2 segments (foot & leg) and 4 rotational joints. The COP (operating point,  $L1=0$ ) is represented by the 2 lower joints at a given time instant. The two upper (anatomic) joints represent inversion/eversion and plantar/dorsi flexion. Changes in  $w1$  correspond to COP forward progression, while changes in  $L2$  correspond to a medial shift of the COP.

**Figure 2:** Effect of age, neuropathy, and ankle brace on maximum inversional foot acceleration (YA: young adult, OA: old adult, PN: peripheral neuropathy).

## THE ORIGIN OF MECHANICAL INTERACTIONS BETWEEN ADJACENT SYNERGISTS IN RAT

### INTRODUCTION

It has been shown that adjacent synergistic muscles do not function as independent units with regard to force transmission. Length changes as well as position changes of a single muscle-tendon complex in rat do not only result in force changes of the muscle that is manipulated, but also in force changes measured at the tendons of adjacent synergists [1, 2]. The underlying mechanism for such mechanical interaction between muscles is force transmission to bone via pathways other than the muscular origin and insertion, i.e. epimuscular myofascial force transmission [3]. Two separate pathways for such force transmission exist: (a) connective tissue at the interface between muscle bellies (intermuscular) and (b) extramuscular connective tissues. As both myofascial pathways are possibly involved, the **purpose** of the present study is to investigate the origin of mechanical interactions between synergistic muscles.

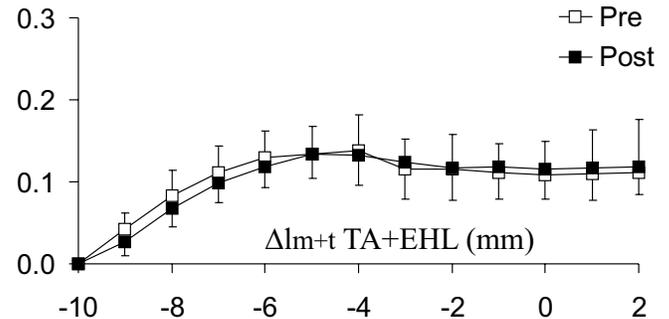

### METHODS

In male Wistar rats ( $n = 8$ ), the proximal and distal tendons of extensor digitorum longus (EDL) muscle as well as the tied distal tendons of tibialis anterior and extensor hallucis longus (TA+EHL) muscles were transected and connected to force transducers. Connective tissues at the muscle bellies of the anterior crural compartment were left intact. Supramaximal stimulation (100 Hz) of the common peroneal nerve excited all muscles maximally and simultaneously. Length-isometric force characteristics of distal TA+EHL were assessed. Simultaneously, forces exerted at the proximal and distal tendons of EDL, kept at constant muscle-tendon complex length and relative position, were measured. Intermuscular interaction was tested in two conditions: (a) after full longitudinal compartmental fasciotomy, and (b) after blunt dissection of the intermuscular connective tissue linkages between EDL and TA. Note that in the latter condition, intermuscular myofascial pathways were eliminated.

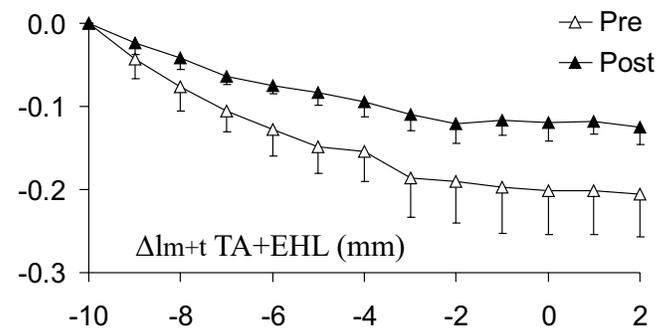

### RESULTS AND DISCUSSION

Distal length changes of TA+EHL altered proximal as well as distal EDL force, despite the fact that EDL muscle-tendon complex length was kept constant (Figure 1). Blunt dissection caused no changes of the TA+EHL length effects on *proximal* EDL force. This indicates that effects of TA+EHL lengthening on proximal EDL force are mediated predominantly by extramuscular myofascial force transmission. In contrast, the amplitude of change in the *distal* EDL force curve decreased significantly (by  $\approx 40\%$ ) subsequent to blunt dissection. Therefore, part of the change of *distal* EDL force is mediated by intermuscular myofascial force transmission.

$\Delta F_{ma}$  EDL *proximal* (N)

$\Delta F_{ma}$  EDL *distal* (N)

**Figure 1:** Changes of distal and proximal EDL active forces ( $F_{ma}$ ) as a function of TA+EHL muscle-tendon complex length.  $F_{ma}$  is expressed as the deviation from the initial value ( $\Delta lm+t$  TA+EHL = -10 mm): EDL *distal*  $F_{ma}$ , pre = 1.74 N (0.10) and  $F_{ma}$ , post = 1.67 N (0.14); EDL *proximal*  $F_{ma}$ , pre = 1.45 N (0.14) and  $F_{ma}$ , post = 1.42 N (0.17). Mean (SD),  $n = 8$ .

### CONCLUSION

It is concluded that mechanical interaction between synergists originates from both intermuscular as well as extramuscular connective tissues. The highest contribution, however, should be ascribed to the latter pathway.

## EVALUATION OF FIVE LIGAMENTOUS STABILIZERS OF THE SCAPHOID AND LUNATE

<sup>1</sup>Frederick W. Werner, <sup>1</sup>Walter H. Short, <sup>1</sup>Jason K. Green, <sup>2</sup>Haoyu Wang  
<sup>1</sup>SUNY Upstate Medical University, email: [wernerf@upstate.edu](mailto:wernerf@upstate.edu)  
<sup>2</sup>Bowling Green State University

### INTRODUCTION

Ligamentous injuries in the region of the scaphoid and lunate are painful and difficult to treat. This biomechanical study evaluated the function of the scapholunate interosseous ligament (SLIL), radioscaphocapitate ligament (RSC), scaphotrapezium ligament (ST), dorsal radiocarpal ligament (DRC), and the dorsal intercarpal ligament (DIC) and assessed the gap between the scaphoid and lunate. Our hypothesis is that the SLIL is the major stabilizer of the scapholunate joint.

### METHODS

Sixteen cadaver forearms were evaluated. Fastrak motion tracking sensors were used to measure the scaphoid and lunate motions. Each wrist was physiologically moved using a wrist joint simulator<sup>1</sup> through repetitive cyclic flexion/extension of the wrist (30° extension to 50° flexion) and wrist radial/ulnar deviation (10° radial deviation to 20° ulnar deviation). Carpal bone motion data were collected in the intact specimens, and in 8 arms after sequentially sectioning the ST, the SLIL, and the RSC. In eight additional arms, data were acquired after sequentially sectioning the DRC, the DIC, and the SLIL. Data were again collected after 1000 cycles of flexion/extension motion. Differences in motion were analyzed using a repeated measures 1 way ANOVA (Duncan's method,  $p < .05$ ). Three dimensional animated models were created of each wrist, based upon serial CT scans. The experimentally collected kinematic scaphoid and lunate data were used to drive the animated motions. To mimic the clinical measurement of carpal instability, the minimum distance between the scaphoid and lunate (excluding the cartilage) was calculated using these models for each arm and for each motion.

### RESULTS AND DISCUSSION

Sectioning of the ST alone produced no statistical changes in scaphoid or lunate angular position (fig 1). Additional sectioning of the SLIL resulted in statistically significant increases in scaphoid flexion and lunate extension during wrist flexion/extension and in lunate extension during wrist radial/ulnar deviation. Sectioning of the RSC after sectioning the ST and SLIL did not cause any additional significant angular changes. However, 1000 cycles of motion caused additional significant increases in lunate extension.

Paralleling the angular changes, there was no change in the gap between the scaphoid and lunate with sectioning of the ST ligament. An increase did occur with SLIL sectioning (fig 2).

In the second series of arms, sectioning of the DRC, or the DRC and DIC did not alter the scaphoid motion. Slight increases in lunate radial deviation were observed with sectioning of the DRC, or the DRC and DIC. Subsequent sectioning of the SLIL caused increases in scaphoid flexion, scaphoid ulnar deviation and lunate extension.

In comparing the two groups of arms, there was a greater increase in lunate radial deviation during wrist radial/ulnar

deviation after cutting the DRC, DIC, and SLIL and 1000 cycles of motion (Group 2) compared to cutting the ST, SLIL, and RSC and 1000 cycles of motion (Group 1). Group 2 visually demonstrated greater instability compared to group 1 as seen in the 3D animations of carpal motion.

### CONCLUSIONS

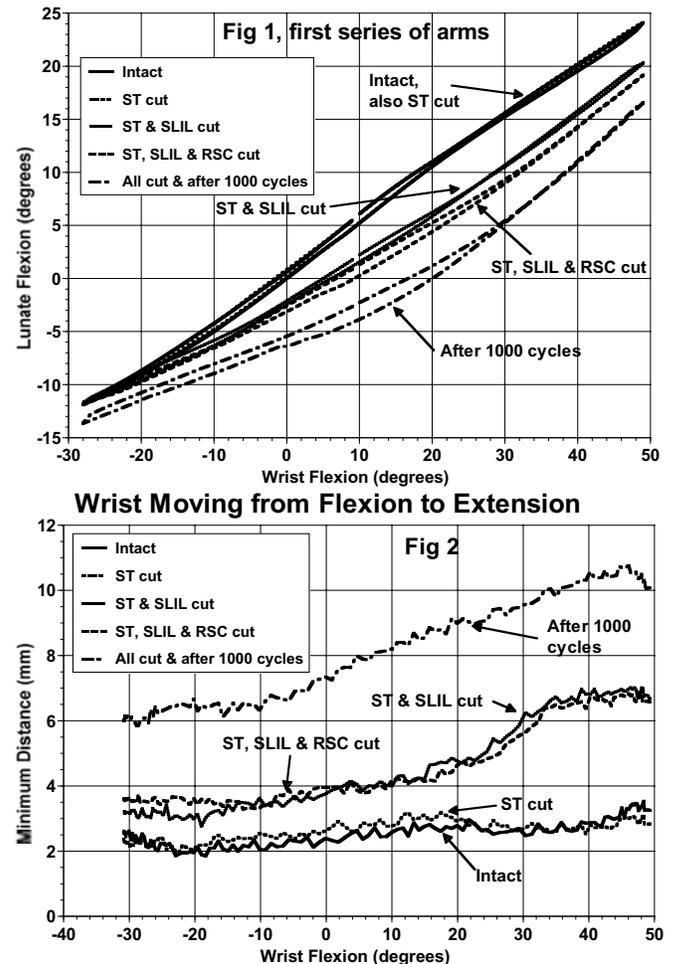

The SLIL was found to be the major stabilizer of the scaphoid and lunate. The RSC and ST are secondary support structures. The DRC and DIC also are secondary stabilizer structures, but may be more important than either the RSC or ST in stabilizing the scaphoid and lunate. Continued wrist use following ligament injury may result in further changes in carpal kinematics.

## A FIBER OPTIC BASED SENSOR FOR MEASURING CHEST AND ABDOMINAL DEFLECTION UNDER IMPACT LOADING

<sup>1</sup>Amber L. Rath, <sup>1</sup>Sarah J. Manoogian, <sup>1</sup>Stefan M. Duma, <sup>2</sup>Brady J. Bolton, <sup>2</sup>Jeff R. Crandall

### INTRODUCTION

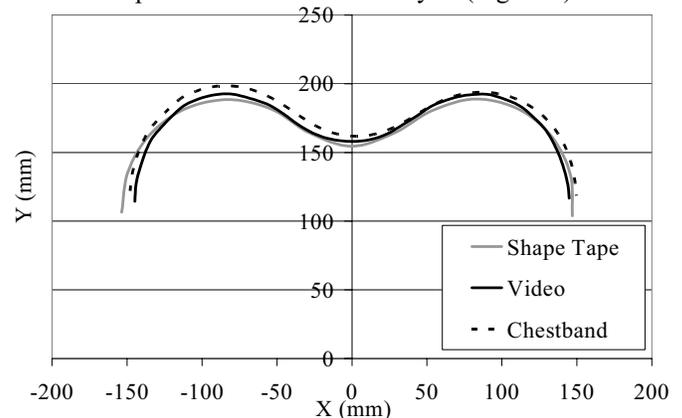

Deflection measurements need to be conducted on both crash test dummies and human cadavers in order to evaluate thoracic and abdominal injury risk. Because internal measurement is not always possible on human subjects, an accurate external measurement technique is desired. The objective of this study is to investigate the use of a fiber optic based sensor, ShapeTape, as an alternative method of measuring abdominal and chest deflection in impact biomechanics applications, and to compare its performance to the historically used chestband [1-3].

### METHODS

The ShapeTape used in this study was 101.2 cm x 1.6 cm x 1.5 mm with 32 sensors and was covered by a protective ribbed sheath with outside dimensions of 101.2 cm x 2.54 cm x 1.27 cm (Measurand Inc, S1680 Analog-output ShapeTape, New Brunswick, Canada). The chestband used in this study was 140 cm x 3.2 cm x 0.35 cm with 42 sets of 4 gauges along its length (Denton, 42 gauge chestband, Rochester Hills, MI). Drift, pressure, and temperature tests were conducted for ShapeTape alone under static conditions, whereas quasi-static and dynamic loading tests were conducted as comparison tests between the chestband and ShapeTape. For both the quasi-static and dynamic loading tests, a chest form was created to represent the torso of a 50th percentile Hybrid III dummy. The instrumented chest form was secured to a rigid base, which in turn was secured to the base of a material testing machine (Instron, Model 8874, Canton, MA). For both sets of tests, five cylindrical indenters were used measuring 5.08 cm, 7.62 cm, 10.16 cm, 12.70 cm, and 15.24 cm in diameter. For the quasi-static tests, the chest form was compressed by the arm of the impactor with a cylindrical indenter in 1 cm increments until a deflection of 6 cm was reached. For the dynamic tests, a loading rate of 150 cm/s was used to reach the target compression of 7 cm.

### RESULTS AND DISCUSSION

Over the period of three hours, there was an average voltage change of 0.26% full scale seen by the 32 ShapeTape sensors, with a maximum of 0.55% full scale drift. This amount of drift is considered negligible. Over the five minute heating of the ShapeTape, the sensors experienced an average voltage change of 1.20% full scale. For the range of forces experienced during distributed airbag loading, 250 N - 750 N, the sensor that was loaded had a 3.24% full scale voltage difference. For the range of forces experienced during focused belt loading, 1000 N - 1600 N, the sensor that was loaded had a 12.32% full scale voltage change. During quasi-static loading, the average error in measuring peak displacement was 3.35% and 1.70% for ShapeTape and the chestband respectively. The average error in measuring peak displacement under dynamic loading was 8.60% and 10.01% for ShapeTape and the chestband respectively. The contour representations of the chest form from the chestband and ShapeTape under both loading conditions were comparable to what was captured from the video analysis (Figure 2).

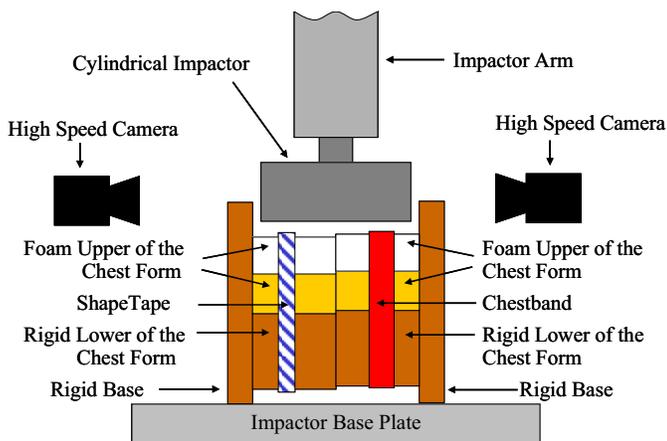

**Figure 2:** Chestband and ShapeTape contours compared to video data points, taken at 6 cm compression for the quasi-static compression test with a 10.16 cm diameter indenter.

### CONCLUSIONS

The contour output for the ShapeTape and chestband were both very similar to the video and overlapped in many cases. From the data collected in this study, ShapeTape appears to demonstrate the same degree of accuracy as the chestband in measuring deflection and visualizing contours during quasi-static and dynamic impact loading.

**INTRODUCTION**

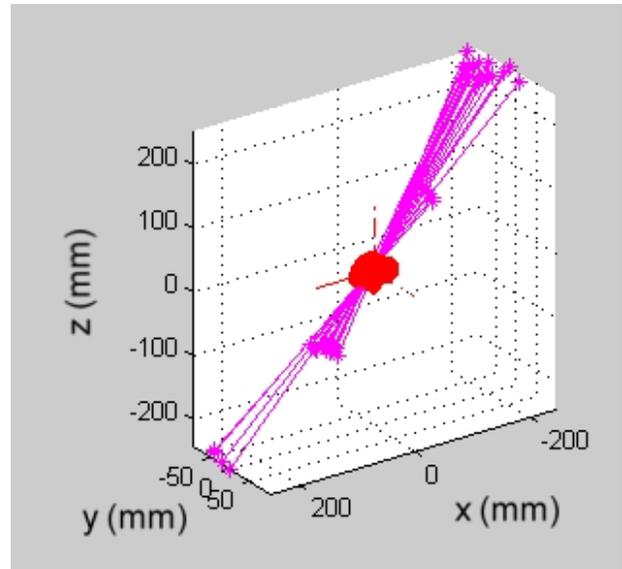

Kinematic profiles of the ankle joint are useful for evaluating pathological joint motion and provide a foundation for the understanding of surgical procedures. No reliable technique exists for accurate in vivo measurements of subtalar joint (SJ) motion. The purpose of this study was to assess normal range of SJ motion in a loaded state using computed tomography (CT).

**METHODS**

Twenty healthy volunteers (10 m, 10 f) with a mean age of 26,3 yrs (range 22-35 yrs) signed informed consent. CT images of the right foot were acquired in neutral position for bone segmentation of the talus and calcaneus. An external load was applied to force the unconstrained foot in eight different extreme positions; dorsiflexion<sup>max</sup>, anterolateral<sup>max</sup>, eversion<sup>max</sup>, posterolateral<sup>max</sup>, plantarflexion<sup>max</sup>, posteromedial<sup>max</sup>, inversion<sup>max</sup> and anteromedial<sup>max</sup>. CT images were acquired in each position using a low-dose technique. After bone contour matching, the positions and orientations of the helical axes were determined for the motions of the calcaneus relatively to the talus between the opposite extreme foot positions. The helical axes were represented in talus-specific anatomic planes as defined by its geometric principle axes.

**RESULTS AND DISCUSSION**

For inversion<sup>max</sup>-to-eversion<sup>max</sup> of the foot, the helical axes of the SJ were found to have a mean inclination from the XY-plane of 49.4±4.3 deg. (Figure 1). The mean deviation of the axes from the XZ-plane was -2.7±7.9 deg. The mean rotation about the helical axes was 37.3±5.9 deg. with a mean translation of 2.3±1.1 mm. Considerable variation of helical axes parameters were found for the motion from dorsiflexion<sup>max</sup>-to-plantarflexion<sup>max</sup> (Table 1). In contrast to inversion<sup>max</sup> and eversion<sup>max</sup> positions of the foot, dorsiflexion<sup>max</sup> and plantarflexion<sup>max</sup> positions were not considered to result in true locking end-positions for the SJ. Helical axes values for the two motions between the intermediate extreme positions were close to the values for inversion<sup>max</sup>-to-eversion<sup>max</sup> (Table 1). Despite some apparent differences between subjects, the intersubject variability of the helical axes was smaller than was expected from previous studies.<sup>1,2,3</sup> This finding might be due to

**Figure 1.** 3D-representation of the helical axes for subtalar motion from inversion<sup>max</sup>-to-eversion<sup>max</sup> of 20 normal right feet. The fixed talus (red) and its principle axes are shown in the center. The helical axes are clipped by a bounding box.

studying motions between extreme positions of a loaded foot, resulting in true locking end-positions for the SJ.

**CONCLUSIONS**

For motions with a considerable inversion and eversion component, the helical axes were reproducible between the different subjects. The largest mean rotation was found for motion between inversion<sup>max</sup>-to-eversion<sup>max</sup>. Dorsiflexion<sup>max</sup> and plantarflexion<sup>max</sup> positions of the foot were not considered to result in true locking end-positions for the SJ.

**INTRODUCTION**

Functional electrical stimulation (FES) can facilitate many activities of daily living for individuals paralyzed by spinal cord injuries [1]. Bilateral activation of the paraspinal muscles via implanted electrodes can improve the seated posture of FES users [2], and may also improve manual wheelchair propulsion efficiency. The goal of this preliminary study was to investigate the effect of stimulating the lumbar trunk extensors via an implanted FES system on propulsion biomechanics. The results may provide insight into the benefit of FES during manual wheelchair propulsion.

**METHODS**

*Subjects:* Three long-time (>12 months) recipients of the CWRU/VA implanted standing neuroprosthesis [1] with motor complete paraplegia participated in this study. The age, height and years of wheelchair use of the two male and one female volunteers were 40.5 ± 9.3 years, 1.72 ± 0.05 meters, and 5.8 ± 0.7 years respectively.

*Experimental protocol:* Subjects' own wheelchairs were fitted bilaterally with SMART<sup>Wheels</sup><sup>TM</sup> instrumented pushrims (Three Rivers Holdings, ILL., Mesa, AZ), and secured to a dynamometer with a four-point tie down system. An OPTOTRAK motion analysis system (Northern Digital Inc., Ontario, Canada) was synchronized with the kinetic system to record kinematic data. Subjects were asked to propel their wheelchairs at a steady-state speed of 0.9, and 1.8 m/s for one minute while real time propulsion speed was displayed on a monitor. All propulsion trials were repeated three times: two with electrical stimulation to the erector spinae ON at 50% and 25% maximal recruitment, and one with electrical stimulation OFF. The order of stimulation condition was randomly assigned. To minimize fatigue, at least one-minute of rest was provided between trials.

*Data analysis:* For each stroke, the start and end of the push phase were determined by the presence/absence of forces detected by SMART<sup>Wheels</sup><sup>TM</sup>. The kinetic data were collected at 240 Hz and linearly interpolated for synchronization with the 60 Hz kinematic data. Since data from both sides were highly correlated (r = 0.68; p < 0.01), average values of both sides were obtained on all biomechanical variables over ten continuous strokes. Descriptive analyses were reported for each speed condition separately. Since one subject was unable to reach the target speed at 1.8 m/s, only data from two subjects are reported under this speed condition.

**RESULTS AND DISCUSSION**

Table 1 summarizes the biomechanical variables while propelling with and without FES. Continuous activation of the paraspinal muscles appears to improve propulsion performance. The mechanical effective force (MEF), the percentage of the resultant force leading to forward propulsion, is generally higher with FES for all speed conditions. Higher propulsive forces and longer stroke cadences were generally observed with stimulation ON. Mean trunk angles increased with FES under all conditions. This ability to lean the trunk forward and return facilitated with FES may help the subjects to transfer power from the upper extremities to the pushrim, thereby increasing MEF [3,4]. Although the low level (25%) stimulation showed less advantage than the high level (50%), it may be less fatiguing with prolonged use and allow a greater degree of trunk mobility. The potential benefit of low activation warrants further investigation.

The generalizability of these results is limited by the small sample size due to the limited availability of the CWRU/VA implanted standing neuroprosthesis. Future studies using a non-invasive surface FES system may be needed to further explore the phenomenon and determine benefits of FES on wheelchair propulsion in the larger SCI population.

**CONCLUSIONS**

Stabilizing the trunk by continuous stimulation of the lumbar erector spinae appears to improve manual wheelchair propulsion. With activation of back muscles, implanted FES users were able to lean forward and thereby increase mechanical effective forces. A future study with a larger sample size is needed to verify these findings.

## DEVELOPING A COMPUTER AIDED DESIGN TOOL FOR INCLUSIVE DESIGN

<sup>1</sup>Victoria Hood, <sup>2</sup>David Loudon, <sup>1</sup>Alexander Nicol, <sup>2</sup>Alastair Macdonald, <sup>1</sup>Benard Conway

<sup>1</sup>Bioengineering Unit, University of Strathclyde, Glasgow, UK,

<sup>2</sup>Product Design Engineering, Glasgow School of Art, Glasgow UK; email: [victoria.hood@strath.ac.uk](mailto:victoria.hood@strath.ac.uk)

### INTRODUCTION

Globally the proportion of older adults in the population is increasing, the fastest growing subgroup being those aged over 80 years. In Europe, it is estimated that 24% of the population will be aged over 65 by 2030 [1]. The majority of these people will remain living in their own home.

The aging process leads to changes in strength, flexibility and balance, which in older adults can combine to limit the use of products or services (transport, buildings etc.)[2]. Inclusive design aims to overcome this by designing products that can be used by all. However, for designers to achieve products that can be used by all it is important to provide them with relevant information on the performance capacity of the older population.

The purpose of this study was to investigate age-related changes in the performance of a range of movement tasks for integration into a computer aided design (CAD) tool for use in inclusive design.

### METHODS

Eighty four healthy older adults (age 60 –88 years) underwent full body 3-D biomechanical assessment of five activities of daily living using a VICON 8-camera motion analysis system (120Hz) with 3 Kistler forceplates. Activities consisted of gait, sit-stand-sit, door opening and closing, stair ascent and descent and lifting a small object to different heights (Figure 1). Vicon BodyBuilder was used to analyze the data and export limb segment positions as a series of rotations and translations from the position of the pelvis segment. Maximum isometric joint moments at the hip and knee over a range of angles were also assessed. Maximum upper limb moments for older adults were determined from the literature.

Custom written software was developed in Visual C++ utilizing the OpenGL 3d library. This software imported the processed data and produced an animated model of a subject performing an activity. This model can be manipulated by the designer by changing the position of the limbs. Limits were placed on joint movement to represent loss of motion in the older adult. The resulting change in joint angles and moments were calculated using inverse kinematics. A plug-in was written for the engineering CAD software package SolidWorks using C++. This enabled a potential product developed using CAD to be imported and attached to the hand of the model (Figure 2). The effects on upper limb joint moments as a result of this potential product were determined.

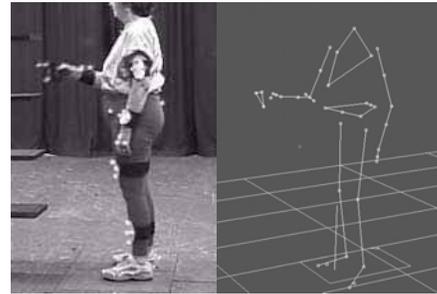

Figure 1: Data collected and processed in VICON.

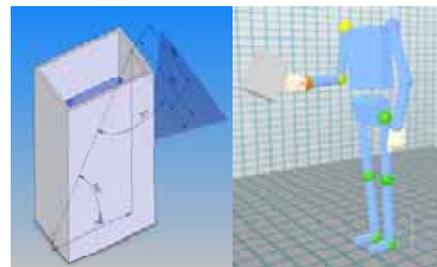

Figure 2: CAD model imported from SolidWorks and attached to model.

### RESULTS AND DISCUSSION

Joint moments are presented in both numerical form and graphically on the model. Joint moments are visualized using a colour scale and expressed as the percentage of the expected age related maximum joint moment at that point in time. This allows designers to quickly visualize when a task may prove too difficult for an older adult to accomplish. Changes can then be made to the virtual design in SolidWorks and the usability of the re-engineered product reassessed.

### CONCLUSIONS

The study demonstrated that biomechanical data can be interfaced with standard CAD software to aid inclusive design. The prototype CAD tool is currently being tested by designers and work is ongoing to develop it further.

## EVALUATION OF AN OPTIMAL CEMENT THICKNESS AROUND THE GLENOID COMPONENT FOR UNCONSTRAINED TOTAL SHOULDER ARTHROPLASTY

<sup>1</sup>Alexandre Terrier, <sup>1</sup>Philippe Büchler and <sup>2</sup>Alain Farron

<sup>1</sup>Orthopaedic Research Laboratory, Swiss Federal Institute of Technology Lausanne, Switzerland

<sup>2</sup>Orthopaedic Hospital, University of Lausanne, Switzerland

### INTRODUCTION

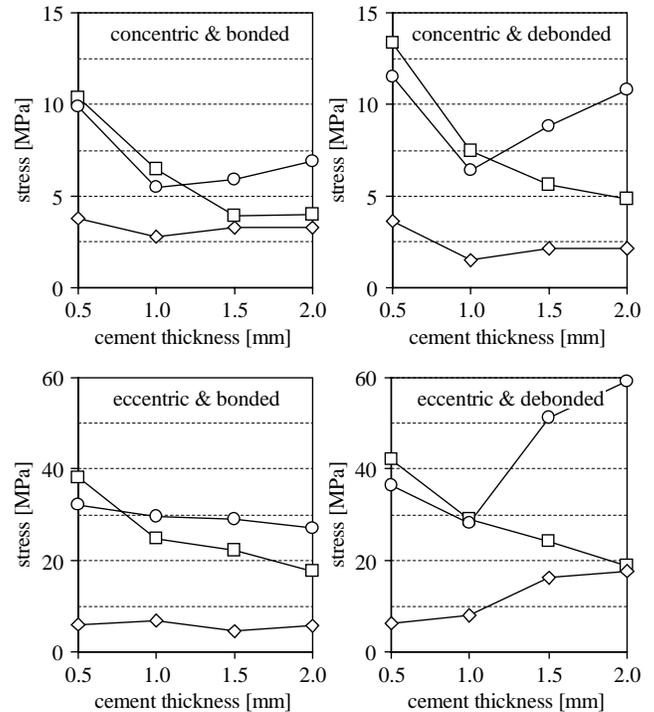

Although shoulder arthroplasty is an accepted treatment for osteoarthritis, loosening of the glenoid component, which mainly occurs at the bone-cement interface, remains a major concern. At the bone-cement interface, radiolucent lines have been observed in 30-95% of patients at follow-up [1]. Radiolucent lines are associated with fibrous tissue formation and glenoid loosening. In vitro tests have shown that thickness of the cement mantle is important for the primary stability of cemented glenoid components [2]; however there is still a lack of information concerning the optimal cement thickness. The aim of the study was to analyze the effect of this parameter on the glenoid stress transfer by means of a finite element model of the shoulder.

### METHODS

The 3D geometry of the scapula was reconstructed from 1 mm CT slices of a cadaver shoulder. The glenoid component was all-polyethylene, keeled with a flat back. Cement thickness was gradually increased from 0.5 to 2.0 mm. Bone, cement and polyethylene were linear elastic. Non homogeneity of bone was derived from CT. At the bone-cement interface two extreme cases were considered: fully bonded and fully debonded. In the latter case, the friction coefficient was 0.6. A 400 N force was applied on the glenoid face, corresponding to the maximal glenohumeral force during abduction [3]. The distribution of this force over the surface was derived from the Hertz theory. Two force distributions were considered: concentric and (posterior) eccentric. Several mechanical quantities were calculated near the bone-cement interface: principal stress within the cement, von Mises stress within the underlying bone, stress and micromotion at the bone-cement interface.

### RESULTS AND DISCUSSION

Within cement, the increase of cement thickness induced a continuous decrease of stress (Figure 1). Below 1 mm, the fatigue limit of the cement (~7 MPa) was exceeded, even in the concentric and bonded case. Within bone, and at the bone-cement interface, there was a stress increase from 1.0 to 0.5 and from 1.0 to 2.0, suggesting a minimum between 1.0 and 1.5 mm. Bone stress was below its failure strength, but interfacial stress was close to the failure limit (~3 MPa). The debonding of the interface, as well as the eccentric loading, induced an overall increase of stress. Peak stress was mainly located at the keel tip, but also along the back-keel edges as cement thickness decreased. Micromotion remained moderate (<30µm) and almost constant (vs. cement thickness) in the concentric case, but was excessive (>150µm) and increasing (vs. cement thickness) in the eccentric case. Peak micromotion

**Figure 1:** Peak value of cement maximum principal stress (square), bone von Mises stress (circle), interfacial shear stress (diamond), for the four cases considered.

was located at the keel faces in the concentric case, but under the back in the eccentric case (rocking-horse effect).

### CONCLUSIONS

Results showed that cement thinning weakens the cement, but also the bone-cement interface along the back-keel edges. Conversely, cement thickening rigidifies the cemented implant, increasing consequently the overall interfacial stress and micromotion. To avoid both excessive cement fatigue and failure of the bone-cement interface, an optimal cement thickness has been identified between 1.0 and 1.5 mm.

Practically, to avoid the formation of large blocks of cement around the implant, we recommend to correct any bone defect of the glenoid by bone grafting and/or compaction. Moreover, future developments of new glenoid designs should include the ability to ensure a homogeneous cement mantle, with a minimum thickness of 1.0 mm.

## BIOMECHANICS OF STAIR DESCENT IN OLDER ADULTS

<sup>1</sup>Victoria Hood, <sup>1</sup>Alexander Nicol,  
<sup>1</sup>Bioengineering Unit, University of Strathclyde, Glasgow, UK;  
 email: [victoria.hood@strath.ac.uk](mailto:victoria.hood@strath.ac.uk)

### INTRODUCTION

Negotiating stairs is one of the most difficult activities of daily living faced by older adults. Falls on stairs are one of the leading causes of accidental death amongst the elderly and the majority of these falls occur during stair descent [1,2].

Many researchers have studied the cardiovascular and musculoskeletal demands of stair ascent but there is little research on the biomechanics of stair descent. The purpose of this study was to investigate the biomechanics of stair descent in older adults.

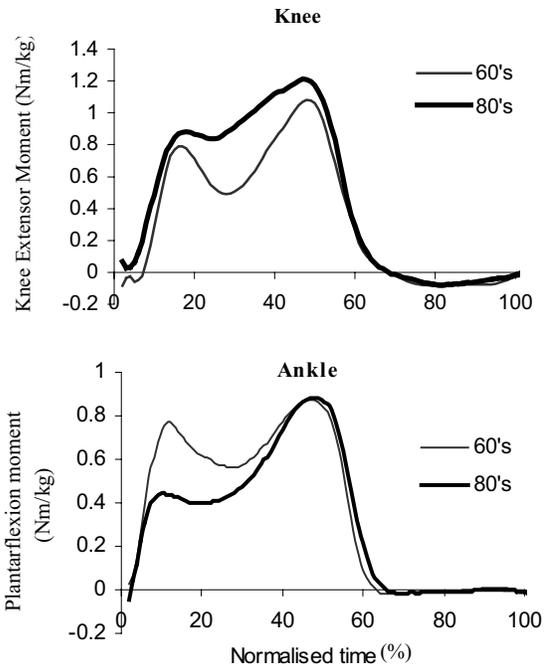

### METHODS

Fifteen healthy men in their 60's (mean age 66.2 years) and thirteen men in their 80's (mean age 82.2 years) underwent full body 3-D biomechanical assessment whilst ascending and descending a flight of four stairs. The second stair of the flight was instrumented using a Kistler forceplate and motion data were captured using an 8 camera Vicon motion analysis system at 120Hz. Subjects attempted 3 trials of stair ascent and descent using a handrail and 3 trials without use of a hand rail. Joint kinetics and kinematics were determined using Vicon BodyBuilder software. Data were normalized to 100 data points from foot contact on one step to foot contact on the step below and then averaged over the subject group.

### RESULTS AND DISCUSSION

Men in their 80's descended the stairs significantly more slowly than the men in their 60's. There was no significant change in the amount of time spent in stance phase between the groups (Table 1). Use of a handrail had no significant impact on temporal step cycle parameters. Both groups were slower than younger subjects (mean age = 28.8 years) reported by Reiner et al. [3].

During the weight acceptance phase men in their 80's had a marked reduction in internal plantarflexion moment accompanied by a small increase in knee extensor moment (Figure 1). Throughout stance phase the knee extensor moment remained higher in the older men. This would indicate that the men in their 80's are using the knee extensors of the trailing leg to reduce the moment required by plantarflexors at initial contact. Overall this results in a more smooth moment generation pattern throughout stance. This pattern was observed both with and without use of a handrail.

**Figure 1:** Sagittal plane moments at the knee and ankle during stair descent averaged for men in their 60's and 80's

### CONCLUSIONS

The strategy older men use to descend the stairs is one which results in a more consistent net moment in the ankle and knee extensors. The increased requirement of the knee extensors with age for stair descent may be a factor that contributes to difficulty performing this task.

## ELECTROMYOGRAPHIC ANALYSES OF STANDING SHOT PUT THROW

<sup>1</sup>Hsiente Peng, <sup>2</sup>Hsiensen Peng and <sup>1</sup>Chenfu Huang

<sup>1</sup>National Taiwan Normal University, Taipei, Taiwan;

<sup>2</sup>National Taipei Teacher College, Taipei, Taiwan; email: [sid125@ms35.hinet.net](mailto:sid125@ms35.hinet.net)

### INTRODUCTION

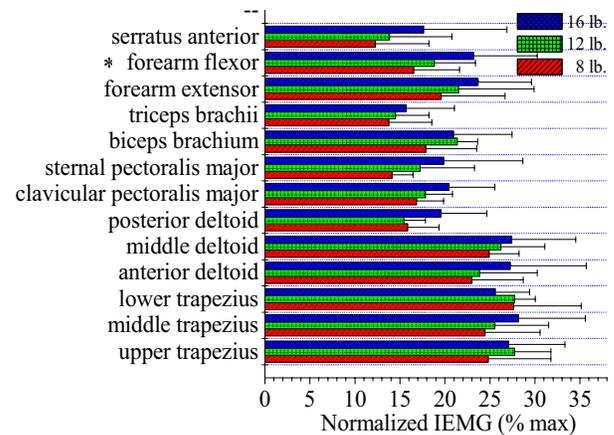

The throwing arm plays an important and crucial part in the shot put event. Shot put is a heavy-weighted throwing event compared with others, such as baseball pitching and javelin throw. Standing shot put throw is a basic training movement for the throwing technique in thrust. Electromyography (EMG) of throwing had been studied by many researchers. Nevertheless the applications on studies of upper extremity of throwing events focused mostly on the baseball pitching [1,2,3,4,]. The baseball is a light-weighted throwing event (about 0.145 kg.). There are few studies on the EMG activity of a heavy-weighted throwing event. So, we selected the shot put as our study. The weight of a shot put for adult male is 16 lb. (7.26 kg.). We also asked the subjects to throw lighter shot puts, which are weighted 8 lb. and 12 lb. This study used dynamic EMG analysis to compare the muscle actions in different shot put weight, and to investigate the sequences of the muscular function and the patterns of the muscular activity.

### METHODS

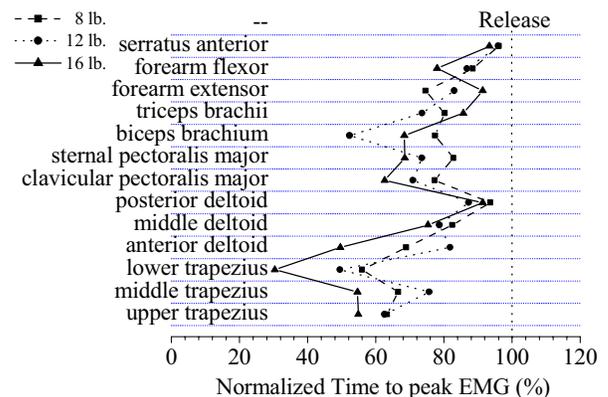

Seven shot putters (age of  $20 \pm 3$  years; height of  $178 \pm 9$  cm; weight of  $100 \pm 24$  kg) served as subjects to perform the standing throw with three weights of the shot put (8, 12 and 16 lb.). Each subject at least performed two throws successfully. The best performance was selected to analyze. Two Redlake high-speed cameras (sampling rate: 125Hz; Motion Scope, San Diego, USA.) and one Biovision system (sampling rate: 1250Hz; Biovision, Wehrheim, Germany.) were synchronized to collect the data. The surface EMG of thirteen muscles was recorded. Raw EMG signals were band-pass filtered (20-400Hz), full wave rectified, and passed through a linear envelope at 10Hz for final interpretation. Integrated EMG signals (IEMG) from the onset of thrust to shot put release of the standing throw trials were then normalized by the maximal signal (%max), which was highest EMG value obtained during the standing throw, for each muscle to indicate relative activation levels. The nonparametric statistical test of Friedman two-way analysis of variance by ranks was conducted for the normalized IEMG of each muscle ( $p < 0.05$ ).

### RESULTS AND DISCUSSION

The distances of 8, 12 and 16 lb. shot put throw were  $15.58 \pm 1.97$ ,  $13.87 \pm 2.27$  and  $11.57 \pm 2.42$  m, respectively. Figure 1 shows the activation levels of the thirteen muscles. The lower, middle and upper trapezius, anterior deltoid and middle deltoid demonstrated stronger activity than the other muscle groups during the standing shot put throws (23 to 28%max). In addition, forearm extensor and flexor also demonstrated strong activity in 16 lb. shot put throw (23%max). There was a trend in majority of the muscle groups, which showed higher EMG activities when throwing the heavier shot put. Only the forearm flexor demonstrated the statistical significance

**Figure 1:** Normalized IEMG of thirteen muscles of seven subjects (mean  $\pm$  %max) throwing with three weights of shot put (8, 12 and 16 lb.). \* The statistical significance was found between the three weights.

**Figure 2:** Time to peak EMG of thirteen muscles of seven subjects (mean). Time was normalized to standing throw duration (100%).

between the three weights of shot put. Figure 2 shows the time to peak EMG of thirteen muscles of seven subjects. The sequences of the muscular function were a little different in three weights of shot put. Generally, the time to peak EMG sequences corresponded to the proximal-distal segmental sequence. But the serratus anterior was an exception. It's time to peak EMG was emerged just before shot put release.

## ANALYSIS OF COLLAGENASE, COLLAGEN, AND GLYCOSAMINOGLYCAN CONTENT OF CYCLICALLY LOADED TENDON EXPLANTS IN CULTURE

<sup>1</sup> Aaditya C Devkota and <sup>1,2</sup> Paul S Weinhold

Departments of <sup>1</sup>Biomedical Engineering and <sup>2</sup>Orthopaedics  
 University of North Carolina, Chapel Hill; email: [aaditya@unc.edu](mailto:aaditya@unc.edu)

### INTRODUCTION

Overuse injuries comprise a significant portion of tendon injuries. These injuries are a combination of simple material fatigue damage as well as the cells' matrix remodeling response to the load stimulus. To better understand the role of the cellular response in overuse injuries, tendon explants were cyclically loaded across one or twelve days with loading regimens of two magnitudes. The sulfated glycosaminoglycan content, collagen content (by measuring hydroxyproline) and the collagenase content were measured.

### METHODS

Avian flexor digitorum profundus tendons were isolated and placed in a custom built load-controlled tissue loading device. Tendons were cyclically loaded to a fixed number of cycles at 3 or 12 MPa (Low, High) across 1 or 12 days (Short, Long). Media was exchanged before and after the full regimen as well as every 3<sup>rd</sup> day.

Media samples were analyzed for collagenase content by measuring the release of a red dye (Azocoll) impregnated in collagen [1]. Samples were activated with APMA to evaluate total potential collagenase activity. Data was normalized by the day 0 value for each sample. Positive and negative controls were included with collagenase injected and freeze-killed trials, respectively.

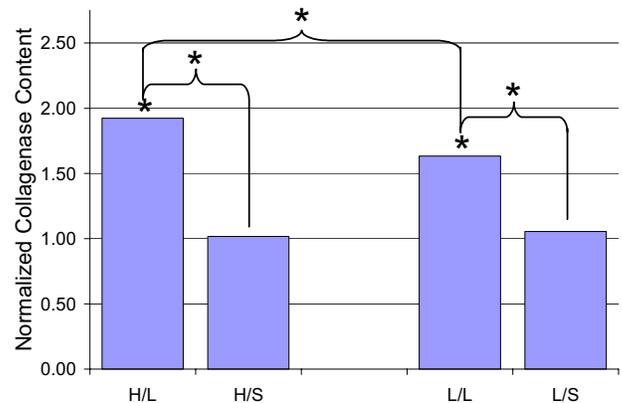

Tissue segments were digested with papain, and then analyzed for collagen content [2] and sGAG content [3]. Collagen content was measured by a spectrophotometer from hydrolyzed digests introduced to Chloramine T with an aldehyde dye, DAB and quantified using hydroxyproline standards. sGAG was measured by a spectrophotometer in a DMMB (blue) buffer and quantified using chondroitin sulfate (shark cartilage) standards. All data was normalized by dry weight of the original tendon segment prior to digest.

**Table 1:** Tissue content of cyclically loaded tendons explants ( $\mu\text{g}/\text{mg}$  dry weight). Groups without a common letter are significantly different ( $P < 0.05$ ).

	Hydroxyproline	Sulfated GAG
<b>High Long (HL)</b>	91.86 $\pm$ 0.661 A	6.725 $\pm$ 0.89 A
<b>High Short (HS)</b>	102.0 $\pm$ 18.92 A	6.628 $\pm$ 1.48 A,C
<b>Low Long (LL)</b>	92.71 $\pm$ 16.25 A	4.914 $\pm$ 0.94 B,C
<b>Low Short (LS)</b>	82.08 $\pm$ 8.882 A	4.203 $\pm$ 0.76 B

### RESULTS AND DISCUSSION

Sulfated GAG concentrations were found to be in the range of macroscopically normal cadaver tendons [3]. A significant difference in the main effect of magnitude was seen. Both high groups, HL and HS, were statistically larger than the low groups, LL and LS, respectively (Table 1), as measured by a two-way ANOVA. While elevated GAGs were expected in

**Figure 1:** Collagenase content of cyclically loaded tendons, normalized by time 0.

the HL [4], the elevated levels in the HS was not expected because a duration dependence (response time) was expected.

Collagen content, measured by hypro content, was found to be in the range of macroscopically normal, cadaver supraspinatus tendons [2]. However, no differences were seen between any of the groups (Table 1). Though collagen content did not differ, collagenase content did. A significant increase in the collagenase content was seen in the HL and the LL groups relative to time zero. This difference was significant by day 9 for the HL group and day 12 for the LL group. Both long groups were significantly larger than their respective short groups indicating a duration dependence of collagenase release. Magnitude also affected the collagenase content as the HL group was found to be significantly larger than the LL group. This difference was not seen between the short groups however, and could be due to a lack of response time. The high levels of collagenase with a concurrent lack of differences in collagen content potentially suggest a high collagen turnover. However, as active and inactive collagenase was measured with the performed assay, it cannot be concluded with certainty how much collagen turnover occurred.

### CONCLUSIONS

Cyclically loaded in vitro tendon explants exhibited significant magnitude dependant GAG increases, as has been observed in overuse tendinopathy lesions. Furthermore, significant differences in collagenase content with a concurrent lack of differences in collagen content was observed, suggesting collagen turnover.

## ARE THE GAIT KINETICS OF WOMEN AND MEN WITH KNEE OSTEOARTHRITIS DIFFERENT?

Monica Maly<sup>1</sup> [mmaly@yorku.ca](mailto:mmaly@yorku.ca), Patrick Costigan<sup>2</sup> and Sandra Olney<sup>3</sup>

<sup>1</sup>School of Kinesiology and Health Science, York University, Toronto Canada

<sup>2</sup>School of Physical and Health Education & <sup>3</sup>School of Rehabilitation Therapy, Queen's University, Kingston Canada

### INTRODUCTION

Despite evidence that the mechanical pathology of knee osteoarthritis (OA) might be unique in women, such as different patterns of joint deformity<sup>1</sup> and muscle weakness,<sup>2</sup> no studies have compared loading patterns in knee OA between women and men. We aimed to evaluate the sex-specific knee and hip kinetics in medial compartment knee OA during gait.

### METHODS

Female Knee OA (FOA): women over age 50 with medial compartment knee OA. Male Knee OA (MOA): men over age 50 with medial compartment knee OA. Pain, stiffness and function were assessed using the Western Ontario McMaster Universities Osteoarthritis Index.

Gait data were collected using the QUESTOR Gait Analysis in Three Dimensions (QGAIT) system, consisting of an Optotrack optoelectric system (Northern Digital, Canada), a force plate (AMTI, USA) and QUESTOR precision radiographs. QGAIT incorporates joint geometry data from standardized radiographs to more accurately transform the surface marker location into the subject-specific joint centre. The radiographs were obtained with subjects standing barefoot on a calibrated turntable, inside a frame fixed relative to the x-ray source. Surface landmarks to be used for gait trials were marked with a lead bead. Anterior-posterior (knee, hip) and lateral radiographs (knee) were obtained. Radiographs were calibrated. Correction vectors were measured from the surface landmarks into the hip and knee joint centre. In addition, medial joint space narrowing (MJSN, mm) was measured. For gait analysis, 6 infrared emitting diodes (IREDs) were used: greater trochanter, lateral femoral condyle, fibular head, lateral malleolus and 2 IREDs on anteriorly projecting probes attached to thigh and shank. Five walking trials were sampled at 100 Hz. Foot contact was determined using trajectory data from the lateral malleolus. Independent t-tests compared FOA and MOA mean age, MJSN, gait speed and WOMAC subscales. A multivariate analysis of covariance (MANCOVA) was performed to compare FOA & MOA gait characteristics, with gait speed and MJSN as covariates.

### RESULTS AND DISCUSSION

The FOA (n=32), aged 66.4 ± 9.4 years were younger than the MOA (n=22), aged 71.0 ± 7.1 years. The MJSN was different between the FOA (2.5 ± 1.6mm) and MOA (1.6 ± 1.5mm, p<0.05). Table 1 summarizes participant characteristics.

Table 1: Participant Characteristics

	Gait Speed (m/s)	WOMAC-Pain (%)	WOMAC-Stiffness (%)	WOMAC-Function (%)
FOA	1.1 ± 0.38	29.9 ± 19.2	44.1 ± 26.8	37.4 ± 21.1

Int Rot Moment (Nm/kg•m)	0.06 ± 0.03	0.05 ± 0.02
Ext Rot Moment (Nm/kg•m)	-0.08 ± 0.40	-0.12 ± 0.07

\*p value < 0.05, \*\*p value < 0.01

### CONCLUSIONS

The FOA walked more slowly than the MOA. Though women had the same level of impairment as men, noted by WOMAC scores, women were younger and appeared to have less severe medial OA noted by a larger medial joint space. Despite using gait speed and MJSN as covariates, significantly different knee and hip kinetics were noted between women and men, suggesting that the sex-specific differences in the mechanical pathology of knee OA should be studied further. However, we acknowledge that a larger sample size will be necessary to confirm these sex-related differences in knee OA gait.

## DYNAMIC STABILITY AND ENERGY EFFICIENCY DURING DIFFERENT SELF-SELECTED WALKING SPEEDS

Heng-Ju Lee and Li-Shan Chou

Motion Analysis Laboratory, Department of Human Physiology, University of Oregon, Eugene, OR

Contact: [Chou@uoregon.edu](mailto:Chou@uoregon.edu)

### INTRODUCTION

It is well documented that a high percentage of falls in older adults occur during walking [1]. Numerous studies have shown relations between changes in gait and risk of falling. Walking speed is generally regarded as a control parameter for human gait transitions. Walking with a preferred gait speed is thought to demonstrate a stable phase relationship and minimum energy expenditure [2]. Motion of the whole body center of mass (CoM) has been used to indicate the mechanical energy expenditure [3] and dynamic stability during gait [4]. Out-of-phase oscillation between kinetic ( $E_k$ ) and potential energy ( $E_p$ ) of the CoM allows energy to be exchanged from one to another [3]. The timing of exchanges between  $E_k$  and  $E_p$  at different walking speeds can provide us a better understanding of energy cost in the elderly. It has been found that CoM motion in the medio-lateral (M/L) direction during gait may have particular importance for balance control [4,5]. However, age related differences in the M/L dynamic stability during varied walking speeds are still unknown. Therefore, the purpose of this study was to quantify the relationship between dynamic stability and energy efficiency in three different walking speeds in young and elderly adults.

### METHODS

Thirteen healthy elderly adults without neurological or musculoskeletal impairment (6 males and 7 females;  $74.7 \pm 5.0$  years;  $165.4 \pm 8.9$  cm;  $69.4 \pm 11.8$  kg) and eighteen healthy young adult subjects (9 male and 9 female;  $25.2 \pm 4.2$  years;  $172.6 \pm 7.7$  cm;  $74.4 \pm 10.5$  kg) were recruited for this study. Subjects were asked to walk with barefoot over level ground along a 10-m walkway. The first condition was their preferred walking speed, and then a distinctly self-selected faster speed followed by a distinctly slower gait.

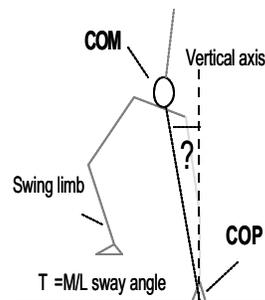

Whole body motion analysis was performed with a 6-camera ExpertVision™ system (Motion Analysis Corp., Santa Rosa, CA). Three-dimensional marker trajectory data were collected at 60 Hz. Twenty-seven reflective markers were placed on bony landmarks of each subject. Whole body CoM position data was calculated as the weighted sum of 13 segments representing the whole body. Linear velocities of the CoM were calculated with the GCVSPL algorithm. The center of pressure (CoP) position was calculated from the ground reaction forces/moments collected from two force platforms (AMTI, Watertown, MA). Instantaneous sway angles in the sagittal and frontal planes were defined as the angle between the inverted pendulum, defined by the CoP and CoM, and the vertical line (Fig.1). Timing offsets between  $E_k$  and  $E_p$  were calculated during single stance phase. Effects of subject group and walking speed on CoM sway angles and energy exchange times were assessed using a two-factor ANOVA with repeated measures of walking speeds.

### RESULTS AND DISCUSSION

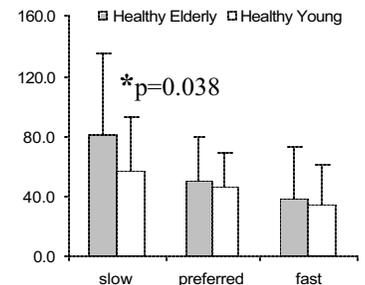

Elderly adults walked significantly slower than young adults for all 3 conditions (preferred, fast, slow: 1.2/ 1.4 m/s, 1.5/ 1.7 m/s, and 0.9/ 1.2 m/s;  $p < 0.001$ ). Also, significant group and

walking speed effects were found in the max. A/P sway angle and stride length. As the walking speed increased, stride length and max. A/P sway angle increased in both groups. Elderly adults showed a more conservative strategy to control body movement in the A/P direction using a shorter stride length to maintain a smaller A/P sway angle than young adults. This finding was similar to other studies [6,7]. Neither significant walking speed effects nor significant group differences were found in the max. M/L CoM sway angle and step width. However, timing offsets between  $E_k$  and  $E_p$  of elderly adults were found to be significantly greater than that of young adults during self selected slower walking speed (81.2 ms vs. 56.8 ms;  $p = 0.038$ ) (Fig 2).

These findings show that in both groups, decreasing walking speed does not cause greater M/L body movements during gait. The M/L sway angle defined in this study might be a walking speed-independent indicator for dynamic stability. Greater timing offsets between  $E_k$  and  $E_p$  of elderly adults during slower walking indicate less efficient in the energy transfer. Inefficient energy transfer during gait would require additional energy to be provided from lower extremity muscles [8,9]. Elderly adults walk with a slower speed may require excessive muscle co-contraction or an increase in muscle tone to compensate the inefficient gait. However, this extra energy consumption might be necessary to avoid any dynamic instability.

**Figure 1:** M/L sway angles defined by the CoP and CoM

**Figure 2:** The energy exchange time (msec) in three different walking speeds

## COMPARISON OF TWO ANKLE ELECTROGONIOMETERS AND MOTION ANALYSIS

Sujani N. Agraharasamakulam, Shaw Bronner and Sheyi Ojofeitimi

ADAM Center, Long Island University, Brooklyn, NY;

Email: [an\\_sujani@yahoo.com](mailto:an_sujani@yahoo.com), web: [www.brooklyn.liu.edu/bbut04/adamcenter/index.html](http://www.brooklyn.liu.edu/bbut04/adamcenter/index.html)

### INTRODUCTION

Flexible electrogoniometers (EG) have been used for gait and sports-specific lower extremity kinematic analysis. The commonly used EG sensor for the ankle is placed parallel to the Achilles tendon (Apara) (SG110, Biometrics, Ltd). Recently, a new ankle EG sensor was developed for placement at the lateral malleolus (Aperp) (SG110/A, Biometrics, Ltd).

In order to test the boundaries of the EG, we selected dancers for our study since they frequently work at extremes of joint motion. The purpose of this study was to examine the concurrent validity of the “new” ankle sensor (Aperp) to Apara EG as well as to a motion analysis (MA) system (the current gold standard), while measuring common dance movements in the sagittal plane.

### METHODS

Seventeen dancers (10 female and 7 male), mean age 20.76 ±2.46 years (age range 18 – 27 years), with an average of 10 years of dance training were recruited for this study. The two flexible strain-gauge EGs were placed at the right ankle of each subject, connected to a portable data-logger, and sampled at 100 Hz. Concurrent recordings were made with a Vicon 5-camera motion capture system (MA), sampled at 120 Hz, in order to verify sagittal plane movements recorded by the EGs. Each dancer performed four repetitions of 10 selected dance movements. The EG data were filtered at 5.5 Hz using a 4<sup>th</sup> order, low pass, zero lag Butterworth filter. The MA data were filtered using an FIR filter and resampled at 100 Hz. Multimodal peak angular displacement data were scored in a custom LabVIEW program.

Concurrent validity intraclass correlation coefficients (ICC) (3, k) comparing: a) the two EGs (Aperp v. Apara), and b) each EG to MA (EG v. MA) were calculated from 2-way ANOVAs ( $p < 0.05$ ), for combined and individual movement conditions (SPSS 13.0).

### RESULTS AND DISCUSSION

ICCs comparing the two EG devices were very high for both combined ( $r = 0.937$ ) and individual conditions (range  $r = 0.842 - 0.971$ ) (Table 1). ICCs comparing each EG device to MA were also high for combined ( $r = 0.954$  and  $0.958$ ) and

individual conditions (range  $r = 0.829 - 0.992$ ).

Previous analyses of the EGs to a protractor have established a high level of accuracy in measurement, with the mean absolute residual error less than  $1.0^\circ$  [1]. Analysis of relative reliability during repeated measures on the same and following day are currently underway.

When used by the same observer, EGs have demonstrated good reliability for repeated measurement of ankle dorsiplantarflexion [2]. However, these investigations focused on mid-range movements. Electrogoniometer measurement error increases with extreme positions [3]. Preliminary laboratory MA measurement of common dance movements reported non-weightbearing and weightbearing angular displacements at the ankle ranging from  $41.4^\circ(\pm 2.3)$  dorsiflexion to  $55.4^\circ(\pm 2.5)$  plantar flexion [4]. Because motion greatly exceeds those seen in gait analysis, the selection of EGs to measure dance movement required validation.

Subjects found the new ankle sensor (Aperp) to be more comfortable. Apara sensor breakage was frequent due to the stresses placed upon it by extreme plantar flexion. The Aperp sensor did not break during the course of this study.

### CONCLUSIONS

Reliability and validity of EGs to measure basic dance movements in the laboratory is a crucial precursor to workplace exposure-risk analyses. Both ankle EGs were highly correlated to MA and to each other, making them acceptable for use in this population. The greater comfort and durability of the new Aperp sensor makes it appealing for worksite use.

## HEAD ACCELERATION IS LESS THAN 10 PERCENT OF HELMET ACCELERATION DURING A FOOTBALL IMPACT

Sarah Manoogian, David McNeely, Mike Goforth, Gunnar Broinson and Stefan Duma  
Virginia Tech – Wake Forest, Center for Injury Biomechanics; Email: [manoogsj@vt.edu](mailto:manoogsj@vt.edu), Web: [www.CIB.vt.edu](http://www.CIB.vt.edu)

### INTRODUCTION

Sports-related concussions constitute 20 percent of brain injuries each year in the United States.<sup>1</sup> Concussion research has included a variety of instrumentation and techniques to measure head accelerations. These include headbands, helmet attachments, and video reconstructions. Most recently, the Head Impact Telemetry (HIT) System (Simbex, Lebanon, NH), a wireless system that provides real-time data from impacts, is used to measure *in-situ* head accelerations in collegiate football.<sup>2</sup> The purpose of this study is to measure linear head acceleration of a Hybrid III dummy using both accelerometers mounted at the center of gravity of the HIII head and the in-helmet HIT System. By comparing these two measured head accelerations and the helmet acceleration during a pendulum impact, it is shown that the response of the head and the helmet vary greatly and the in-helmet system matches the head and not helmet acceleration.

### METHODS

A study of 50 helmet to helmet tests was performed with the impacting helmet mounted on a Hybrid III headform and neck (Figure 1). This assembly was mounted on a pendulum, 20 kg total mass, that impacted at a range of velocities from 3 m/s to 6 m/s. The impacted helmet was mounted to a HIII headform and neck and then to a full HIII body. Instrumentation included an accelerometer mounted directly to the inside of helmet at the location of contact and two measures of head cg acceleration, a triaxial accelerometer cube in the HIII head and the HIT System. Four locations on the struck helmet were tested by rotating the full HIII body while keeping the pendulum configuration the same.

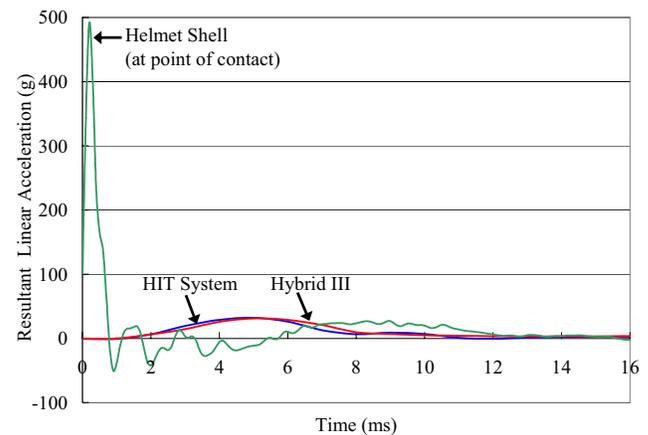

**Figure 1:** The impacted helmet was mounted to a HIII headform and neck and then to a full HIII body.

### RESULTS AND DISCUSSION

These tests illustrated that the helmet acceleration in response to impact varies from the head cg acceleration in amplitude

and the time to peak. Overall the peak acceleration for the helmet at the point of contact was 16.6 (+/- 3.2) times greater than the head cg peak linear acceleration for that impact. For example, Figure 2 illustrates that for one impact, the helmet acceleration was approximately 500 g compared the actual head cg of 32 g measured by the dummy. Moreover, the HIT System measured nearly identical to the dummy peak value and curve shape as the HIT System recorded a peak 33 g for the same impact. Additionally, the time from contact to peak head acceleration, 5.82ms (+/- .78ms), is longer than time to peak helmet acceleration, .42ms (+/- .17 ms). The peak magnitude, time to peak, and waveform shape of the HIT System measure match the in head acceleration values and not the helmet shell acceleration values.

**Figure 2:** For the same impact, the helmet acceleration was approximately 500 g compared to the Hybrid III cg measure of 32 g and the HIT System measure of 33 g.

### CONCLUSIONS

In summary, both the HIT System and the accelerometers in the HIII head measure a similar head acceleration response which varies greatly in magnitude and shape from the helmet response. In 2001 Lewis did a study that proved that wearing a helmet reduced the peak acceleration of the head by approximately a third since the helmet would absorb part of the impact's energy.<sup>3</sup> Therefore this paper presents consistent findings that the impact response of the head cg is much less than that of the helmet.

## THE VARIABILITY OF DYNAMIC AND SPATIO-TEMPORAL PARAMETERS OF THE RUNNING STRIDE

<sup>1</sup>Marina Gouvali and <sup>2</sup>John H. Challis

<sup>1</sup>Department of Sports Medicine and Exercise Biology, University of Athens, Greece; email: [mgouvali@phed.uoa.gr](mailto:mgouvali@phed.uoa.gr)

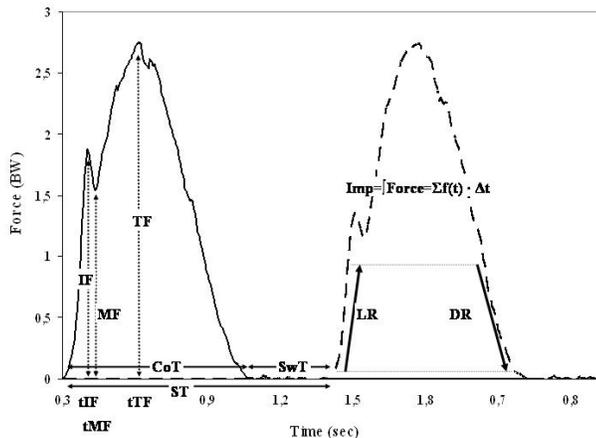

<sup>2</sup>Biomechanics Laboratory, The Pennsylvania State University, USA; email: [jhc10@psu.edu](mailto:jhc10@psu.edu)

### INTRODUCTION

Variability associated with individual running performance is apparent when an effort has to be repeated, even though conditions remain the same. Variability seems to increase when time between sessions increases [1] suggesting higher biological rather than methodological variability. Previous studies examining day-to-day variability have only measured a limited number of steps, for example 5 or 10 [2], which may not adequately sample the variability which exists in one day. The purpose of this study was to examine the variability of dynamic and spatio-temporal parameters of the running stride between sessions conducted on different days for 90+ steps per day.

### METHODS

Seven females and six males voluntarily participated in the study (Age F: 25.8±3.3 yrs, M: 26.9±3.6 yrs, Height F: 167.3±2.3 cm, M: 184.8±5.3 cm, Mass F: 62.9±6.7 kg, M: 83.3±10.7 kg). All subjects provided informed consent for all procedures, which were approved by the Institutional Review Board.

**Figure 1:** Key variables selected for analysis from a force-time curve.

Vertical ground reaction forces (GRF) and temporal parameters were collected with the aid of a Gaitway Instrumented Treadmill (Kistler Instrument Corporation) with two built-in force plates and were further analyzed with Gaitway Software 1.0 and MATLAB 6.5. Data were sampled at 500 Hz and filtered with a Butterworth filter (2<sup>nd</sup> order, cutoff frequency 30Hz). They were normalized for force by dividing by body weight. The protocol included 2 sessions separated by a day. Each session consisted of 4 running trials (5 min each) at 4 different speeds (F: 2, 3, 4 m/s, preferred speed, M: 3, 4, 5 m/s, preferred speed). GRF and spatio-temporal parameters for both legs were collected between the 4<sup>th</sup> and 5<sup>th</sup> min (~100 strides). The following variables were

selected for analysis: *IF*: impact force (BW), *tIF*: time of IF (s), *MF*: minimum force (BW), *tMF*: time of MF (s), *TF*: thrust force (BW), *tTF*: time of TF (s), *Imp*: impulse (BW·s), *LR*: loading rate (BW·s<sup>-1</sup>), *DR*: decay rate (BW·s<sup>-1</sup>), *ST*: step time (s), *CoT*: contact time (s), *SwT*: swing time (s), *SL*: step length (m), *SF*: step frequency (steps·s<sup>-1</sup>) (Figure 1).

Assessment of intra-day variability was evaluated using the coefficient of variation for the whole curve (*CoV*), as well as for each parameter (*CV*). Inter-day effect was tested by multivariate analysis of variance with repeated measures ( $p < 0.05$ ).

### RESULTS

The coefficient of variability for the whole curve ranged between 4.5-6.0%. Variability between consecutive strides was higher when calculated separately for each parameter (2-20%) and was the least for *ST* and *SF*. Regarding the force variables, the force acting to propel the body (*TF*) was less variable (2.5%) than the force acting to absorb the impact (*IF*) (9.7%).

**Table 1:** Means and CV of the GRF and temporal parameters. (\* $p < 0.05$ )

Day	1		2	
	Mean	CV	Mean	CV
<i>IF</i>	1.73	10.0	1.73	9.2
<i>tIF</i>	0.036	16.7	0.035	16.1
<i>MF</i>	1.49	11.4	1.46	10.6
<i>tMF</i>	0.047	13.3	0.047	12.7
<i>TF*</i>	2.47	2.6	2.44	2.4
<i>tTF</i>	0.107	7.0	0.106	6.9
<i>Imp*</i>	0.36	1.7	0.35	1.4
<i>LR</i>	63.04	12.1	66.13	12.5
<i>DR</i>	4.58	2.6	4.59	2.2
<i>ST</i>	0.366	3.6	0.363	3.2
<i>CoT</i>	0.237	7.8	0.238	7.7
<i>SwT</i>	0.129	18.4	0.125	16.9
<i>SL</i>	1.249	20.1	1.242	19.8
<i>SF</i>	2.75	2.7	2.77	2.4

The results produced no significant differences for most GRF and temporal means and *CV* between sessions separated by a day; significant, but small, differences existed only for *TF* and *Imp* (Table 1).

### CONCLUSIONS

Variability in the force-time pattern between consecutive strides is high and dependent on the nature of the variable, indicating that the number of trials to be analyzed should be determined according to which parameters are of interest. Running performance can be replicated without significant systematic error after one day. In conclusion, one session can be considered as satisfactory for analyzing the dynamic and temporal characteristics of the running stride.

## RELATIONSHIP BETWEEN SOFT TISSUE DEFORMATION AND APPLIED PRESSURE ALONG THE SECOND RAY OF THE PLANTAR NEUROPATHIC FOOT

<sup>1</sup>Donovan J. Lott, <sup>2</sup>Paul K. Commean, <sup>2</sup>Kirk E. Smith, <sup>1</sup>Michael J. Mueller

<sup>1</sup>Program in Physical Therapy and <sup>2</sup>Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, MO

### INTRODUCTION

Neuropathic foot ulcers are one of the most common lower extremity complications for people with diabetes mellitus (DM) and peripheral neuropathy (PN). High plantar pressures commonly seen in people with DM and PN compress and damage soft tissue of the foot contributing to the occurrence of these ulcers. The aim of this study was to determine the relationship between soft tissue deformation and applied pressure along the second ray of feet of individuals with DM, PN, and a history of a plantar ulcer.

### METHODS

Ten subjects (6 males/4 females, mean age  $58.0 \pm 10.3$  years, mean BMI  $32.6 \pm 9.5 \text{ kg/m}^2$ ) with DM (2 Type 1/8 Type 2, mean duration of DM  $16.5 \pm 10.0$  years), PN, and a history of a plantar ulcer participated.

Plantar pressure data were recorded using the FSCAN system (Tekscan, South Boston, MA, USA) during spiral X-ray computed tomography (SXCT). SXCT scans of the subjects' feet were performed as described in detail elsewhere [1]. The subject applied a load of  $\leq 45 \text{ N}$  (10 lbs.) for the first "preload" scan. For the second "loaded" scan, the subject applied a load of approximately 50% of his/her body weight. The alignment of the anatomical data from the SXCT scans with the pressure data from the FSCAN system was performed as described in detail elsewhere [2]. The second ray was determined in a similar manner by aligning the pressure data with the second metatarsal and second proximal phalanx. All testing was done with the subjects barefoot.

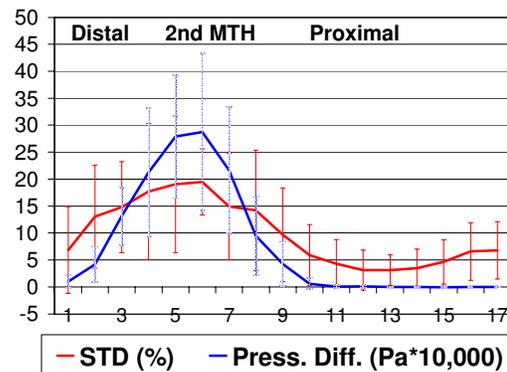

Soft tissue thickness was determined by measuring the distance from the most inferior aspect of the bone to the surface of the skin. Soft tissue deformation (STD) (strain) was defined as:  $\frac{([\text{soft tissue thickness from preload scan}] - [\text{soft tissue thickness from loaded scan}])}{[\text{soft tissue thickness from preload scan}]} * 100$ . Soft tissue thickness measurements were taken from 11 sensor pixels (5.08 mm spacing) proximal to the metatarsal head to five sensor pixels distal to the metatarsal head (for a total of 17 measurements per condition over 86.36 mm [3.4 inches]).

A Pearson correlation coefficient was performed for statistical analyses to determine the relationship between the STD and the applied pressure along the second ray.

### RESULTS AND DISCUSSION

Figure 1 shows the average STD and the pressure difference between the two scans along the second ray. At the location of the second metatarsal head (MTH), the mean STD was

$19.5 \pm 6.1\%$ , and the mean pressure difference was  $287.3 \pm 145.5 \text{ kPa}$ . The mean correlation coefficient for the ten subjects demonstrates a strong relationship between soft tissue deformation and applied pressure along the second ray ( $r = 0.93$  for the 17 points of data).

**Figure 1:** Mean Soft Tissue Deformation (in percentage) and Pressure Difference between loaded and preload conditions (in  $\text{Pa} \times 10^4$ ) along the second ray.

### SUMMARY

This is the first study that has examined STD at several points along a ray of the plantar foot in patients with DM and PN. Our data suggest that the deformation that occurs along the second ray in patients with DM and PN is strongly correlated with the applied pressure at these same points. Our results at the MTH are generally consistent with those of others. Cavanagh found an average STD of 45.7% at the second MTH with a load of full body weight [3] while we found an average STD of 19.5% with a load of approximately 50% body weight. Future research can build upon these findings by analyzing how the use of footwear and orthotic devices affect the pressure distribution and STD along the second ray of the plantar foot for optimal footwear prescription for people with DM and PN.

## AN IMPROVED SURROGATE METHOD FOR DETECTING THE PRESENCE OF CHAOS IN GAIT

David Miller, Nicholas Stergiou and Max J. Kurz

HPER Biomechanics Laboratory, University of Nebraska at Omaha, Omaha, NE

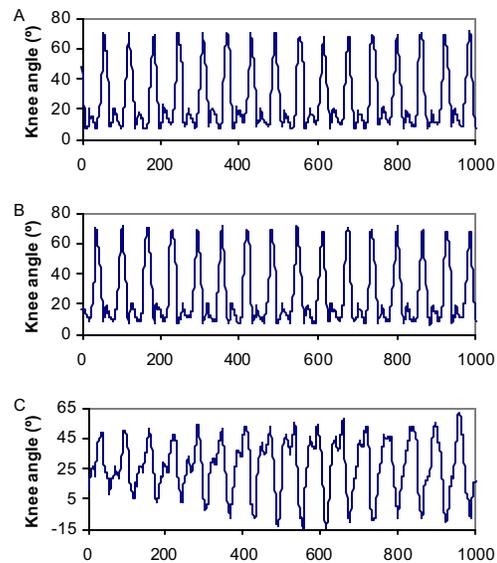

E-mail: [djmiller@mail.unomaha.edu](mailto:djmiller@mail.unomaha.edu), web: <http://www.unocoe.unomaha.edu/hper/bio/home.htm>

### INTRODUCTION

Surrogate analysis is essential to prevent the misdiagnoses of a purely random signal as deterministic chaos [1]. Several surrogate algorithms have been presented that attempt to destroy the chaotic features of a time series while maintaining the essential linear features. If the original time series is statistically different from the surrogate then, the fluctuations in the time series have a deterministic structure. Alternatively, a failure to find significant differences between the surrogate time series and the original time series indicates that the fluctuations are merely random noise. Recently, the surrogate algorithm of Theiler et al. [3] has been applied to support the notion that fluctuations in human gait have a deterministic pattern [1]. However, inspection of the generated surrogate indicates that much of the essential geometric features of the gait time series are destroyed (Figure 1A and C). In this case, it is questionable if this surrogate can be used to effectively discern the difference between chaotic fluctuations and random noise in a gait time series. Recently, Small and Tse [2] have overcome this difficulty with a pseudoperiodic surrogate (PPS) algorithm that preserves the inherent periodic components of the time series while destroying the subtle nonlinear structure. Although this algorithm appears promising, it has not been tested in human gait patterns. Here we show that the PPS algorithm provides a more robust verification of the presence of chaos in gait by preserving the essential features of the time series.

### METHODS

Six subjects walked at a self-selected pace on a treadmill for two minutes while the sagittal knee angles were captured with a 3D optical capture system. Surrogates of the respective time series were generated based on the PPS [2] and Theiler's algorithms [3]. Theiler's algorithm reorganizes the phases of the complex conjugate pairs in the frequency domain such that surrogate contains linearly filtered independent and identically distributed noise. The PPS algorithm generates a surrogate that follows the same vector field as the original time series, but is contaminated with dynamic noise. The PPS algorithm requires that the user define the embedding dimension, the time lag, and the noise radius. The embedding dimension and time lag were calculated with the Tools from Dynamics Software (Applied Chaos, LLC). Noise radius (?) was chosen such that the fine intercycle dynamics were removed, but the intracycle dynamics were preserved. If ? is too small, then the surrogate and the original time series are identical. If ? is too large, then the surrogate is a series of uncorrelated random noise. We selected ? to be the value that maximizes the expected number of short segments (length 2) to be the same between the surrogate and the original time series [2]. The largest Lyapunov exponents of the respective time series were calculated to test the null hypothesis that the surrogate and the original time series had the same dynamics.

**Figure 1:** Exemplar original knee angle time series (A), PPS (B), and Theiler's surrogate (C).

### RESULTS AND DISCUSSION

Significant differences ( $p < 0.05$ ) were found between the original and the respective surrogate time series. Both surrogate tests indicated that fluctuations in the knee time series had a deterministic structure that was significantly different from random noise. However, inspection of Figures 1A and C verifies that Theiler's algorithm alters the original geometric structure of the time series. Hence, it is trivial to find a significant difference between the surrogate generated by Theiler's algorithm and the original time series. It appears that Theiler's algorithm is of limited use for verifying the presence of chaos in gait patterns with an underlying periodic structure. Inspection of Figure 1A and B indicates that the PPS algorithm maintains the essential geometric structure of the gait time series. In fact, the surrogate and the original gait time series appear virtually indistinguishable. These results support the notion that the PPS algorithm is more suitable for detecting the presence of subtle chaotic fluctuations that appear in gait. The PPS algorithm should be adopted in future investigations to rigorously verify that fluctuations in gait patterns are in fact chaotic and not random noise superimposed on top of the time series.

## VALGUS LOADING CAUSES INCREASED *IN VITRO* ACL STRAIN IN SIMULATED JUMP LANDING

<sup>1,2</sup> Thomas J. Withrow, <sup>1</sup> Laura J. Huston, <sup>1</sup> Edward M. Wojtys, and <sup>2</sup> James A. Ashton-Miller

<sup>1</sup>University of Michigan – Medsport and Department of Orthopedic surgery;

<sup>2</sup>University of Michigan – Department of Biomedical Engineering; email: withrow@umich.edu.

### INTRODUCTION

Anterior cruciate ligament (ACL) injury has been associated with abrupt deceleration while running, cutting or landing<sup>3</sup>. Videotape analyses of these injuries has implicated valgus configuration of the lower extremity as a potential injury risk factor.<sup>5</sup> The previous experimental studies that have examined this injury mechanism have done so using sub-physiologic loading magnitudes and rates<sup>2,4</sup>. In this study, we investigated the effect of valgus loading on ACL strain response in a dynamic loading configuration that better simulates landing from a jump with pre-activated knee muscles. We tested the null hypothesis that the addition of a valgus knee impact moment would not significantly increase peak relative strain in the anteromedial ACL bundle compared with a flexion impact moment loading of similar magnitude.

### METHODS

Ten fresh cadaveric limbs were studied [mean (SD): 70.3 (15.4) years; 4 males; 6 females; ages 45 to 89]. Specimens were cut 15 cm proximal and distal to the knee joint and potted using polymethyl-methacrylate. A testing apparatus was constructed to simulate the position of a single extremity

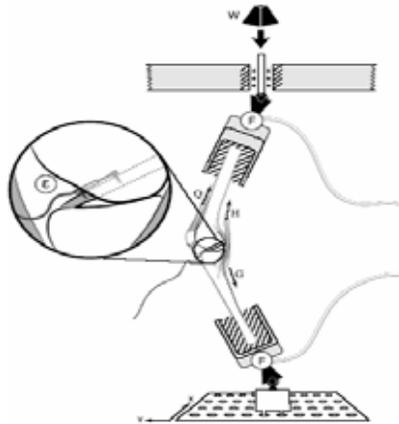

Figure 1. Schematic of test set-up

as it strikes the ground while landing from a jump or during a run/stop maneuver (Figure 1). Pre-impact muscle precontractions of the quadriceps, medial and lateral hamstrings, and medial and lateral gastrocnemius muscle-equivalents were achieved by pretensioning 7 kN/mm springs to maintain the initial angle of 25° knee flexion prior to impact. The impact force magnitude and its lever arm about the knee joint could be preset. The impact loading direction was standardized to either apply a flexion moment in the sagittal plane (“Flexion only” trial) or by additionally inclining the entire construct into 15 degrees of abduction a “Flexion + Valgus” moment trial.

A 150 N weight was released from a fixed height to strike an impact rod in series with the proximal femur. This exerted an impulsive compressive force and flexion moment resulting in an increase in knee flexion angle. Two 3-axis load cells (“F”) measured the 3-D forces and moments delivered to the knee construct, as well as the 3-D reaction forces and moments. A 3-mm DVRT (Microstrain, Burlington, VT) mounted on the ACL anteromedial bundle recorded its relative

strain<sup>1</sup>. Impact forces, quadriceps muscle force, and ACL strain data were recorded at 2 kHz using a 16-bit A/D board, while tibiofemoral kinematics were tracked at 400 Hz using an Optotrak 3020 system to the nearest mm and degree. A repeated measures (“ABA”) experimental design was run consisting of 10 ‘Flexion only’, 10 ‘Valgus + Flexion’, and 10 ‘Flexion only’ trials were run. The last five trials under each condition were analyzed. The peak relative strains for individual specimens were normalized by dividing them by the mean peak relative ACL strain under both ‘Flexion only’ conditions. A paired Wilcoxon signed rank test was used to test the null hypothesis with a  $p < 0.05$  significance level.

### RESULTS AND DISCUSSION

The mean (SD) peak impact force rose to 1,670 (390) N over a 30 ms time course, thus confirming the physiologic nature of the test. The impact forces did not differ between the ‘Valgus + Flexion’ and ‘Flexion only’ tests [1,620 (390) vs. 1,790 (380) N, respectively]. The mean (SD) relative strain during the ‘Valgus + Flexion’ loading was 4.3 (2.7)%, whereas the corresponding ACL strain measured 3.5 (2.8)% during the ‘Flexion only’ moment impact. Thus, we rejected the null hypothesis because the peak normalized relative ACL strain in the Valgus + Flexion configuration was significantly higher than that in both the initial ‘Flexion only’ configuration ( $p=0.04$ ) and final ‘Flexion only’ ( $p=0.02$ ) conditions. Mean (SD) peak normalized ACL strain when the joint was loaded in ‘Valgus + Flexion’ was 1.28 (0.38) [non-dimensional units] across all specimens, while the mean (SD) ACL strain when loaded by a ‘Flexion only’ impact moment was 1.00 (0.32). The pretensioned muscle-equivalent springs gave an immediate rise in tension upon stretch, similar to a lengthening contraction condition *in vivo*. Any test order effect that may have been present was minimal because there was no significant difference in the peak strains measured under the two ‘Flexion only’ conditions.

### CONCLUSIONS

In the slightly flexed knee, preloaded by quadriceps, hamstring and gastrocnemius muscle forces, relative ACL strain was significantly higher under a valgus + flexion impact loading than under a flexion-only impact loading.

## LACK OF HAMSTRING TENSION CAUSES INCREASED ACL STRAIN IN A SIMULATED JUMP LANDING

<sup>1,2</sup> Thomas J. Withrow, <sup>1</sup> Laura J. Huston, <sup>1</sup> Edward M. Wojtys, and <sup>2</sup> James A. Ashton-Miller

<sup>1</sup> University of Michigan – Medsport and Department of Orthopedic surgery;

<sup>2</sup> University of Michigan – Department of Biomedical Engineering; email: withrow@umich.edu.

### INTRODUCTION

An anterior cruciate ligament (ACL) injury can significantly affect short and long-term physical activity and health in an athlete<sup>4</sup>. ACL injuries have been associated with abrupt deceleration while running, pivoting, awkward landings, and “out of control” play<sup>3</sup>. A factor in these injuries may be the state of lower extremity muscle recruitment at the time of impact. For example, for a given quadriceps activity, a decrease in hamstring muscle activity has long been viewed as hazardous for the ACL. Previous experimental studies have demonstrated the protective effects of hamstring muscle force, but only at low and non-physiologic loading magnitudes and rates<sup>1,2</sup>. In these experiments we investigated ACL strain under more physiological loading levels associated with landing a jump with precontracted quadriceps and gastrocnemius muscles. We tested the (null) hypothesis that, compared with the presence of a hamstring force, lack of hamstring forces would not affect the peak strain measured in the anteromedial bundle of the ACL

### METHODS

Ten fresh cadaveric limbs were studied [mean (SD): 74 (17) years; 5 males; 5 females; age 45 to 100 years]. Specimens were divided 15 cm proximal and distal to the knee joint and potted using polymethylmethacrylate. A testing apparatus was constructed to simulate the position of a single extremity as it strikes the ground while landing on one leg from a jump or run/stop maneuver. Pre-impact muscle preloads of the quadriceps, medial and lateral hamstrings, and medial and lateral gastrocnemius muscle-equivalents, the initial angle of knee flexion, and impact force magnitude and its direction about the knee joint could all be preset. The stiffness of each muscle-equivalent was 7 kN/mm. In all trials, an initial knee flexion angle of 25 degrees was used and the impact loading direction was standardized.

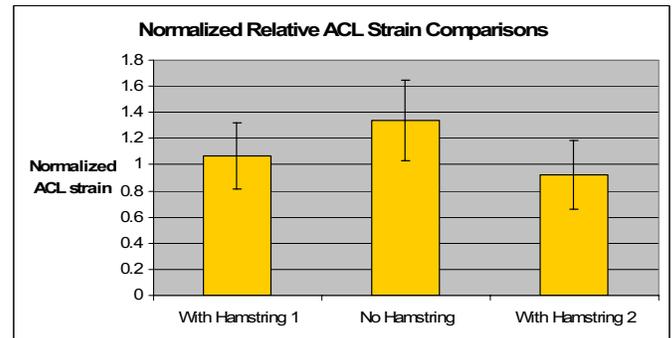

A 150 N weight was released from a fixed height to strike an impact rod in series with the proximal femur. This exerted an impulsive compressive force (peak < 30 ms) resulting in an increase in knee flexion angle. Two 3-axis load cells measured the 3-D forces and moments delivered to the construct. A 3 mm DVRT (Microstrain, Burlington, VT) was mounted on the ACL anteromedial bundle to record its relative strain<sup>1</sup>. Impact forces, quadriceps muscle force, and ACL strain data were recorded at 2 kHz using a 16-bit A/D board, while tibiofemoral kinematics were tracked using an Optotrak 3020 system (Northern Digital, Inc, Waterloo, Canada) and recorded at 400 Hz to the nearest mm and degree. Using a repeated measures trial design, three sets of ten trials were run with (“With Hamstring 1”), without (“No Hamstring”) and with hamstring (“With Hamstring 2”) pre-tension, in that order. The last five trials of each condition were then analyzed for each specimen. The peak relative strains for individual specimens are then normalized by dividing them by the mean peak relative ACL strain in the ‘W/ Hamstring’ tests.

A non-parametric paired Wilcoxon signed rank test was used to test the null hypothesis with  $p < 0.05$  being considered significant.

### RESULTS AND DISCUSSION

The mean (SD) peak impact force was 1,460 (260) N. The impact forces were not significantly different in the ‘No Hamstring’ and ‘With Hamstring’ tests [1,410 (210) vs. 1,480 (280) N, respectively]. The mean peak (SD) relative strain in the ‘No Hamstring’ conditions was 3.1 (1.3)%, whereas the corresponding data was 2.5 (0.8)% in the ‘With Hamstring’ condition. There was no order effect in that there was no significant difference in peak relative ACL strain between the two ‘With Hamstring’ conditions.

Most importantly, the null hypothesis was rejected in that the peak normalized relative ACL strain in ‘No Hamstring’ condition was significantly higher than the corresponding ACL strain in the ‘With Hamstring 1’ condition ( $p=0.004$ ) or ‘With Hamstring 2’ condition ( $p=0.022$ ). These results were obtained with loading levels exceeding bodyweight and impact loading rates typical of landing from a jump. Our results under these more physiological loadings corroborate earlier results at low loads and quasistatic loading rates<sup>1,2</sup>.

**Figure 1:** Comparison of the normalized mean (SD, denoted by vertical bars) peak relative ACL strain in the two test conditions.

### CONCLUSIONS

At physiological loading levels, decreased hamstring tension (and stiffness) led to increased peak relative ACL strain when simulating landing on a flexed knee with precontracted quadriceps and gastrocnemius muscle-equivalents. Lack of an order effect precludes this result having been due to the sequence of testing or cumulative soft tissue damage.

**FINITE ELEMENT ANALYSIS OF A TOTAL ANKLE ARTHROPLASTY OVER ONE STANCE PHASE**

<sup>1</sup>Nick Byrne, <sup>2</sup>Heidi-Lynn Ploeg, and <sup>3</sup>Daren Deffenbaugh

<sup>1</sup>Department Biomedical Engineering, University of Wisconsin, Madison, WI, USA; email: [njbyrne@wisc.edu](mailto:njbyrne@wisc.edu)

<sup>2</sup>Departments of Mechanical and Biomedical Engineering, University of Wisconsin, Madison, WI, USA

<sup>3</sup>DePuy Orthopaedics, Inc. a Johnson & Johnson company, Warsaw, IN, USA

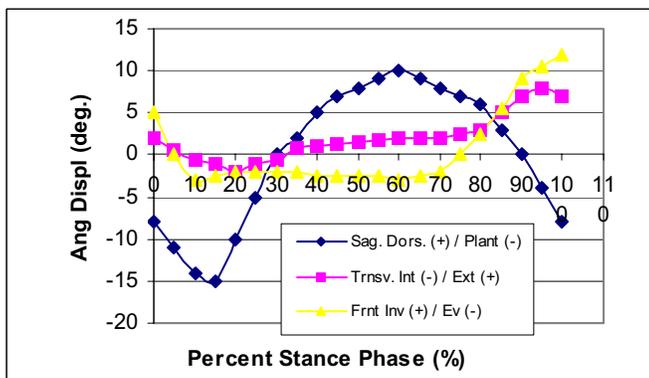

**INTRODUCTION**

It is known in the biomaterials and orthopedics communities that excessive wear debris in orthopedic implants, in combination with excessive bone-implant interface stress can lead to osteolysis of the supporting bony structures. Osteolysis can cause component loosening, migration, and subsidence [1]. These are the biggest concerns to engineers and surgeons when providing total ankle joint replacements. In total ankle replacement (TAR) specifically, clinical follow-ups have shown the talar component to experience loosening and subsidence more frequently than desired [2].

The purpose of this project is to determine the maximum contact stresses present and maximum polyethylene (PE) deformation resulting between the talar component and polyethylene tibial insert of the size 4 AGILITY Ankle implant (DePuy Orthopaedics, Inc., a J&J co., Warsaw, IN) through one stance phase of the gait cycle under physiological loading. Maximum interface stress between the talar component and the supporting bone will also be investigated to determine the effect of torsion in the transverse plane.

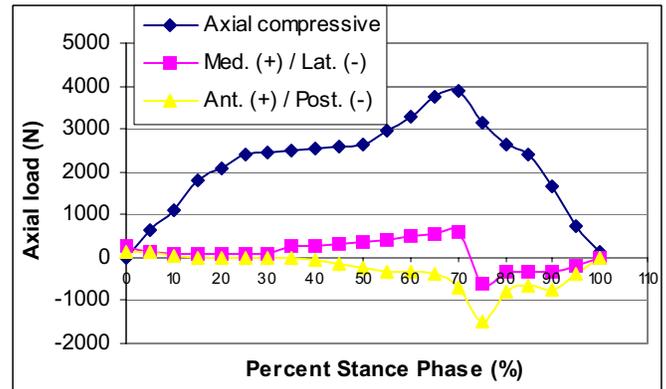

**METHODS**

Physiological forces and displacements will be applied to the AGILITY components at every five percent of the stance phase of the gait cycle, resulting in 21 total models. A quasi-dynamic analysis of one movement through the stance phase of gait will result from the combination of these 21 models. Component models will be aligned in their respective positions (Figure 1) [3] in Unigraphics, from EDS Corp., Plano, TX.

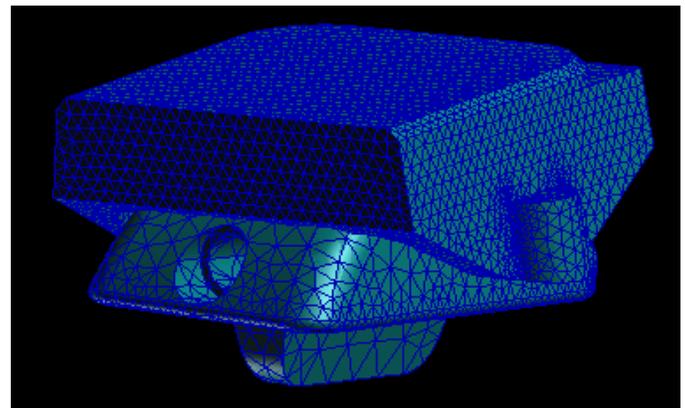

**Figure 1:** Talus Position in Sagittal, Transverse, and Frontal Planes over Stance Phase of Gait

The solid models will be imported into PATRAN, from MSC Software Corp., Santa Ana, CA, where the boundary conditions, material properties, and mesh will be defined. Model 15 of 21 is shown below (Figure 3). A physiological varying torsional load will also be applied, although it is not shown.

**Figure 2:** Loads on Ankle Joint in 3 Directions over Stance Phase of Gait Cycle

**Figure 3:** FE mesh of the AGILITY Ankle at 70% of the stance phase of gait: 8° dorsiflexion, 2° external rotation, 2° eversion

**RESULTS AND DISCUSSION**

Preliminary analysis has shown that maximum contact stresses and polyethylene deformation occur at 70-75% of the stance phase. This was expected, as axial loads (Figure 2) [4] are the greatest and dorsiflexion is also substantial. It is expected that areas of high contact stress and large PE deformation on each of the 21 discrete computational models will combine to closely resemble the wear patterns found on the clinical retrievals of PE tibial inserts. It is also expected that in positions under heavy torsional loading, large medial-lateral contact stresses will be observed in the talus, which may translate into possible large shear forces at the talus-bone interface.

## ELIMINATION OF ECG CONTAMINATION FROM EMG SIGNALS: AN EVALUATION OF CURRENTLY USED REMOVAL TECHNIQUES.

<sup>1</sup>Janessa D. M. Drake, <sup>1</sup>Jack P. Callaghan

<sup>1</sup>Faculty of Applied Health Sciences, Department of Kinesiology, University of Waterloo, Canada  
 Email: jdrake@ahsmaail.uwaterloo.ca, web: [www.ahs.uwaterloo.ca/kin/people/faculty/callaghan.htm](http://www.ahs.uwaterloo.ca/kin/people/faculty/callaghan.htm)

### INTRODUCTION

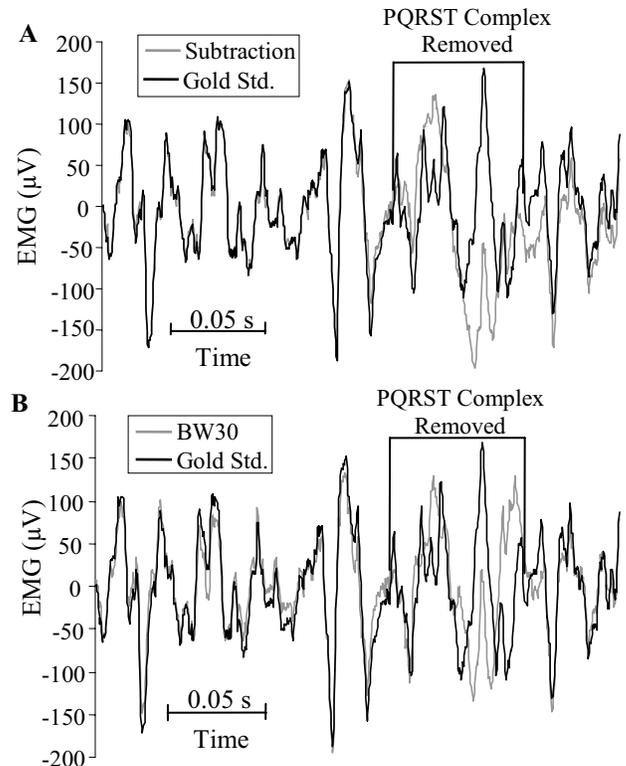

Trunk electromyography (EMG) is often contaminated with heart muscle electrical activity (ECG) due to the proximity of the collection sites to the heart and the volume conduction characteristics of ECG through the torso. Few studies have quantified ECG removal techniques relative to an uncontaminated EMG signal (gold standard or criterion measure), or made direct comparisons between different methods for a given set of data. The purpose of this study was to concomitantly evaluate four current and commonly used methods for ECG contamination removal from EMG signals.

### METHODS

ECG recordings at two intensity levels (rest and 50% maximum predicted heart rate) were superimposed on 11 uncontaminated biceps brachii EMG signals (rest, 7 isometric, and 3 isoinertial levels). The removal methods used were high pass digital filtering (HPF: finite impulse response (FIR) using a Hamming window, and 4<sup>th</sup> order Butterworth (BW) filter) at five cutoff frequencies (20, 30, 40, 50, and 60Hz), a template technique (template subtraction, and a zero-replacement template), combinations of the subtraction template and HPF, and a frequency subtraction/signal reconstruction method. Four performance indicators were calculated from the cleaned signals: root mean square error, mean power frequency, and two coefficients of determination. The indicators were individually ranked from a low of 1 up to 23, averaged, and natural logged for each contraction level. A two-way ANOVA with two repeated measures was used to investigate the effects of the contraction level, heart rate level, and cleaning method. A Least Square Means test was used to decipher interactions.

### RESULTS AND DISCUSSION

For muscle activation levels between 10-25% of maximum voluntary contraction (MVC), the template subtraction and BW with a 30Hz cutoff were the two best individual methods for maximal ECG removal with minimal EMG distortion (Figure 1), ranking 3 and 5 out of 23 respectively across all contraction and heart rate levels. Only combinations of the subtraction and filtering outperformed these methods (Table 1). The subtraction method has been shown to be more

**Figure 1:** A comparison of the uncontaminated EMG signal (Gold Standard) and the cleaned contaminated signal using the BW30 (A) and subtraction (B) methods.

effective than gating [1], and using a FIR with a 30Hz cutoff to be more effective than with a 60Hz cutoff [2] for ECG removal. This study supports these findings.

### CONCLUSIONS

For the EMG levels evaluated in this study, the BW filter with a 30Hz cutoff provided the optimal balance between ease of implementation, time investment, and performance across all contractions and heart rate levels.

## DO EXERCISE BALLS PROVIDE A TRAINING ADVANTAGE FOR TRUNK EXTENSOR EXERCISES? A BIOMECHANICAL EVALUATION.

<sup>1</sup>Janessa D. M. Drake, <sup>1</sup>Steve L. Fischer, <sup>1</sup>Stephen H. M. Brown, <sup>1</sup>Jack P. Callaghan

<sup>1</sup>Faculty of Applied Health Sciences, Department of Kinesiology, University of Waterloo, Canada

Email: jdrake@ahsmaail.uwaterloo.ca, web: [www.ahs.uwaterloo.ca/kin/people/faculty/callaghan.htm](http://www.ahs.uwaterloo.ca/kin/people/faculty/callaghan.htm)

### INTRODUCTION

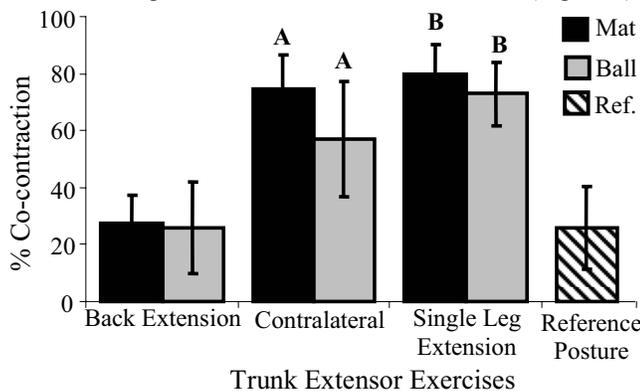

The use of exercise balls is becoming widespread in the exercise and rehabilitation communities even though the effects of performing trunk extensor exercises on an exercise ball have not been assessed. Only a few abdominal muscle exercises have been quantitatively evaluated in both the traditional (mat) and ball styles [1], but the reported benefits for these exercises on a ball have been equivocally applied to all exercises. To address the effect of an exercise ball on extension exercises, a direct comparison of the same exercises on a mat and on a ball is required. The purpose of this study was to evaluate differences in the biological response of muscle activation, lumbar spine posture, and loading variables for extensor exercises performed on two surfaces.

### METHODS

Bilateral muscle activation was recorded from seven sites (rectus abdominis (RA), external and internal obliques (EO/IO), latissimus dorsi, thoracic and lumbar erector spinae (TES/LES), and multifidus (MULT)) on eight subjects. Three-dimensional lumbar spine postures (ISOTRAK, 3Space), and upper body kinematics (video) were recorded while the participants performed the exercises. An EMG-driven model was used to estimate spinal loading. Two-way repeated measures analyses of variance (ANOVA) were used ( $\alpha=0.05$ ). The surface main effect and surface-exercise interactions were reported since the objective of this work was to assess surface type. A Least Square Means test was used to decipher surface-exercise interactions.

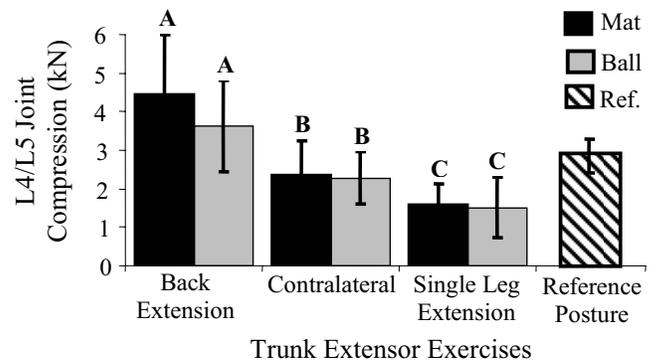

### RESULTS AND DISCUSSION

Co-contraction of trunk flexor and extensor muscles was reduced by 30.4% and 9.5% respectively for the contralateral and single leg extension exercises when performed on the ball, but was unchanged for the back extension exercise (Figure 1).

**Figure 1:** Percent peak co-contraction between left and right trunk flexors (RA, EO, and IO muscles), and trunk extensors (TES, LES, and MULT muscles).

The peak lumbar extension and range of lateral bend and axial twist postures attained during the exercises did not differ between surfaces. Lower spinal loading (compression and anterior-posterior shear) was observed on the ball (Figure 2). Peak muscle activation remained unchanged or decreased when the extension exercises were performed on the exercise ball. The magnitude of muscle activation for the exercises performed on the surfaces were similar to literature values [2,3]. The assumption that the use of an exercise ball will always create a greater challenge for the musculoskeletal system was not supported by the findings of this study.

**Figure 2:** Mean EMG-driven model estimates of maximum L4/L5 joint compression across the participants (N = 8). The significant differences between surfaces for each exercise are indicated with the same letter.

### CONCLUSIONS

In a healthy young population there does not appear to be any training advantage to performing extensor exercises on an exercise ball versus a floor surface. However in a rehabilitation scenario, these exercises performed on a ball could reduce low back loading and hence the potential for re-injury would be reduced. Those desiring exercises that elicit high levels of muscle activation and co-contraction can obtain the same or higher levels by performing these trunk extensor exercises on a mat.

## MOMENT ARMS AND MOMENT POTENTIAL BALANCE AT THE INDEX MCP JOINT

<sup>1</sup>William L. Buford, Jr., Shukuki Koh, Clark R. Andersen, Steven F. Viegas  
 Orthopaedic Research Labs, University of Texas Medical Branch,  
 Galveston, TX, <sup>1</sup>email: wbuford@utmb.edu

### INTRODUCTION

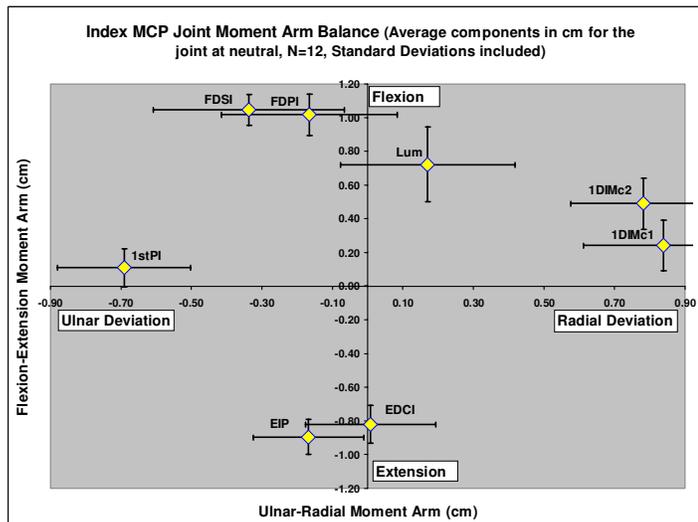

This study extends prior investigations of muscle moment arms at the index metacarpo-phalangeal joint (MCPJ) to provide a more detailed description of muscle balance. By combining moment arm data with known tension fractions a renewed understanding of moment potential balance helps to describe clinical conditions as well as provide knowledge relevant to reconstruction and joint arthroplasty.

### METHODS

Twelve fresh cadaver arms (6 male, 6 female, average age 71) were acquired through the Texas willed body program. Specimens were dissected through limited incisions but sufficiently to attach nylon cable to the index finger tendons using previously described methods.<sup>2</sup> The muscles studied were the flexor digitorum profundus, flexor digitorum sublimus, extensor digitorum communis, extensor indicis proprius, first palmar interosseous, lumbrical, and two paths of the first dorsal interosseous based on origination on the first metacarpal and the second metacarpal (FDPI, FDSI, EDCl, EIP, 1stPI, Lum, 1DIMc1, and 1DIMc2). Muscle excursions, flexion-extension (FE) and ulnar-radial (UR) MCPJ angles were measured and moment arms determined using methods previously described.<sup>1, 2</sup>

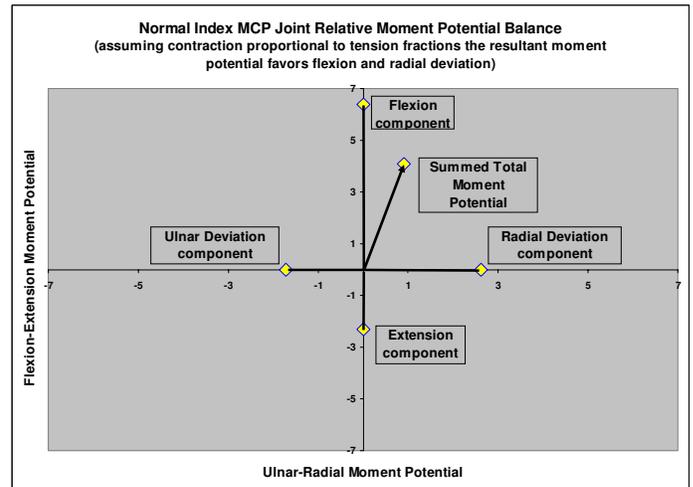

### RESULTS AND DISCUSSION

The average UR moment arm values for each muscle with the MCPJ at neutral are combined with the same for FE as described in an earlier study.<sup>2</sup> Results yield the moment arm balance described in Figure 1.

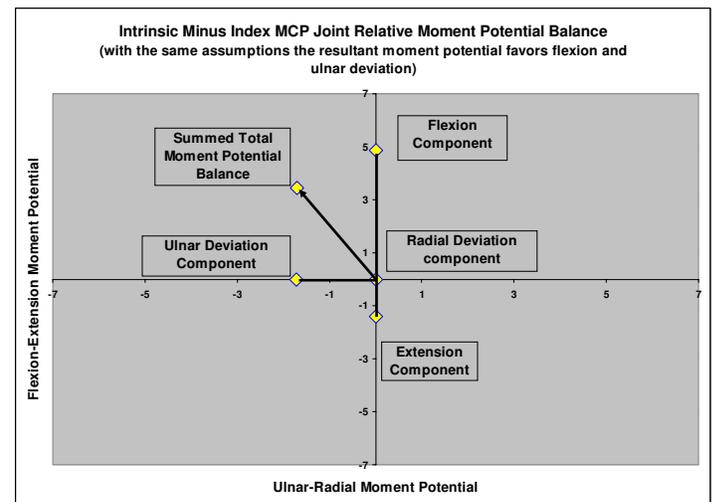

**Figure 1.** Average moment arms for the index MCPJ at neutral, indicating primary FE and UR functions.

To provide an indication of moment potential balance, the moment arms are multiplied by the respective muscle tension fractions<sup>3</sup> and combined to indicate the potential moment in the principal rotation directions (flexion, extension, ulnar and radial deviation). The result for the normal hand appears in Figure 2.

**Figure 2.** Summary of the moment producing potential of the muscles at the index MCPJ for the normal hand.

When the effects of the intrinsic muscles are removed these results define the moment potential balance for the intrinsic minus hand shown in Figure 3.

**Figure 3.** Index MCPJ moment potential balance without the effects of the intrinsic muscles.

### CONCLUSIONS

These results combining improved investigations of moment arms for the index in FE and UR motion with previously described tension fractions provide a clear graphical understanding of joint muscle balance. For example, it is readily seen by comparing figures 2 and 3 that the intrinsic minus joint will eventually migrate ulnarly. Also it can be concluded that arthroplasty should seek to reconstruct the balance defined by Figure 2.

## KINETIC ANALYSIS OF MANUAL WHEELCHAIR PROPULSION OVER THREE SURFACES

Jennifer Mercer, Michael Boninger, Alicia Koontz, Jon Pearlman, and Rory Cooper  
 Human Engineering Research Laboratories, VA Medical Center, University of Pittsburgh, Pittsburgh, PA 15206;  
 email: [merceroj@herlpitt.org](mailto:merceroj@herlpitt.org), web: [www.herlpitt.org](http://www.herlpitt.org)

### INTRODUCTION

Manual wheelchair users (MWUs) encounter a variety of floor surfaces and obstacles during activities of daily living. Some obstacles, such as carpet and ramps, are more difficult to negotiate than a smooth surface [1]. MWUs must increase their propulsion force, stroke frequency, or contact time to propel over these more difficult floor surfaces. Previously, propulsion forces, rate of force application, and stroke cadence have been associated with secondary injuries of the wrist [2] and shoulder [3]. The purpose of this study was to evaluate the biomechanics of wheelchair propulsion over tile, carpet, and up a ramp. We expected to see an increase in propulsion force, torque, rate of force application, pushrim contact time, and cadence, along with decreased velocity, as the MWU propels over carpet and up a ramp as compared to tile.

### METHODS

Twenty-three male subjects were consented at The 2004 National Veterans Wheelchair Games (St. Louis, MO). Inclusion criteria included ownership of a manual wheelchair that subjects were capable of propelling and age between 18 and 65 years. Subjects were excluded based on a self-reported history of heart or cardiovascular conditions. Subjects had an average age, height, and weight of 45.8±8.6 years, 1.8±0.14 m, and 99.3±26.4 kg respectively.

The SMART<sup>Wheel</sup> (Three Rivers Holdings, LLC), a wireless force and torque sensing wheelchair wheel, facilitates biomechanical analysis of wheelchair propulsion over real world obstacles [4]. A SMART<sup>Wheel</sup> was secured to each subject's manual wheelchair. Subjects were asked to propel at a self-selected comfortable speed over tile, low-pile carpet, and up an ADA compliant ramp while pushrim forces and torques were recorded by the SMART<sup>Wheel</sup>. All biomechanical variables (Table 1) were calculated based on an average of 5 strokes.

Six separate one-factor ANOVAs with Bonferroni post-hoc analysis were used to compare each of the biomechanical variables (dependent variables) during propulsion over three surfaces (independent factor with three levels).

### RESULTS AND DISCUSSION

Table 1 summarizes the comparison of biomechanical variables for wheelchair propulsion over three surfaces. Significant differences were found between the ramp and both tile and carpet for all but one variable (cadence). MWUs used increased resultant force, wheel torque, rate of force application, and contact time. They also propelled slower over the ramp compared to tile and carpet. The same trends were observed for propulsion over carpet compared to the tile, but no significant differences were detected between these two surfaces.

In accordance with our hypothesis, MWUs had to increase their propulsion force, wheel torque, rate of force application, and contact time in order to negotiate the ramp. The MWUs did not increase their stroke cadence but instead went slower up the ramp. Low-pile carpet was used in the study (due to availability) and it may not have provided enough resistance to show significant difference in propulsion over carpet compared to propulsion over tile, as we had expected.

### CONCLUSIONS

Unfortunately, using increased force and rate of force application has been previously linked to injury [2,3]. Even with this increased effort, MWUs still propel slower on the more challenging obstacles. It is important that MWUs are able to maintain their independence, without increasing their risk of secondary injuries. Future studies should investigate how changes in wheelchair setup and/or propulsion training protocols can minimize the risk factors for secondary injury that were observed in this study.

### INTRODUCTION

Peak plantar pressure (PPP) during walking has been used extensively as an indicator of risk for skin breakdown in the diabetic foot. Although skin breakdown is associated with high PPP, researchers have not been able to identify a critical magnitude of PPP that adequately predicts skin breakdown in the neuropathic population. We speculate that the change in plantar pressure at the PPP location, a “peak pressure gradient, (PPG)”, is more important than the PPP because a PPG may identify a concentration of stress (a harmful vertical shearing) to the soft tissues. The purposes of this presentation are to a) describe methods for obtaining the PPG, and b) determine if the PPG at the PPP location is substantially higher in the forefoot than the rearfoot (even compared to PPP) in subjects with diabetes (DM) and a history of plantar ulcer. Skin breakdown typically is in the forefoot rather than the rearfoot despite fairly similar PPPs [1]. A much higher PPG at the PPP location in the forefoot compared to the rearfoot may partially contribute to a differential in skin breakdown location.

### METHODS

The PPG at the PPP location can be calculated by

$$PPG = \max\left(\frac{\partial P}{\partial r}\right)$$

where  $\frac{\partial P}{\partial r}$  (space rate of change of pressure on the plantar surface) is the directional derivative of pressure P at the PPP location on the plantar surface in any direction given by vector  $\vec{r}$ .

Plantar pressure data during walking were collected on 10 subjects (6 Males/4 Females, mean age 58.0±10.3 years, mean BMI 32.6 ±9.5 kg/m<sup>2</sup>) with DM (2 Type 1, 8 Type 2, and mean duration of DM 16.5 ± 10.0 years), PN, and a history of a plantar ulcer.

An F-scan system (Tekscan, South Boston, MA, USA) was used to collect the plantar pressure data during walking at a self-selected pace in standardized shoes with a 1-inch heel [2]. The recorded plantar pressure data were analyzed for the PPP and PPG for the forefoot and rearfoot. The PPG at the location of the PPP was calculated after a bicubic polynomial spline smoothing of the pressure data. The PPP and PPG at the PPP location for each area of interest were averaged over three steps during walking.

Analysis: A one tailed, paired t-test on the ratios of PPP and PPG between the forefoot (FF) and rearfoot (RF) was used to determine differences in PPP and PPG between the FF and RF.

**Table 1:** Mean PPP and PPG at Forefoot and Rearfoot

PPP FF (kPa)	PPP RF (kPa)	PPG FF (kPa/mm)	PPG RF (kPa/mm)
347.80	279.17	32.84	12.05
± 75.45	± 97.16	± 15.52	± 5.30

### RESULTS AND DISCUSSION

The mean PPG was 171% higher in the FF compared to the RF in subjects with diabetes and a history of plantar ulcer while the mean PPP was only 25% higher in the FF compared to the RF (Table 1). The mean PPG FF/RF ratio (3.09) was

**Table 2:** Mean Ratios of Individual Forefoot to Rearfoot Values for PPP and PPG; and Results of Paired t-test Comparison

(PPP FF)/(PPP RF)	(PPG FF)/(PPG RF)	P value
1.41 ± 0.75	3.09 ± 1.54	0.001

significantly greater than the PPP FF/RF ratio (1.41) (p<0.001, Table 2). The PPG likely is much lower in the RF than the FF because of differences in soft tissue thickness and shape of the underlying bony structures. A much higher PPG at the PPP location in the FF compared to the RF may be one reason why skin breakdown typically occurs in the FF rather than the RF despite fairly similar PPPs. Because the PPG may identify harmful vertical shearing of soft tissues on the plantar foot, we propose that it is an important variable to characterize the pressure distribution on the plantar surface and to predict potential plantar skin injuries on the neuropathic foot.

### CONCLUSIONS

We describe a new variable, the PPG, which may provide important information about the risk for skin breakdown. PPG is much higher in the FF compared to the RF and this may help to explain why most ulcers occur in the FF despite similar PPPs. Evenly distributed high plantar pressures likely do not cause skin breakdown. We believe that the space rate of change in plantar pressure at PPP location, the PPG, is an important variable to help identify risk for skin breakdown on the neuropathic foot, and that it deserves further investigation.

## KINEMATICS OF RUNNERS WITH AND WITHOUT PATELLOFEMORAL PAIN DURING PROLONGED TREADMILL RUNNING

<sup>1</sup> Tracy A. Dierks, <sup>1,2</sup> Irene Davis, <sup>1</sup> Kurt T. Manal, and <sup>3</sup> Joseph Hamill

<sup>1</sup>University of Delaware, Newark, DE, USA; <sup>2</sup>Drayer Physical Therapy Institute, Hummelstown, PA, USA; <sup>3</sup>University of Massachusetts, Amherst, MA, USA; email: tdierks@udel.edu, web: http://www.udel.edu/PT/davis/index.htm

### INTRODUCTION

It has been suggested that abnormal lower extremity kinematics during running are related to patellofemoral pain (PFP). Specifically, during the first half of stance when the knee is loaded, excessive internal rotation of the femur may result in lateral patellae maltracking [1,2]. Similarly, the patellofemoral joint may also be influenced by excessive knee valgus, which may be partly due to increased femoral adduction [1]. Also, it has been reported that PFP is associated with weak hip abductors and external rotators [3]. Therefore, these abnormal femoral motions may become more exaggerated in an exerted state, such as at the end of a prolonged run. Conversely, PFP has also been associated with decreased knee flexion during functional activities, which is thought to reduce the loads on the patellofemoral joint [1]. Further, the coupling that occurs between the knee and the foot may result in a decrease in rearfoot eversion as well [2].

While abnormal kinematics are believed to be related to PFP, few studies have examined the relationship between kinematics and PFP during running. Furthermore, no studies have investigated kinematics in a PFP group while running with pain and in an exerted state. Therefore, the purpose of this study was to compare the lower extremity kinematics of runners with PFP to uninjured runners over the course of a prolonged run. It was hypothesized that runners with PFP would display larger angular peaks for motions at the hip and that they would increase more than the uninjured group by the end of the run. It was also expected that the PFP group would exhibit smaller peaks at the knee and the rearfoot and that these values would decrease by the end of the run, whereas the uninjured group would display increases.

### METHODS

Twenty runners with PFP and 20 healthy, uninjured runners participated in the study. All were between the ages of 18 and 45 and ran a minimum of 10 miles per week. The PFP group consisted of runners who experienced anterior knee pain for a minimum of two months when running. The tested limb in the PFP group was the side with the most painful knee, while the uninjured group was chosen randomly.

Three-dimensional kinematic data (120 Hz) were collected while subjects performed a prolonged run on a treadmill at a self-selected pace. The prolonged run ended when one of three events occur: 1) 85% of the subject's heart rate maximum was reached, 2) a score of 17 was reached on a rating of perceived exertion scale, and 3) for the PFP group, a

score of 7 was reached on a visual analog scale for pain. Twenty consecutive footfalls were collected at the beginning and at the end of the run. For each subject, the peak angular values for rearfoot eversion, tibial internal rotation, knee flexion, knee internal rotation, knee adduction, hip adduction, and hip internal rotation were determined for each stance phase and then averaged. A 2-way repeated measures ANOVA (group x time) was used to determine differences for each kinematic variable ( $p \leq 0.05$ ).

### RESULTS AND DISCUSSION

The expectation that the PFP runners would display changes different from the uninjured runners in their peak values throughout the run was not supported. No interactions were found for any of the kinematic variables. As expected, the main effect for peak knee flexion was different between the two groups, with the PFP group exhibiting less knee flexion than the uninjured group (Table 1). The observed decreased knee flexion may be a compensatory strategy that was adopted to reduce knee pain because increased knee flexion will increase patellofemoral compressive forces, thus producing greater pain. For the main effect of time (begin to end), peaks for eversion, tibial internal rotation, knee internal rotation, and hip adduction all significantly increased from the beginning of the run to the end (Table 1), which is consistent with the literature [4]. This suggests that, regardless of group, as runners progress from a non-exerted to an exerted state, there is an increase in peak motions. While the majority of these observed increases were only between one to two degrees, both groups changed by approximately the same amount. In the PFP runners, these small increases may have been enough to bring them to their pain threshold, as 13 of 20 runners ended the run due to pain.

### CONCLUSIONS

Based on the results of this study, runners with PFP exhibited less knee flexion than uninjured runners, which may be a mechanism to guard against pain. With the exception of knee flexion, both groups displayed similar peak angles at the beginning and end of the prolonged run. By the end of the run, these peak angles typically increased in a similar fashion between the two groups.

<sup>1</sup>Ph.D Candidate, Department of Mechanical and Materials Engineering, Queen's University, Canada; [amiri@me.queensu.ca](mailto:amiri@me.queensu.ca)

<sup>2</sup>Ph.D, Department of Mechanical and Materials Engineering, Queen's University, Canada; [wyss@me.queensu.ca](mailto:wyss@me.queensu.ca)

### INTRODUCTION

The goal of this study was to see if the geometry of the tibial plateau and meniscal surfaces in the passive computer knee models can be considered as a combination of simple rigid geometries. It was also desirable to assess the role of each part of the proposed geometry in guiding the passive pattern of motion. The latter was done by eliminating different parts of the geometry from the complete model and comparing the simulation results before and after each elimination. It has been found that the resulting pattern of motion of the proposed geometry matches the experimental data and the constrained-based knee model. The comparisons between the results of different geometrical configurations led to the understanding of the roles of each part of the geometry in guiding the passive motion.

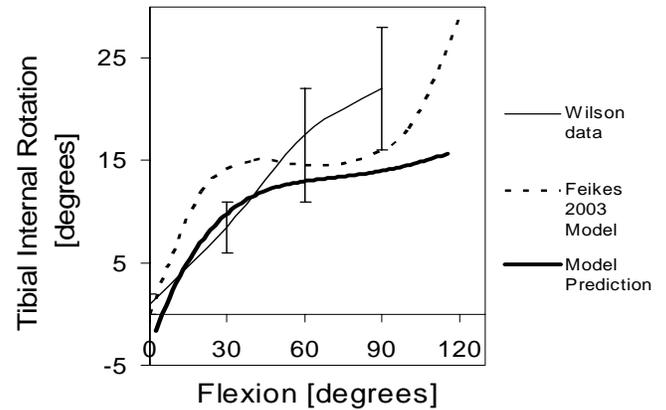

### METHODS

The data reported in the literature regarding the profile of the tibial plateau in different planes were used to construct the simplified tibial geometry. The geometry of the tibial plateau surfaces in the sagittal plane has been reported to be flat in the lateral part, and a combination of a flat surface and a 11° slope in the medial portion [1]. The medial side of the tibial eminence in the frontal plane has a radius matching the femoral condyle [2], and it was modeled as a wedge with the profile in the frontal plane and extruded antero-posteriorly [3]. The lateral side of the tibial eminence was simplified as an incomplete cone [3]. The geometry of the medial meniscal surface was considered rigid and located at the extreme end points it can reach in its range of motion [4,5]. The profile of the meniscal geometry was generated considering the fact that the meniscal geometry follows the femoral surface shape. The lateral meniscus was considered as an extension to the flat lateral tibial surface [6].

Ligaments were modeled as non-linear springs and their stiffness, initial strains, and insertions points were extracted as average values reported in the literature [7,8]. A scanned femoral surface was used and all the elements were put together in ADAMS (dynamic simulation software package). A gradual flexion imposed to the model, and the kinematics response of the model was measured. Subsequently, different parts of the tibial geometry were eliminated separately and simulation was performed for each case.

### RESULTS AND DISCUSSION

The internal-external rotation of the tibia and its anterior-posterior movement were determined for the complete configuration. Figure 1 compares the internal external rotation of the tibia with the results of the experimental data reported by Wilson et al. [9] and the prediction of the constrained-based model proposed by Feikes et al. [10]. Table 1 shows the internal tibial rotation for different configurations.

**Figure 1:** Comparison of the model prediction with the published experimental data and the constrained-based model

Geometric Configuration	Tibial Rotation				
	Flexion	30°	60°	90°	120°
All Elements present		9.7	13.4	13.8	17.3
Excluding Lateral Meniscal		9.3	15.7	48.1	48.2
Excluding Medial Meniscal		6.2	8.2	10.1	8.7
Excluding Lateral Cone		8.2	13.3	14.1	16.6
Excluding Medial Eminence		8.9	12.9	14.5	28.7

**Table 1:** Tibial internal rotation for different geometric configurations at different flexion angles.

### CONCLUSIONS

Based on the fact that the proposed simplified geometrical configuration replicates the natural passive kinematic patterns, it can be concluded that the recommended geometry includes the important shapes that have influence in guiding the passive motion. The medial meniscus has shown important roles in forcing the joint to undergo higher internal rotation during flexion, while the lateral meniscal extension and medial eminence seem to have a role in preventing the joint from going to excessive internal rotations.

## ANKLE PLANTAR FLEXOR FORCE CAPACITY DURING TOE WALKING

### INTRODUCTION

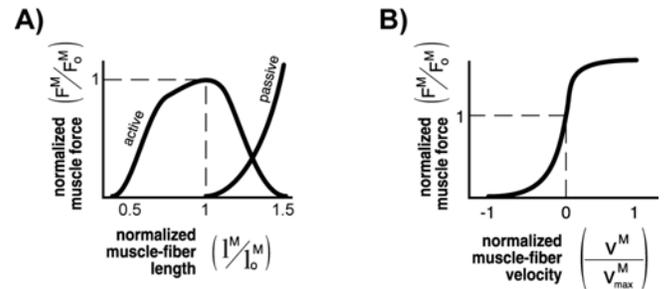

Toe walking, a gait deviation associated with a variety of neurological disorders, has been suggested to provide a compensatory advantage due to an observed reduction in net plantar flexor moment in terminal stance compared to heel-toe walking [1, 2]. Perry et al. [3], however, showed that although the net plantar flexor moment decreased during toe walking, muscle activity recorded from the plantar flexors increased, reflecting the need for greater muscle effort (defined by the level of motor unit recruitment). They hypothesized that the dichotomy between increased muscle activity and decreased joint moment was due to a reduction in force generation capacity associated with the increased plantar flexion angle. The goal of the present study was to explicitly test this hypothesis using forward dynamical simulations of toe and heel-toe walking to assess the force generating capacity of the plantar flexors by examining each muscle's contractile state (i.e., fiber activation, length and velocity).

### METHODS

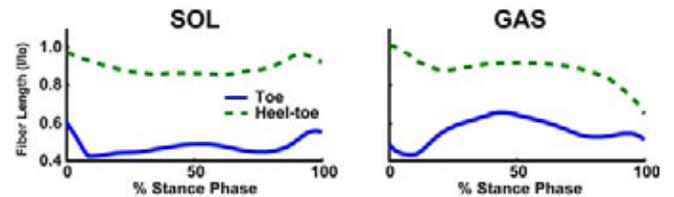

Forward dynamical simulations of toe and heel-toe walking were generated using dynamic optimization and a previously described 2D musculoskeletal model developed using SIMM [4], which consisted of a trunk and two legs (femur, tibia, patella and foot for each leg) and fifteen individual muscle actuators per leg [5]. The muscle force generating capacity was governed by normalized force-length and force-velocity relationships (Fig. 1). Muscle excitation patterns were modeled using block patterns and parameter optimization using a simulated annealing algorithm to fine-tune the onset, duration and magnitude of the individual muscle excitation patterns such that the simulations reproduced group averaged experimental kinematic and ground reaction force data previously collected from 10 able-bodied subjects during toe and heel-toe walking [3]. From the walking simulations, individual muscle fiber lengths and velocities during stance were determined from the model and normalized to the optimal fiber length and maximum contraction velocity of each muscle, respectively.

### RESULTS AND DISCUSSION

Despite a two-fold increase in soleus (SOL) activation during toe walking, the corresponding SOL muscle force averaged over the stance phase decreased by 13%. Similarly, a 40% increase in gastrocnemius activation during toe walking only produced a 2% increase in muscle force. The lack of increased force production with greater activation was attributed to a poor contractile state during toe walking, primarily muscle fiber lengths (Fig. 2) that were too short on the active force length relationship (Fig. 1A) as a result of the increased plantar flexion angle. The average fiber velocities were similar

**Figure 1:** Governing intrinsic muscle properties used in the model: A) normalized force-length and B) force-velocity relationships [4]. With deviations from the muscle fiber's optimal length and increasing rates of shortening, the ability of a muscle to produce force decreases.

**Figure 2:** Simulation soleus (SOL) and medial gastrocnemius (GAS) muscle fiber lengths during the stance phase normalized to their optimal lengths.

between the two walking tasks. These results were consistent with Hampton et al. [1] who showed that plantar flexor force decreased during toe walking. Their study used a static decomposition of the ankle joint moment derived from inverse dynamics. However, their analysis did not consider the contractile state of the muscles (i.e., fiber activation, length and velocity) in their assessment of muscle effort. Our simulation-based analysis suggests that toe walking may not be an advantageous compensatory strategy as previously suggested [1, 2] due to the increased muscle activation necessary to overcome the poor contractile state [3]. However, it is possible that spasticity and prolonged equinus foot posture may alter the intrinsic muscle properties such that peak muscle force is generated at shorter fiber lengths [6]. Assessing this possibility remains as future work.

## CHANGES IN LOWER EXTREMITY JOINT STIFFNESS WITH LANDING AFTER FATIGUE

<sup>1</sup> Thomas W. Kernozek, <sup>2</sup> Robert Ragan, <sup>2</sup> David Bushke, <sup>2</sup> John Hart, <sup>1</sup> Mark Iwasaki

<sup>1</sup>Department of Health Professions, <sup>2</sup>Department of Physics, University of Wisconsin-La Crosse, La Crosse, WI; email: [kernozek.thom@uwlax.edu](mailto:kernozek.thom@uwlax.edu); web: <http://perth.uwlax.edu/faculty/kernozek/>

### INTRODUCTION

There may be a specific level of joint stiffness necessary for optimal performance and injury reduction<sup>1</sup>. Too much joint stiffness has been linked to some shock related boney injuries such as stress fractures<sup>2</sup>. Others have suggested that too little joint stiffness may result in soft tissue injury<sup>3</sup>. As a result, there may be an optimal level of joint stiffness to minimize the injury risk. Current focuses of jump-training programs seem to be specific instruction to reduce lower extremity stiffness<sup>4</sup>.

Other than paper by Madigan and Pidcoke<sup>5</sup>, landing after fatigue has not been investigated. As a result, this study examined the influence of fatigue on the lower extremity stiffness of the knee and ankle in landing.

### METHODS

Eight male and eight female recreational athletes volunteered to be in the study. Eight single legged landing trials were performed from a 40-centimeter height. Kinematic data were recorded using a six-camera three-dimensional motion analysis system with 16 retro-reflective markers using the Helen-Hayes marker set. Kinematic data were collected at 240 Hz and raw coordinate data were filtered at 10 Hz. Kinetic data were recorded simultaneously using a Bertec force platform and were synchronized in time with the kinematic data. Kinetic data were sampled at 1200 Hz. Subjects were then asked to perform a protocol consisting of performing a squatting activity on a Smith machine until fatigue ensued. Subjects performed four sets of 60% of their one-repetition maximum squat, each to fatigue failure. Three sets were performed before four single-limb landings were recorded from a 40-centimeter height. The subjects then performed one more squat set to fatigue, to control for muscle recovery, before landing four more times. Inverse dynamics calculations were performed in the Kintrak software package and rotational spring stiffness was calculated with a custom program in Matlab. Joint angles and moments at the knee and ankle were used to calculate rotational stiffness before and after fatigue. Stiffness was calculated by dividing the joint moment by the change in angular displacement respectively for the knee and ankle<sup>6</sup>. Averages of the eight trials per condition were used. A two-way analysis of variance with one between factor (gender) and one within factor (fatigue) were used to compare stiffness at the ankle and knee.

### RESULTS AND DISCUSSION

Lower extremity stiffness was different at the ankle and knee joint with fatigue ( $p < 0.05$ ). Figure 1 depicts how these stiffness variables at the knee and ankle change with fatigue. The joint stiffness was not different across gender, nor was there an interaction between gender and fatigue. Stiffness at the ankle increased about 10% with fatigue while knee stiffness decreased about 22% with fatigue.

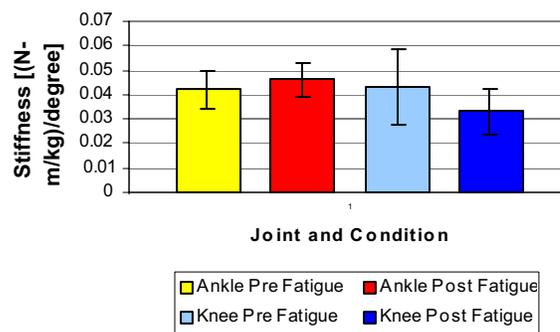

Figure 1. Landing joint stiffness changes pre and post fatigue.

### CONCLUSIONS

Not surprisingly, the squat-induced fatigue protocol reduces knee stiffness. The fact that ankle stiffness appears to compensate by increasing is somewhat surprising, and is perhaps in response to the lower knee stiffness. Further research should investigate how this adapted strategy influences injury.

## THE APPLIED FORCE PATTERNS OF CHEST COMPRESSION DURING CARDIOPULMONARY RESUSCITATION

<sup>1,2</sup>Jui-Yi Tsou, <sup>3</sup>Chih-Hsien Chi and <sup>1</sup>Fong-Chin Su

<sup>1</sup>Institute of Biomedical Engineering, National Cheng Kung University, Tainan, Taiwan

<sup>2</sup>Department of Physical Therapy, Fooyin University, Kaohsiung, Taiwan

<sup>3</sup>Department of Emergency Medicine, National Cheng Kung University Hospital, Tainan, Taiwan  
email: [fcsu@mail.ncku.edu.tw](mailto:fcsu@mail.ncku.edu.tw)

### INTRODUCTION

Manual chest compression is essential to maintain adequate blood circulation during cardiopulmonary resuscitation (CPR). It is a skillful movement in demand of proper force control and coordination [1]. Fractures of ribs and sternum due to chest compression during CPR are most commonly reported complications [2]. It not only increases the likelihood of damage to underlying organs but also may impair ventilation and complicate recovery [3].

Therefore, to understand the characteristics of compression force is important for proper force control and decreasing the risk of fractures [4]. The aim of this study was to investigate the three-dimensional (3-D) force patterns of manual chest compression during CPR.

### METHODS

Six experienced professional CPR rescuers (3 female, 3 male, age:  $36\pm 4.7$  yrs, height:  $165\pm 6.9$  cm, weight:  $65\pm 17$  kg) participated in this study.

The six-axial force load cell (AMTI MC3A-6-1000, Advanced Mechanical Technology, Inc., Watertown, MA) attached on the standard Resusci<sup>®</sup> Anne manikin (Laerdal Medical, Wappingers Falls, NY) were used to collect the 3-D compression forces at sampling rate of 1000 Hz. Three markers were attached on the load cell to define the coordination system of the load. The Expert Vision motion system (motion analysis Corp., Santa Rosa, CA) was used to collect the load cell motion at sampling rate of 100 Hz.

The subjects were kneeling beside the manikin and compressed on the load cell to perform CPR with a compression-ventilation ratio of 15/2 and frequency of 100 compressions per min over a session of 5 min. During the 5 min session of CPR, the data was recorded three times at the first, middle and last period. Each period was 20 second. (0:20-0:40, 2:20-2:40 and 4:20-4:40). The applied 3-D forces of chest compression were transformed from the local coordinate system of the load cell to the global coordination system.

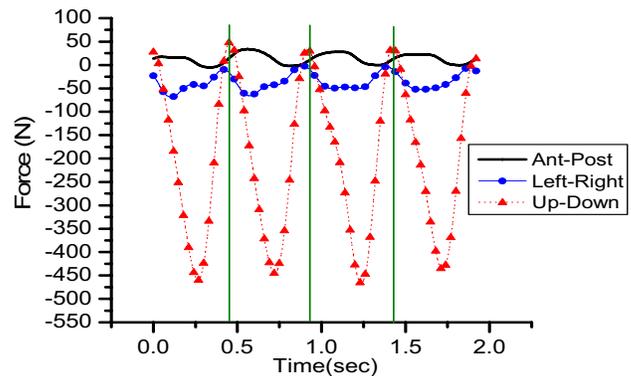

### RESULTS AND DISCUSSION

The magnitude of up-down direction force was downward  $482\pm 29.4$  N (Figure 1). This force fell on the range between 411 and 548 N as expected. There was no significant difference between three periods. It indicates that the experienced rescuers could maintain a constant compression deep during 5 min CPR.

During compression phase, the right direction force rose rapidly to the peak and then decreased (Figure 1). The mean force of

right direction was  $47\pm 19.2$  N. It may account for asymmetry of resultant force of two hands. The rescuers were almost the left hand beneath. While performing CPR with both hands, the shoulders, arms and hands of the rescuer form a triangle, apparently shifting the pressure to the more lateral hypothenar part of the heel of the hand [4] and then result in the right lateral force.

The same observation applies to the force in anterior-posterior direction. While compression, the forward force increased to  $31\pm 9.7$  N. It may result from the anterior shifting movement of the trunk.

**Figure 1:** The mean magnitude of 3-D compression force pattern

### CONCLUSIONS

From this study, we found that the compression force is not a pure downward force. The other two components of chest compress forces may be affected by body movement. The different resultant force may be also effect the type of fracture. Further researches can use this finding and method to determine the relationship between applied force, body movement, depth of compression, and fracture for developing more efficient and safe CPR.

## A COMPREHENSIVE APPROACH TO STUDYING MILD TRAUMATIC BRAIN INJURIES IN MOTOR VEHICLE CRASHES

Zhifeng Kou, Mariusz Ziejewski  
 North Dakota State University  
 email: zhifeng.kou@ndsu.edu

### INTRODUCTION

Mild traumatic brain injury (MTBI) has the incidence rate of 1.2 million people in the United States, and most of whom are caused in motor vehicle crashes (MVC) [1]. However, the biomechanics of MTBI is not well understood. Biomechanical study of the injury mechanisms of MTBI is difficult due to the non-applicability of the various surrogates including animals, volunteers, and cadavers that were traditionally used in impact biomechanical studies. This study was to determine a method used in a comprehensive study of MTBI involved in MVCs.

### METHODS

Our biomechanical approach consists of several steps and all of them are well-accepted methods: 1.) Crash investigation of MVCs on scene. In this step, we could determine the Delta V (the maximum change in velocity at the time of collision) by using Crash3 program [2,3], the angle and type of impact. 2.) Computer modeling of vehicle occupant. We used the Articulated Total Body (ATB) computer software to analyze the human body dynamics [4]. The vehicular acceleration time histories employed in the ATB simulations were based on the analyses performed using well-accepted methods in the engineering community that include vehicle-specific bumper rating strength, extent and nature of structural damage to vehicle, etc. The data set of occupant body including the segments' geometric and mass properties are computed using the Generator of Body Data (GEBOD) computer program [5]. 3.) Assessment of the state-of-the-art biomechanical predictors of brain injury. Based on the body kinematics data, we developed a computer program to calculate the results of the following, but not limited to, models published in the literature: a) resultant maximum linear and angular accelerations, the Head Injury Criteria (HIC), the Generalized Model for Brain Injury Threshold (GAMBIT), the Head Impact Power (HIP), and the Power Index (PI). 4.) Correlation of the biomechanical prediction with medical results. All of the patients in our study had complete medical record. If a patient is identified as MTBI by either clinical neurological diagnosis and/or neuropsychological assessment using the definition by American Congress of Rehabilitation Medicine [6], this patient case was called an affirmative MTBI case. We considered the occurrence of MTBI as a dependent variable and the parameters of each biomechanical model as an independent variable. By using logistic regression analysis, we could determine the power and statistical significance of each biomechanical predictor in predicting MTBI and the

contribution of each biomechanical predictor in the injury mechanisms of MTBI.

### RESULTS AND DISCUSSION

In our ongoing effort of biomechanical reconstruction of motor vehicle accidents, we collected the consent of 20 (n=20) patient cases with complete crash data and medical records. Of these patients, 8 (40%) (n1=8) of them are affirmative MTBI patients and 12 (60%) (n2=12) of them are non-MTBI patients used as control group. Two groups have the similar patterns in their gender and age distributions (Table 1).

**Table 1:** Patients' demographic data

MTBI		Gender Distribution	Age Distribution			
			Age	#	Age	#
Yes	n1=8	female = 8 male = 4	21-30	3	31-40	3
			41-50	4	>50	2
No	n2=12	Female = 6 Male = 2	21-30	0	31-40	2
			41-50	5	>50	1

The logistical regression results show that all of the biomechanical parameters are statistically significant in predicting MTBI; however, their predicting power are different and categorized from high to low in terms of -2log likelihood ratio shown in Table 2 from left to right.

### CONCLUSIONS

Our comprehensive method proved to be effective and practical in studying of MTBI.

## IDENTIFYING VULNERABLE PLAQUES USING MRI-BASED FINITE ELEMENT ANALYSIS

Zhi-Yong Li and Jonathan H Gillard

Department of Radiology, Cambridge, UK; email: ZYL22@cam.ac.uk

### INTRODUCTION

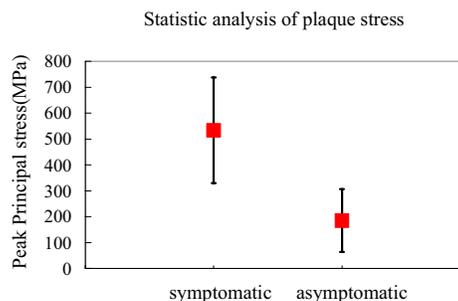

Atherosclerotic vascular disease is the most common cause of morbidity and mortality in the world. Plaque rupture has been identified as a critical step in the evolution of arterial plaques<sup>1</sup>, whereas the biomechanics of plaque rupture is still not fully understood<sup>2,3</sup>. To explore the role of biomechanics in the assessment of risk of rupture in carotid atheromatous plaque using high-resolution MRI, we used finite element analysis based on the magnetic resonance imaging (MRI) method to simulate the mechanism of carotid plaque in asymptomatic and symptomatic subjects.

### METHODS

Sixteen subjects, eight symptomatic and eight asymptomatic, underwent high-resolution multi-sequence in vivo MR imaging of the carotid bifurcation. All the imaging studies were conducted on a 1.5 Tesla whole body system using a customized four-channel phased array coil wrapped around the neck. The following axial 2D, ECG-gated, blood-suppressed, fast spin echo pulse sequences were used: intermediate T2 weighted (TR/TE: 2\*RR/46) with and without fat saturation, T2 weighted (TR/TE: 2\*RR/100), STIR (TR/TE/TI: 2\*RR/46/150), and fat-suppressed T1 weighted (TR/TE: 1\*RR/ 7.8). The pixel size was 0.4x0.4x3mm in all cases. Segmentation was based primarily on the STIR sequence, which was deemed to be most accurate for fibrous cap and lipid core, when compared with histology. Each patient axial MR slices were segmented manually and all contours were traced to generate the boundaries of lipid core, fibrous cap, vessel lumen and wall based on net intensity characteristics. The mesh was generated for each slice and finite element analysis was conducted in each case to determine the stresses within every plaque. The linear elastic model was used to model the plaque components. The material properties (Young's modulus and Poisson's ratio) were chosen based on recent publications<sup>4</sup>. In this study, the Young's moduli used were: arterial wall 16.8 kPa, fibrous cap 700 kPa and lipid core 6.25 kPa, and a Poisson's ratio of 0.49999 was used for all components. The internal luminal pressure was assigned at 15kPa. Statistical analysis was carried out for the comparison of symptomatic and asymptomatic patients.

### RESULTS AND DISCUSSION

Analysis was carried out for every slice that covers the plaque along the vessel for each patient. The peak stresses are illustrated to be within the disease part of the vessel. The slice with peak stress was chosen for each patient for the comparison between symptomatic and asymptomatic patients. High stress concentration happened at the shoulder region of the symptomatic patient and the maximum stress is 344.2 kPa, while in asymptomatic patient, the stress distribution is much

**Figure 1:** Comparison of plaque mean stress with standard derivation between symptomatic and asymptomatic patients

more averaged and the maximum stress is 150 kPa. The mean Principal stresses in the plaques of symptomatic patients are significantly higher than those of asymptomatic patients (533.4±185.3 versus 203.5±121.3 kPa, p<0.1). In Figure 1, mean stress with standard deviation is shown for symptomatic and asymptomatic patients and this demonstrates a significant difference between these two groups.

### CONCLUSIONS

This Finite element analysis suggests that the maximum stresses within the plaques of symptomatic patients are higher than those of asymptomatic patients. Mechanical stress in the carotid plaque, therefore, ought to be regarded as a complementary indicator of plaque rupture risk alongside the traditional measure of stenosis. A combination of high resolution MR and finite element analysis could potentially act as a useful tool for assessment of risk in patients with carotid disease.

**Vibration Analysis of Tennis Racket caused by Impact between Different Configuration and Additional Weight**

Yuh-Yih Lin, Chun-Ling Cho and Chen-Kai Su  
 Taipei Physical Education College, Taiwan, ROC  
 email: [nigleben@yahoo.com.tw](mailto:nigleben@yahoo.com.tw)

**INTRODUCTION**

In the present-day tennis game, it has become the time of power. No matter serve or swing is pointed to the velocity and power. Some tennis players like to add lead to the tennis racket to increase the racket power, but they don't understand what configuration to reduce vibration of the racket and increase racket power.

The purpose of this research is to analyze the vibration effect of tennis racket caused by impact in different configuration and additional weight to achieve the vibrant minimization. It can also increase the power of ball.

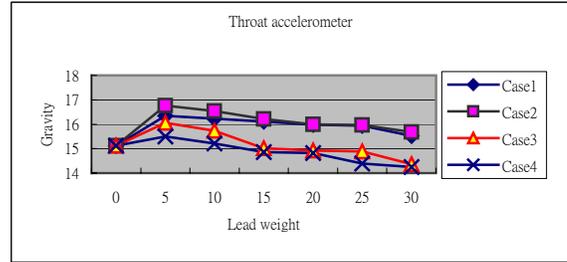

**METHODS**

In this experiment, we have fixed a tennis racket weight 300±5 grams to a Kistler Force Plate and kept the face of the tennis racket horizontalized to the ground, and then strung the racket with 50 lb tension on strings. We drop the tennis balls from one meter height to the face of the racket. We add 5,10,15,20,25 and 30 grams lead weight to racket in four configurations. These configurations are side of the back, side of the center, side of the forehand and top of the racket. We can analyze relationship of configuration and weight to the vibration of racket. Therefore we drop the ball to the center of percussion (COP) and 4 cm off-COP. We compare the difference with COP and off-COP and analyze the vibration of racket.

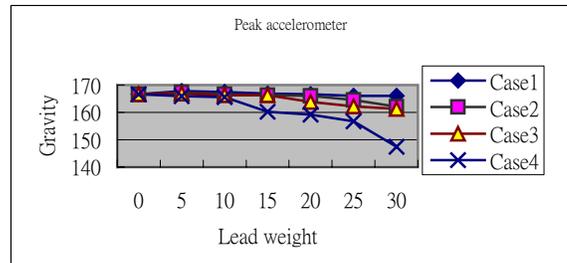

At the throat and head of the tennis racket, we have attached two accelerometers to capture the vibration signal of the racket. We then used two different softwares, Bioware and ACQ, to analyze the raw data from different configurations and additional weight.

**RESULTS AND DISCUSSION**

Data is collected from a total of 250 balls, including four configurations of side of the back, center, forehand and peak of the racket and add 5,10,15,20,25 and 30 grams lead weight to racket. The information of the throat accelerometer is in figure 1. We can compare the relationship between impact force and lead weights. The information of the peak accelerometer is in figure 2. We can compare the relationship between impact force and lead weights. For example, we add 30 grams lead weight to the top of the racket. It's effective to

**Figure 1:** Relationship of the lead weight and impact force in throat accelerometer.

**Figure 2:** Relationship of the lead weight and impact force in peak accelerometer.

the racket without additional weight. If we add 5,10 and 15 grams lead weight to side of the back and center, it can't evidently reduce the vibration of racket.

This study demonstrates that the incidence of lead weights and the configuration of adding weights. We find that influence of the weights and configurations. In the side of forehand and peak of the racket, it can reduce the vibration of the racket.

**CONCLUSIONS**

The study defined the vibration for the different configurations of impact and additional weights. But it is important to understand what configuration we add lead and how many weights we increase.

### INTRODUCTION

Backhand stroke is a frequently used tennis technique and the improper backhand is believed as a major factor leading to tennis elbow. The effective integration of the whole body segments as a kinetic chain transferring the momentum to the racket via the trunk and upper extremity is essential. The purposes of this study were to develop a kinetic chain model of the upper extremity in one-handed backhand stroke, and to analyze the momentum transfer from the trunk, upper extremity to racket in order to provide valuable information about the mechanisms of tennis backhand stroke.

### METHODS

Six right-handed elite male tennis players (age:  $26 \pm 2.71$  yrs, height:  $175 \pm 7.74$  cm, body mass:  $73 \pm 7.25$  kg) with many years tournaments experience were recruited in this study. The skill level of tennis players were rated as 5.5-6.0 according to the United States Tennis Association. The Expert Vision motion system with six cameras (Motion analysis Corp., Santa Rosa, CA, USA) was used to collect the tennis one-handed backhand motion at sampling rate of 60 Hz. Sixteen markers were attached on the selected anatomic landmarks unilaterally, and three attached on the racket to define the coordinate system of the trunk, upper arm, forearm, hand, and racket. Ten trials of backhand stroke were collected with a 3-minute rest between trials. Linear momentum ( $L$ ) is the product of the segment mass ( $m$ ) and velocity ( $v$ ) in the gravitational segment centre of mass position. Angular momentum in the segment coordinate system ( $H'$ ) is defined as the product of the principal moment of inertia ( $I$ ) and angular velocity in segment coordinate system ( $\omega'$ ). The calculation of three components of moment of inertia relative to the segment centre of mass was also adapted from the previous study [1]. The racket's moment of inertia about three orthogonal axes (longitudinal, frontal, and transverse) were computed using the pendulum method [2]. In order to obtain the segmental contribution of the upper extremity to backhand drive performance, we transferred linear and angular momentums from segmental coordinate system into the court coordinate system, in which the opposite of driving (leading) direction is X-axis, right hand side of the court as the Y-axis, and upward direction as Z-axis.

### RESULTS AND DISCUSSION

The results showed the time periods of 0.40 seconds (0-24 frames) before impact and 0.27 seconds (25-40 frames) after the impact during the one-handed backhand stroke. Our results showed that the trunk has larger influence on linear momentum than angular one during the backhand stroke. Considering the resultant linear momentums of the backhand stroke, the trunk demonstrated the largest magnitude followed by the racket, forearm, upper arm, and hand. The largest trunk contribution

was supported by Field and Altchek [3]. The forward, leftward, and upward trunk movements were essential for generating the racket linear momentum and stabilization of the trunk is also considered to be very effective for the sequential transfer the high force and energy through trunk. However, the insufficient angular momentums of trunk and upper arm external rotation, the potential weak links in the kinetic chain, may predispose the forearm and hand segments to the increased loads (Figure 1). The players relied on the elbow joints to generate the racket velocity and might increase the loads as well as the potential injury to this region [4]. The hand segment had a small resultant angular momentum may suggest that the players keep the hand segment stably throughout the backhand stroke. The possible explanation may be that the skilled players maintained their wrist in a relatively fixed and extended position. The small magnitudes of linear and angular momentums in hand segment may indicate the hand keeps stably in extended position for the momentum transfer rather than power generation throughout the backhand for the prevention of tennis elbow.

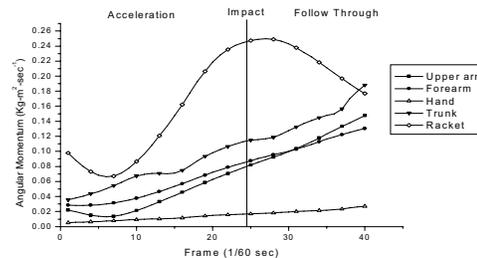

Figure 1: The resultant angular momentums of the segments.

### CONCLUSIONS

The efficient kinetic chain of backhand stroke successfully transferred the momentum from proximal trunk to distal hand segments. The segment dropout or kinetic chain breakage decreases the ultimate force and energy available to the racket-ball, and puts abnormally large strains on the surrounding segments. The coaches and clinicians need to advise the tennis players to use the advantage of large trunk muscles and to improve the strength of shoulder rotator cuff muscles to generate the racket momentum for reducing the tennis-related injuries.

### INTRODUCTION

To evaluate risk of compression fracture of osteoporosis vertebrae, current diagnosis methods such as measurements of bone mineral density by DXA are not sufficient, because mechanical strength is not evaluated directly. Mechanical strength of vertebra depends on patient-specific factors, which are shape, cortical thickness, density distribution of cancellous, material properties of bone tissue, and so on. So that patient-specific mechanical analysis is required. In previous study, finite-element (FE) analyses based on CT images of osteoporosis patient's vertebrae were carried out and its availability was confirmed. In this study, FE analyses of osteoporosis vertebrae undergoing drug treatment were also performed over time. Effect of drug therapy to mechanical strength recovery of vertebrae was discussed.

### METHODS

Analysis target was L1 vertebra because it was located near the inflection point of spine and favorite site of osteoporosis fracture. X ray CT images were taken at 1mm intervals from 4 osteoporosis patients. All of them were Japanese female whose age was 60, 53, 71 and 72 years old respectively. Patient-specific FE models of L1 based on CT images were obtained by using "Mechanical Finder (RCCM Co.)" as shown in figure 1. This is computer software for bone strength analysis considering individual bone shape, cortical thickness and bone density distribution. Shell elements were used for cortical bone. Young's modulus of each element was given one by one calculating from bone density and CT value. Relationship between the mechanical properties and bone density proposed by Keyak [1] was used. Simple compressive loading was considered, that is, bottom surface was fixed and uniform pressure was applied to upper surface of vertebra [2].

### RESULTS AND DISCUSSION

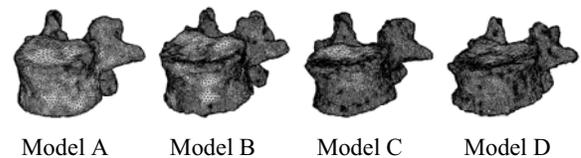

Figure 2 shows density and compressive principal strain distribution of model A at the central section before and after therapy. Drug effect in the model A was most significant. High-density area increased after therapy initiation at cortical bone and whole cancellous bone. After a year, local high strain region before therapy was almost disappeared and cancellous bone strain were totally reduced. It would be effective to prevent compression fracture of vertebra. Figure 3 shows average density and compressive principal strain of the 4 models. Drug therapy seemed to work for reinforcing strength of vertebrae in case A and B. Drug effect was also observed in case D, even though average density was not changed. Bone trabecular structure seems to be changed reducing average strain in this case.

### CONCLUSIONS

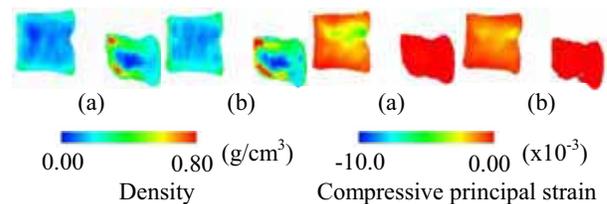

Strength recovery of osteoporosis vertebra due to drug therapy was analyzed quantitatively by patient-specific FE analysis.

**INTRODUCTION**

Mechanical strength analysis using finite-element (FE) method is effective to predict a risk of compression fracture of osteoporosis vertebrae. Bone fracture in clinical case of osteoporosis sometimes occurs under the dynamic load condition during transition process from sitting down position to standing position. Patient-specific dynamic FE analysis is necessary to evaluate mechanical strength of osteoporosis for the clinical condition. In this study, dynamic FE analyses of osteoporosis vertebrae were performed considering individual shape and material property based on CT images of patients. Differences of fracture risk depending on patient’s case and availability of dynamic analysis was discussed comparing with the results of the static analysis.

**METHODS**

Finer finite-element meshing is required for patient-specific analysis to reflect individual bone shape and material properties. We used finite-element code “NEXST\_Impact (FSIS, Japan)” [1], which can solve large-scale dynamic problem by using parallel processing. Analysis target was L1 vertebra because it was located near the inflection point of spine and favorite site of osteoporosis fracture. X ray CT images were taken at 1mm intervals from 4 Japanese female osteoporosis patients whose age was 60, 53, 71 and 72 years old. Patient-specific FE model of L1 based on CT images were obtained by “Mechanical Finder (RCCM Co.)” that was software to make FE models considering individual bone shape and density distribution. Young's modulus of each element was given one by one calculating from bone density and CT value. Relationship between the mechanical properties and bone density proposed by Keyak [2] was used. An example of FE model and its density distribution of whole model and central section are shown in figure 1. Simple dynamic compressive loading was considered in the analyses, that is, bottom surface was fixed and uniform step pressure was applied to upper surface of vertebra [3]. Dynamic analysis was done in the  $t=0.0(\text{ms})$  to  $t=5.0(\text{ms})$  range by setting time of loading as  $t=0.0(\text{ms})$  and analysis time step was  $2.0(\mu\text{s})$ .

**RESULTS AND DISCUSSION**

Figure 2 shows Mises stress distribution by time steps in dynamic analysis. Stress wave propagated along high-density region. Peak of stress in dynamic analysis occurred slightly delay after loading. High stress widely occurred at the anterior surface of cortical bone. It is reasonable because load seems to concentrate at cortical bone by low load sharing at cancellous bone in osteoporosis vertebrae. Table 1 shows maximum Mises stress value of dynamic analysis and static analysis of the 4 models. Results of dynamic analysis exceeded that of static analysis in 3 models. It was suggested that static analysis

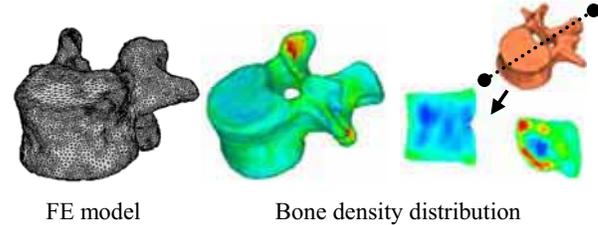

solution give us underestimation of bone fracture risk of vertebrae in comparison with clinical condition that involves dynamic loading.

**CONCLUSIONS**

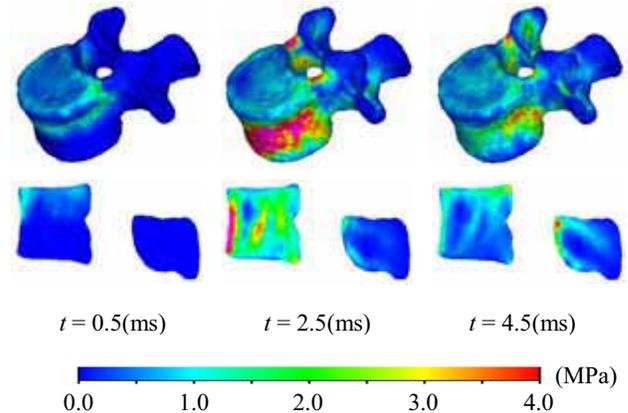

Stress wave propagation process of osteoporosis vertebra was shown precisely by patient-specific dynamic FE analysis.

## INFLUENCE OF HARDNESS OF BED ON HIP JOINT WITH USE OF TRUNK TREMOR

<sup>1</sup>Maya Kawabata, <sup>1</sup>Kazuyuki Mito, <sup>2</sup>Hitoshi Makabe, <sup>3</sup>Byung-Chan Min, <sup>4</sup>Kenichi Kaneko, <sup>1</sup>Kazuyoshi Sakamoto

<sup>3</sup>Hanbat National University, Korea, <sup>4</sup>Fuji University, Japan; <sup>1</sup>email:sakamoto@se.uec.ac.jp

### INTRODUCTION

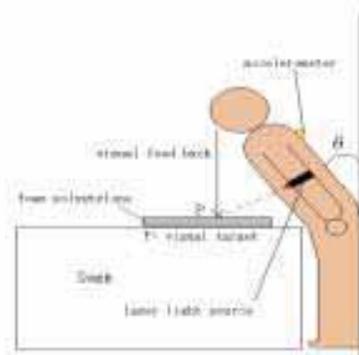

Researches of tremor, which is invisible mechanical vibration of body parts, have been published for finger and upper limb. The mechanism of tremor was resolved that the generation was caused by both central nervous and reflex nervous systems [1,2]. The study for trunk, however, has not been reported. Therefore, in the study, the function of hip joint was evaluated by trunk tremor after sleep with use of beds with different hardness.

### METHODS

In the first place, the characteristics of trunk tremor by the change of bend angle of trunk were measured as fundamental data. In the next place, the influence of sleep on the trunk tremor was researched with different kinds of bed.

Subject slept for eight hours (night sleep) and 90 minutes (day sleep). The former sleep started at 0:00 and latter sleep started from 13:00. The day sleep period was adopted due to one cycle of sleep period. Subject used two kinds of bed, that is, soft and hard beds which rate of the hardness of beds was 1.35. The soft bed made of material with low elasticity, while the hard bed was on the market. Tremor of trunk under the bent posture was measured before and after the sleep.

Measurement system for trunk tremor is shown in Fig.1. Subject gazed a target point P to hold a bent angle  $\theta$  chosen in the experimental protocol, in which the bent angles were taken to be 0, 20, 40, and 60 degrees. Tremor was detected by accelerometer (9G111BW, NEC Sanei) glued with both sides adhesive tape on upper part of the back around vertebra thoracica I. The resultant raw wave was sampled by 100Hz, transformed by AD converter, and stored to computer. The power spectrum was obtained by FFT (Fast Fourier Transform). The tremor was evaluated by total of power spectra (TP) in frequency range from 2.5 to 40 Hz. The frequency range was also divided into two frequency bands, i.e., lower band of 2.5 to 6 Hz and higher band of 6 to 40 Hz. The former and the latter bands showed the reflex nervous component and the central

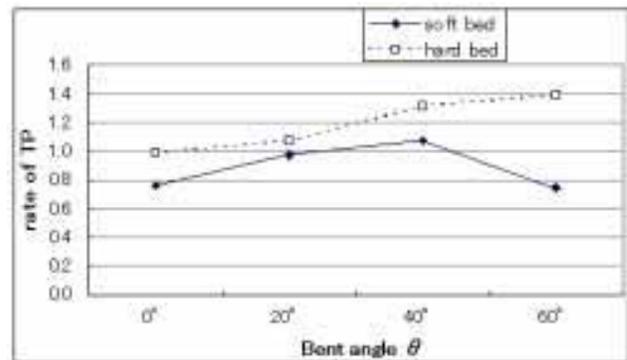

**Figure 1:** Experimental system for measurement of trunk tremor.

nervous component, respectively [1,2]. The subjects were ten aged 21 to 64 years old.

### RESULTS AND DISCUSSION

The total power for the change of bent angle was evaluated, since larger angle gave larger load to hip joint for the maintenance of posture. The results showed that larger bent angle was charged, the larger total power was obtained. The tendency was obtained remarkably for the lower frequency band (2.5 to 6 Hz). Namely, the reflex nervous contributed predominantly for the hold of bend posture.

The influence of day sleep for two kinds of beds on the total power of tremor was not recognized significantly, but the influence of the night sleep was recognized significantly for the bent angles of 40 and 60 degrees as shown in Fig.2. The sleep with soft bed denoted lower amplitude of tremor as compared the sleep with hard bed. Especially, the bent angle 60 for soft bed showed the value less than unity. The case meant the amplitude of trunk tremor after sleep decreased as compared with the value before sleep. Analyzing the influence of trunk tremor due to sleep, the function of hip joint could be revealed.

**Figure 2:** Rate of total power (TP) after night sleep based on TP before the sleep with use of soft and hard beds for bent angle  $\theta$ . Unity of the rate value denotes the value before sleep

### CONCLUSIONS

Characteristics of tremor in bent posture for normal subjects were elucidated. The results could be applied to evaluate the degree of hip disorder. The influence of night sleep with beds of different materials due to trunk tremor was recognized, so the relax of muscles for hip joint could be evaluated with use of trunk tremor

### INTRODUCTION

In modern information society an increasing number of jobs induce musculoskeletal disorders (MSD) even though the work is characterized by low physical exposure levels. Development of prediagnostic tools may be a step towards efficient strategies aiming to prevent MSD as well as improving the understanding of the basic mechanisms of muscle pain and disorders induced by low-force contractions.

In order to identify possible precursors to muscle pain and disorders, the electromyogram (EMG) has been used to identify muscle fatigue development for prevention purposes. However, during low-force work tasks such as computer work the sensitivity and the ability of the EMG to detect muscle fatigue is limited. Recently, the mechanomyogram (MMG), suggested to reflect the “mechanical counterpart” to the motor unit electrical activity, has been shown to be a promising method for detection of muscle fatigue during such low-force contractions [1]. Since experimentally induced muscle pain seems to be reflected in the MMG rather than the EMG activity [2], it is in this study hypothesized that a low-force contraction of a painful muscle compared to a no pain muscle may evoke a different MMG response. Further, that this pain related difference will be more pronounced in the MMG than in the EMG response.

### METHODS

Eight patients (5 females, 3 males) with unilateral epicondylitis lateralis were sitting with the elbows flexed 90 degrees, the forearms pronated and resting on horizontal platforms. In this position they performed static wrist extension at 10% of maximal voluntary contraction (MVC) for 10 min against a force transducer with both the afflicted arm (AA) and the non-afflicted arm (NA) in a random order. During the static contraction, MMG was recorded by an accelerometer placed on m. extensor carpi radialis (ECR) and bipolar surface EMG was recorded from ECR, m. extensor carpi ulnaris (ECU), and a forearm flexor muscle (FLEX). The MMG and EMG were analyzed for root mean square amplitude (MMGrms and EMGrms). Furthermore, subjective perceived exertion was rated by the Borg scale from 0 (no perceived exertion) to 10 (maximum perceived exertion) during the 10% MVC contraction.

### RESULTS AND DISCUSSION

The performed force level was on average 9.9 (SD 0.2)% MVC for AA and 10.1 (SD 0.5)% MVC for NA with no significant difference, showing that the task of meeting the target force of 10% MVC was accomplished successfully for

both arms. Despite of that, the subjects reported significantly higher level of perceived exertion during the contraction in the AA compare to the NA trial.

EMGrms of ECR increased with time from 45.7 (SD 15.3) to 63.1 (SD 29.5)  $\mu\text{V}$  in AA and from 48.6 (SD 18.5) to 58.4 (SD 23.2)  $\mu\text{V}$  in NA, with no significant difference between AA and NA. However, the MMGrms of ECR tended to increase more in the AA trial (from 0.05 (SD 0.03) to 0.16 (SD 0.14)  $\text{m}^*\text{s}^{-2}$ ) during the contraction compared to the NA trial (from 0.04 (SD 0.02) to 0.08 (SD 0.06)  $\text{m}^*\text{s}^{-2}$ ). Increase in MMGrms has previously been shown simultaneously with a decreased twitch force [1]. In accordance with this, the pronounced time wise change in the ECR MMGrms of AA during the 10% MVC contraction in the present study may be interpreted as a decreased force output of the activated low-threshold motor units. In order to meet the same force level either an increased activation of the ECR or of some of the synergist muscles is necessary. In line with this, the ECU EMGrms of AA increased significantly from 51.6 (SD 19.5) to 68.8 (SD 18.3)  $\mu\text{V}$  while no change was seen with time for NA. For FLEX EMGrms no difference was found between AA and NA. These findings may support the *pain adaptation model* proposing a change in muscle activation due to pain [3]. The increased activation of ECU in AA was not a compensation for a larger antagonist activity. Rather, it may be considered to make up for the corresponding force deficit of the fatigued ECR muscle. A faster fatigue development of the AA was evidenced by the larger increase in perceived exertion.

### CONCLUSIONS

The results indicate that the MMG activity in contrast to the EMG is modulated in the afflicted arm of patients with epicondylitis lateralis. MMG could possibly be useful as a non-invasive method to investigate changes in the neuromuscular system and may be developed to serve as a prediagnostic tool for objective identification of MSD.

**TRUNK STIFFNESS IMPROVEMENT BY PHYSICAL THERAPY/EXERCISE DURING UNSTABLE SITTING**

H. Lee, K. P. Granata, M. Piechoski  
 Musculoskeletal Biomechanics Laboratory, Virginia Tech  
 Department of Engineering Science & Mechanics.  
 School of Biomedical Engineering & Science

email: [Granta@vt.edu](mailto:Granta@vt.edu) web: <http://www.biomechanics.esm.vt.edu/msbiolab/>

**INTRODUCTION**

Many studies have examined the role of physical therapy (PT) and/or exercise on prevention, rehabilitation and recurrence rate of low back pain (LBP). One of the aims of PT exercises is to modify the neuromuscular control of spinal stability. However, effect of PT exercises on neuromuscular control of the trunk is still unclear.

Research demonstrates that seated sway can be used to identify differences in neuromuscular control between patients with LBP and asymptomatic controls [1]. Therefore, the purpose of this present study was to test whether PT exercises influences neuromuscular control of stability by assessment of seated sway.

**METHOD**

A control group of twenty-seven subjects and a PT-exercise group of twenty-eight subjects with no previous history of low back pain were tested. Subjects in the PT-exercise group participated in a program consisting of 8 PT exercises every day for 12 weeks. Both control and PT-exercise subjects performed a seated sway test at baseline (week 0) and once every 4 weeks for an interval for 12 weeks. To measure trunk sway, each subject maintained an upright seated posture on a flat platform. They sat with thighs resting horizontally on the platform and knee flexed 90° hanging over the edge of the platform. Leg and foot supports were provided to prevent any lower-limb movement. Subjects were required to sit quietly for 90 seconds with a barbell of 0% and 30% of body weight on their shoulders. Trunk sway was recorded at 1000 Hz from a force plate underneath the seat/platform and filtered at 10 Hz using a fourth order Butterworth digital filter.

The center of pressure trajectories were calculated from the force and moment data. Analysis included mean sway frequency in anterior/posterior and lateral directions, a total CoP path length traveled per second, and 95% confidence ellipse area of COP.

**RESULTS AND DISCUSSION**

There was no significant difference in performance between the groups at initial assessment. After 12 weeks of PT the PT-exercise group had smaller ellipse area but longer path length

Table 1, Mean (standard deviation) ellipse area and path length of the seated sway center of pressure (COP) movement while holding a barbell on the shoulders with 0% and 30% of body weight.

VARIABLE	GROUP	LOAD <sup>A</sup>		GENDER <sup>B</sup>		TOTAL <sup>C</sup>
		0 %	30 %	MALE	FEMALE	
Ellipse Area (mm <sup>2</sup> )	CONTROL	20.08 (14.68)	48.39 (29.69)	30.05 (23.72)	39.35 (30.57)	34.23 (27.32)
	EXERCISE	13.23 (7.19)	23.02 (11.06)	17.92 (9.89)	18.39 (11.37)	18.12 (10.52)
Path Length (mm/s)	CONTROL	9.58 (2.33)	10.42 (2.56)	9.50 (2.53)	10.55 (2.32)	1.00 (2.48)
	EXERCISE	13.02 (3.57)	13.84 (4.27)	11.95 (3.31)	14.90 (3.99)	13.43 (3.94)

A: Load was significant at p < 0.0001 for EA and p < 0.006 for PATH.

B: Gender was significant at p < 0.005 only for PATH.

C: Total EA and PATH between groups were significant at p < 0.001 and p < 0.001, respectively.

(Table 1). This indicates that the PT-exercise group moved more but constrained the movement within a smaller area. This suggests possible differences in effective trunk stiffness between groups. To verify this, we created a mechanical inverted pendulum held upright by steel springs stretched from the pendulum to its base. When disturbed the pendulum-spring system would oscillate and COP was recorded. Using a stiff spring the ellipse area was smaller but path length was longer than when using a more compliant spring. This was because the system with greater stiffness oscillated at a higher frequency than a system of less stiffness (Figure 1). Similarly, mean sway frequency of the PT-exercise group was greater than in the control group (p < 0.0001 anterior/posterior only).

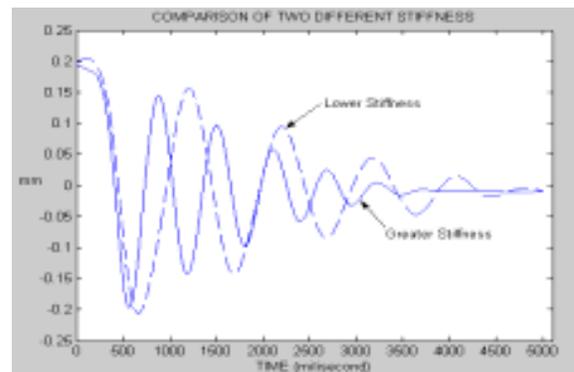

Figure 1: CoP displacements from inverted pendulum with springs of two different stiffness.

**CONCLUSION**

Following a 12 week program of PT exercise the postural control of the trunk demonstrated characteristics consisted with increased trunk stiffness. Results suggest PT-exercises contribute to improved neuromuscular control of stability. Further research is necessary to identify specific neuromuscular contributions to spinal stability and the factors that influence them.

## SIMULATION OF FORWARD FALLS: EFFECTS OF FALL STRATEGY AND AVAILABLE MUSCLE STRENGTH ON INJURY RISK

<sup>1</sup> Jia-Hsuan Lo and <sup>1</sup> James Ashton-Miller  
<sup>1</sup> University of Michigan, Ann Arbor  
 email: [joshualo@umich.edu](mailto:joshualo@umich.edu)

### INTRODUCTION

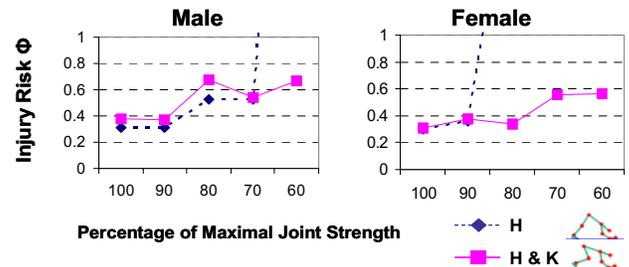

Skilled use of the upper extremities can significantly reduce the magnitude of the fall-related impact force on the distal forearm during a forward fall [1]. However, simulations have shown that age-related decline in arm muscle strength reduces the ability to arrest a forward fall without a risk of torso and/or head impact [2]. It is not known whether lower extremity movement strategies used during the fall might ameliorate this effect. To investigate this we used direct dynamics simulations to test the hypothesis that the use of knee flexion in a forward fall reduces the impact severity in the presence of an age-related strength decline.

### METHODS

A 2-D sagittal-symmetric, 7-segment rigid body model was used to simulate forward falls from a 20° forward inclination. Segments were connected by revolute joints, and the movement of each joint was driven by a pair of agonist and antagonist joint muscle torque actuators. Each actuator employed a Hill-type model with muscle excitation-activation dynamics [3]. A feedback proportional controller was used to drive each joint to a prescribed configuration (given target angle maintained with zero angular velocity) for the first impact. After the first impact, a final prescribed configuration was given to the controller. Gender differences were simulated by appropriate body segment and joint torque data, while age-related strength declines of 30% were assumed for healthy older adults. We simulated two fall strategies with different first impact configurations (Fig. 1): hip flexion with (“H & K”) or without knee flexion (“H”), by constraining the prescribed joint angle ranges. The optimal prescribed joint configuration was then found via a global optimization method (“GCLSOLVE” [4]) that minimized the impact injury risk  $\Phi$ , defined as the maximal ratio of the peak impact forces at wrist, elbow, knee and head to their corresponding fracture tolerances. The objective function was constrained by available joint torques for each age and gender group.

### RESULTS AND DISCUSSION

For both young men and women, both fall strategies (“H” and “H & K”) resulted in similar impact injury risks. However, in the presence of age-related strength decline, the “H” (“Hip

**Figure 1:** Injury risk,  $\Phi$ , versus joint strength relationships.

Flexion Only”) strategy becomes ineffective for avoiding head impact for both genders, as reflected in  $\Phi$  (Fig 1). The simulations suggest that the better fall strategy for older women is to flex both hips and knees (the ‘H & K’ strategy) such that they land first on the hands and soon after on the knees. For the older men and young adults the hip flexion strategy (‘H’) was only slightly better than the ‘H & K’ strategy, the latter affording the largest head clearance (Fig. 1 & Table 1). The older adult falls resulted in greater injury risks (old:  $\Phi=0.53$  &  $0.55$  vs. young:  $0.31$  &  $0.30$  for men and women, respectively; Table 1), while their kinetic energy at impact was similar to those in the young. The optimizer selected straighter elbow angles at impact in order to compensate for strength decline, and this is the main reason for the greater  $\Phi$  in the old (see  $\theta_{\text{Elbow}}$  in Table 1). These results reflect a forward fall from near-upright stance; further simulations are needed to study arrest behaviors during gait.

### CONCLUSIONS

- 1) Knee flexion reduces the risk of head impact in a forward fall arrest.
- 2) The hip and knee (‘H & K’) flexion strategy is the better of the two arrest strategies, particularly in older women.
- 3) Straighter impact elbow angles are required to avoid head impact in the presence of age-related strength declines.

**MECHANICAL PROPERTIES OF THE SHOULDER LIGAMENTS  
 UNDER QUASI-STATIC AND DYNAMIC LOADING**

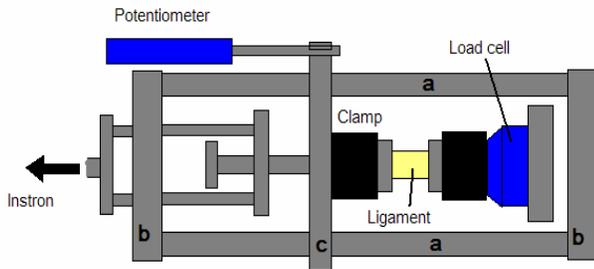

<sup>1</sup>Sung-Woo Koh, <sup>1</sup>John M. Cavanaugh, <sup>1</sup>James P. Leach, and <sup>2</sup>Stephen W. Rouhana  
<sup>1</sup>Wayne State University, Detroit, MI and <sup>2</sup>Ford Motor Company, Dearborn, MI, sungwookoh@hotmail.com

**INTRODUCTION**

The tensile properties of the shoulder ligaments under dynamic loading have not been investigated. A recent finite element model showed the ligaments in the shoulder were subjected to dynamic tensile loading during 8.65 m/s lateral shoulder impact [1]. The mechanical properties of shoulder joints under dynamic loading are needed to better understand shoulder injury mechanisms, to improve shoulder finite element models and to further develop the shoulder of car crash dummies.

**METHODS**

Thirty-three fresh human shoulders were harvested and bone-ligament-bone specimens of acromioclavicular joint (AC), coracoclavicular ligament (CC) and sternoclavicular joint (SC) were obtained. The age range of test subjects was 47 to 95 years, with 13 shoulders from males and 10 from females. A test fixture and clamps specifically designed for this ligament study and a high-speed Instron machine were used (Fig 1). One quasi-static rate (0.1 %/sec) and two high rates (nominally, 15,000 %/sec and 40,000 %/sec) were used in this study.

**Figure 1.** Diagram of the shoulder ligament test setup. Thompson shafts (a) and aluminum plates at the ends (b). The fixture included an additional aluminum plate (c) which was connected and moved with the Instron actuator.

**RESULTS AND DISCUSSION**

Eighty-three specimens were tested at three different strain rates. In acromioclavicular joint (AC) tests, ligament failure was the most common failure mode. In coracoclavicular (CC) bone-ligament-bone tests, the majority of specimens failed at the ligament. In sternoclavicular joint (SC) tests, the specimen failed at the bone in most cases. In AC and CC tests, 15,000 %/sec tests and quasi-static tests had more bone fracture cases than 40,000/sec tests. The Young's modulus and ultimate load of the three joints were found to be significantly lower in the 0.1 %/sec tests compared to the 15,000 %/sec tests but not significantly different between 15,000 %/sec and 40,000 %/sec tests (Table 1). There was no significant relationship between the ligament cross sectional area and subject age, height and weight. In addition, there was no significant relationship between mechanical properties of the shoulder joints and anthropometric data or age. However, specimens from younger subjects were not available for this study. This appears to be the first published study describing the mechanical and structural properties of the AC and SC. The 40,000 %/sec strain rate is the highest published strain rate ever used and analyzed for ligament studies. Overall, the shoulder ligaments showed larger ultimate strain and smaller ultimate stress and Young's modulus than animal or human knee ligament [2]. The capacity of large ultimate strain in shoulder ligaments may contribute to the large range of motion attainable in the shoulder.

## LOWER EXTREMITY MUSCLE ACTIVITIES OF TRANS-FEMORAL AMPUTEES WHEN A SLIP OCCURS IN GAIT

<sup>3</sup>Northwestern University Medical School, Chicago, IL, 60611, USA

### INTRODUCTION

Lower extremity muscle activities always play an important role of human locomotion and balance. In nowadays, surface electromyography (sEMG) is a major method to identify muscle activities. So that, many researchers have used sEMG to investigate the human balance strategies in slips and falls [1, 2]. In comparison with the healthy person, the trans-femoral amputee's ability to recover from slips is weakened obviously due to the absence of one leg. The purpose of this study is to investigate that the sEMG response of trans-femoral amputees when a slip occurs at the heel contact (HC) moment in gait.

### METHODS

Six male unilateral trans-femoral amputees and five male healthy non-amputees participated in the current study. Each subject was required to walk at a self-selected comfortable pace along a 5 m plastic walkway, and to perform two walking trials on dry and oily conditions respectively. In oily condition, the motor oil (40#) was evenly applied across 2 m long in the middle of the walkway. A pair of parallel bars was used to protect the subjects against real falls.

The sEMG data were recorded using several bipolar surface electrodes (DE-2.1, Delsys Inc., Boston, MA, USA), which were placed on the skin overlying the muscle bellies of tibialis anterior (TA), gastrocnemius medialis (GM), rectus femoris (RF), biceps femoris (BF), gluteus maximus (GMA), gluteus medius (GME), erector spinae (ES), obliquus externus abdominis (OA) on both sides, unless the muscle was unavailable because of amputation. For analysis, the instantaneous power (IMP) was employed. Each IMP was then low-pass filtered and normalized to its own mean value. At the same time, the Qualysis Motion Capture System (Qualysis Medical AB, Sweden) were employed to record the kinematics data of each trail at 200 Hz synchronously.

### RESULTS AND DISCUSSION

When a slip occurred at HC moment for normal people, the power increase of TA, BF, GMA, GME and ES muscles on the anterior leg was observed obviously. All these muscles contracted to lock the ankle, knee, hip and waist joints. And then, if the body fell backward continuously, the power of RF and GMA muscles on the posterior leg increased significantly in order to support the falling body. Thus, it was demonstrated from the muscle activities that there were two steps to recover from a slip-and-fall event, "anti-slip" and "anti-fall", for healthy persons.

However, the muscle responses of trans-femoral amputees differentiated from that of non-amputees for the absence of their legs. When the anterior prosthetic limb encountered a

slip at HC moment, which is mostly happened while the subjects walking on slippery surface, the absence of some body parts on the amputated side made the subject unable to sense the slip in time, so that, no timely anti-slip adjustment was implied soon enough. In these cases, slips usually induced complete falls. The function of the GMA muscle on the prosthetic side was mainly to "pull" back the sliding leg when fall had taken place, while the GMA muscle on the intact side contracted to support the falling trunk.

In other cases that the sound limb was anterior and encountered a slip at HC moment, the sliding limb could be locked and stabilized in time but the prosthetic limb was usually not competent for supporting the body. In this situation, the GMA muscle on the sound side cooperated with other muscles together to stabilize the sliding leg. If balance was regained rapidly, the process would continue. Nevertheless, if the adjustments on the sound side could not overcome the perturbation, the GMA muscle on the prosthetic side would act to support the falling trunk. Whether the prosthetic could do so, would depend on the function of the prosthesis. Therefore, the fall danger for amputees is much higher than non-amputees.

### CONCLUSIONS

1) For normal persons, the anti-slip and anti-fall response strategies are employed in sequence to regain balance when a slip occurred. But for the absence of some muscles it is difficult for trans-femoral amputees to regain balance. 2) GMA muscles always made enormous contribution to balance control in the slip events, and it was much more obvious for the trans-femoral prosthesis users than for normal people. Moreover, the GMA muscle on the prosthetic limb acted as the compensation of the absent muscles. 3) The sEMG of GMA muscles were very sensitive to slips and could be used for slip detecting. The knowledge could be helpful for detecting the slip event and developing the device preventing the falls.

## Phase plane analysis of stability in turning movement in subjects with functional ankle instability

<sup>1,2</sup> Nobuhiro Kito, <sup>3</sup> Koichi Shinkoda and <sup>3</sup> Naohiko Kanemura

<sup>1</sup>Kawashima Orthopaedic Hospital, <sup>2</sup>Programs for Health Sciences, Graduate School of Health Sciences, Hiroshima University, <sup>3</sup>Division of Physical Therapy and Occupational Therapy Sciences, Graduate School of Health Sciences, Hiroshima University, ; e-mail: kito1@muse.ocn.ne.jp

### INTRODUCTION

Functional ankle instability (FAI), a tendency for the foot to repeatedly sprain or give way, is a late complication in roughly 10 to 30% of acute ankle sprains. Postural control deficits during quiet standing after acute ankle sprain and in those with FAI have been frequently reported. The task of maintaining posture during quiet standing may not place adequate demands on the postural control system to detect deficits stemming from FAI. In addition, Balance Testing is commonly done using force plates and some measure of the center of pressure movement called, postural sway. Several different parameters are used to quantify postural sway, such as mean sway path, area measures, sway area and velocity measures, mean sway velocity. However, it is now obvious that physical systems are dynamic systems. Their activities are inherently nonlinear, and so nonlinear tools are required in order to understand and manage FAI. The dynamic systems approach suggests a different approach that concentrates not on the number of parameters of stability, but on the consistency of motion as a measure of stability. Our purpose deals with a phase plane analysis of COP (center of pressure) trajectory during the turning movement. This turning movement during in the standing position is one movement complicated by "giving way". Understanding the normal control mechanisms of the turning movement, based on measuring and analyzing variations in the mechanisms of affected ankles, is a prerequisite to evaluating possible treatment outcome.

### METHODS

Three subjects with unilateral FAI (mean age 25.5 years) and one control subject with a healthy ankle (age 24 year) consented to participate in this study. FAI was defined as an individual having sustained an inversion ankle sprain. The same ankle also needed to have had a feeling of "giving way". Mechanical instability was assessed with the Anterior Drawer and Talar Tilt tests by taking at stress radiography. First, the subject stood with weight evenly distributed on the force plate. Then the subject transferred his/her body weight onto the right leg and turned that produced external pelvic perturbation relative to the weight-bearing femur. After returning to the neutral position, the subject transferred his/her weight onto the left leg and turned again. This was repeated 2 times, with each series of movements being 40 seconds in length. Phase plane analysis of COP was performed to assess postural stability during the turning movement. Plotting the COP state variables, in this case displacement and velocity, in the medio-lateral (M/L) and anterior-posterior (A/P) direction is an informative tool for quantifying balance control. In addition, plotting the vertical floor reaction force (Fz) variables, in this case the Fz value and 1-time differentiation value, is an

informative tool for quantifying the body weight transfer onto the supporting leg.

### RESULTS AND DISCUSSION

On the phase plane plot in the M/L direction, difference became clear between subjects with FAI and the subject with a healthy ankle. In the subject with a healthy ankle, the trajectory on the phase plane in the M/L direction was divided into two trajectories: an acceleration trajectory in shifting weight, and a limiting cycle/ convergent trajectory above the x-axis on the phase plane for turning movement (Figure 1). These two trajectories were called Phase 1 and 2, respectively, for convenience. In subjects with FAI, two trajectory patterns on the phase plane in the M/L direction were recognized. One pattern did not show a limiting cycle trajectory for the turning movement, but rather the trajectory rapidly converged above the x-axis on the phase plane (Figure 2). The other pattern did not typically converge at one point above the x-axis on the phase plane during turning posture is maintained (Figure 2).

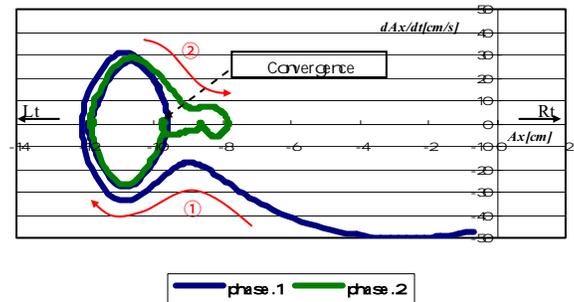

Figure 1: Phase plane in M/L direction of left healthy ankle

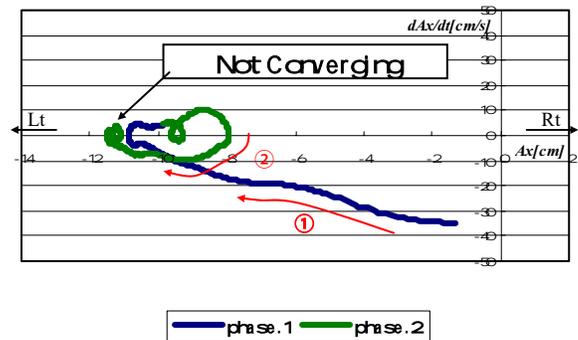

Figure 2: Phase plane in M/L direction of left FAI ankle

### CONCLUSIONS

We believe that the quantity and quality of COP during the twisting motion may be connected with a person's likelihood of "giving way". Analysis by phase planes in the M/L direction of COP during the twisting motion could potentially be used as a screening tool for people who are at risk for FAI and as an evaluation tool to determine the success of treatments that address the causes of FAI.

**RELATIONSHIP BETWEEN ELBOW FLEXION ANGLE AND JOINT LOADING  
 OF THE UPPER EXTREMITY DURING A CLOSE-CHAIN EXERCISE**

**INTRODUCTION**

Push-up is a close-chain exercise that is commonly used to strengthen the upper extremity. Clinically, close-chain exercises are encouraged for the earlier stage of the rehabilitation program because they produce smaller shearing forces across the joints than open-chain exercises. Nonetheless, there is very little research regarding the kinematics of the close-chain exercise of the upper extremity. The purpose of this study is to investigate the relationship between the elbow flexion angle and joint loading during a close-chain exercise of the upper extremity.

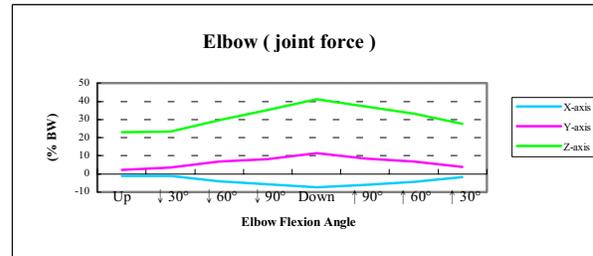

**METHODS**

Fourteen male subjects volunteered in this study. Their average age was 24.5 years, with an average height of 168.9 cm, and average weight of 65.9 Kg. The subjects were asked to perform push-up exercises with their hands in neutral position. The Expert Vison motion system (Motion Analysis Corp., Santa Rosa, CA, USA) with six CCD cameras and two Kistler force-plates (Type 9281B, Kistler Instrument Corp., Winterhur, Switzerland) were used to measure relative joint positions and ground reaction forces. The kinematics and kinetics of the upper extremity were calculated by inverse dynamics and Newton-Eulerian's equation. The correlation between the elbow flexion angle and joint loading during a close-chain exercise of the upper extremity were analyzed.

**RESULTS AND DISCUSSION**

Results showed that the loading biomechanics of the upper extremity differed with different elbow flexion angles. The maximum loading occurred when the elbow flexion angle was greater than 90° (p<0.01). The joint forces in axial, medial/lateral, and anterior/posterior directions increased as the degrees of elbow flexion increased (Figure 1). The maximum valgus moment, flexion moment, and pronation moment were 11.2, 39.9, and 9.8 N-m respectively (Table 1). During the push-up exercise, the greatest loading was calculated with the maximum elbow flexion ( the lowest trunk position).

In addition to the effective dampers and springs of wrist and shoulder, the elbow played a very important role of energy dissipation. Taking the effect of elbow motion into consideration, our three-mass-model was more precise in simulating the motion of upper extremity during a close-chain exercise [1].

**Figure 1:** Joint force (% B.W.) vs. degree of elbow flexion angle during a push-up cycle.

**CONCLUSION**

In this study, the relationship between elbow flexion angle and joint loading during a close-chain exercise were demonstrated. Although the maximum valgus moment during push-up exercise (11.2±3.7 N-m) was far less than the maximum valgus moment during sports ( i.e., 64 N-m in pitching), the peak joint loading occurred between 90 to 120 degrees of elbow flexion. Therefore, keeping elbow flexion less than 90 degrees during a close-chain exercise might be a safer strategy for strengthening of the upper extremity.

## METABOLIC COSTS OF FORWARD PROPULSION AND LEG SWING AT DIFFERENT RUNNING SPEEDS

<sup>1</sup> Bas Moed and <sup>2</sup> Rodger Kram

<sup>2</sup> Department of Integrative Physiology, University of Colorado, USA; email: [bassiemoed@hotmail.com](mailto:bassiemoed@hotmail.com)

### INTRODUCTION

We further investigated the cost of forward propulsion and the cost of leg swing across a range of submaximal running speeds by using an applied horizontal force (AHF) at the waist and external swing assist (ESA) forces at the feet. We hypothesized that the absolute costs of forward propulsion and leg swing would be greater at faster speeds.

### METHODS

Seven well trained runners volunteered and ran at three different speeds: 2, 3 and 4 m/s. At each speed, they ran normally and completed five trials with 10% body weight (BW) AHF in combination with 0, 1, 2, 3 and 4% BW ESA force, afterwards. The AHF was applied continuously at the waist. ESA was applied at the feet and helped to initiate and propagate leg swing during the first half of the swing phase.

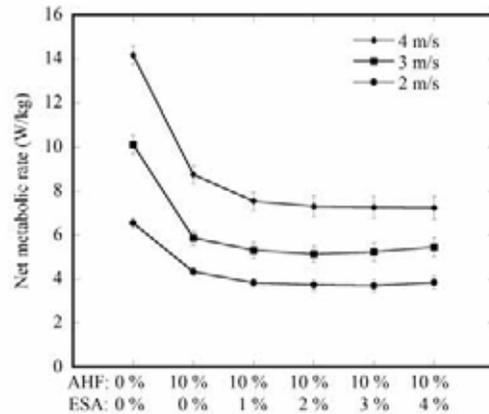

**Figure 1:** Schematic of the experimental set-up.

Oxygen consumption and carbon dioxide production were measured during a standing trial and were subtracted from gross running values to yield net metabolic rate (W/kg). We estimated the absolute cost of forward propulsion as the difference in metabolic rate between normal running and running with 10% AHF. The difference between running with 10% AHF and the minimum metabolic rate of the 10% AHF combined with ESA, reflected the absolute cost of leg swing.

Kinematic variables (step time, contact time and swing time) and kinetic variables (braking and propulsive impulse of the ground reaction force) were measured for each step, using a force-treadmill.

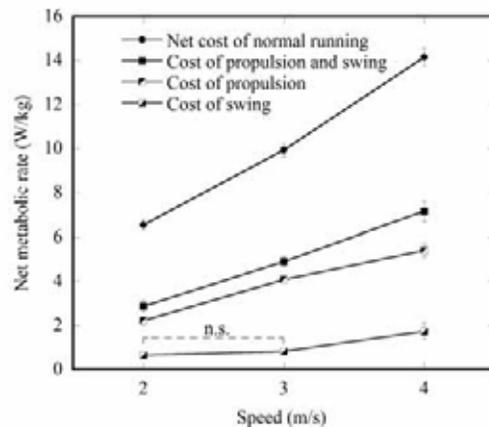

### RESULTS AND DISCUSSION

The absolute costs of forward propulsion and leg swing both increased with speed. The relative costs of propulsion and swing remained at nearly the same percentage of the total. The increase in the absolute cost of forward propulsion with speed may be explained by shorter contact times and greater

**Figure 2:** Net metabolic rate versus running condition for each speed. Data points are means  $\pm$  SEM (error bars).

braking and propulsive impulses [1]. The increase in the absolute cost of leg swing may be explained by a greater mechanical internal work rate at faster speeds [2].

**Figure 3:** Net metabolic rate versus speed for the cost of normal running, cost of propulsion, cost of leg swing, and the sum of the cost of propulsion and leg swing.

The relative costs of leg swing (~10%), forward propulsion (~40%) and supporting body weight (suggested to be the remaining part; ~50%) are compatible with previous studies [1,3,4].

**A COMPUTATIONAL MODEL OF THE PREGNANT OCCUPANT:  
 LOCAL UTERINE COMPRESSION EFFECTS THE RISK OF FETAL INJURY**

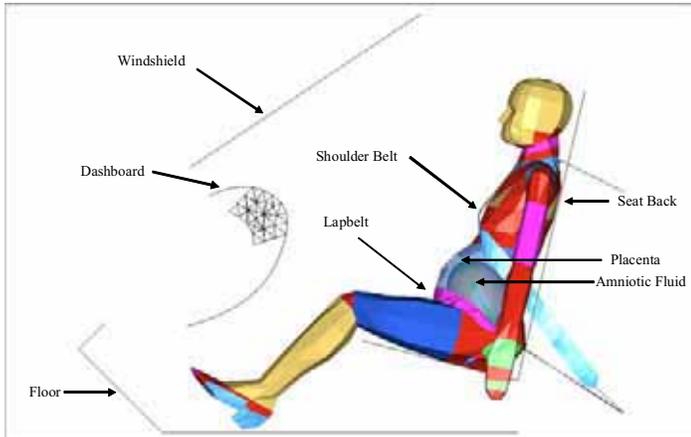

Stefan M. Duma, David M. Moorcroft, Joel D. Stitzel, Greg G. Duma  
 Virginia Tech – Wake Forest, Center for Injury Biomechanics; Email: [Duma@vt.edu](mailto:Duma@vt.edu); Web: [www.CIB.vt.edu](http://www.CIB.vt.edu)

**INTRODUCTION**

Automobile crashes are the largest single cause of death for pregnant females and the leading cause of traumatic fetal injury mortality in the United States (US) (Weiss, 2002). Unfortunately, fetal injury in motor vehicle crashes is difficult to predict due to the fact that real world crash data is limited and cadaver studies are not feasible. The purpose of this study was to develop a computational model of the pregnant occupant, and to identify the best correlation between uterine compression and risk of fetal injury as predicted by the strain at the uterine-placental interface.

**METHODOLOGY**

A finite element and multi-body model of the 30 week pregnant small female was created using the MADYMO software package (Figure 1). The finite element abdomen consists of the uterus, placenta, and amniotic fluid that are supported by two pairs of ligaments and surrounded by fat. These structures were imported into a multi-body model of the small female in order to examine overall crash kinematics.

**Figure 1:** Simulation configuration of pregnant occupant in passenger position with three-point belt.

Four techniques were used to validate the pregnant model. First, a global biofidelity response was evaluated by using a seatbelt to compress dynamically the pregnant abdomen (Moorcroft, 2003). Second, a similar validation procedure was performed with a rigid bar and these results were also consistent with previous data. The third technique involved validating the model against real-world crashes in order to investigate the model’s ability to predict injury. The fourth method compared the physiological failure strain from placental tissue tests to the model failure strain.

Next, a total of 15 computer simulations were performed on the right-front passenger seat. The test matrix consisted of simulations with five different lap belt locations with each evaluated at three velocities (13 kph, 35 kph, 55 kph). Abdominal measurements were taken at five locations, named AB1, AB2, AB3, AB4 and TH1 ranging from the upper pelvis

to the lower thorax. Linear regression analysis was used to correlate the peak uterine compression values to the peak strain at the uterine-placental interface (UPI) and subsequent risk of fetal injury.

**RESULTS**

Using fatal crashes from pregnant occupants (Klinich et al., 199b), the model showed strong correlation ( $R^2 = 0.85$ ) between peak strain at the uterine-placental interface (UPI) as measured in the model compared to risk of fetal demise as reported in the real-world crashes over a range of impact velocities and restraint conditions. Tissue tests suggest approximately a 60% failure strain for UPI tissues which is in agreement with the model’s prediction of 75 % risk of fetal loss at a 60% strain in the UPI. In summary, the global, injury, and tissue level validation techniques all indicate the model is good at predicting injurious events for the pregnant occupant.

The peak uterine strain increased with crash speed and lap belt height except for the top belt location. However, overall compression, which is the peak compression value for all locations, was constant over the range of lap belt locations for a given speed; 20% for 13 kph, 35% - 40% for 35 kph, and 50% for 55 kph. The best correlation was between AB 4 and peak UPI strain for all three impact velocities (Table 1).

**Table 1:** Correlation coefficient values for each uterine compression measurement versus peak UPI strain.

Measurement Location	13 kph	35 kph	55 kph	All speeds
AB 1	0.48	0.62	0.69	0.53
AB 2	0.50	0.69	0.77	0.65
AB 3	0.24	0.45	0.72	0.05
AB 4	0.92	0.97	0.92	0.93
TH 1	0.20	0.14	0.33	0.26

**CONCLUSION**

The AB 4 (upper abdomen) measurement location correlated the best because the strain is measured in the uterus at the placental location, which is at approximately the same height as the AB4 measurement location. Therefore, it is suggested as best practice to measure abdominal loading at the uppermost uterine location in an attempt to predict injury to the UPI and risk of fetal demise. It is important to note that all simulations indicate that it is safest for the pregnant occupant to ride in the passenger seat while wearing a three-point belt and utilizing the frontal airbag when possible.

### 3D ARTHROKINEMATIC ANALYSIS OF COUPLED MOTION IN THE HUMAN UPPER-CERVICAL SPINE: IN VITRO ANALYSIS OF HIGH VELOCITY THRUST TECHNIQUES

Cattrysse Erik, Baeyens Jean-Pierre, Clarys Jan-Pieter, Van Roy Peter  
 Dep. Experimental Anatomy, Vrije Universiteit Brussel, Brussels, Belgium

#### INTRODUCTION

Three dimensional analysis of coupled segmental motions in the cervical spine was only studied sparsely and in pure moment analysis. Only preliminary information exists on the kinematics of manual segmental mobilization. The present study focuses on the in vitro registration of upper cervical segmental coupled motions during manually performed therapeutic high velocity thrust techniques (HVT). The aim of the study was to collect qualitative information on the kinematics behavior of the upper-cervical spinal motion segments during planar induced movements and while applying manual therapeutic manipulation techniques. The information can help to understand the effect of manual therapy on spinal motion.

#### METHODS

Seven cervical spine specimens were taken from embalmed human cadavers at the level of the occiput to the first thoracic spine. Each specimen was clamped on a rigid stand to hold T1 in such a way that the cervical spine was fully free to move. 3D electromagnetic tracking sensors were fixed on the head, C1 and C2. Subsequently, each specimen was first moved in the three main planes of motion. Consecutively in 4 specimens a segmental manipulative high velocity thrust in axial traction direction was performed on the level of C0-C1 followed by a segmental rotational high velocity thrust on the level of C1-C2. The position and orientation of each sensor were collected by an electromagnetic tracking device (Flock of birds-Ascension technologies). At a later stage, the positions of local anatomical landmarks were digitized with a 3D drawing stylus (3DX-Microscribe). The individual sensor data were used to describe coupled movements by means of the parameters of the finite helical axes (Spoor and Veldpaus, 1980; Woltring et al., 1994) for discrete sampling ranges of the movements between the different bones: i.e. orientation, position, shift along and rotation about the estimated helical axis. The anatomical data were used for the definition of local bone embedded co-ordinate systems. To analyze the 3D arthrokinematics of the atlanto-occipital and atlanto-axial joints, the finite helical axes were related to a co-ordinate system based on the centre line through mastoid processes and the transverse processes of C1 and C2. The effect of segmental manual high velocity thrust techniques were analyzed in a six degrees of freedom approach. The results are analyzed by the Euler angle approach and finite helical angles representations.

#### RESULTS AND DISCUSSION

The results show that all planar induced movements include 3-dimensional coupled motions. During the main flexion-extension motion on the atlanto-occipital segment important associated rotation and lateral bending takes place that can even equal or sometimes exceed the main motion. During HVT

traction on the C0-C1 level the thrust results in a 3-dimensional translation. The main direction is lateral, coupled with a smaller axial and sagittal displacement. The rotational HVT on the level C1-C2 results in an additional axial rotation component of approximately 2°, with almost no rotational components in flexion-extension or lateral bending directions (fig 1). This axial rotation component is however again accompanied by translational displacements in all three directions. The largest translation takes place in the lateral direction (fig 1).

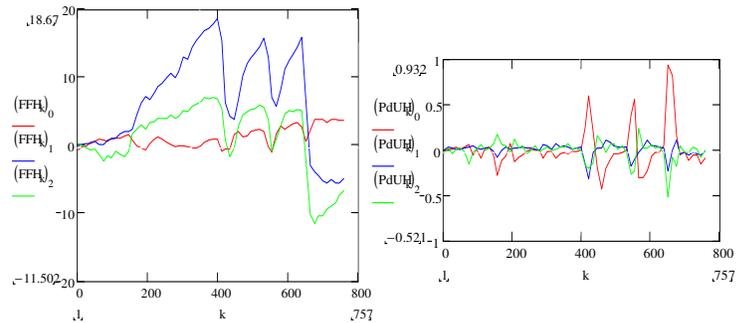

Fig.1 cumulative helical angles (left) and intra-articular translations (right) C1-C2 during rotational HVT (specimen 4)  
 (FFH)0≈flexion-extension (PdUH)0≈ lateral translation  
 (FFH)1≈axial rotation (PdUH)1≈ cranio-caudal translation  
 (FFH)2≈lateral bending (PdUH)2≈ sagittal translation

#### CONCLUSIONS

These results show that manual induced segmental coupled movements in the upper cervical spine can be analyzed in vitro by means of an electromagnetic tracking device. The largest motion at the atlanto-occipital level is flexion-extension as is described in literature (Panjabi et al., 1993), while at the atlanto-axial level the rotation is the motion with the largest amplitude. HVT-techniques can induce axial translational displacements and additional axial rotation in traction and rotation techniques respectively. Therapists have to realize however that coupled rotations and translations take place. In the presented HVT's these coupled motions can not be excluded and may increase stress on vital structures.

#### INTRODUCTION

Three dimensional analysis of segmental motion coupling was only studied sparsely and in pure moment analysis. The present study focuses on the in vitro registration of upper cervical segmental coupled motions during manual induced axial rotation and lateral bending. The aim of the study was to create a suitable setup for collecting qualitative information on the kinematics of the atlanto-axial joint during planar induced movements, and to compare patterns of motion coupling.

#### METHODS

Seven cervical spine specimens were taken from embalmed human cadavers from the occiput to the first thoracic spine. Each specimen was clamped on a rigid stand to hold T1 in such a way that the cervical spine was fully free to move. 3D electromagnetic tracking sensors were fixed on the occiput, C1 and C2. Subsequently, each specimen was moved in the main planes of motion. The position and orientation of each sensor were collected by an electromagnetic tracking device (Flock of birds-Ascension technologies). At a later stage, the positions of local anatomical landmarks were digitized with a 3D drawing stylus (3DX-Microscribe). The individual sensor data were used to describe coupled motions by means of the parameters of the finite helical axes (Spoor and Veldpaus, 1980; Woltring et al., 1994) for discrete sampling ranges of the movements between the different bones. The anatomical data were used for the definition of local bone embedded coordinate systems. To analyze the 3D arthrokinematics of the atlanto-axial joint, the finite helical axes were related to a coordinate system based on the centre line through the transverse processes of C1 and C2 and the midpoint of the anterior side of the arcus of C1 and corpus of C2. The results are analyzed by the finite helical angles representations

#### RESULTS AND DISCUSSION

The results show that main planar axial rotation and lateral bending motions include 3-dimensional coupled motions. Tabel 1 shows that the coupling pattern during axial rotation is

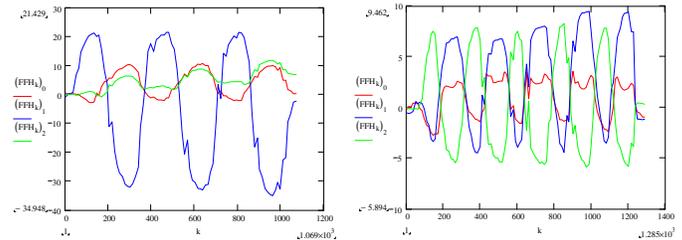

Fig 1. : Cumulative finite helical angles C1-C2 during axial rotation (spec 7) (FFH)<sub>0</sub>≈flexion-extension; (FFH)<sub>1</sub>≈axial rotation; (FFH)<sub>2</sub>≈lateral bending

Fig 2. : Cumulative finite helical angles C1-C2 during lateral bending (spec 7) (FFH)<sub>0</sub>≈flexion-extension; (FFH)<sub>1</sub>≈axial rotation; (FFH)<sub>2</sub>≈lateral bending

coupled contralateral lateral bending in 5 out of 7 specimens (fig.1). During lateral bending the coupled rotation is ipsilateral in 6 out of 7 specimens.

#### CONCLUSIONS

These results indicate that the experimental setup is suitable for the analysis of coupled rotations in the upper cervical spine. The results of the arthrokinematic analysis of manual induced planar motions are parallel to the findings of an experimental setup applying controlled forces and moments (Panjabi et al., 1993).

## Motion Characteristics of the Innominate-hip complex under increasing passive loads

Melanie Bussey

University of Otago, email mbussey@pooka.otago.ac.nz

### INTRODUCTION

The human pelvis provides the bony link between the spinal column and the lower limbs, acting as an intermediary in the load transfer mechanism from the trunk to the legs and *vice versa*. A problem encountered in modelling research is the representation of the pelvis as a solid or rigid body, thus pelvic joint motion is ignored. To increase our understanding of the mechanisms involved in loading injury to the lumbar spine there is a need for research combining lower limb and spine kinematics with pelvic joint kinematics to identify the extent and nature of motion in the lumbar-pelvic-hip complex. The aim of the present research was to examine the motion characteristics of the innominate-hip complex under normal passive loading conditions and specifically, to determine the contribution of relative innominate bone motion within the complex.

### METHODS

Thirty healthy subjects (16 females and 14 males) between the ages of 20 and 40 gave their informed consent to participate in this study. A magnetic tracking device (Fastrack, Polhemus Incorporated, Colchester, VT, USA) was used to track the motion of the pelvis, innominate bones and femurs as the hip was passively loaded in 10° increments. A standardization frame was used to standardize the passive loading of the hip in two separate constraint conditions up to maximum lateral flexion (AB) and external rotation (ER). The frame constrained the hip so that only motions in the frontal and transverse planes were allowed (i.e., the femur was constrained in the directions of flexion and extension). Thus, the hip orientation was described relative to the pelvis as a y x y sequence of Euler angles. In each load position the transverse ( $I_{NSy}$ ) and sagittal plane ( $I_{NSz}$ ) angles of the innominate bones were calculated from digitized pelvic landmarks. Finally, the innominate motion was described as absolute angular displacement between the neutral and loaded positions.

To determine whether there was an effect of Hip Condition or Load Position on the ROM of the innominate and hip, means and standard deviations for motion measured in the final positions of each hip condition were calculated. The dependant variables  $H_{ABx}$ ,  $H_{ERY}$ ,  $I_{NSz}$  and  $I_{NSy}$  were each tested in a GLM univariate analysis, F-ratios and alpha levels derived for each source of variance (Hip Condition, Load Position and Load Position x Hip Condition). Where significant differences between Positions were found a Tukey *post-hoc* test was used to determine which Positions were significantly different.

### RESULTS

Firstly, as expected the femur motion increased significantly with each successive Position. So,  $H_{ERY}$  increased significantly ( $p < 0.001$ ) with increasing external rotation stress

and  $H_{ABx}$ , also increased significantly ( $p < 0.001$ ) with increasing lateral flexion stress. Secondly, the only significant Position effect in innominate bone displacement was about the y-axis ( $I_{NSy}$ ) in the ER condition where there was a significant change ( $p = 0.001$ ) in innominate motion with increasing stress. The evidence from the Tukey *post-hoc* test showed that the increase in ROM from Position 1 to Positions 3, 4 and 5 was significant, the mean difference between Positions 1 and 3 was  $-0.84^\circ$  (95% CI =  $-1.37$  to  $-0.32^\circ$ ). There was a very low ability to adequately predict  $I_{NSy}$  innominate from  $H_{ERY}$  of the femur as determined through regression plots ( $R^2 = 0.10$  right, Figure 8 and  $R^2 = 0.13$  left, Figure 7). The combination of small ROM and large individual variability make such across-subject comparisons difficult.

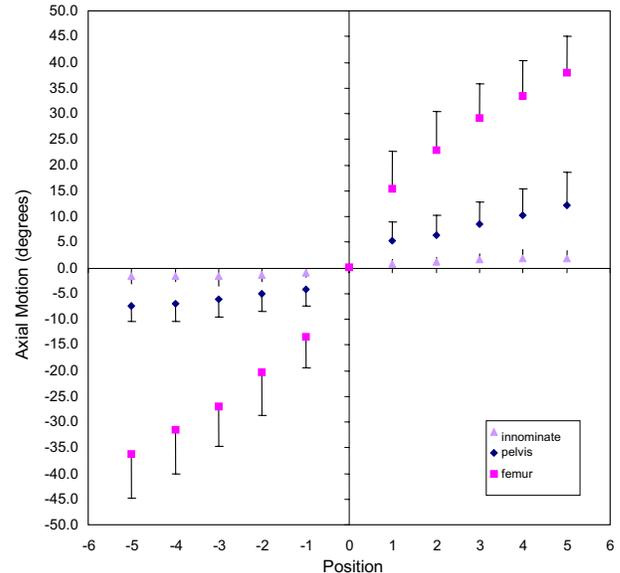

Figure 1: Means and standard deviations for the left (-) and right (+) hip, pelvis and innominate bones in each of the loaded positions of the ER hip condition.

### DISCUSSION AND SUMMARY

The present study demonstrated that the greatest change in innominate bone ROM occurs within the first 15-20° of hip motion and that increased load on the innominate from the hip does not significantly increase the displacement of the innominate bones. Although the ranges of innominate bone motion were significantly smaller compared to pelvic or femur motion, the innominate bone motion accounted for 3 to 5% of the total x and y femur rotations. The results of this study support the theory that the main functional role of the pelvic joints (apart from aiding in childbirth) is to reduce the injurious torque from the hip to the lumbar spine.

## SCALING OF MUSCLE VOLUMES IN THE UPPER EXTREMITY

email: kholzbaur@stanford.edu

### INTRODUCTION

Humans vary greatly in size and shape, yet biomechanists often use generic musculoskeletal models with average parameters to examine questions of muscle function and coordination. While this approach allows researchers to investigate general principles underlying human movement, it is unclear how conclusions derived from studies of generic models apply to individuals of different sizes.

Muscle force-generating properties used in musculoskeletal models are often derived from cadaveric studies of muscle architecture. This could complicate scaling of generic models for two reasons. First, cadaveric specimens may not accurately reflect the absolute or relative sizes of muscles in young, healthy subjects. Second, cadaveric studies of muscle architecture often focus on individual muscle groups; this is especially true for the upper limb, where muscle parameters have been quantified separately for the shoulder [1], elbow [4], and forearm [2,3]. This study addresses both issues in the upper extremity by i) measuring volumes for all muscles of the upper limb in young, healthy subjects using magnetic resonance imaging, and ii) comparing these data to the different sources available in the literature.

### METHODS

Five subjects (4 females, 1 male, 24-37 years) with no injury or pathology of the upper limb were studied. All subjects provided informed consent. Each subject was imaged supine in a 1.5T MRI scanner (GE Healthcare, Milwaukee, WI). Axial images were acquired from shoulder to wrist using a 3D spoiled gradient echo sequence with 3 mm sections. Shoulder images were obtained with the body coil with TE = 3 ms, TR = 11.6 ms, flip angle (FA) = 30°, matrix = 512x192, and field of view (FOV) = 32 cm. Elbow and forearm images were acquired using a flexed array long bone coil (Medical Advances, Milwaukee, WI) with TE = 5 ms, TR = 23 ms, FA = 45°, matrix = 320x192, and FOV = 16 cm.

To calculate muscle volume, we reconstructed the three-dimensional geometry of the upper limb muscles. Muscle boundaries were segmented in the axial images and a three-dimensional polygonal surface was created for each muscle from the outlines (3D-Doctor, Able Software Corp., Lexington, MA). Muscle volumes were then normalized by the corresponding volume reported in the literature [1-4] to produce a “scaling ratio”. For a given muscle, a ratio greater than 1 indicates that its volume is larger than the cadaver data. To determine if muscle volumes obtained from the different literature sources represent the relative proportion of muscle volumes for a single individual, we compared scaling ratios across upper limb segments for each subject.

### RESULTS AND DISCUSSION

The ratios between the volumes measured in this study and the volumes from cadaveric data ranged from 0.91 to 3.73. While scaling ratios varied across subjects, all muscles scaled by approximately the same ratio for each subject. For example, the scaling ratios for deltoid, a shoulder muscle, and extensor carpi radialis brevis (ECRB), a forearm muscle, were approximately equal (Fig. 1, red squares). Similarly, the ratios for brachioradialis, an elbow muscle, and pronator quadratus (PQ), a forearm muscle, were comparable (Fig. 1, blue triangles).

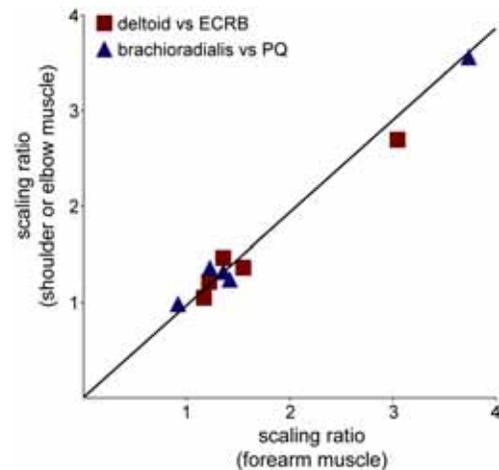

Figure 1: Scaling ratios for example proximal muscles vs. forearm muscles.

Muscle volumes reported in cadaveric studies are equivalent to the volumes measured in the females in this study (height ranged from 157 to 165 cm). The one male subject evaluated here (height = 175 cm) had substantially larger muscle volumes. Data from different architecture studies scaled uniformly to muscle volume for a given subject. That is, when scaling ratios for shoulder or elbow muscles were plotted against ratios for forearm muscles, all points fell close to a line with slope equal to one. This is encouraging for researchers who must combine data sets from multiple studies to estimate force-generating properties for the entire upper limb. It also provides preliminary support for application of modeling results to individuals of varying size. Our ongoing studies will examine muscle scaling in a larger group of subjects.

## EFFECTS OF POWER GENERATION ON EVALUATING IMPACT ATTENUATION IN LANDING

Kurt Clowers and Songning Zhang

Biomechanics/Sports Medicine Laboratory, The University of Tennessee, Knoxville, TN, USA

email: [kclowers@utk.edu](mailto:kclowers@utk.edu)

### INTRODUCTION

A common and acceptable activity used to measure the power output of the lower extremity is the vertical jump [1]. Studies have compared the biomechanical characteristics of landing and jumping with the same level of participation [2, 3] and others have compared the physical activity level or experience in landing and jumping biomechanics [4, 5]. Thus, differences could be observed in the impact attenuation during landing in athletes with different maximum power generation capabilities. Therefore the purpose of this study was to compare the effects of power generation capacity on impact attenuation during a drop landing activity.

### METHODS

Twelve male recreational athletes performed five drop landing trials from three heights in two different protocols (PT). Subjects were divided into one of two groups (Grp) based on their maximum vertical jump height: non-elite (Grp 1, N=8) and elite (Grp 2, N=4), which was used as an index for lower extremity power capacity. All subjects performed five landing trials from heights of 40, 60, and 80 cm in the protocol one (PT1) and from 70%, 100%, and 130% of their jump height (H) in the protocol two (PT2).

A force platform (1080 Hz, AMTI) and a 6-camera motion analysis system (120 Hz, Vicon) were used to collect ground reaction force (GRF) and 3D kinematic data simultaneously during the testing session. Kinematic and GRF data were smoothed at 8 and 20 Hz respectively, using a fourth-order Butterworth low-pass filter. The 3D joint kinematic and kinetic variables were computed using Visual3D software (C-Motion, Inc.) in conjunction with a customized computer program. A mixed design three-way repeated measures ANOVA (Grp × PT × H) with Grp as the between-subject factor was used to evaluate selected joint kinematic and kinetic variables ( $p < 0.05$ ).

### RESULTS AND DISCUSSION

The mean maximum knee flexion angle was significantly greater in PT2 than PT1 for Grp1. The maximum knee flexion angle increased significantly as height increased for both groups. For Grp1 in PT1 the maximum knee flexion angle increased 11% from H 1 to 2 and 27% from H 1 to 3. However, in PT2 the increases were 11% and 21% from H 1 to 2 and from H 1 to 3 respectively.

The mean peak knee extensor moment was significantly greater in PT1 than PT2 for Grp1 (Table 1). The peak knee extensor moment in PT1 for Grp1 increased 21% and 68% from H 1 to 2 and H 1 to 3 respectively. However, in PT2 the increases were 16% and 31% for Grp1. Conversely, the peak hip extensor moment in PT1 for Grp1 increased 29% and 61%

and for PT2 the increases were 31% and 69% from H 1 to 2 and H 1 to 3 respectively. Similarly, the peak ankle plantar flexor moment in PT1 for Grp1 increased 8% and 16% but for PT2 the increases were 16% and 16% from H 1 to 2 and H 1 to 3 respectively.

**Table 1:** Average peak joint moments (Nm/kg).

Grp	PT	H	Hip	Knee	Plantar
			Extensor	Extensor	Flexor
1	1	1	3.4±1.1	2.5±0.4	1.5±0.5
		2	4.4±1.2 <sup>a</sup>	3.0±0.8 <sup>a</sup>	1.6±0.5 <sup>a</sup>
		3	5.5±1.9 <sup>a,b</sup>	4.2±1.0 <sup>a,b</sup>	1.8±0.4 <sup>a,b</sup>
	2	1	2.9±0.9	2.3±0.3 <sup>*</sup>	1.4±0.4
		2	3.8±1.1 <sup>a</sup>	2.7±0.3 <sup>*,a</sup>	1.7±0.5 <sup>a</sup>
		3	4.9±1.3 <sup>a,b</sup>	3.1±0.4 <sup>*,a,b</sup>	1.6±0.3 <sup>a,b</sup>
2	1	1	2.9±0.6	2.3±0.3	1.8±0.3
		2	4.0±0.4	2.8±0.2 <sup>a</sup>	1.9±0.2 <sup>a</sup>
		3	5.0±1.6	3.6±0.8 <sup>a,b</sup>	2.0±0.3 <sup>a,b</sup>
	2	1	4.2±0.9	2.6±0.3	1.8±0.2
		2	4.7±1.0	3.3±0.6 <sup>a</sup>	1.9±0.4 <sup>a</sup>
		3	5.4±1.4	3.8±0.4 <sup>a,b</sup>	2.1±0.3 <sup>a,b</sup>

<sup>\*</sup>: Significantly different from protocol 1.

<sup>a</sup>: Significantly different from height 1.

<sup>b</sup>: Significantly different from height 2.

There were greater increases in the hip and ankle moment for PT2 while smaller increases for PT1 in Grp1 but not Grp2. The knee moment demonstrated greater increases for PT1 but smaller increases for PT2 in Grp1 only. The moment data indicates that there is greater effort by the knee musculature for Grp1 to attenuate the impact forces for PT1 but actually less effort by knee and greater effort by the hip and ankle musculature for PT2 to absorb the impact forces.

### CONCLUSIONS

Protocol differences were found in individuals who did not participate in jumping sports and who landed from absolute heights. For the PT based on a percentage of maximum vertical jump heights, smaller increases in knee kinematics and knee moments were found in Grp1 only. These results suggest individuals possessing greater power generation capabilities and/or conditioning may be more capable attenuating impact forces in drop landings.

### ***Introduction***

The balance control is needed when an specific skill learning is developed. This is truth when you work with sports techniques learning that needs the refined postural and balance control to optimize the motor performance. So, it could be thought that the sports technique learning would develop a better postural control in the individual that practice those activities. The sportive indoor climbing make the athlete be exposed to certain unusual postural conditions as lower visual inputs defined by the high he is positioned; irregular feet support and the need of an horizontal force avoiding the posterior fall. Those conditions make occur a continuous postural instability during the activity and demand a bigger motor control (reflex, automatic and conscious motor behaviors) developing beside the technique learning, a better balance control. This could be seeing in a posturography test. In the present study, we analyze the equilibrium, the strategy and the sensory analyses score (for somatosensory, visual and vestibular systems) during four stand quietly posturography conditions in indoor climbing individuals and controls.

### ***Methods***

Forty normal individuals of both sex and mean age of 23,67 years, divided between two groups according to their sports practice (indoor climbing group – G1 and controls – G2) were called as voluntaries. This two groups were sex and mean age matched. The balance test used was the modified sensory organization test (mSOT) from the Pro Balance Master posturography developed by NeuroCom<sup>®</sup> and that presents four defined test conditions: (1) eyes open and fixed platform; (2) eyes closed and fixed platform; (4) eyes open and sway referencing platform; (5) eyes closed and sway referencing platform. The statistics was done as t student-test for independent samples.

### ***Results and Discussion***

The results were indicative to a significant difference ( $p < 0,05$ ) in the number 4 mSOT's condition ( $p=0,04$ ) and in the visual system sensorial analyses ( $p = 0,01$ ). Showing the indoor climbing group, G1, to have better performance than controls when the visual system is the biggest responsible for balance control, and the

somatosensory and vestibular system are for somewhat being mistaken. This is different to the prevalence of the support surface dependence balance control that is found in controls, when the individual goes better in the test when the support surface is fixed. We can state yet that was found a tendency analyses in the somatosensory system score indicating better balance performance in the G1.

The strategy scores analyses (hip and ankle strategies) didn't show any differences between G1 and G2 in any posturography's condition. As the postural and balance control strategy is specific of standing posture perhaps it's not available during climbing and so it's not learned or developed during this sports practice.

### ***Conclusion***

This study has concluded that due to their daily training, climbers presented an increase in the activity in their visual and somatosensory systems. This phenomenon either improved their postural control explaining the large difference in the analysis score of the visual system and a tendency to a significant difference between the groups in the analysis score of the somatosensory system.

## THE EFFECT OF INITIAL LEAN ON HUMAN POSTURAL SCALING

### INTRODUCTION

We examined how the central nervous system adjusts postural responses with initial forward lean of the body. Postural feedback responses appear to scale nonlinearly with perturbation magnitude in order to accommodate biomechanical constraints such as allowable ankle joint torque [1]. Initial forward leaning, which is observed among the elderly who are inactive or afraid of falling, brings subjects nearer to the limit of stability [2] and alters the biomechanical constraint. We hypothesized that the central nervous system is aware of body dynamics and further restrains postural responses when subjects initially lean forward prior to a perturbation.

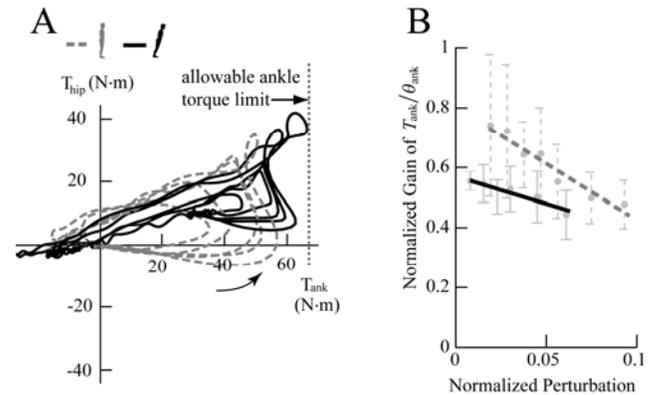

### METHODS

We applied fast backwards perturbations of various magnitudes to 12 healthy young subjects (3 male, 9 female) aged 20 to 32 years. Subjects were instructed to quietly stand on a hydraulic servo-controlled force platform with their arms crossed over their chests, and to recover from a perturbation by returning to their upright position. Initially subjects were either standing upright or standing with a half-maximum forward lean. Half-maximum lean is defined as the posture, in which the center of pressure is located at half the maximum magnitude that subjects could achieve without stepping or falling. The force platform translated backward with various ramp displacements ranging 1.2 – 15 cm, all with the duration of 275 msec. Perturbations occurred in blocks of seven displacements, with the perturbation size for each block randomized. For each trial, kinematics and ground reaction force data were recorded and then used to compute net joint torques, employing a least squares inverse dynamics method.

To examine the scaling of multi-joint postural responses, we examined the changes in trajectories of ankle vs. hip joint torques as a function of perturbation magnitude and initial lean. We used optimization methods to identify a set of equivalent feedback control gains for each trial so that the biomechanical model incorporating this feedback control would reproduce the empirical response [1]. There are three components to this identification: a 3-segment inverted pendulum biomechanical model of body dynamics, a linear feedback control to stabilize this model [3], and an optimization procedure to produce model responses with the best fit to the data. We compared the joint torque trajectories with a predicted constraint on allowable ankle torque, and also examined how the identified feedback gains changed with initial lean.

### RESULTS AND DISCUSSION

We found that joint torque and feedback gains gradually scaled as a function of perturbation magnitude before they

**Figure 1:** Changes in postural response scaling for two different initial postures. (A) Trajectories of joint torques also scaled with initial lean. Joint torque for leaning trials more conservatively scaled for forward posture. (B) Normalized feedback gains and their linear regressions as a function of perturbation magnitude for upright posture (dashed line) and forward lean posture (solid line).

reached the biomechanical constraint, and scaling became more severe with initial forward lean (see Fig. 1). For example, the model suggests that the magnitude of ankle joint angle feedback to ankle torque was smaller in leaning trials than on initially upright trials, as if the subjects experienced a larger postural perturbation in leaning trials. These results imply that the central nervous system restrained postural responses to accommodate a more limiting biomechanical constraint imposed by the forward posture. The gradual scaling of postural feedback gains indicates that the postural control can be interpreted as a feedback scheme with scalable gains.

### CONCLUSIONS

Human postural responses scale as a function of perturbation magnitude as well as initial lean to accommodate biomechanical constraints. This scaling implies that the central nervous system is aware of body dynamics and biomechanical effects of initial position so it can restrain postural responses when subjects initially lean forward.

### INTRODUCTION

Human postural responses appear to scale as a function of perturbation magnitude to accommodate biomechanical constraints [1]. Scaling occurs in a gradual manner before discrete biomechanical constraints such as limitations on allowable ankle torque become active, implying a continuous neural representation of the constraints. We developed an optimal control model of human postural scaling using a constraint-penalized control objective, and examined whether the model could reproduce this gradually scaling of postural responses as perturbation magnitude increases.

### METHODS

Fast backwards perturbations of various magnitudes were applied to 12 healthy young subjects (3 male, 9 female) aged 20 to 32 years [1,2]. Subjects were initially either standing upright or leaning forward on force platform and returned to their upright posture after perturbation stimulus. For each trial, kinematics and ground reaction force data were recorded and then used to compute net joint torques. We previously used system identification to determine subjects' feedback gains for each perturbation [1]. Here, we tested whether a single objective function could reproduce these gains, using a simple parametrization of the constraint dynamics.

We modified a previous linear feedback controller [3] for a 3-linkage biomechanical model of the body. Control gains were obtained by minimizing a control objective including a representation of biomechanical constraints. This representation determines whether the central nervous system (CNS) accommodates the constraints in a gradual manner or by an abrupt change of response. The maximum allowable ankle torque acts as a discrete constraint on postural feedback responses to support surface perturbations. If the CNS were to represent this constraint in a discrete manner, the CNS would uniformly scale postural responses with perturbations until the maximum ankle torque were reached. For larger perturbations, it would abruptly switch feedback gains to a different value to accommodate the discrete constraint. Neural networks are typically better suited to representing constraints in a more continuous manner, similar to a penalty function. If the CNS were to have a continuous representation, it would continuously scale control gains as a function of postural challenges so that the responses would be gradually adjusted to satisfy the constraints. We modeled this concept with an optimal control design. The objective included a penalty against violating the maximum allowable ankle joint torque constraint. We compared the model's feedback scaling behavior against the human experimental data.

**Figure 1:** Postural scaling responses. (A) Empirical feedback gains scaled with perturbation magnitude as well as initial lean. (B) Feedback gains computed by optimization model also scaled gradually in a manner similar to data. (C) Joint torque trajectories computed from optimal control model. Gray dotted lines are for upright trials, black solid lines are for leaning trials.

### RESULTS AND DISCUSSION

The optimal control model was able to roughly reproduce gradually-scaled postural responses in accordance with biomechanical constraints. The results suggest that the nervous system may represent potentially discrete constraints, such as a threshold torque before heel lift-off, in a continuous manner. It appears unnecessary for the CNS to store postural responses as a large number of muscle activation trajectories. Rather, a family of responses could be encoded by a much smaller number of feedback gains, whose scaling in turn could be encoded by a minimal set of parameters.

### CONCLUSIONS

The constraint-penalized objective was able to reproduce the postural scaling with perturbation as well as initial lean. Gradual scaling of postural response by a penalty function implies that the nervous system may represent biomechanical constraints in a more continuous manner. The existence of the global objective based on the biomechanical model also suggests that the CNS is aware of body dynamics and flexibly scales postural response to accommodate biomechanical constraint, rather than discretely selects the preprogrammed responses.

## Relationship between rotational movement and translational movement during the golf swing

<sup>1</sup>Mutsuko Nozawa, <sup>2</sup>Hidetsugu Nishizono and <sup>2</sup>Norihiro Shima  
<sup>1</sup>Takeo Maruyama, <sup>1</sup>Syuichiro Yazawa and <sup>1</sup>Kazuhiro Suda  
<sup>1</sup>Tokyou Institute of Technology; e-mail: mnozawa@o.cc.titech.ac.jp  
<sup>2</sup>National Institute of Fitness and Sports in Kanoya

### INTRODUCTION

Several studies of golf swings were investigated the rotation of the trunk and the movement of arms and hands by many researchers. However, a good performance in golf swing is the result of a complex multi-joint movement that is dependent on the forces applied at the feet.

The purpose of this study was to measure and analyze ground reaction forces (GRF) from both feet during the golf swings using a driver. Furthermore, we attempted to clarify the relationship between the rotational movement of the body and the free moment about a vertical axis in the golf swing.

### METHODS

Fifteen right-handed male golfers (8 professional golfers in Japan and 7 amateur golfers), with a mean ( $\pm$ S.D) age, height, body mass of  $36.2 \pm 9.1$  years,  $170.1 \pm 4.0$  cm,  $72.8 \pm 8.0$  kg respectively, volunteered to participate in this study. Each golfer carried out 5 shots using a driver. The measurements of kinematics data during the swings were established with the optical motion capture system VICON612 (Vicon Motion Systems Ltd., Oxford, UK) with ten cameras operating at 250 frames per second placed around the subject who performed the golf swing.

At the exact same instant, the GRF's acting at both feet was recorded using one Kistler force platforms. Forces and moments were sampled at 1K Hz using standard coordinate conventions where the positive Fx force was the subject pushing forward, positive Fy was pushing toward the right (away from the direction of the ball flight), and positive Fz was down. We analyzed the golf swing from the start of the downswing to the impact with the ball. 3 trials were randomly selected from the 5 shots, and then the data was normalized according to total time

### RESULTS AND DISCUSSION

#### 1. Swing time and club head speed

Table 1 show the swing time and club head speed (HS) at impact, hip and shoulder range of the motion (ROM) with the mean ( $\pm$ S.D) respectively.

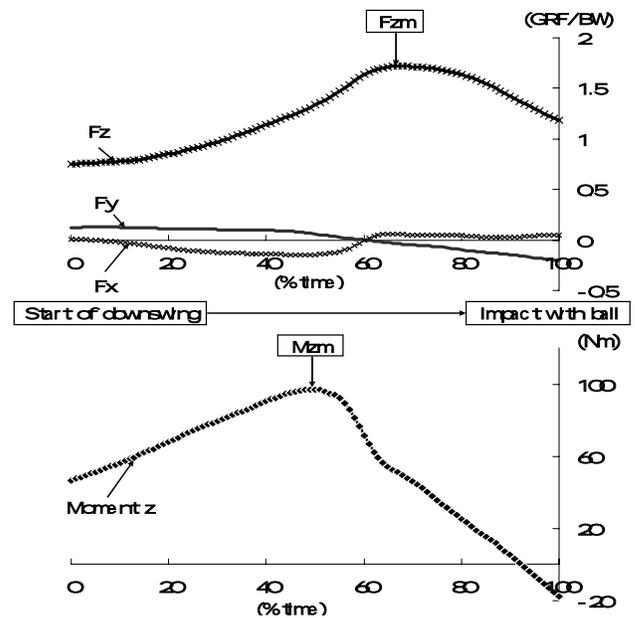

**Table1.** Club head speed and hip and shoulder ROM

subject	HSmax (m/s)	Time(s)	ROMHip(deg)	ROMShoulder (deg)
Mean $\pm$ SD	38 $\pm$ 27	03 $\pm$ 004	86 $\pm$ 109	114 $\pm$ 131

#### 2. The patterns of GRF and free moment forces

The free moment about the vertical axis increased toward middle range between start of downswing and impact with ball, then reached its maximum value (Mzm). Rotations of both the hip and shoulder were going at maximal value in order to build up energy at the top of the backswing. In addition to that,

forces acting the both feet also exert a turning effort on trunk rotation. After Mzm appeared, the vertical GRF attained the maximum value (Fzm), which indicates that the free moment decreased toward the impact, resulting in the transfer of force to the target foot (left foot; right-handed). While forces transferred, knee joint and hip joint tended to be flexed. As a result of forces acting on the entire body appeared maximum value in order of increasing the free moment and the vertical GRF during middle downswing. This phenomenon occurred in all subjects for this study.

**Figure1.** The GRF and free moment patterns

### CONCLUSIONS

The maximum value of free moment about the vertical axis appeared first during middle downswing in the golf swing, and then the maximum value of vertical GRF appeared in all of the golfers. This suggested that a result of forces acting on the entire body was changed by rotations of hip and shoulder and the flexions of the knee joint and hip joint.

### Introduction

Muscle weakness is one of the earliest and most common symptoms of patients with osteoarthritis (OA) (1). Although many experimental models of OA include muscular weakness, no model has studied this factor satisfactorily for long periods of time. The purpose of this study was to assess muscle weakness over a period of six months in order to validate an experimental model of muscle weakness for future use in the study of OA.

### Methods

Muscle weakness was produced by monthly injections of the neurotoxin clostridium botulinum type A (BTX-A) in the quadriceps muscle of six New Zealand white rabbits. Muscle weakness was assessed by calculating the difference in knee extensor torque between experimental and contralateral hind limb (which was injected with a saline solution). Knee extensor torques were obtained at three different knee angles with a custom-built force sensor bar placed distally on the tibia. Knee extensor torque was produced with supramaximal stimulation (100 Hz, 500 ms) of the quadriceps muscles through the femoral nerve. Maximum isometric knee extensor torque was recorded at multiple knee angles in order to investigate if muscle weakness between hind limbs persists over a physiological range of motion. Muscle mass of the rectus femoris, vastus lateralis, vastus intermedius and vastus medialis muscles was evaluated post mortem using a commercial scale with an accuracy of 0.001g. All outcome measures are reported as relative percent deficits, comparing the BTX-A injected hind limb to the contralateral (sham) hind limb.

### Results and Discussion

Muscle weakness across all three tested knee angles was approximately 60%, suggesting that BTX-A had a similar effect across the physiological range of motion and produced weakness over the six months testing protocol (Figure 1).

Atrophy, measured as the deficit in muscle mass between experimental and control limbs, was greatest for the vastus lateralis and smallest for the vastus medialis (Figure 2). This difference in atrophy may represent a difference in fiber type composition between the quadriceps muscles. BTX-A has been reported to have a greater effect on fast-twitch (type II) muscle fibers (2).

### Conclusions

Monthly injections of BTX-A, a potent neuromuscular blocking agent, over a six months period, created a chronic functional muscle weakness model in the New Zealand white rabbit. This model may be used to systematically study the possible effects of muscle weakness on joint degeneration, either as an isolated intervention, or in combination with other interventions known to create knee joint degeneration.

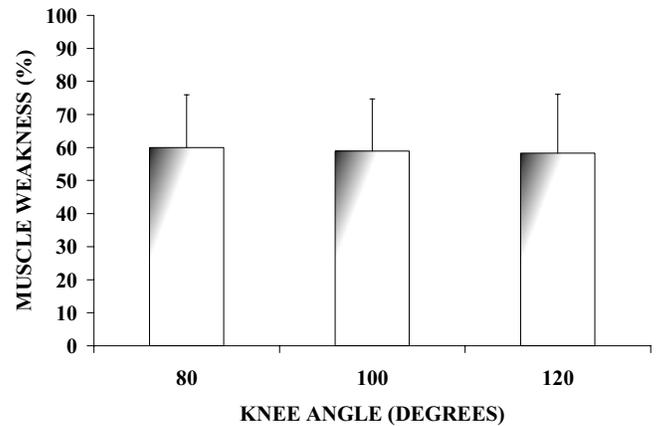

Figure 1. Muscle weakness (mean and standard deviation) of the knee extensor muscles obtained at three different joint angles.

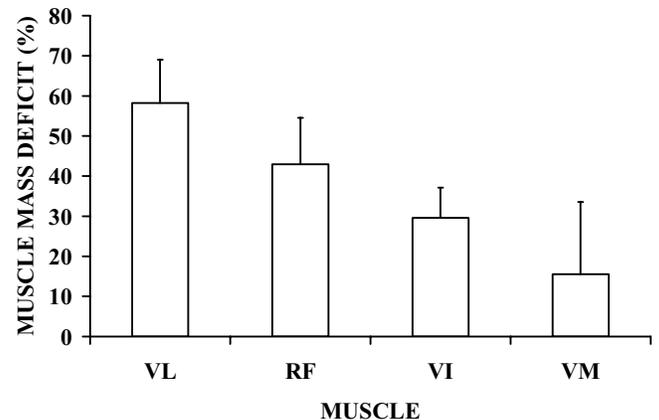

Figure 2. Muscle mass deficit (mean and standard deviation) of the knee extensor muscles (VL = vastus lateralis; RF = rectus femoris; VI = vastus intermedius; VM = vastus medialis).

# Computer simulation for internal-stability of foot longitudinal arch strengthened by plantar soft tissues and plantar static friction

WU Lijun(email: biomech@163.com), KONG Kangmei, QI WeiLi

Laboratory of Surgery, The Second Affiliated Hospital, Shantou University Medical College, Shantou, Guangdong, China, 515041.

**【Abstract】 Objective:** To investigate anatomic structure and biomechanical mechanism for internal-stability of foot longitudinal arch, to offer quantitative academic base for normal arch internal-stability strengthened by plantar soft tissues and plantar static friction, and to calculate the stress distribution in plantar longitudinal arch changed by arch collapse. **Methods:** The method of reconstruction by CT images is adopted, which produces 3D model of foot arch in order to research its anatomic structure of medial and lateral longitudinal arch. The finite element method is also applied to establish biomechanical model of longitudinal arch of second ray of foot, which can analyze its stress distribution in standing phase. **Results:** A 3D computer model of longitudinal arch of normal foot and a finite element model of its second plantar longitudinal arch were created. When simulating naked foot standing with plantar static friction, Von Mises stress of second metatarsal bone and plantar aponeurosis were respectively 1.31MPa and 0.89MPa. When simulating naked foot standing with no plantar static friction, Von Mises stress of second metatarsal bone and plantar aponeurosis increased respectively to 2.35MPa and 1.22MPa. When simulating naked foot standing following surgical plantar aponeurosis release, Von Mises stress of second metatarsal bone and plantar aponeurosis were changed respectively to 3.21MPa and 0.02MPa. When simulating naked foot standing following arch collapse or flat foot standing, Von Mises stress of second metatarsal bone and plantar aponeurosis were changed respectively to 1.66MPa and 1.22MPa. **Conclusion:** Von Mises stress are concentrated mainly on second metatarsal bone and plantar aponeurosis when naked foot standing. Plantar soft tissues and plantar static friction can produce a marked effect to reduce degree of stress concentration in foot longitudinal arch, and can strengthened arch internal-stability. If foot arch collapses or flattens, degree of stress concentration of arch will aggravate over normal arch, and flat arch is disadvantageous to protect internal-stability of foot.

**EFFECT OF SUN LIGHT ON SURFACE TEMPERATURE OF ARTIFICIAL SPORT SURFACES**

Toyoaki Aoki  
 Biwako Seikei Sport College,  
 Kita-hira, Shiga-cho, Shiga 520-0503, Japan, e-mail: [aoki@bss.ac.jp](mailto:aoki@bss.ac.jp)

**INTRODUCTION**

Introductions of artificial sport surfaces such as artificial turf and all-weather track, have been increasing year by year. We have studied the comparisons of surface temperatures of sport surfaces, and reported the results regarding to the seasonal change in the surface temperatures of artificial and natural turfs (1).

In this paper, I would like to report the relationship between the surface temperatures of sport surfaces and illuminance of sun light.

**METHODS**

The artificial and natural turfs were long-pile type (65mm in depth, sand-rubber infill system) and sand based type (warm season turf), respectively. The all-weather and sand tracks were urethane polymer type (13mm in depth) and soil covered with sand type (100mm in depth), respectively.

The surface temperatures were measured with a infrared thermometer (type UT-02F, Horiba Co., Japan). The illuminances on the surface from the sun were measured with a photo recorder (type PHR-51, T and D Co., Japan).

The measurements of temperatures and illuminances were performed on sunny days from February 2004 to December 2004 and at 2 hour intervals from 9:00 to 17:00 on each day.

**RESULTS AND DISCUSSION**

Monthly change in surface temperatures of the artificial turf with time is shown in Fig.1. The surface temperature increased with day from Feb.(winter) to Aug.(summer). The maximum temperature was 67.5°C at 13:00 on Aug.11.

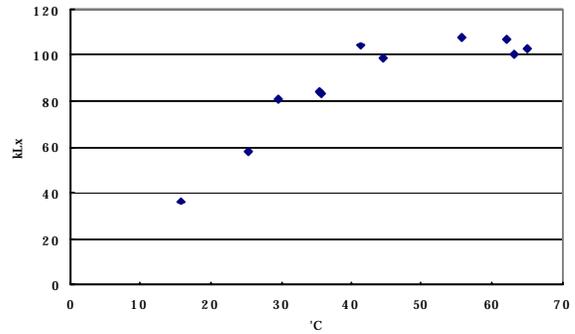

Fig.2 Relationship between surface temp. of artificial turf and illuminance of sun light.

Figure 2 shows relationship between the surface temperature of artificial turf and illuminance of sun light at 11:00 shown in Fig.1. The surface temperature increased with illuminance up to 100 kLx and after that, became a leveling off. In summer, ground temperature had an impact on the surface temperatures.

The other surface temperatures of sport surfaces investigated in this study resulted in the same pattern as shown in Fig.1 and Fig.2.

Details of this study will be presented in the conference.

## VARIATION IN AVERAGE AND PEAK LUMBAR DISC STRESSES BY LEVEL DURING FLEXION USING A COMBINED EXPERIMENTAL AND FINITE ELEMENT APPROACH

Naira Campbell-Kyureghyan and William Marras  
Ohio State University Biodynamics Laboratory; email: [marras.1@osu.edu](mailto:marras.1@osu.edu)

### INTRODUCTION

Significant effort has been invested in developing FE models in the field of spinal biomechanics. Various loading conditions have been used for investigation of spinal component behavior. However, nearly all previous studies have applied artificially set loads, which make it difficult to compare to real life situations. Accordingly, the aim of this study was to develop a subject-specific component model of entire lumbar spine capable of determining the response to realistic motion under experimental settings. This paper presents the prediction of the lumbar intervertebral disc stress distribution at different levels during flexion using a human subject-linked FEM.

### METHODS

The present study was in-depth, not cross-sectional, and a single subject-specific experiment was performed. A 24-year-old male subject was required to lift a 6.8 kg box from 88 cm above the floor and at a horizontal distance of 74 cm from the subject. The box was lifted from its initial position to approximately waist level at an upright standing posture and then returned to the initial position. Lumbar Motion Monitor (LMM) data was collected throughout the experiment to capture the torso angle change with respect to the initial position.

Stresses in the components of the lumbar spine, vertebral bodies, intervertebral discs, and ligaments, were calculated using a newly developed finite element model [1]. The model is capable of simulating large displacement, dynamic, sagittally-symmetric flexion and the components were validated against experimental results. Subject-specific neutral standing position lumbar spine geometry [2] is predicted as the starting point for the calculation, and the movement of the top of T<sub>12</sub> is determined using LMM [3] measurements from actual flexion motion. The motion of the remainder of the lumbar spine is calculated from the interaction of the top movement, material properties, and geometry within the finite element model.

The computational model was used to determine the internal motion and forces of the lumbar spine based on the LMM measurements collected during the experiment. Maximum values during the flexion task were extracted for the compressive stress at the disc centroid and the maximum compressive and tensile stresses in the annulus.

### RESULTS AND DISCUSSION

Results are presented in Figure 1 for the centroidal axial stress in the disc, maximum annular anterior compressive stress, and maximum annular posterior tensile stress for a lifting task. All

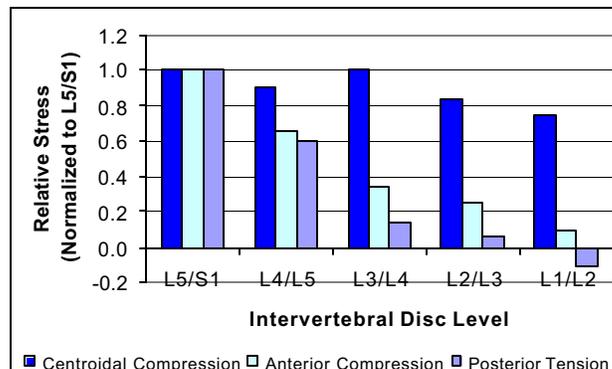

Figure 1: Variation of intervertebral disc stress with level.

stresses are normalized to the L<sub>5</sub>/S<sub>1</sub> values. The compressive stress is relatively constant for disc levels from L<sub>5</sub>/S<sub>1</sub> to L<sub>3</sub>/L<sub>4</sub>. In contrast, the maximum anterior and posterior stresses are larger for L<sub>5</sub>/S<sub>1</sub> and steadily decrease at higher levels. In fact, at the L<sub>1</sub>/L<sub>2</sub> level the stress was almost uniform in compression, even on the posterior annulus.

The relatively constant centroidal stress is due to the somewhat uniform distribution of purely compressive shortening between the discs. However, the rotation due to bending varies greatly between levels, with the largest rotations observed at L<sub>5</sub>/S<sub>1</sub>. The larger rotations, and hence bending moments, generate larger stresses at the outer layers of the discs.

### CONCLUSIONS

The maximum stress in the disc is known to initiate rupture [4]. Although techniques exist for determining the maximum centroidal compression, experimental methods alone are unable to establish the maximum stresses *in-vivo* due to measuring difficulties. Previous finite element models have investigated the distribution of stress within the disc, but have not considered the full lumbar spine under realistic displacement motions. The present model demonstrates the ability to link experimental and analytical methods and calculate the stress distribution for actual motion.

## PREDICTION OF INTERVERTEBRAL DISC CREEP DURING FLEXION USING A COMBINED EXPERIMENTAL AND FINITE ELEMENT APPROACH

Naira Campbell-Kyureghyan and William Marras  
Ohio State University Biodynamics Laboratory; email: [marras.1@osu.edu](mailto:marras.1@osu.edu)

### INTRODUCTION

Injuries to the spine can occur through acute trauma, or as the result of the accumulation of damage over time. There is no simple explanation due to the multi-factorial character of low back disorders (LBD), but creep of the intervertebral disc has been identified as a predictor of damage [1]. This study presents the prediction of the intervertebral disc creep during flexion using a combined approach of a human subject experiment and finite element model of the lumbar spine.

### METHODS

The present study was in-depth, not cross-sectional, and a single subject-specific experiment was performed. The experiment involved lifting a 6.8 kg box from its initial position, 88 cm above the floor and 74 cm from the subject, to approximately waist level at an upright standing posture and then returning it to the initial position. A 24-year-old male subject was required to repetitively carry out the sagittally symmetric lifting task at 6 lifts/min. for 20 minutes. Lumbar Motion Monitor (LMM) data, capturing the torso angle change with respect to the initial position, was continuously collected for the entire duration of 240 flexion cycles, with rest between the cycles.

A newly developed finite element model [2] was used to calculate the deformations and stresses in the components of the lumbar spine, including the vertebral bodies, intervertebral discs, and ligaments. The model is capable of simulating large displacement, dynamic, sagittally-symmetric flexion and the components were validated against experimental results. The initial model configuration is derived from the subject-specific neutral standing position lumbar spine geometry [3], and the movement of the top of the T<sub>12</sub> vertebrae is determined using Lumbar Motion Monitor [4] measurements from the actual flexion motion. The finite element model then calculates the motion of the remainder of the lumbar spine from the interaction of the T<sub>12</sub> movement, material properties, and geometry.

The computational model was used to determine the motion and stress in the lumbar spine based on the LMM measurements collected during the experiment. The axial deformation at each disc level was extracted from the results for further study.

### RESULTS AND DISCUSSION

The axial deformation at the L<sub>5</sub>/S<sub>1</sub> level over the 20 minutes of repeated flexion is shown in Figure 1. The creep accumulates rapidly at the beginning of the cyclic flexion. The rate of accumulation gradually decreases, with the creep

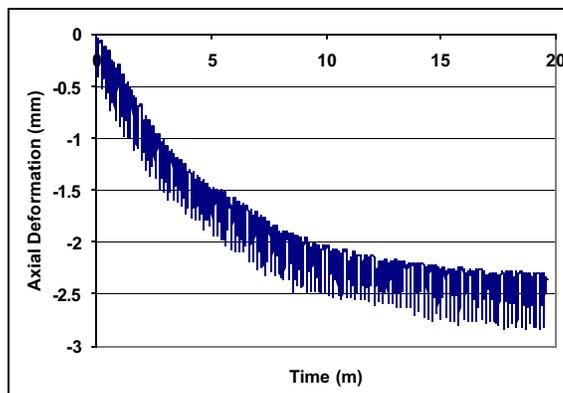

Figure 1: Axial deformation (creep) of L<sub>5</sub>/S<sub>1</sub> intervertebral disc.

asymptotically approaching a stable value from 15 to 20 minutes into the task. Similar behavior, with slightly different magnitudes, was seen at the other intervertebral disc levels.

Limited data is available that considers cyclic loading on the discs over long periods, as opposed to creep or relaxation loading, and presents sufficient information on the testing methods, specimens, and results as to be useful. One set of such data was obtained in a series of experiments performed for 6 hours of pure compressive loading of an intervertebral disc at 1 Hz [5]. The results showed a trend similar to the current study, with creep gradually stabilizing over the course of the experiment at approximately 2.25 mm.

### CONCLUSIONS

Creep is an important risk dimension for LBD. Repetitive loading can cause damage to the spine at levels below maximum [6] and creep is an indicator of this cumulative effect. In addition, excessive creep can change the distribution of forces in the spine, increasing loads on the facets and decreasing tension on the ligaments, reducing their effectiveness. The present study demonstrates the ability to link experimental and analytical methods and calculate the disc creep for actual repetitive flexion motion.

## THE GROUND REACTION FORCE AND ELECTROMYOGRAPHIC PATTERNS OF TAI CHI GAIT

<sup>1</sup> Yu-Hsiang Nien, <sup>2</sup> Shi-Po Chang, <sup>1</sup> Long-Ren Chuang, <sup>1</sup> Wen-Tzu Tang  
<sup>1</sup>Institute of Coaching Science, National College of P.E. & Sports, Taiwan

### INTRODUCTION

In the past few years, Tai Chi has become more and more popular in the west. Until now, there are more than one hundred articles about Tai Chi in the MEDLINE database. According to these studies, Tai Chi is beneficial to cardiorespiratory function, balance, postural control, strength, flexibility, and psychological profile [1]. However, most studies focused on Tai Chi training performances, the mechanisms of Tai Chi are still unclear [2,3]. In addition, the subjects in these studies were the beginner (who practiced Tai Chi for only 1 year or less) or amateur. They could not perform the typical characteristics of Tai Chi. In order to understand the mechanisms of Tai Chi, the foundation have to be identified. There are many movements in Tai Chi, like classical Yang style 108 forms, simplified style 24 forms etc. In these different forms, Tai Chi gait is the fundamental movement of Tai Chi. Therefore, the purposes of this study were to understand the ground reaction force and electromyographic patterns in Tai Chi master.

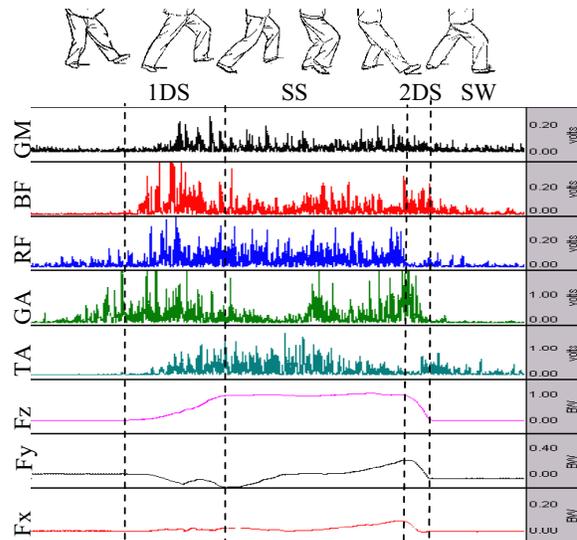

### METHODS

A Tai Chi master was selected to be subject in this study (38 years, 166 cm height, 77 kg weight). He has been practicing Tai Chi for at least 2 hours every day for 15 years. The subject was asked to do the Tai Chi gait at a self-determined speed for five trials in the experiment. The gait cycle was determined by the video from digital camera, and divided into four phases: first double support phase (1DS), single limb stance phase (SS), second double support phase (2DS), and swing phase (SW). One digital camera (JVC, 60 Hz) positioned laterally 4m from the subject to check the subject movement, such as foot contact and toe-off. The 3D ground reaction force pattern was collected by a force plate (AMTI, 1000 Hz). The electromyography (EMG) pattern was measured by surface electrodes (Biovision, 1000 Hz) on each of following four muscles of the left leg: gluteus maximus (GM), rectus femoris (RF), biceps femoris (BF), tibialis anterior (TA), and gastrocnemius (GA) to record the muscle activities. The EMG data were processed by full-wave rectification (band-pass filtered at 10-500 Hz). All data was synchronized and calculated by SIMI motion system (SIMI Reality Motion Systems GmbH, Germany).

### RESULTS AND DISCUSSION

Tai Chi gait is a slow movement which requires the lower limbs to move with joints in flexion position. The typical GRF and EMG patterns for the Tai Chi master are displayed in Figure 1. The average duration of Tai Chi gait cycle was  $3.07 \pm 0.38$  second. The percentages of the four phases were: 21% (1DS), 35% (SS), 9% (2DS), and 35% (SW).

By comparing the Tai Chi gait with normal gait [4], the results show that not only the gait cycle duration, but also the

percentage of SS phase of Tai Chi gait was longer than normal gait. According to the GRF, the master demonstrated good control of GRF during the gait. He maintained low level body position while traveling slowly and steadily from one leg to another. A stable GRF was followed during body weight shifting, while the balance of the whole body was maintained. In addition, from EMG patterns, compared to normal gait, the BF and RF muscles had longer proportion of co-contraction. That may also help to maintain the weight shifting during 1DS to SS phase.

Based on these findings, it is not difficult to infer that the improvement of muscle strength after long term Tai Chi training. Therefore, it had also explained some of the effect of Tai Chi training in previous studies.

### CONCLUSIONS

Different muscular control strategies involved in Tai Chi gait was determined in this study. The long duration of muscle co-contraction during Tai Chi gait should be one of the important factors of Tai Chi movements. The findings could provide the information for future investigations or Tai Chi training intervention.

## INVESTIGATING FULL FIELD DEFORMATION OF SOFT TISSUE UNDER SIMPLE SHEAR TESTS BY THE FOURIER TRANSFORM MOIRÉ METHOD

Deng-Lin Guo, Bo-Shao Chen and Nai-Shang Liou  
Department of Mechanical Engineering, Southern Taiwan University of Technology  
Yuang-Kang City, Tainan Hsien, Taiwan 710 R.O.C; email: [nliou@mail.stut.edu.tw](mailto:nliou@mail.stut.edu.tw)

### INTRODUCTION

Soft tissues usually exhibit anisotropic and nonlinear material responses. In order to understand the mechanical properties of soft tissues, well controlled mechanical tests are required. Uniaxial tensile tests are the most common mechanical tests for soft tissues since soft tissues mainly sustain tensile load. However the shear deformation of soft tissue could affect the load transfer mechanism of soft tissues when soft tissues are subjected to complex deformations. Finite simple shear is a uniform deformation that can provide information (in addition to what tensile tests provide) about the mechanical properties of planar soft tissues. However test configurations like specimen geometry and the boundary condition can affect the deformation homogeneity during finite simple shear test. In order to ensure that the parameters of constitutive equations obtained from finite simple shear tests are appropriate, the deformation homogeneity of specimens during simple shear tests should be investigated.

The finite element method was used to study finite simple shear deformation of parallel-fibered planar soft tissues [1]. The purpose of this study is to use the Fourier transform moiré method to examine the deformation uniformity of porcine skin during finite simple shear tests. The effects of a different aspect ratio and clamping prestrain of the porcine skin specimen were examined.

### METHODS

The Fourier transform moiré (FTM) method was used to investigate the in-plane full-field deformation of porcine skin specimen under simple shear tests (Figure 1). The FTM method, developed by Morimoto [2,3], is a useful tool for in-plane full-field displacement and strain measurements because the setup is simple, sensitivity and resolution can be varied if necessary and the signal-to-noise ratio is high. The main steps of the FTM method include calculating the Fourier spectrum of the image, obtaining one harmonic of the spectrum, shifting the harmonic toward the origin of the spatial frequency axis and computing the complex moiré fringe pattern. Displacement and strain of the specimen can be obtained from the phase of complex moiré fringe pattern. FTM is an objective method as all computation steps can be done by computer once the image of the deformed specimen is obtained so human error can be minimized.

The procedures for preparing specimen grids on soft tissue specimens and for analyzing deformation in a series of images by using FTM method are detailed in ref [4]. Three aspect ratios (sample dimensions of 5x5, 5x3.75, 5x2.5 cm) were examined. They allowed the effect of different aspect ratios on the strain fields during simple shear tests to be investigated. The deformations of samples due to clamping prestrains were also investigated.

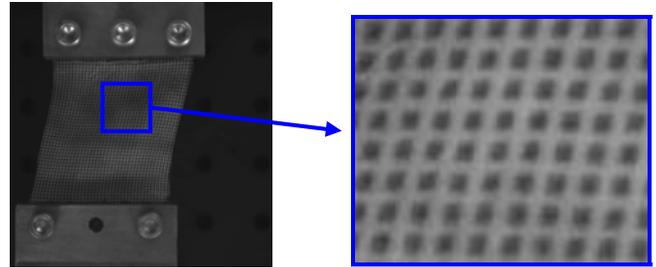

Figure 1: Schematic of in-plane full-field deformation measurement by the FTM method.

### RESULTS AND DISCUSSION

Strain fields, computed from FTM complex moiré fringe patterns (figure 2), were used to examine the in-plane deformation uniformity of samples with different aspect ratios at different shear angles during simple shear tests. The FTM method can be used to validate the soft tissue constitutive model used by the finite element method.

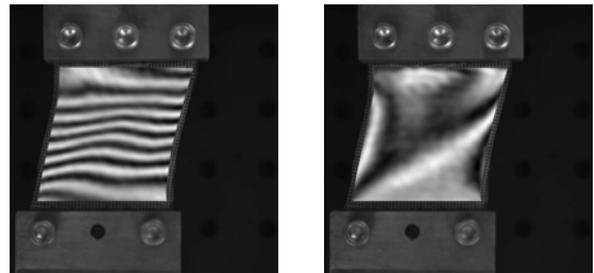

Figure 2:  $u$  and  $v$  field complex moiré fringe patterns of a 5x5 cm specimen at  $10^\circ$  shear angle.

If no pre-tension is applied to planar soft tissue sample prior to simple shear test, the out-of-plane deformation of samples under simple shear test can be significant when the shear angle is large. Future work will include out-of-plane deformation measurement and finite element simulations of soft tissues during simple shear tests.

### INTRODUCTION

The resting position is generally regarded as the position of a joint in which the joint tissues are under least amount of stress and where the joint capsule has its great laxity. It is frequently chosen as the ideal position for evaluation and early treatment of painful and inflammatory joint or joint with hypomobility [1]. For glenohumeral (GH) joint, according to the data in cadaver study reported by Hsu, the resting position was located at an average position of 39 degree of abduction in the scapular plane [1]. However, as far as we know, no research has determined the resting position of GH joint in vivo model. Therefore, the purpose of this study is to define the resting position of the GH joint by investigating the total displacements of humeral head and total rotation range of motion (ROM) of the GH joint at each GH abduction angle in normal subjects.

### METHODS

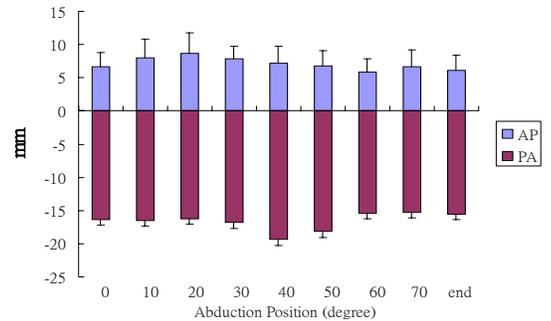

Seventeen normal subjects were recruited. All subjects were seated on the sturdy chair with a designed clamp grapping the spine of the scapula and clavicle. The lateral border of the scapula was also blocked. One adjustable lower arm brace was put on the elbow to immobilize it at 90° flexion. The center of rotation (COR) of GH joint was estimated with the modified methods [2]. The constant relationship between the markers of Fastrack tracking device and COR within local coordinate system were then established.

For measuring the displacements of humeral head, an 80 N force was applied during anterior-posterior (A-P) glide and posterior-anterior (P-A) glide and the markers will be tracked. The displacement of COR could be computed according to the constant relationship. A torque transducer was used during rotation ROM of GH joint to ensure a consistent torque of 4 Nm of internal rotation (IR) moment and external rotation (ER) moment. The markers were tracked during joint play movement and rotation ROM in the plane of scapula from neutral position to end range of GH abduction at 10 degree intervals. Three repeated displacements of COR and rotation ROMs were computed.

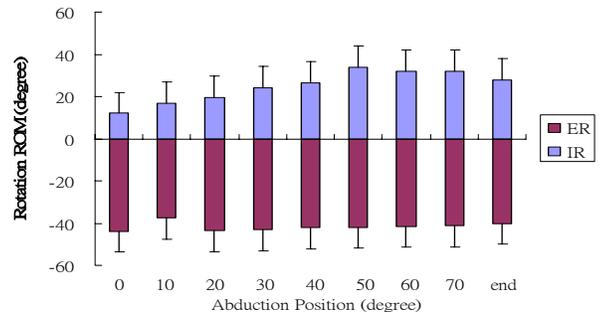

All three replicates of displacement measurements and the rotation measurements were used for data analysis. Intra-class correlation coefficient was used to test the Intrasession reliability of the displacements of humeral head and rotation ROMs. To determine the resting position, the method employed by Hsu et al. was followed [2].

### RESULTS AND DISCUSSION

Intrarater reliability, ICC(2,1) values, were depicted in Table1. The average values of A-P, P-A displacements, IR and ER ROMs were shown in figure 1 and figure2.

**Figure 1:** The average values of A-P and P-A displacements at multiple GH joint abduction angles.

**Figure 2:** The average values of IR-ER ROMs at multiple GH joint abduction angles.

The resting position is defined as the midpoint of the shared range of 95% confidence intervals of the predicted abduction angles where peaks of maximal displacement and rotation occurred in this study. It provides fundamental information to the practice of orthopedic manual procedures in physical therapy.

## ENERGY FLOW IN HIGH HEEL SHOES IN WALKING

F. Ju, F.S. Cui, Z.S. Liu, \*H.P. Lee and C. Lu  
Institute of High Performance Computing, 1 Science Park Road,  
#01-01 The Capricorn, Singapore 117528; email: hplee@ihpc.a-star.edu.sg

### INTRODUCTION

High heel shoes lead the feet weak and prone to injury and serious foot ailments. Hansen et al. [1] investigated the effects of shoe heel height on the rollover characteristics of the biologic ankle-foot system. Stefanyshyn et al. [2] studied the Influence of high heel shoes on mechanical behaviours of normal female gait with four different patterns shoes with high heels. The effect of insoles on the plantar pressure distribution was studied by Lemmon et al. [3] with the finite element method (FEM). More recent research on the foot-shoe system with FEM approaches can be found in [4] and [5]. Studies and observations have found that women walking in high heel shoes experience the excessive side to side motion at the ankle joints and feet, resulting in excessive stresses in the foot ball, calcaneus and joints. These stresses are caused by the contact-impact between the shoe and the ground and, sequentially, propagate into the foot. The whole course can be viewed as a process of energy transformations.

The objective of this study is to investigate the energy flow transmission in high heel shoes under contact-impacts during walking. The effect of the stiffness of shoe soles on the stress distribution in the foot-shoe system will be highlighted.

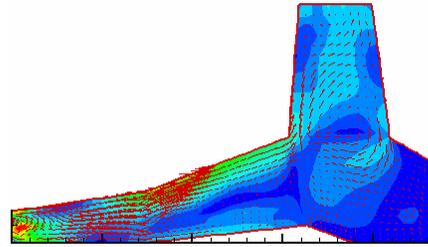

### METHODS

A simplified 2D finite element model including the shoe sole and the foot is established to investigate mechanical and structural characteristics of the foot-shoe system. Only the shoe sole is considered to focus on the interactive effect of the foot and the shoe. The foot is modeled as bones, joints and a layer of soft tissue material at the bottom of the foot. The nominal stiffness, a product of Young's modulus and sole thickness, is used to represent the elasticity of shoe soles.

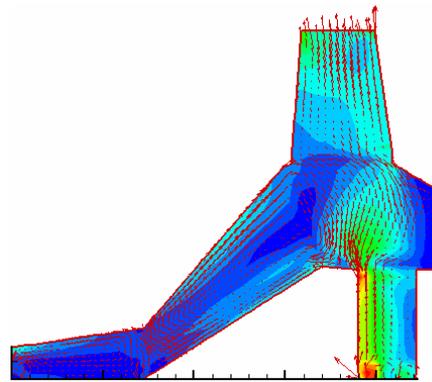

Structural Intensity (SI) method is employed to characterize the energy flow transmission and stress distribution and propagation in system under various impact-contact conditions. The concept of SI was first introduced to extend the vector acoustics approach to energy flow in structures-born sound fields. SI is the power flow per unit area of cross section elastic medium and offers full information of the paths of energy transmission and positions of sources and sinks [6].

### RESULTS AND DISCUSSION

Shoes with the heel height of 3, 6 or 9 cm and various stiffness of shoe soles are used for numerical study. Different stages during walking are considered in the analysis. Figures 1 and 2 show respectively the SI vector and stress contour of the flat and high heel shoes, which clearly indicate the paths of energy transmission and stress distributions in the system. The energy flow patterns show that strain energy distributes and transmits favorably in a flat shoe due to the presence of the soft sole layer, while it reaches the calcaneus with a higher intensity in

**Figure 1:** SI vector and stress contour of a flat shoe under contact-impacts

**Figure 2:** SI vector and stress contour of a high heel shoe under contact-impacts

a high heel shoe regardless of the sole. Soft shoe soles with smaller stiffness can greatly improved the stress concentration at the calcaneus area and ankle joints for flat shoes. However, much greater stress concentrations are found for high heel shoes and soft shoe soles can hardly improve the uneven distribution of stresses in most cases.

### CONCLUSIONS

Structural Intensity provides rich information for energy flow transmission in foot-shoe system under the contact-impact during walking. Severe stress concentrations in the calcaneus area are found for high heel shoes, and soft shoe soles do not help much in evening up the stress distribution.

It is relevant to indicate that 2D models are effective to study the mechanical phenomenon of the walking impact of the foot-shoe system but too restrictive for quantitative analyses. 3D models will be developed in our further study.

## THE EFFECT OF MOVEMENT SPEED AND EXTERNAL LOAD ON JOINT CONTRIBUTIONS DURING LOWER EXTREMITY EXTENSIONS

<sup>1</sup> Sean P. Flanagan and <sup>2</sup>George J. Salem

<sup>1</sup>Department of Kinesiology, California State University, Northridge,  
<sup>2</sup>Department of Biokinesiology and Physical Therapy, University of Southern California;  
 email: [sean.flanagan@csun.edu](mailto:sean.flanagan@csun.edu), web: [www.csun.edu/~sflanagan](http://www.csun.edu/~sflanagan)

### INTRODUCTION

Determining the individual joint contributions during a variety of tasks has been the goal of many biomechanical investigations striving to quantify mechanical demand and provide insight into how multi-joint movement is controlled. Many of these investigations have been conducted with the task performed under a single set of experimental conditions, limiting the generalizability of the results to other movement conditions. They also do not provide information on how the joint contributions are adjusted in order to meet differing task objectives.

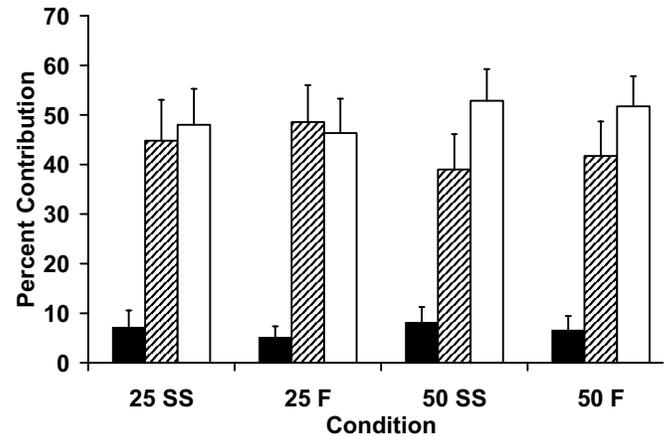

The purpose of this investigation was to examine the effect of movement speed on the mechanical demand distribution across the lower extremity joints during the barbell squat activity, and to determine if mechanisms by which this distribution occurred were load-specific.

### METHODS

Eighteen healthy, young adults who were familiar with the squat exercise performed 3 sets of 3 repetitions of a squat under two different loading conditions (25% and 50% of a 3 repetition maximum) and two different movement speed conditions (self-selected and as fast as possible). Standard inverse dynamics techniques were used to calculate the instantaneous net joint moment (NJM), angular velocity ( $\omega$ ) and NJM power (P). Average NJM,  $\omega$ , and P were calculated using numerical integration. The average P at the hip, knee, and ankle were summed to create a lower extremity power score. The percent contribution of each joint was determined as the quotient of the individual P divided by this score. The relative adjustments in the average NJM and  $\omega$  between the self-selected and fast conditions were calculated by dividing the outcome variables associated with the fast condition by the like outcome variables associated with the self-selected condition (F/SS). For all analyses, alpha was set at 0.05.

### RESULTS AND DISCUSSION

The percent contribution for each joint under each condition is presented in Figure 1. The contribution from the hip and ankle significantly increased with load, but significantly decreased with speed. Conversely, the contributions of the

**Figure 1.** Percent contribution of the ankle (black), knee (striped) and hip (white) for the 25% and 50% self-selected (SS) and fast (F) conditions.

knee significantly decreased with load but significantly increased with speed. There were no significant interactions.

Analyses of the average NJM and angular velocity at each joint (Table 1) indicate that the redistribution of demand as a result of increased movement speed was brought about by specific changes in the average NJM at each joint. While the changes in angular velocities were greater than changes in NJM, they were not significantly different between joints.

### CONCLUSIONS

A different, but identifiable movement control strategy appears to be employed in response to increases in movement speed compared to increases in external resistance. However, the magnitude of the speed response strategy is affected by external loading. The results of this investigation indicate that the joint contributions quantified under one set of experimental conditions are not generalizable to other experimental conditions.

### ACKNOWLEDGEMENTS

The authors wish to thank James Gordon, Kornelia Kulig, Jill McNitt-Gray, and Christopher Powers for their contributions towards this investigation.

### INTRODUCTION

Hepatic radio-frequency ablation is an important surgical operation that deliver electrical energy of 460~550 kHz into liver tissue by using specified medical device [1]. Ablation probes are inserted percutaneously into tissues where tumors exist. Then electrical energy is delivered through the probes and the electrical energy turn into the thermal energy and heat the tissue to over 45-50 °C which cause cell necrosis and get rid of the tumors. It is very important to estimate the effective necrosis range as correctly as possible. Numerical analysis for the bipolar RFA is proposed to do this estimation in this study.

### METHODS

The shape of ablation electrode was considered as a straight rod. Ablation electrode consists of the conducting tip and shaft. In this simulation the length of the conducting tip was assumed to be 3 cm, and the diameter to be 2 mm. And the shafts were assumed to be adiabatic. The liver model is a cubic shape having the dimensions of 10 cm × 10 cm × 7 cm.

Heat transfer in the liver tissue is governed by the following heat conduction equation

$$\rho c \frac{\partial T}{\partial t} = \nabla \cdot k \nabla T + \vec{E} \cdot \vec{J} - Q_{ex}$$

where  $\rho$  is density,  $c$  is heat capacity,  $k$  is thermal conductivity,  $\vec{J}$  is current density vector,  $\vec{E}$  is electric field intensity vector, and  $Q_{ex}$  is the metabolic heat source term. We assumed the metabolic heat source term is insignificantly small so that it was ignored.

The surface temperature in the liver model was assumed to be constant at 27 °C. For the simplicity, we calculated only the half of the model by using the symmetry condition. AC current of 2000mAh was used for the simulation.

CFD-ACE(U) TM Ver. 2002 (CFD Research Corporation, 215 Wynn Drive, Huntsville, AL 35805) was used for the computation.

### RESULTS AND DISCUSSION

The maximum temperature was 101.4 °C, and the effective necrosis range, which is in the temperature range of above 60 °C, was about 5 cm in length (Figure 1). High temperature regions above 80 °C were near the conducting tips, however, the isothermal surface of 60 °C covers the center part of the liver between the two electrodes.

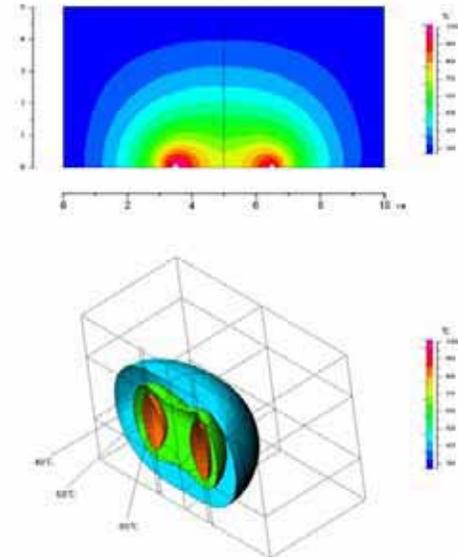

Figure 1: Isothermal surfaces (40 °C, 60 °C, 80 °C).

In Lee et al. the inhomogeneity of liver tissue may cause the complicate electrical, thermal phenomena [2]. In addition, the blood flows in the liver obviously interfere during the RFA treatment. Also the temperature dependent properties of liver such as thermal conductivity, tissue heat capacity, tissue electrical conductivity and so on must be considered in the future work.

### CONCLUSIONS

We conducted a three-dimensional numerical analysis on the bipolar hepatic RFA. As a result, we could get a reasonable necrosis range. Though there are significant limitations, this study still shows that the numerical method can be a useful tool for estimation of the effective necrosis range and diagnosis for the RFA treatment in near future.

## TOE-WALKING IN INTACT INDIVIDUALS ARISING FROM EMULATED CONTRACTURES OF SOLEUS, GASTROCNEMIUS AND HAMSTRING MUSCLES

Andrej Olenšek, Zlatko Matjačić  
Institute for Rehabilitation, Republic of Slovenia  
email: andrej.olensek@ir-rs.si

### INTRODUCTION

Toe-walking is very common gait irregularity in individuals with spastic plantarflexors and hamstrings. Identification of primary cause of toe-walking in particular patient is of utmost importance for deriving appropriate treatment. We therefore need an effective method for proper biomechanical characterization of particular gait irregularity.

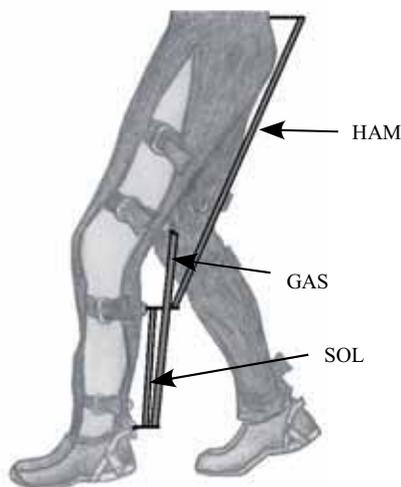

Recently two studies investigated compensatory gait deviations where toe walking was imposed in healthy adults by emulating a muscle contracture [1] or using special taping technique to form an equinus constraint [2]. Results lead to conclusion that different gait compensations should be expected when toe-walking is imposed by different constraints.

The purpose of this study is to emulate muscle contractures in individuals free from neuromuscular impairments as described in [1] and investigate which gait compensations arise when toe-walking is elicited by muscle contractures of soleus, gastrocnemius or hamstrings.

### METHODS

Figure 1 shows schematic drawing of the system that adds mechanical stiffness in parallel with particular muscle to emulate muscle contractures. Imitating primary gait irregularity by emulating contractures of soleus (SOL), gastrocnemius (GAS) or hamstring (HAM) muscles results in toe-walking but have characteristic compensatory gait deviations.

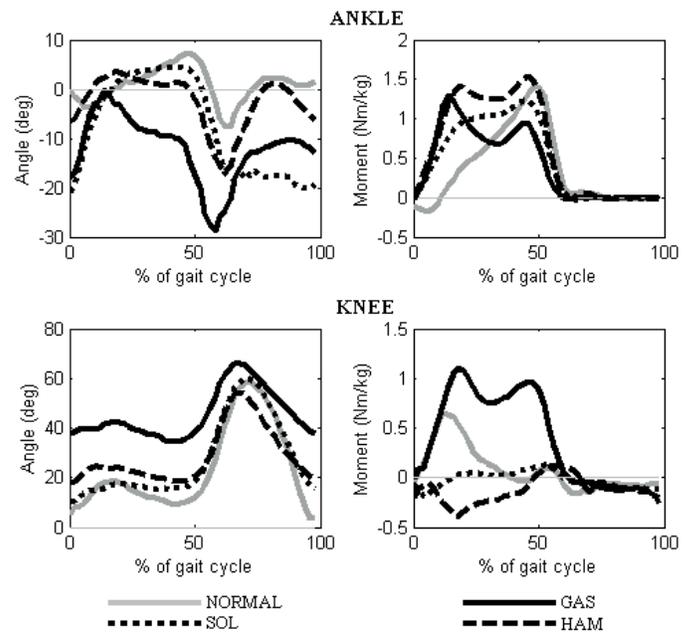

A volunteer equipped with the system walked along a 7 m walkway with walking speed approximately 1 m/s. We used VICON motion analysis system and two AMTI force plates for recording gait kinematics and kinetics of lower extremities.

**Figure 1:** Imposing various mechanical constraints to form muscle contracture emulations forcing the subject to toe-walk

### RESULTS AND DISCUSSION

Figure 2 presents ankle and knee angle and moment trajectories for different muscle contracture emulations imposed. All restrictive patterns are characterized with substantial plantar flexion and double-tooth moment trajectory which is consistent with results as recorded in Goodman et al. [1] and Matjačić et al. [2].

**Figure 2:** Ankle and knee angle and moment under different experimental conditions

Somewhat more distinctive are knee recordings when observing particular contracture emulation. Prolonged knee flexion and knee extensor moment throughout the stride as recorded in GAS muscle contracture emulations are consistent with results as reported by Matjačić et al. [1] and Goodman et al. [2]. On the other hand knee extensor moment was substantially diminished and excursions in knee angle were less evident when emulating SOL and HAM contractures.

### CONCLUSION

Results indicate that particular gait impairment will result in very distinctive secondary biomechanical effects and the proposed methodology for emulating muscle contractures may produce results that are potentially valuable for identifying compensatory gait deviations in clinical practice.

### INTRODUCTION

The shocks transmitted to the musculoskeletal system from external ground reaction impacts have been described as responsible for a number of musculoskeletal pathologies including tibial stress fractures, knee and hip osteoarthritis and lower back problems [1]. The aim of this study was to ascertain the relationship between lower leg muscle activity and *in vivo* accelerations measured at distal and proximal tibial sites. Previous studies have primarily investigated the relationship between external ground reaction force and a single proximal tibial site [2] or across joints. These designs exclude the parameter of shock transmission along a single long bone and the possible damping effect of muscle stiffness. In order to avoid the uncertain influence of complicating factors encountered in a previous study [3] in which tibial acceleration transmission was determined during running, this study was restricted to very controlled, static trials.

### METHODS

Six voluntary male healthy subjects participated in this study and the data of one subject (36 year, 88 kg) are presented in this abstract. Tibial accelerations were measured using 3D accelerometers (Kistler®, mass <2.5 g) attached to Apex® pins (diameter 3.0mm, length, 60mm) inserted approximately 1.5 cm into the distal and proximal tibia. Pin insertion was conducted under local anaesthetic and the experimental protocol was limited to three hours. Surface electromyography (EMG) electrodes recorded the activity of the gastrocnemius medialis (GM) gastrocnemius lateralis (GL), soleus (SOL), tibialis anterior (TA) and intramuscular EMG wires were used for tibialis posterior (TP). The summed integral of the EMG linear envelopes was referred to as the tibial muscle envelope. A custom made pneumatic impactor initiated impacts under the heel. The ankle joint was maintained in 90° and the knee angle at 180° (full extension). The impact force (F) was measured with a one dimensional force transducer (Kistler®). The sampling rate for all analog data was 1000Hz. Maximal voluntary isometric contractions (MVC) for each muscle were performed and to control muscle pre-activation three activation levels were defined at 0%, 30% and 60% of the MVC EMG amplitudes for GM and vastus medialis (VM). Ten impacts were initiated at each activation level. Accelerometer axes were mathematically aligned with the anatomical tibia axis using a correction algorithm based upon reflective markers recorded by a movement analysis system (ProReflex®, Qualysis, Sweden). F and the tibial accelerations were compared for the three activation levels and the effect of the tibial muscle envelope (sum of EMG integrals 50 ms prior to 50 ms after impact) upon the shock transmission from distal (accTD) to proximal tibia (accTP) was investigated (figure 1).

Shock transmission was calculated as  $\text{accTD} - \text{accTP}$ . ANOVA and correlation statistics were calculated in Statistica®.

**Figure 1:** Scatter plot of acceleration damping (accTD-accTP) vs summed EMG integrals of the tibial muscle envelope:  $r = 0.36$ ,  $p = 0.06$ . Two trials were not accepted due to knee angle variation.

### RESULTS AND DISCUSSION

Significant differences ( $p \leq 0.05$ ) in F and accTD were found between the 0% and 30% and the 0% and 60% levels, accTP was not significantly influenced. F and accTD correlated significantly with the tibial muscle envelope activity ( $r = 0.77$  and  $0.62$  respectively,  $p \leq 0.05$ ), accTP did not. Figure 1 shows that the transmission from distal to proximal tibia was not significantly correlated with muscle envelope activity. A trend towards increased damping was, however, shown ( $r = 0.36$ ,  $p = 0.06$ ), and it remains to be seen how the inclusion of further subjects in the analysis influences this result.

### CONCLUSIONS

The very controlled nature of the external impacts combined with the accuracy in orienting the accelerometer axes provided prerequisites for precise description of shock transmission. The data are an important contribution to the understanding of musculoskeletal control and also raise questions concerning previous studies where accelerations were only measured at one tibial location.

## THE EFFECTS OF PERIODIZED COMPLEX TRAINING PROGRAMME ON MILITARY PHYSICAL FITNESS AND FIGHTING ABILITY

<sup>1</sup> Wen-Lan Wu, <sup>2</sup> Wen-Zen Chen and <sup>2</sup> Jasson Chiang

<sup>1</sup> Faculty of sports medicine, Kaohsiung Medical University, Taiwan, [wenlanwu@kmu.edu.tw](mailto:wenlanwu@kmu.edu.tw)

### INTRODUCTION

Complex training is a way to develop muscle strength, speed and technique, simultaneously [1]. This study is planned to examine the effects of periodized complex training method by comparing the basic physical fitness and fighting ability improvements before and after the training sessions in order to confirm the practical use of periodized complex training in military training promotion.

### METHODS

The training program includes one hour of training per day, five days per week, and a total of twelve week. Thirty subjects were randomly assigned to either the control group (n=15) or the experimental (n=15) group. These subjects were currently serving more than six months in the military. A Kistler Quattro Jump force platform system (Kistler 9290AD, Switzerland) and the Biodex System 3 isokinetic dynamometer (Biodex Systems Inc. Shirley, New York) were used in this study to observe the jumping performance and work output from the isokinetic dynamometer, respectively.

### RESULTS AND DISCUSSION

In this experiment, the upper extremity muscle strength and muscle endurance tests after twelve weeks of physical trainings that include 60 seconds of pull-up, total work of ten repetitions of isokinetic shoulder flexion/extension at 60° and 180°/sec, both experimental and control groups showed significant improvements after the sessions. However, other than pull-ups, the improvement rates differ significantly between the two groups as experimental group is substantially higher than control group. Although the improvement rates in isokinetic muscle strength at 60° and 180°/sec are greater in experimental group than that of control group, there is no significant difference between the two, reflecting insufficiency of upper extremity training in the routine. In abdomen muscle endurance (60 seconds of sit-up) tests, the improvement rates showed significant differences of 8.17% and 4.93% in experimental and control group, respectively. The experimental group is substantially higher than control group. The lower extremity jumping tests showed 10.92% and 5.59%

of significant explosiveness improvement rates in experimental and control group, correspondingly. On the other hand, the muscle endurance improvement rates showed no significant difference between experimental (10.01%) and control (9.43%) group. According to above-mentioned results, we found that the improvement rates for both lower extremity explosiveness and muscle endurance in experimental group are similar. However, the improvement rates in control group are 5.59% and 9.34%, respectively. It revealed that the effects of periodized complex training method are more profound in promoting lower extremity explosive force than in muscle endurance. Furthermore, the influence of twelve-week physical training on cardiopulmonary endurance is shown in the scores of 3000-meter run and bleep-test (indirect VO<sub>2</sub>max estimation), where average improvement rates of experimental groups are significantly higher than control group. These results reflected the Fartlek training method used in our physical training program, applying various training velocity in uphill, downhill and stepping exercising modes, could directly elevate the cardiopulmonary performance in exercises. The study also reveals that under fighting ability categories of basic grenade throwing and 500-meter obstacle run the improvement rates are both significantly greater in experimental group than control group. Regression equation demonstrated that shoulder isokinetic muscle strength at 60°/sec and abdomen muscle endurance are factors determining basic grenade throwing scores. Furthermore, shoulder isokinetic muscle strength at 60° /sec, abdomen muscle endurance and the VO<sub>2</sub>max are directly related to performances of 500-meter obstacle race.

### CONCLUSIONS

In this study we found a close relationship exists between military physical fitness and fighting ability. Simply follow our training program and military people will soon get fitness and wellness results.

## KINETIC FACTORS INFLUENCING THE GAIT TRANSITION SPEED DURING HUMAN LOCOMOTION

Alan Hreljac, Rodney Imamura, Rafael F. Escamilla, W. Brent Edwards, and Toran Furch  
 Department of Kinesiology & Health Science, California State University, Sacramento  
 email: ahreljac@csus.edu

### INTRODUCTION

Several researchers [1,2,3,4] have hypothesized that the gait transitions of quadrupeds are triggered by kinetic factors, such as musculoskeletal stresses, particularly at joints. Utilizing invasive techniques, it has been shown [1,2,4] that small horses, dogs, and goats reduced bone and joint strain when changing gait from a trot to a gallop. Non-invasive techniques (ground reaction forces-GRFs), have also been used [3] to make similar conclusions regarding a group of large horses.

Two studies [5,6] which have applied the non-invasive technique [3] to humans, found little evidence to suggest that external kinetic variables (GRFs) were related to the gait transition of humans. No human studies have examined the relationship of joint kinetic variables to the gait transition speed. The primary purpose of this project was to examine whether lower extremity joint kinetic factors are related to the gait transition during human locomotion.

### METHODS

Following the determination of the preferred transition speed (PTS) of each of the 16 subjects using methodology described in previous studies [5,6,7], subjects walked down a 25 meter runway, and over a floor mounted force platform at five speeds (70, 80, 90, 100, and 110% of the PTS), and ran over the force platform at three different speeds (80, 100, and 120% of the PTS). Speed was monitored by three sets of infrared photocell timing lights. Reflective markers, placed on the greater trochanter, knee joint center, lateral malleolus, and head of the fifth metatarsal were recorded by a single digital video camera (240 Hz), in the right sagittal plane. A trial was considered successful only if the speed fell within  $\pm 5\%$  of the target speed, the landing foot completely contacted the force platform, and if there was no visible change in stride length.

Two-dimensional (2-D) kinematic data were synchronized with GRF data (960 Hz). The raw 2-D coordinate data were smoothed using a 4th order, zero lag, Butterworth filter. Joint moments were determined by inverse dynamics calculations. Joint powers were calculated as the product of the respective joint moment and angular velocity. Prior to analysis, all

variables were normalized by dividing by body mass. Dependent variables (DVs) included maximum ankle dorsi- and plantar flexor moments, maximum knee extensor moment, and maximum power absorption and generation at the ankle and knee. A repeated measures MANOVA compared average values of all DVs between speed conditions. If the hypothesis tested was to be accepted for a DV, the value of the DV would increase as walking speed increased, then decrease when gait changed to a run (at the PTS). For all comparisons,  $\alpha = 0.05$ .

### RESULTS AND DISCUSSION

The maximum dorsiflexor moment was the only DV which increased as walking speed increased, and decreased when gait changed to a run (Table 1). At the low running speeds tested during this study, many subjects exhibited a mid- or forefoot striking pattern, producing an initial dorsiflexion velocity. This movement is controlled eccentrically by the plantar flexors, just as the initial plantar flexion velocity during walking is controlled eccentrically by the dorsiflexors. Changing landing strategy in this way would transfer stress from the dorsiflexors to the plantar flexors at the PTS.

### CONCLUSIONS

The dorsiflexor moment which occurs soon after foot contact is the only variable tested which appears to be related to the gait transition during human locomotion. This supports the results of previous studies [7,8] which have concluded that an important factor in changing gaits at the PTS is the prevention of stress in the dorsiflexor muscles.

## PASSIVE LENGTH-TENSION PROPERTIES OF HUMAN GASTROCNEMIUS CHANGE AFTER ECCENTRIC EXERCISE

<sup>1</sup>Phu Hoang, <sup>1</sup>Rob Herbert and <sup>2</sup>Simon Gandevia

<sup>1</sup>School of Physiotherapy, University of Sydney, Australia,

<sup>2</sup>Prince of Wales Medical Research Institute, University of NSW, Australia; email: [s.gandevia@unsw.edu.au](mailto:s.gandevia@unsw.edu.au)

### INTRODUCTION

It is well documented in animal and human studies that eccentric contractions increase the passive stiffness of muscle. However, the increase in muscle passive stiffness of human muscles after eccentric exercise has only been shown by indirect measurements of the whole muscle group using torque-angle relations or by observing a change in resting joint angles.

This study applied a new method which derives the length-tension relation for human gastrocnemius in vivo [1] to measure changes in the passive behaviors of human gastrocnemius after a bout of eccentric exercise. A second aim of the study was to examine the relations between the changes in muscle passive stiffness and levels of perceived muscle soreness that arises after eccentric muscle damage.

### METHODS

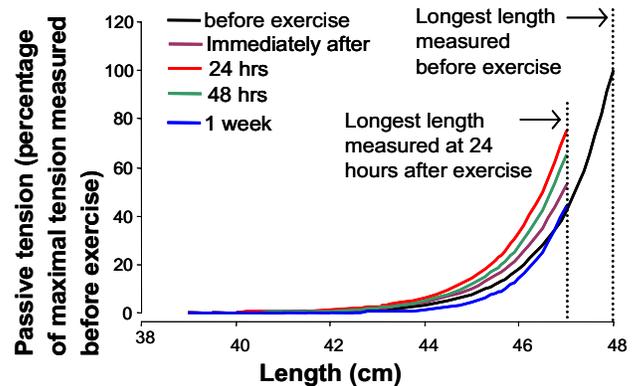

Twelve subjects performed one-hour of eccentric exercise with the right leg by walking backwards downhill on a treadmill. Passive ankle torque of the right ankle was measured at 8 different knee angles by rotating the ankle within available range. Measurements were performed in all subjects before and immediately after exercise and 24 hours later. Further measurements were made at 48 hours and one week after exercise in a subset of 6 subjects. Passive length-tension relations of gastrocnemius were computed from passive ankle torque and ankle angle data [1].

Comparisons were made between passive length-tension relations of gastrocnemius before exercise and those at various times after exercise. As soreness after exercise commonly limited passive dorsiflexion by about 10°, especially at 24 hours, we compared muscle passive tension at the longest lengths measured at 24 hours. The tension was normalized as percentage of passive tension at the longest length measured before exercise. Stiffness of gastrocnemius (expressed in N/m) in the sitting (knee and ankle angles at 90°) and standing (knee at 0° and ankle at 90°) postures was also calculated from the measures before and after exercise.

At each time point after exercise, subjects were asked to rate the "level of perceived muscle soreness" during walking based on a visual analogue scale anchored at 0 (no soreness) and 10 (maximal soreness).

### RESULTS AND DISCUSSION

An example of passive length-tension curves of gastrocnemius before exercise and at different points of time after exercise for one subject is shown in Figure 1. For this subject, compared with the control value before exercise, passive tension of gastrocnemius at the maximal comfortable length increased 25% immediately after exercise, 77% at 24 hours, 54% at 48 hours and returned within 3% of the control value at one week.

**Figure 1: Passive length-tension curves of gastrocnemius of one subject measured before and at various times after exercise**

Passive tension was re-scaled as percentage of maximal tension of gastrocnemius measured before exercise. The tension at the longest comfortable length measured at 24 hours was always higher than pre-exercise level during one week after exercise. For this subject there was an increase of 24.7% immediately after exercise, 77.4 % at 24 hours, 54.1% at 48 hours and 3% at one week.

All subjects showed a similar time course. Mean muscle passive tension significantly ( $p < 0.05$ ) increased immediately after exercise ( $34.7 \pm 7.3\%$ ), peaked at 24 hours ( $88.4 \pm 12.6\%$ ), then declined but remained significantly higher than before exercise at 48 hours ( $45.5 \pm 4.4\%$ ) and stayed high (but not significant) one week after ( $14.6 \pm 8.7\%$ ). These observations support comparable reports in previous studies [2]. Stiffness of gastrocnemius calculated in sitting and standing posture increased immediately after eccentric exercise and stayed increased for at least one week. The relative changes of muscle stiffness were similar in both positions.

All subjects reported some mild soreness immediately after exercise. On subsequent days, the soreness increased and peaked at 48 hours (mean score 3.3 and 3.5 at 24 and 48 hours respectively) and had disappeared at 1 week in all but one subject. There was no correlation between measures of tension or stiffness and the level of pain reported by individual subjects at any time point after the exercise.

### CONCLUSIONS

Using a new, more direct measurement method, we report that a single bout of eccentric exercise increases passive stiffness of human gastrocnemius muscles. The increase peaks in 24 hours and is nearly fully resolved within a week. The relative increase in tension was similar across the physiological range of lengths. The levels of pain after exercise did not correlate with the levels of increased muscle stiffness.

## LOAD DISTRIBUTION DURING SIT-STAND-SIT USING AN INSTRUMENTED CHAIR

Susan K. M. Wilson, Alexander C. Nicol  
Bioengineering Unit, University of Strathclyde  
Email: [s.k.m.wilson@strath.ac.uk](mailto:s.k.m.wilson@strath.ac.uk) , web: [www.strath.ac.uk](http://www.strath.ac.uk)

### INTRODUCTION

Older adults have more difficulty in rising from a chair due to physical changes that occur due to ageing, as well as the design of chairs [1]. Ageing causes a decline in muscle strength and a reduction in control noted particularly as the elderly are more prone to falls. There are many aspects of chair design that can influence the ability of the elderly to rise including chair height, type of seating surface, cushions, foot placement, and armrests [2].

### METHODS

A portable instrumented chair was designed to measure the forces through the body during standing up and sitting down by means of force plates and transducers. Two Kistler force plates (FPs) are located in the floor for measuring individual foot forces, and a third force plate is located beneath a cushion on the seat. The armrests were instrumented with pylon transducers to measure 3 dimensional forces through the upper limbs. The equipment is integrated with a Vicon 612 motion analysis system (©Oxford Metrics) to enable synchronization of data. The chair can be adjusted in height by means of a hydraulic jack and support rods which are locked in place, and the height of the armrests can also be adjusted (figure 1).

The chair was adjusted to 87.5% of knee height and each subject was asked to stand up and sit down from the chair at their own pace. Two floor mounted force plates were used during testing and the results summed for the graph in figure 2. Each subject was asked to rise without using the armrests. Two different types of seat cushions were used during testing: a polyurethane foam with a vinyl cover (soft cushion) and a high density foam with a cotton cover (hard cushion). Data was recorded in 6 degrees of freedom for both the floor and seat force plates.

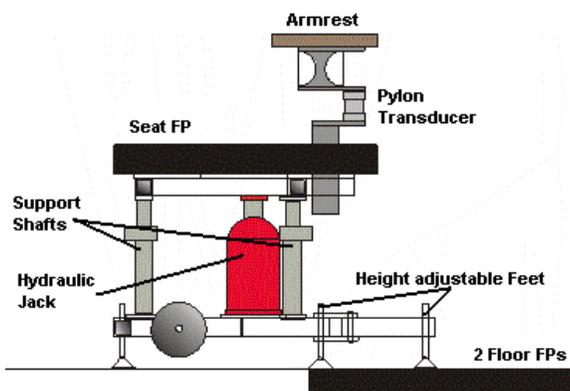

Figure 1: Diagram of components of the instrumented chair.  
FP: Force Plate.

### RESULTS AND DISCUSSION

Figure 2 illustrates the vertical forces that arose from the seat and floor force plates during testing. At the start of testing the subjects body weight was distributed 80% through the ischial tuberosities to the seat and 20% through both feet to the floor. It can be seen that zero force at the seat FP indicates lift-off from the seat which occurs momentarily before peak vertical foot floor force.

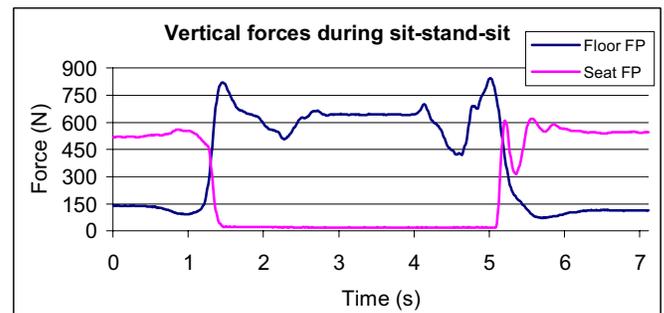

Figure 2: Vertical ground reaction forces at the seat and floor force plates during rising to stand and sitting down.

Figure 3 displays a peak horizontal force measured at the seat of 100N when rising to stand which occurred at the same instant when the vertical forces at both the seat and floor FPs were of equal magnitude (figure 2).

This variation in reaction forces may have been due to the seat height being lower than knee height, requiring more momentum to be generated in the forward direction to assist rising and control in sitting. These results indicate that sit-stand-sit is a complex movement that occurs in more than one plane and requires further detailed analysis in 3dimensions.

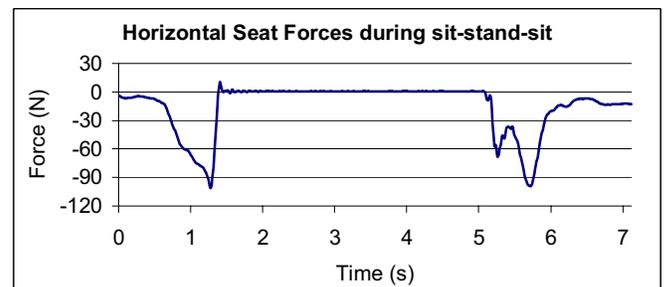

Figure 3: Horizontal forces measured at the seat and floor force plates during rising to stand and sitting down.

## NON-INVASIVE MEASUREMENT OF PASSIVE LENGTH-TENSION PROPERTIES OF HUMAN GASTROCNEMIUS MUSCLE FASCICLES, TENDONS, AND WHOLE MUSCLE-TENDON UNITS IN VIVO

<sup>1</sup>Phu Hoang, <sup>2</sup>Gabrielle Todd, <sup>2</sup>Robert Gorman, <sup>2</sup>Simon Gandevia and <sup>1</sup>Rob Herbert

<sup>1</sup>School of Physiotherapy, University of Sydney, Australia; email: [R.Herbert@fhs.usyd.edu.au](mailto:R.Herbert@fhs.usyd.edu.au)

<sup>2</sup>Prince of Wales Medical Research Institute, University of New South Wales, Australia

### INTRODUCTION

We present a new method for non-invasive measurement of passive length-tension properties of human gastrocnemius muscle fascicles, tendons, and whole muscle-tendon units *in vivo*. The method relies on the assumption that the gastrocnemius is the only muscle that crosses both the ankle and the knee, so changes in ankle torque-angle properties that accompany changes in knee angle can be attributed to changes in the length of gastrocnemius. The contributions of muscle fascicles and tendons to elongation of the muscle-tendon unit are determined with ultrasonography.

### METHODS

Passive ankle torque and ankle angle data were obtained as the ankle was rotated through its full range of motion with the knee in a range of positions. Changes in the length of the whole muscle-tendon unit (MTU) of gastrocnemius were calculated from joint angles and anthropometric data. Passive length-tension curves of the whole gastrocnemius MTU were extracted from torque-angle data based on the assumption that passive ankle torque is the sum of torque due to structures which cross only the ankle joint (this torque was a 6-parameter function of ankle joint angle) and a torque due to the gastrocnemius muscle (a 3-parameter function of knee and ankle angle). Parameter values were estimated with non-linear regression and used to reconstruct passive length-tension curves of the gastrocnemius [1].

We have examined the reliability of the measures of length-tension curves of gastrocnemius MTU by measuring length-tension curves from 11 subjects on three occasions, twice on the same day and on a third occasion at least one week later. The curves were reproducible with average root mean square error was 3% and 6% of maximal passive tension for pairs of measurements within a day and a week apart respectively.

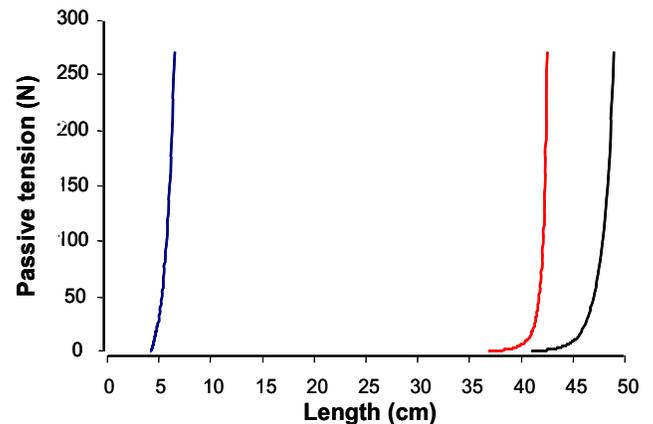

Simultaneously, ultrasonography was used to measure changes in length of muscle fascicles. The methods were similar to those described by Kubo *et al.* [2]. Changes in tendon length were then calculated as change in length of the muscle-tendon unit minus change in length of muscle fascicles. Passive length-tension curves of muscle fascicles and of the tendon were then generated.

Passive length-tension curves provided estimates of muscle-tendon slack length (the length below which there was no tension). The length of muscle fascicles at muscle-tendon slack length provided estimates of muscle fascicle and tendon slack lengths. These were used to calculate strains of muscle-tendon, muscle fascicle and tendon.

### RESULTS AND DISCUSSION

An example of a passive length-tension curve of the gastrocnemius MTU from one subject is shown in Figure 1. The mean ( $\pm$  SEM) maximum passive tension from 9 subjects

was  $280 \pm 22$  N, the mean slack length of the muscle-tendon unit was  $41 \pm 1$  cm, and the mean maximum *in vivo* length was  $50 \pm 1$  cm. The muscle-tendon slack length is within the physiological range but close to the shortest *in vivo* length.

**Figure 1:** Passive length-tension curves of gastrocnemius muscle-tendon unit (black line, using method in ref [1]), fascicles (blue line, using ultrasonography), and tendon (red line, by subtraction) of one subject. For this subject, the tendon contributed 71% to the total lengthening of the whole muscle tendon unit.

The figure also shows passive length-tension curves of muscle fascicles and tendons. Even at these low passive tensions, tendons undergo functionally important elongation. In the subject shown in the figure, tendon contributed 71% of the total lengthening of the whole MTU. The mean contribution of muscle fascicles and tendons to the changes of the whole MTU from measurements of 9 subjects was  $36 \pm 4\%$  and  $64 \pm 4\%$  respectively. These confirm findings of our previous studies in animals [3] and humans [4].

The mean slack length of muscle fascicles ( $n = 9$ ) was  $3.5 \pm 0.2$  cm. This is similar to the recent findings of Muraoka and colleagues [5]. Average maximum *in vivo* passive strain of muscle fascicles and tendon was  $91 \pm 9\%$  and  $11 \pm 2\%$  respectively.

### CONCLUSIONS

The new method enables measurement of passive length-tension properties of human gastrocnemius *in vivo*. It shows that, even with passive tension, strains in the whole tendon (extramuscular tendon plus aponeurosis) of human gastrocnemius are very large, and tendon elongation accounts for most of the change in muscle-tendon length.

## KNEE KINEMATICS OF TOTAL KNEE REPLACEMENT PATIENTS: PRE AND POSTOPERATIVE ANALYSIS USING COMPUTER GENERATED IMAGES

Christopher J. Barr<sup>1</sup>, Alexander.C. Nicol<sup>1</sup>, Mark Blyth<sup>2</sup>, Martin Sambrook<sup>3</sup>

<sup>1</sup>Bioengineering Unit, University of Strathclyde, <sup>2</sup>Orthopaedic Dept, Glasgow Royal Infirmary, <sup>3</sup>Radiography Dept, Glasgow Royal Infirmary. email: [Christopher.Barr.100@strath.ac.uk](mailto:Christopher.Barr.100@strath.ac.uk), web: [www.strath.ac.uk/bioeng](http://www.strath.ac.uk/bioeng)

### INTRODUCTION

Gait analysis has previously been conducted on osteoarthritic patients [1]. Techniques have been developed to study the contact areas of the knee in vivo, but these are in non-weight bearing conditions, and on healthy subjects [2]. The current project aims to show a comparison of knee kinematics in pre- and post-operative knee replacement surgery, using computer animation to represent a patient specific model of the knee joint interactions under every day conditions.

### METHODS

Nine patients were recruited from the waiting lists for total knee replacement (TKR) from the orthopaedic department in Glasgow Royal Infirmary hospital. All were selected on the criteria that they suffered from osteoarthritis of the knee joint, and had no secondary conditions that affected their gait.

Each subject underwent preoperative gait analysis using a Vicon 612 Motion Analysis System (©Oxford Metrics). A cluster set of 4 markers was attached to the thigh, shank and pelvis segments. All boney landmarks were then identified, and virtual points were made at each landmark. Each subject was then asked to perform the following every day activities: level walking, ascending and descending stairs, and chair rising and sitting. This was repeated one year postoperatively.

Preoperative magnetic resonance (MR) images were taken for each subject. Postoperatively, Computerized Tomography (CT) scans were taken, as the implant could not be imaged using MR. The scans were rendered into 3D images, which were then combined with gait analysis data and animated in Virtual Reality Modeling Language (VRML).

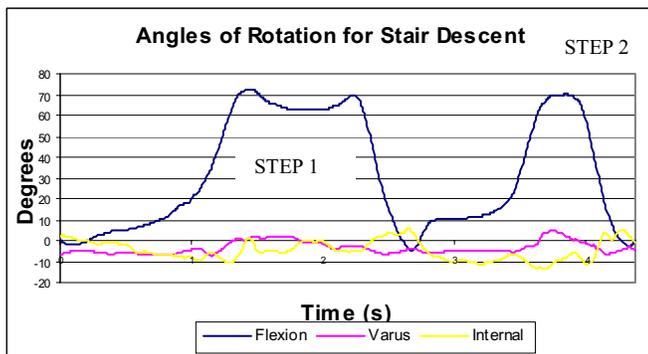

Figure 1: Typical flexion angles stair descent

### RESULTS AND DISCUSSION

Figure 1 details angles of rotation during stair descent in the preoperative patient. All subjects reported this to be the most difficult task. The difference in pattern of flexion angle in the two steps demonstrates the difficulties experienced by the

subject when descending the stairs. The lack of smooth motion in internal and valgus rotation illustrates the lack of muscle control during motion.

A 3D surface image of the knee joint was created using MIMICS software from Materialise (figure 2). Preoperatively, 44 axial slices of 3 mm thickness were taken from MRI. Postoperatively 144 slices of 1mm thickness were taken from CT. For each image, each slice was surfaced by outlining the contour of the bone. The dimensions of the scan were input into the software and the slices were then stacked to create a 3 dimensional model.

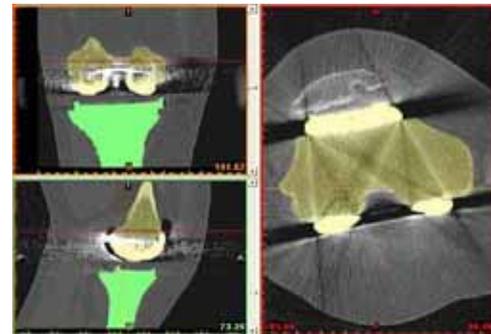

Figure 2: 3D rendering of the knee joint

The 3D model of the knee joint was exported as a VRML file and an animation of the pre- and postoperative knee joint was produced (figure 3). This shows the knee joint at 70° flexion during stair descent, with a slight varus and external rotation, as shown in figure 1. This method allows for the visualization of 3D motion between the tibia and femur during everyday activities. The comparison of pre and postoperative animations will provide data that can be incorporated in preoperative planning of TKR for a wide spectrum of patient groups.

## THE DEVELOPMENT AND EVALUATION OF A 3-DIMENSIONAL, IMAGE-BASED, PATIENT-SPECIFIC, DYNAMIC MODEL OF THE HINDFOOT

<sup>1</sup>Carl Imhauser, <sup>2</sup>Sorin Siegler, <sup>2</sup>Jason Toy, Richard Brand, <sup>3</sup>Jayaram Udupa

<sup>1</sup>Institute of Orthopaedic Research and Biomechanics, Ulm, Germany; email: [carl.imhauser@medizin.uni-ulm.de](mailto:carl.imhauser@medizin.uni-ulm.de)

<sup>2</sup>Drexel University, Philadelphia, Pennsylvania

<sup>3</sup>Medical Image Processing Group, University of Pennsylvania, Philadelphia, Pennsylvania

### INTRODUCTION

A confirmed dynamic model of the hindfoot enables parametric analyses to determine how the following injuries or treatments affect hindfoot mechanics (kinematics, flexibility, contact forces and ligament loads): tearing ligaments and repairing them (tenodesis), changing articulating surface geometry (arthroplasty), and constraining a joint (arthrodesis). The model predictions may provide guidelines for altering existing treatments or designing new ones to more closely restore normal hindfoot mechanics. The objective of this study was to develop and evaluate 3D, subject-specific, dynamic hindfoot models ( $n = 6$  *in vitro*) using 3D stress MRI data [1].

### METHODS

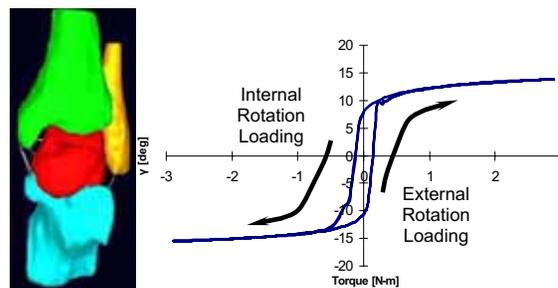

Existing software (3DVIEWNIX<sup>TM</sup> [3], Geomagic Studio<sup>TM</sup>) were used to obtain the subject's bone surface geometry and collateral and subtalar ligament insertion data from MR images. Non-linear load-strain functions described the structural properties of the ligaments [4]. Cartilage's elastic modulus and an exponential term modeled its non-linear compression characteristics [5]. The ADAMS 2003<sup>TM</sup> software generated and solved the dynamic equations of motion.

Each model (healthy and with ligament injury) was evaluated through subject-specific stress MRI experiments [1] and arthrometer tests [2]. The model used the same forces (inversion, anterior drawer, rotation) and boundary conditions as the experiments. Model output corresponded to the experimental measurements (helical axis parameters, flexibility).

### RESULTS AND DISCUSSION

The model with intact ligaments predicted the experimental inversion and anterior drawer kinematic patterns of the ankle joint complex, but under-estimated ankle joint motion and over-estimated subtalar joint motion. Similar to the experimental data, releasing the anterior talofibular ligament and the calcaneofibular ligament caused rotations at the ankle joint complex and at the ankle joint to increase in inversion compared to the intact condition. Unlike the experimental data, the model over-estimated rotations at the subtalar joint.

Similar to experimental data, the modeled ankle joint complex had hysteresis and had high flexibility in the unloaded neutral zone, followed by rapidly decreasing flexibility at the extremes of the range of motion in all directions (Figure 1). The model revealed that hysteresis coincided with low contact forces and with switching contact locations at the articulating

**Figure 1:** *In vitro* model (left). Predicted load-displacement curve (right).

surfaces. The low flexibility region coincided with increasing contact forces and with no change in contact location.

The ligament strain and loading patterns were sensitive to ligament removal. Sensitivity analyses indicated that rotations caused by altering ligament orientation were smaller than rotations caused by lateral ligament removal; therefore, the model may be sensitive to predicting the changes that occur during ligament rupture. Hindfoot mechanics were sensitive to bone morphology and ligament insertion location.

The results indicate that the structural properties of the subtalar joint's interosseous ligament and cervical ligament must be quantified. The models' assumptions and limitations include differences between the experimental and modeled boundary conditions, exclusion of the cartilage geometry, and estimation of the subtalar ligaments' structural properties.

### CONCLUSIONS

Future work will focus on quantifying the structural properties of the subtalar ligaments, developing a larger group of patient-specific models, and performing statistical analysis on output data. Despite the models' assumptions and limitations, they may be a valuable tool to explain fundamental mechanical phenomenon such as joint hysteresis and to do the previously described parametric analyses.

## HAND MOVEMENT ANALYSIS OF THE ELDERLY WHEN USING A REMOTE CONTROL

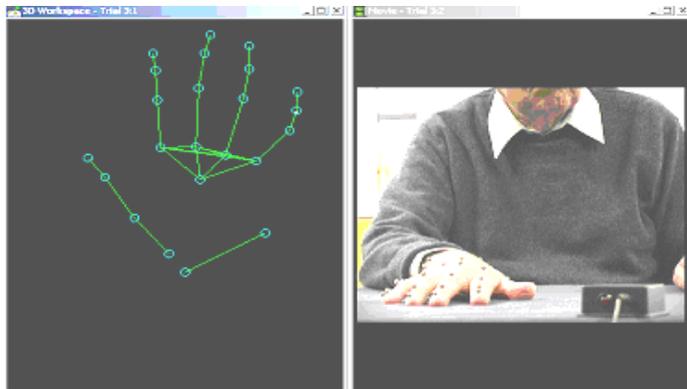

Sivaram Shanmugam, Victoria Hood, Alexander .C. Nicol, Bernie .A. Conway  
 Bioengineering Unit, University of Strathclyde, Glasgow  
 Email: [sivaram.s@strath.ac.uk](mailto:sivaram.s@strath.ac.uk) , web: [www.strath.ac.uk/bioeng](http://www.strath.ac.uk/bioeng)

### INTRODUCTION

Hand function decreases with age in both men and women due to age related degenerative changes in the musculoskeletal, vascular and nervous systems [1]. Functional performance in activities of daily living and recreational activity of the elderly are determined to a large degree by in-hand manipulation and dexterity. One of the most predominant activities an elderly person does is to watch television. With the advent of interactive television they are able to watch both digital TV as well as to surf the Internet, and the remote control is the way in which they are able to choose what they want to do. The aim of the current project is to study the ability of older subjects to perform basic remote control manipulations and also to specify the minimal functional requirements to perform this activity of daily living.

### METHODS

Three groups of healthy and normal to their age elderly subjects in the age range of 60-69, 70-79, 80+ years were recruited. Three-dimension biomechanical evaluation of the hand was carried out using a Vicon 612 (Oxford Metrics) motion analysis system (Figure 1a). Twenty-three, 6 mm markers were skin mounted at the mid point of each joint (Figure 1b). Subjects were asked to press a number on the remote control for a single button test or a set of three numbers sequentially for a three-button test (Table 1). Subjects preformed 10 single button tests and 10 three-button tests.

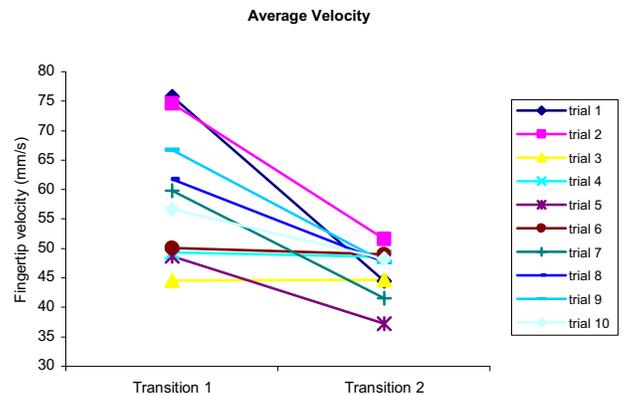

**Figure 1a** Screenshot of image from Vicon software. **Figure 1b** Video image of markers.

The infrared signal from the remote was captured by a video camera, which was in turn connected to the workstation. Digit span of up to nine numbers was assessed to check the short-term memory, and working memory was assessed with the digit span on the remote control. Digit span is the measure of how many sequential digits can be taken in, stored, processed, and recalled in the correct order. Bodybuilder software was used to process and analyze the data.

### RESULTS AND DISCUSSION

The measures that were analyzed include velocity and acceleration profiles of the tip of the finger, which is used for the desired activity. Reaction time, time of button contact and time difference between two button contacts were also looked into. The graph (Figure 2) below shows the average velocities of the fingertip between two button contacts, in the three-button test in an 80-year-old subject. Transition 1 is the period from which the fingertip goes from button 1 to button 2 and transition 2 is the period from button 2 to button 3 in the three-button test (Table 1). The graph clearly indicates that the average velocity during transition 1 is more than that of transition 2. Possible explanations include, the emphasis on the pre-planning process, online control and corrective directional measures and other strategic considerations.

**Figure 2** Average velocities during a three-button trial in an 80-year-old subject.

### INTRODUCTION

Sit-to-stand (STS) is a requisite activity for most daily activities. The incidence of fall in stroke patients usually occurs during postural transition, and the use of cane is suggested to increase the standing stability [1]. However, the influence of cane on STS has not been well studied yet. The purpose of this study was to determine the effect of cane support on the movement pattern of rising from a chair in hemiparetic patients and the healthy adults.

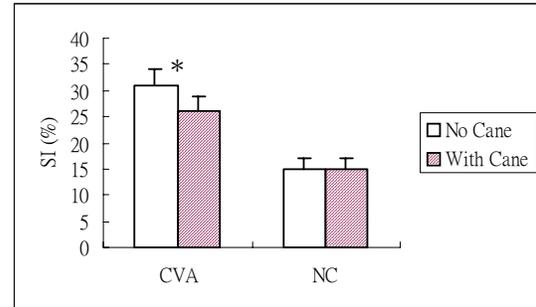

### METHODS

This was a cross-sectional experimental design. The mild-moderate hemiplegic patients with cerebrovascular accident (CVA) were recruited. Nine hemiplegic patients (mean age: 61.00±13.51 years old; 4 left hemiparesis and 5 right hemiparesis) were chosen as the experimental group, and eleven healthy adults (61.45±12.14years) were the control group. Participants performed rising from a chair in two conditions: (1) arm hanging by sides (no cane; NC), and (2) supported on a regular cane (with cane; WC). The data of 3-dimensional motion analysis (Vicon 250, Oxford, USA) and force (AMTI, USA) were recorded. A symmetry index (SI) was calculated [2] by the differences between the vertical ground reaction forces of the right and left limb (i.e.,  $SI = (Fz_R - Fz_L) / (Fz_R + Fz_L) \times 2$ ).

### RESULTS AND DISCUSSION

The movement time (MT) in CVA group was longer than normal controls ( $p < 0.01$ ) during STS with and without a cane. Compared with no support, the maximal extension moments of affected knee in CVA patients during STS with a cane were significantly increased (Table 1). In addition, the maximal knee extension moments in the sound side of CVA patients were significantly greater than those of the dominant side of healthy adults ( $p < 0.05$ ) during STS with no support, but no significant difference between 2 groups during STS with a

cane. There was a significant improvement in the symmetry of CVA subjects during STS with a cane, because SI decreased significantly from 31 % to 26 % (Figure 1).

**Figure 1.** Symmetry index (SI) of stroke (CVA) and normal controls (NC) during sit-to-stand with and without a cane.

\*  $p < 0.05$ .

### CONCLUSIONS

Hemiplegic patients could exert more force on affected leg during STS with a cane comparing with STS without any support. Using a cane may increase the stability to use the affected side for hemiplegic patients, as well as to reduce the motion time and symmetry during sit-to-stand task [3]. The psychological effect of using a cane to hemiplegic patients needs further studied.

## BIOCHEMICAL RESPONSE OF MENISCAL TISSUE TO ALTERED LOADING CAUSED BY PARTIAL MENISCECTOMY

Tammy L. Haut Donahue, Jeff A. McHenry, Barbara Zielinska  
 Department of Mechanical Engineering  
 Michigan Technological University; Houghton, Michigan email: thdonahu@mtu.edu

**INTRODUCTION:** Altered mechanical loading of meniscal tissue occurs following various injuries and surgical treatments such as anterior cruciate ligament (ACL) transection and meniscectomy. The degenerative sequel of the joint following partial meniscectomy is well documented. However, most studies have focused on the degradation of the articular cartilage of the joint. Few studies have focused on how the meniscal tissue responds to the altered loading [1]. Other musculoskeletal tissues, such as cartilage and bone, have been shown to respond to altered loading with a biochemical response that in turn mediates tissue remodeling. The biochemical events resulting from altered loading of meniscal tissue have received little attention.

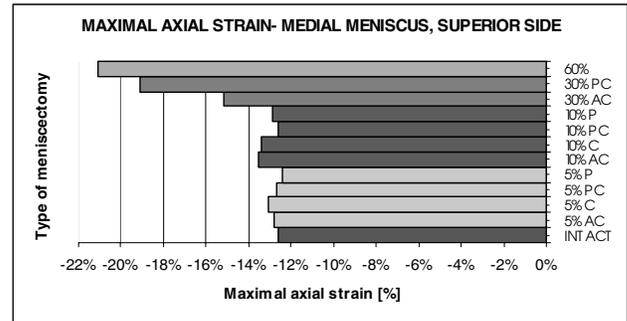

**METHODS:** Utilizing a previously validated finite element (FE) model [2], partial medial meniscectomies were simulated by removing various amounts of tissue from varying locations in the white-white or white-red meniscal zones, and documenting the changes in contact mechanics. Either 5%, 10%, 30% or 60% of tissue was removed from the anterior-central (AC), central (C), posterior-central (PC), or posterior (P) region (Figure 1). The change in contact area, maximum and mean contact pressure, and maximum and mean axial strain were documented for both the superior and inferior surface of the meniscus.

This data was then used as input to a custom built bioreactor for unconfined dynamic compression of meniscal explants. Eight porcine knee joints were obtained with 24 hours of death and the menisci aseptically removed and a 6mm biopsy punch used to harvest 6 explants from each meniscus. The explants were maintained in DMEM/F12 media with 10% fetal bovine serum and 1% penicillin/streptomycin for 48 hours before they were subjected either 0%, 5%, 10% or 20% axial compression at 1 Hz for 2 hours. Following compression, the meniscal explants were bisected into a superficial and deep zone and post-incubated for 24 hours. Regional expression of nitric oxide (NO) released into the media from the explants was quantified using the Griess reaction and was normalized to the wet weight of the explant.

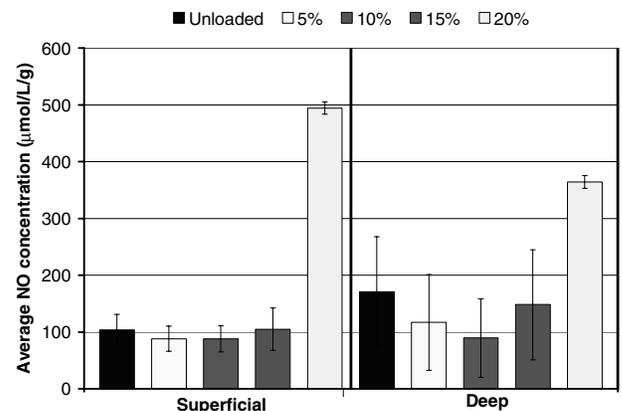

**RESULTS AND DISCUSSION:** The results indicate that the mean axial compressive strain is approximately 2-3% for the intact, 5% and 10% meniscectomy. The mean strains increase minimally for 30% and 60% meniscectomies (data not shown). The maximum again is fairly consistent at 13% until more than 10% of the tissue is removed, where it increases to over 20%.

When this range of strains was applied to meniscal explants it appears that the deep zone produces more NO, with a significant upregulation following 20% compressive strain which is associated with removing more than 10% of the meniscus. Additionally the unloaded controls appear to produce an elevated amount of NO compared to explants

compressed to 5% or 10%, possibly indicating that both overloading and underloading of meniscal tissue is damaging.

**Figure 1.** Maximal axial strains in the medial meniscus following various partial meniscectomies.

**Figure 2.** NO production from the superficial and deep zones of medial meniscus explants.

**CONCLUSIONS:** This work will provide a better understanding of the role of mechanical stimulation in the physiology and pathophysiology of the meniscus. The data gives clear indication to surgeons that removing more than 10% of the meniscus leads to axial strains which produce damaging biochemicals. Joint degeneration is the first step in the etiology of osteoarthritis. Improved treatment following meniscal excision will depend on an understanding of mechanotransduction in meniscal tissue. The findings of this work will have significant implications in the development of pharmaceutical and biophysical interventions for the treatment of the degenerative joint disease osteoarthritis.

## MUSCLE TISSUE COMPOSITION, MUSCULAR TENDERNESS, AND FORCE PRODUCTION IN SUBJECTS WITH UNILATERAL EPICONDYLITIS LATERALIS

<sup>1</sup>Pernille Kofoed Nielsen, <sup>1</sup>Anne Katrine Blangsted, <sup>1</sup>Henrik Baare Olsen and <sup>1</sup>Karen Søgaard

<sup>1</sup>Department of Physiology, National Institute of Occupational Health, Denmark;

email: [pkn@ami.dk](mailto:pkn@ami.dk), web: [www.ami.dk](http://www.ami.dk)

### INTRODUCTION

Musculoskeletal disorders and pain in the forearm region due to low-force exposure are major problems in the industrialised world. Nevertheless, the pathophysiology is poorly understood.

Prolonged static contractions and ongoing repetitive low-level activity in the forearm muscles is well-known risk factors for development of epicondylitis lateralis. Therefore, it may be speculated that in addition to changes in the tendon also muscular changes may be detectable. Indeed, by the use of biopsy technique, morphological changes in the forearm muscle have been identified in patients diagnosed with epicondylitis lateralis [1]. Such morphological changes could be caused by facilitated formation of non-contractile tissue in the muscle, which may be detectable by non-invasive methods such as ultrasonography [2,3]. Contractile tissue in a healthy muscle will appear dark separated by sharp, bright lines, whereas muscles with different neuromuscular diseases are brighter and more diffuse in the structure [4]. Further, if the contractile tissue is affected it would also be expected to affect the force generating capacity.

The hypothesis of the present study was that in subjects with clinically diagnosed epicondylitis lateralis, the maximal voluntary contraction force (MVC) in wrist extension is lower and the ultrasound image of the muscle is brighter in the afflicted (pain) arm compared to the non-afflicted (no-pain) arm.

### METHODS

B-mode ultrasonography was performed bilaterally at the middle part and proximal part of the m. extensor carpi radialis (ECR) on eight patients (5 females, 3 males) with unilateral epicondylitis lateralis. An ultrasound scanner fitted with a 12 MHz linear matrix transducer (LOGIQ 7, M12L, GE-Medical) was used. Gain settings were standardized and kept constant. The transducer was placed perpendicular to the ECR muscle during examination. Each image consisted of pixels with grey-scale values ranging from 0 to 255. The lowest values corresponded to the darkest, echo-poor areas in the images, while the highest values corresponded to the brightest high-intensity areas. A computerized texture analysis calculating the mean grey-scale intensity was used to characterize the images [5].

Next, the muscular tenderness, measured as pressure pain threshold (PPT) was determined with an electronic pressure algometer (Somedic, Hörby, Sweden) [6]. The diameter of the contact area was 10 mm and the pressure was applied perpendicularly to the skin at the middle part of ECR and with a speed of 20 kPa/s. The subjects marked the PPT by pressing

a button when the sensation of “pressure” changed to “pain”. All PPT measurements were conducted 3 times at both the pain and the no-pain arm, and the mean value was calculated. MVC was measured during a wrist extension. The subjects were sitting with the elbows flexed 90 degrees, the forearm pronated and resting on a horizontal platform. In this position they performed a MVC against a force transducer with both the pain arm and the no-pain arm in random order. Moment arm was measured and the wrist extension torque was calculated. Results are presented as mean (SD).

### RESULTS AND DISCUSSION

The mean grey-scale intensity for the middle and proximal measuring sites was 42.86 (10.66) and 46.6 (11.6) for the pain arm compared to 41.50 (8.52) and 37.9 (15.4) for the no-pain arm. The mean PPT was 339 (172) kPa/s for the pain arm compared to 371 (148) kPa/s for the no-pain arm, and the mean MVC torque was 10.3 (4.6) Nm and 11.1 (SD 4.9) Nm, respectively. There were no significant differences.

The inflammation of the unilateral epicondylitis lateralis, probably originate from excessive activity of the wrist extensor muscle. Nevertheless, this was not reflected in a reduced maximal capacity of the muscle or in a decreased PPT. Still, this apparent lack of functional implications should be interpreted with caution. The non-afflicted arm serves as control and the study design does not allow any estimation of the initial condition of the afflicted arm before the symptoms emerged. However, the finding of a well preserved force capacity in the muscle indicating unaffected contractile tissue was corroborated by the results from the ultrasound grey-scale analysis.

### CONCLUSIONS

In this study, we found no indications of an influence of epicondylitis lateralis on the function, the PPT, or the tissue composition in ECR. However, a case-control study design may be needed to support this conclusion.

## 3D KINEMATIC AND KINETIC DATA OF TOTAL KNEE ARHTROPLASTY DURING THE STANCE PHASE OF LEVEL WALKING USING A MOVING VIDEO-FLUOROSCOPE

<sup>1</sup> Monika S. Zihlmann, <sup>1</sup> Hans Gerber, <sup>1</sup> Edgar Stüssi

<sup>1</sup>Laboratory for Biomechanics, HCI E411, ETH Zurich, 8092 Zurich, Switzerland

Correspondence to Monika S. Zihlmann: [zihlmann@biomech.mat.ethz.ch](mailto:zihlmann@biomech.mat.ethz.ch)

### INTRODUCTION

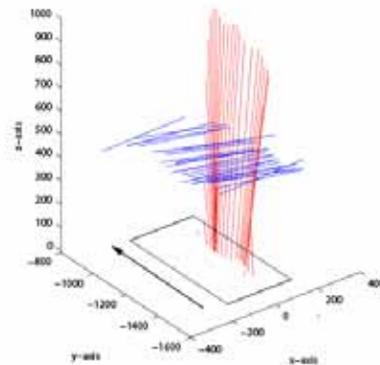

Accurate in vivo kinematic and kinetic data of total knee arthroplasties, TKA, are important to understand the complexity of knee joint mechanics after knee joint surgery. This knowledge is crucial to reduce high stresses and strains on the ligamentous structure as well as on the implant parts. A better understanding could lead to better surgical strategies, improved implant designs, and increase patient's satisfactory rate. Video-fluoroscopy is a well established method to get accurate kinematic information of artificial joints by a three-dimensional numeric reconstruction of the single plane projection view of the fluoroscopic images. Until now, this method was limited to kinematic data only. Very accurate in vivo kinematic and kinetic data of TKA can be received by coupling instrumented gait analysis and video-fluoroscopy simultaneously and using a movable fluoroscopic system, proposed by Zihlmann et al. [1]. The goal of the present study was to get kinematic as well as kinetic data of TKA during the stance phase of level walking.

### METHODS

One subject with a TKA (balanSys™ fixed bearing, Mathys AG Bettlach, Switzerland) was asked to perform several gait cycles. *Fluoroscopic motion tracking*: The c-arm of the pulsed fluoroscopic unit (Philips Medical Systems, Switzerland) was mounted on a motor driven trolley. The system accelerates and decelerates thereby keeping the knee joint within the field of view of the fluoroscopic image (25frames/s). *Optical tracking*: The subject's condyles and the position of the unit mover were tracked by the optical tracking system VICON (VICON Motion Systems Ltd.) with 100Hz. *Ground reaction forces*: Five force plates (KISTLER AG, Switzerland) were fixed on a basement which was mechanically decoupled from the surrounding ground avoiding an interaction with the unit mover during the level walking tasks. The time of all measurement systems was synchronised. *3D reconstruction of the 2D fluoroscopic images*: Distortion of the fluoroscopic images was corrected by a calibration grid. A full three dimensional analysis of each image was achieved by fitting a synthetic x-ray projection of the tibial and femoral component onto the original in each image [2]. The reconstruction of the implant's position and orientation (6DOFs) was performed relative to the focus of the fluoroscopic image. *Transformation into global coordinate system*: A calibration frame was fixed on one force plate on a defined position. Because the distance of the grid lines were known, the exact position in the global coordinate system of the fluoroscope's focus was calculated.

### RESULTS AND DISCUSSION

The fluoroscopic system was able to track the knee joint so that the implant components were in the field of view of the fluoroscope during the stance phase of the gait cycle. During this phase, ground reaction forces were available. Figure 1 shows the finite axis of rotation between femoral and tibial component in the global coordinate system. The force vectors of the third force plate are plotted in the same figure. By reducing the ground reaction force into the axis of rotation the net forces and moments of the TKA can be estimated.

**Figure 1:** Axis of rotation between tibial and femoral component in the global coordinate system and force vectors of one force plate (4D plot with  $\Delta t = 40$ ms. Y-axis is gait direction)

### CONCLUSIONS

This pilot study shows that the presented measuring technique enables the capture of kinematic and kinetic data of the stands phase of level walking simultaneously by coupling instrumented gait analysis and a movable fluoroscopic system.

### INTRODUCTION

Balance dysfunction and falls are a major problem in patients with Parkinson's disease (PD). The causes of these falls are multifactorial and may include muscle weakness, sensory deficiencies, postural instability, and extrapyramidal dysfunction [1]. The knee extensor muscles are important contributors to postural and locomotor stability. Clinically, loss of strength in these muscles is associated with movement dysfunction [2]. Despite evidence supporting the importance of knee extensor strength in the performance of functional activities, observed associations between measures of knee strength and function in patients with PD have not been made. The purpose of this study was to explore associations between knee extensor peak strength and dynamic balance control in patients with PD.

### METHODS

Forty-four patients with idiopathic PD (age: 66±11 yrs; mass: 82.1±17.1 kg; height: 174.3± 9.2 cm; Hoehn and Yahr (H&Y) disability score: 2.3± 0.5) volunteered to undergo strength, functional reach, and motion analysis testing.

Isokinetic knee extension strength was measured unilaterally by a KinCom dynamometer (Chattecx, Chattanooga, TN). The participants were positioned against a back support providing a hip flexion angle of approximately 90°. Stabilizing belts were secured over the chest, lap, and distal one-third of the thigh during testing. The resistance pad was positioned approximately 2cm above the lateral malleoli. Knee extension range of motion was 10–90°, and all tests were performed at 60°/s. Participants practiced three submaximal repetitions of extension before the start of testing. During testing, participants performed 3 sets of 3 maximal exertion repetitions with 1~2 minutes rest between sets for both legs. During recording, consistent motivational verbal prompts were given. Peak torque was determined for each repetition and was averaged over the nine repetitions for each leg. The peak torque for each leg was averaged prior to statistical analysis.

The Functional reach test (FRT) was administered as a measure of balance control using a leveled yardstick attached to the wall at the height of the subject's right acromion. To measure the maximal reaching distance, an examiner recorded the subjects initial and end reach positions. Subjects stood comfortably with feet shoulder-width apart, made a loose fist, and, without touching the wall, placed the arm parallel to the yardstick (initial position). Subjects then reached as far forward as they could without raising their heels of the floor (end position). The mean difference between the initial position and the end position for the 3 test trials was calculated as the functional reach.

The peak distance between the center of pressure and whole body center of mass (COP-COM) was calculated as an indicator of dynamic balance control while participants performed gait initiation trials. For each participant, one or two practice trials were followed immediately by three data

collection trials for each leg performed at a self selected pace. Kinematic data were collected during the experimental trials using a six camera 3D Optical Capture system (Peak Performance Technologies, Englewood, CO) and ground reaction forces were sampled at 300Hz using a Kistler force platform. Force platform data were subsequently used to calculate the instantaneous COP. Twenty markers placed over boney landmarks were used to construct a simple nine segment model. Estimates of segment mass centers were based on Dempster's anthropometric data and the calculation of the location of the whole body center of mass (COM) was calculated using the Peak performance Software. The distance between the vertical projections of the COM and the COP was calculated using software developed in the Center for Human Movement Studies.

Pearson's correlations were performed to assess relations between PD disability, lower extremity strength, and dynamic balance using SPSS 11.0 for Windows (Chicago, Illinois).

### RESULTS AND DISCUSSION

The correlations between dependent variables ranged from poor to moderate in each evaluation (Table 1).

**Table 1.** Pearson's correlations between PD disability, muscle strength, and balance performance. \* p <0.001

	H&Y	STRENGTH	FRT	COP-COM
H&Y score	-----	-0.498*	0.015	-0.554*
STRENGTH	-0.498*	-----	0.006	0.522*
FRT	0.015	0.006	-----	0.054
COP-COM	-0.554*	0.5228	0.054	-----

Greater strength was significantly related to dynamic balance (COP-COM). FRT performance was not related to disease severity, muscular strength, or dynamic balance performance. As expected, the less disabled patients were stronger and displayed greater dynamic balance control.

Strength has been previously associated with both FRT performance and peak COP-COM in older adults [3,4] but appears only to be related to the COP-COM during dynamic tasks in patients with PD. Of interest, FRT performance does not relate to disease severity or dynamic balance control during locomotor activities in this population. These findings highlight the importance of rehabilitative strategies aimed at maintaining strength in patients with PD and suggest that FRT performance is not an appropriate measure of dynamic balance control or a marker of disease severity in this population.

## VIRTUAL MODELS AND PROTOTYPE OF INDIVIDUAL ANKLE FOOT ORTHOSIS

Slavyana Milusheva, Dimitar Tochev, Liliya Stefanova, Yuli Toshev  
Institute of Mechanics and Biomechanics, Bulgarian Academy of Sciences, Sofia 1113, Bulgaria  
[slavyana@imbm.bas.bg](mailto:slavyana@imbm.bas.bg); [ytoshev@imbm.bas.bg](mailto:ytoshev@imbm.bas.bg)

### INTRODUCTION

Ankle-foot orthoses are used mainly in case of disability of neurological origin (cerebral palsy, stroke, spinal cord injury) or musculoskeletal origin (trauma, ageing).

The study is oriented to develop new orthoses to assist the very frequently observed gait abnormalities relating the human ankle-foot complex using CAD modeling.

Computer modeling is a perspective method for optimal design of prosthesis and orthoses. Using CAD geometry different tests could be made without loosing of material and essential design variables could be modified.

### METHODS

The main goal is to assist the ankle-foot flexors and extensors during the gait cycle (stance and swing). To realize this aim it is necessary to propose an orthosis model developed based on the 3D biomechanical lower limb model.

Using CAD technology different models of the system AFO (Ankle-Foot-Orthosis) are developed. On the base of the 3D models, the physical AFO models could be elaborated and it is possible to use advanced design and manufacturing technologies: computer aided design (CAD), computer aided manufacturing (CAM) and to combine with computer numerical control (CNC). As result CAD/CAM/CNC could be combine also with rapid prototyping (RP) and rapid tooling (RT). Laser scanning is used to obtain the individual surfaces of patient ankle-foot in order to create a solid model of ankle-foot.

### RESULTS AND DISCUSSION

A basic virtual model of the experimental active ankle-foot is developed and shown on (Fig. 1). The model is based on laser scanning and on the contours representing the ankle-foot geometry. Surface and solid models were constructed in Pro/Engineer. The deformation analysis of the 3D model of the new proposed orthoses in Pro/Mechanica is performed. Using Rapid Prototyping technology a physical prototype is manufactured and is under investigation (Fig.2)

Fig. 1 Virtual ProEngineer Model of Ankle-Foot Orthoses

Fig. 2 Physical Model of Ankle-Foot Orthoses using Rapid Prototyping

### CONCLUSIONS

An appropriate AFO design is achieved and manufactured using Rapid Prototyping technology. The difference with the traditional approaches is that the proposed AFO is made using optimal orthoses design on the base of laser scanning by manipulating CAD/CAM methods. The designed AFO is under FEA tests for breaking resistant by frequency and temperature loads.

## OPTIMAL ARM STROKE FOR COMPETITIVE FREE STYLE SWIMMING

<sup>1</sup> Shinichiro Ito

<sup>1</sup>Department of Mechanical Engineering, The National Defense Academy Japan;  
 email: [ito@nda.ac.jp](mailto:ito@nda.ac.jp), web: [www.nda.ac.jp/~itoh/](http://www.nda.ac.jp/~itoh/)

### INTRODUCTION

Advancing movement of an animal in water can be roughly divided into two categories, locomotion of the maximal efficiency (the minimal energy consumption mode) for an usual motion and that of the maximal speed (the maximal thrust mode) for an urgent evacuation or a predatory action instinctively. For competitive swimming, an operation of the maximal propelling force is desirable. On freestyle swimming, forms of the operation are calculated by using equations of turtles' instinctive locomotion[1].

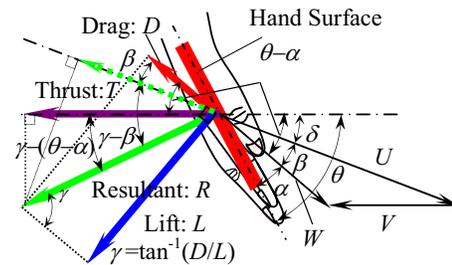

### METHODS

Under a quasi-steady condition, flow induced forces of a hand change by its postures. Thrust force  $T$  is generated from a lift force  $L$  and a drag force  $D$  generated by the flow shown in Figure 1. The thrust force  $T$  is balanced with the drag force  $D_{DP}$  by the whole body in a constant swimming speed. The formulae of balance of such forces are established, and those formulae are exactly corresponded to the ones of turtles[1]. They are solved concerning the thrust force and the efficiency based on a posture of hand whose lift-drag characteristics are obtained by experiments.

Wind tunnel tests are performed with a plaster replica of a hand including a palm paddle and forearm of an excellent swimmer. As an aspect ratio changes, significant differences in characteristics of lift-drag forces appear with varying sweepback angles  $\psi$  whose convention is shown in Figure 2. Sweepback angles of the hand,  $\psi=135^\circ$ ,  $90^\circ$  and  $45^\circ$  correspond to the catch, the pull and the finish phase on freestyle stroke respectively. With the variation of sweepback angle  $\psi$ , the hydrodynamics characteristics against angle of attack  $\alpha$  are measured in a wind tunnel with a Reynolds number which is almost equivalent to the relative inflow velocity in water to the hand of actual swimming.

### RESULTS AND DISCUSSION

The maximum thrust can be obtained when  $\theta=90^\circ$ . Namely, the hand plane is perpendicular to the axis of the advancing direction. Each of the maximal points for each  $\psi$  has the angle of attack  $\alpha=90^\circ$ . That is to say, the hand should be driven along the body axis parallel to the advancing direction for the entire drag forces to be used. The maximal value of the coefficient of thrust at  $\psi=90^\circ$  is 0.808, which is 6.2% larger than that at the maximal efficiency. On the other hand, the maximum efficiency  $\eta_{max}$  can be obtained when the motion of the palm paddle corresponds to an S-shaped pull motion. The maximal value of the efficiency at  $\psi=90^\circ$  is 0.380, which is 7.1% smaller than that at the maximal thrust.

Driving velocity:  $U$  Advancing velocity:  $V$   
 Relative velocity:  $W$  Tilt Angle of hand:  $\theta$   
 Angle of attack:  $\alpha$  Driving angle:  $\delta$

Figure 1: Forces and velocities on a hand paddle

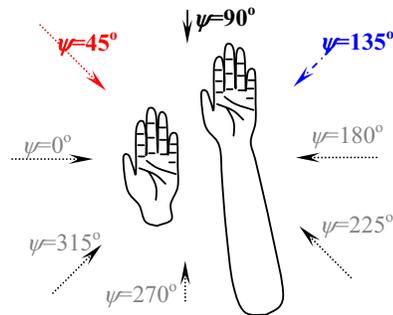

Figure 2: Hand and arm replica used in experiment and Sweepback angle  $\psi$  defined by Schleihauf[2].

### CONCLUSIONS

The calculations show very interesting and unexpected results which differ from what were said conventionally. An S-shaped pull stroke, a popular form for the conventional front crawl, is resulted as a form of the maximum efficiency mode utilizing lift and drag force by hands. On the other hand, Drag type swimming is the fastest swimming form which generates the maximum thrust. It happened to coincide with the form of Ian Thorpe who has four individual world records.

## NEW METHOD FOR COUPLED FLUID-STRUCTURE INTERACTION PROBLEMS IN BIOMECHANICS

<sup>1</sup>Damian J. J. Farnell, <sup>2</sup>Tim David and <sup>3</sup>David C. Barton

<sup>1</sup>Department of Medicine, University of Liverpool, Liverpool, UK <sup>2</sup>University of Canterbury, Christchurch, New Zealand

### INTRODUCTION

There are many examples in nature of situations in which a fluid interacts strongly with a flexible structure. Examples range from flapping flags to biological “systems” that are often critical to our survival, e.g. blood flow in the cardiovascular system. The role of numerical simulation of such complex systems is becoming increasingly important as they often yield insight into the fundamental behavior involved. Historically, numerical codes to analyse the dynamic behavior of structures (based on explicit finite element methods e.g. [1]) have evolved separately from those for fluids that are based on computational fluid dynamics (CFD) theory, with the resulting computational complexity and cost reducing the range of applications to which the coupled methodology has been applied. An alternative approach is described here, based on a Lagrangian dynamics approach, embedded in a commercial CFD package (FIDAP). This has the advantage of (relative) computational simplicity and flexibility. The basis of the approach is outlined below followed by a description of its application to two particular problems in biomechanics: blood flow through a heart valve and the swimming action of certain eel-like fish.

### METHODS

The flexible structure is treated as an  $N$ -tuple pendulum with stiffness and damping terms at each “hinge.” Each element of the pendulum is assumed to be rigid with uniformly distributed mass. There is only one degree of freedom associated with each element (its rotation), plus an additional freedom for the leading edge of the piecewise-linear structure in the case of the “swimming fish”. A Lagrangian is formed from the potential, kinetic and dissipative energy terms of the structure and this is manipulated to form the Euler-Lagrange equations, solution of which yields the motion of the structure. The main external forcing terms in the equations are the pressure differential acting on each element but may also include other terms e.g. due to muscle forces in swimming fish. The structural dynamics solver is written as a subroutine to the commercial CFD package FIDAP that solves the Navier-Stokes equations for the fluid domain in question. The motion of the structure is imposed as a moving boundary condition on the fluid and, in a circular fashion, the pressures generated by the fluid are applied in the Euler-Lagrange equations for the structure. Hence, we solve the two physical problems using a weakly coupled solver, and this approach has been shown to be both highly efficient and accurate [2].

### RESULTS AND DISCUSSION

Figure 1 shows a typical result from a 2D coupled analysis of an aortic heart valve. In this case, the two leaflets have been modeled independently, allowing flow asymmetries to develop. Animations of the complete cardiac cycle have been generated which show clearly the full opening and closing of the leaflets and the associated flow vortices.

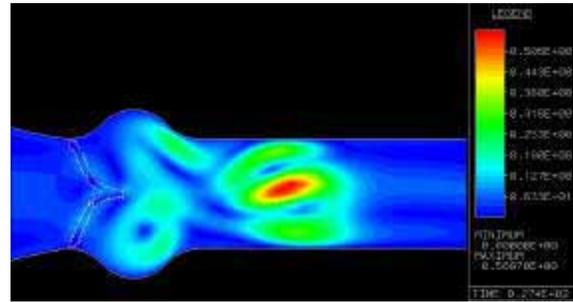

Figure 1: Typical CFD velocity field during diastole for artificial heart valve simulation. The “inlet” from the left ventricle is shown on the left and the two aortic leaflets are shown in outline in white.

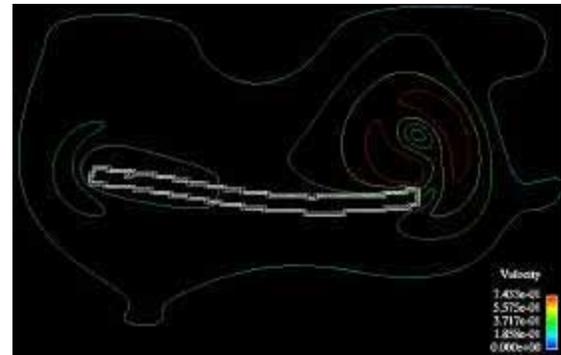

Figure 2: Typical streamlines from the forwards swimming “fish” simulation. The left hand end of the white outline represents the leading end (“head”) of the fish.

Figure 2 shows a typical result from the swimming fish simulation. Unlike the heart valve case, the leading edge of the structure is not constrained in space and terms representing the fish’s muscle forces are added to the Euler-Lagrange equations. By changing the parameters of the system, it was possible to reproduce both forwards and backwards swimming motions, with quite different vortex structures formed in the two cases. These results are in good agreement with experimental observations [3].

### CONCLUSIONS

A novel method has been developed for numerically simulating coupled fluid-structure interaction problems in nature. The method has been applied to several problems, including heart valve dynamics and the swimming action of certain fish, and shown to be robust, efficient and reliable. In principle, it will be possible to extend the method to other problems (e.g. retinal tears in the posterior chamber of the eye) and to fully three-dimensional analysis.

## A STOCHASTIC MODEL FOR LIGAMENT MECHANICAL FAILURE

<sup>1</sup>Raffaella De Vita and <sup>1</sup>William S. Slaughter

<sup>1</sup>Mechanical Engineering Department, University of Pittsburgh, PA  
 email: [rad15@pitt.edu](mailto:rad15@pitt.edu), web: [www.pitt.edu/~rad15](http://www.pitt.edu/~rad15)

### INTRODUCTION

Ligaments are composed of elastin and collagen fibers embedded in a matrix of water, proteoglycans, glycolipids and fibroblasts. Their main function is to guide and to restrain joint motion in order to maintain joint stability. The joint stability is seriously affected when ligament injuries, such as second-degree and third-degree sprains, occur. The treatment and prevention of these injuries require a thorough understanding of the ligament failure mechanisms.

In the present study, a constitutive model will be formulated to describe the failure behavior of ligamentous tissue by taking into account the tissue morphology. The model is able to reproduce the toe region, the linear region and, most importantly, the failure region of the stretch-stress relationship as observed in tensile tests along the fiber direction of the medial collateral ligaments (MCLs) [1].

### MODEL FORMULATION

The ligamentous tissue is idealized as composed of N parallel collagen fibers. Elastin and matrix contributions to the tissue mechanical behavior are neglected. The collagen fibers are assumed to contribute to the tissue load only after becoming straight and before breaking. Moreover, they are modeled as a linear elastic material with negligible bending stiffness.

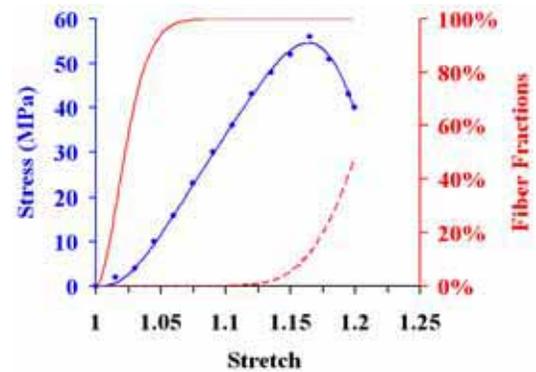

Each fiber is characterized by a straightening stretch,  $\lambda_s^i$ , and a failure stretch,  $\lambda_f^i$ . The fiber straightening stretches and failure stretches for the N fibers are distributed randomly according to Weibull cumulative distributions,

$$G_1(\lambda_s^i) = 1 - e^{-\left(\frac{\lambda_s^i - 1}{\beta_s}\right)^{\alpha_s}} \quad \text{and} \quad G_2(\lambda_f^i) = 1 - e^{-\left(\frac{\lambda_f^i - 1}{\beta_f}\right)^{\alpha_f}} \quad (i = 1 \dots N),$$

where  $\alpha_s$ ,  $\alpha_f$  are the shape parameters and  $\beta_s$ ,  $\beta_f$  are the scale parameters. The overall tissue stress,  $\sigma$ , and the individual fiber stresses,  $\sigma^i$ , are defined as follows:

$$\sigma = \frac{1}{N} \sum_{i=1}^N \sigma^i \quad \text{with} \quad \sigma^i = \begin{cases} K \left( \frac{\lambda}{\lambda_s^i} - 1 \right) & \text{if } 1 < \frac{\lambda}{\lambda_s^i} < \lambda_f^i; \\ 0 & \text{otherwise,} \end{cases}$$

where K is the fiber stiffness,  $\lambda$  is the overall tissue stretch, and  $\lambda/\lambda_s^i$  is the fiber stretch relative to the taut configuration. Finally, five structural parameters,  $\alpha_s$ ,  $\alpha_f$ ,  $\beta_s$ ,  $\beta_f$ , K, need to be determined in order to replicate the typical stress-stretch relationship of ligaments.

**Figure 1:** The blue circles are experimental data [1] while the blue line represents the model fit. The red lines represent the straight fiber fraction (—) and the broken fiber fraction (---) predicted by the model.

By following Lanir's approach [2], the presented model is easily generalized to a three-dimensional continuum model to account for the ligament finite deformations and anisotropy.

### RESULTS AND DISCUSSION

The model parameter values were determined by curve fitting tensile experimental data on goat MCLs [1]. Their values were found to be  $K=460$  MPa,  $\alpha_s=1.74$ ,  $\beta_s=0.02$ ,  $\alpha_f=8.10$ , and  $\beta_f=0.18$  by implementing the simplex optimization method ( $R^2=0.99$ ). The experimental data and the model fit at the best fitting parameters are depicted in Figure 1. The fractions of straight fibers and broken fibers, as predicted by the model, are also shown.

The constitutive model is an improvement over the previously presented structural models for connective tissues [3,4] in which the collagen fibers are assumed to have the same failure stretch in the taut configuration.

Three-dimensional constitutive models are necessary to accurately define the ligament mechanical response [5]. However, since quantification of collagen fiber architecture and multiaxial experimental data on ligament failure remain unavailable, the three-dimensional structural model generalization cannot be validated.

## A CROSS SECTIONAL MRI STUDY OF THE M. RECTUS FEMORIS MORPHOLOGY IN CYCLISTS, RUNNERS AND SPRIENTERS

<sup>1</sup> Kenneth Meijer, <sup>2</sup>Diantha Michels, <sup>1</sup>Henk de Feyter, <sup>1</sup>Gustav Strijkers, and <sup>2</sup>Hans HCM Savelberg

<sup>1</sup> Department of Biomedical Engineering, Technische Universiteit Eindhoven, The Netherlands,

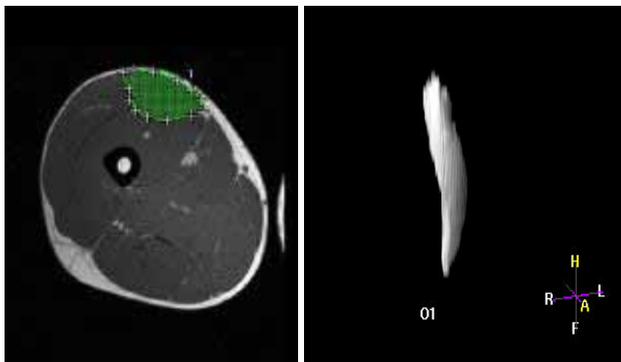

<sup>2</sup> Department of Health Sciences, Maastricht University, The Netherlands; email: [Kenneth.Meijer@bw.unimaas.nl](mailto:Kenneth.Meijer@bw.unimaas.nl)

### INTRODUCTION

Muscles are highly adaptable. In response to internal and external stimuli they remodel their volume by changing their length and their physiological cross sectional area (PCSA). A recent comparison of knee extension torque in cyclists and runners has indicated that cyclists have a shorter m. rectus femoris (RF) compared to runners, but that the PCSA is similar in both groups [1]. It was argued that this difference was related to a difference in use of the RF in these sports. However, inferring muscle morphology from torque data is prone to error. Therefore, the aim of this study was to study RF morphology more directly. For this purpose we assessed the RF morphology by taking MRI scans for three types of athletes: cyclist (C), distance runners (D) and sprinters (S).

### METHODS

Athletes were recruited at sport clubs and assigned to the C, D or S group based on performance criteria. A total of 45 cross sectional MRI scans (weighed T1; 1.5 T Philips S15/ACS scanner) were made of the right upper leg to create muscle images (figure 1). The images were analyzed using Easyvision to quantify the RF muscle belly length, muscle belly width in left-right (L-R) direction and anterior-posterior (A-P) direction as well as muscle volume. This data was fed into a 3-D model of the RF [2] to estimate the muscle fiber length and PCSA. Differences in muscle belly length, L-R and A-P width, volume, fiber length and PCSA between the groups were tested using a one-way ANOVA.

**Figure 1:** Left panel: region of interest of the m. rectus femoris in cross sectional slice of the upper leg. Right panel: reconstruction of m. rectus femoris volume and the used frame of reference (R=right, L=left, H=head, F=feet and A=anterior)

### RESULTS AND DISCUSSION

Each group consisted of nine subjects. There were no significant differences between the subjects in the respective groups in terms of age, height, weight and femur length.

**Table 1:** Morphological data for m. rectus femoris. Significant differences are indicated by \* ( $P < 0.05$ )

Parameter	Cyclists	Distance	Sprinters
		Runners	
volume (cm <sup>3</sup> )*	317.3 ± 46.7	338.4 ± 58.5	393.6 ± 74.8
belly length (cm)	33.3 ± 2.5	34.0 ± 2.7	34.4 ± 2.5
L-R width (cm)	7.4 ± 0.6	7.6 ± 0.7	7.9 ± 0.9
A-P width (cm)	5.1 ± 0.6	4.6 ± 0.7	5.6 ± 1.2
fiber length cm	10.4 ± 0.6	10.4 ± 0.8	10.8 ± 0.93
PCSA (cm <sup>2</sup> )	30.7 ± 4.3	32.6 ± 5.4	36.5 ± 6.2

Table 1 summarizes the data from the analysis of the MRI images and the model predictions. Statistical analysis revealed that muscle volume was the only parameter that was significantly different between the groups. Post-hoc tests revealed that this was attributed to the difference between the cyclists and the sprinters. It should be noted that the differences in A-P width ( $P=0.068$ ) and PCSA ( $P=0.08$ ) approached significance.

The volumes measured in this study were 106-155% larger than values reported from anatomical studies on cadaver material [3]. Likewise, estimates for fiber lengths were 33-38% larger and PCSAs were 65-82% larger in this study compared to previous studies [3]. These differences probably reflect the high training level of the subjects that participated in this study as well as possible shrinkage of cadaver material.

### CONCLUSIONS

The data of this study do not support the hypothesis that a difference in the RF knee extension torque between cyclist and runners results from morphological adaptations [1]. Alternative explanations like length dependent muscle activation and differences in co-contraction levels to explain the results of Savelberg and Meijer (2003) are discussed.

## UTILITY OF THE FRONTAL PLANE PROJECTION ANGLE OF THE KNEE DURING SINGLE LEG SQUATS

John D. Willson<sup>1</sup> and Irene Davis<sup>1,2</sup>

<sup>1</sup> Department of Physical Therapy, University of Delaware, Newark, DE, USA

<sup>2</sup> Drayer Physical Therapy Institute, Hummelstown, PA, USA

### INTRODUCTION

Abnormal lower extremity mechanics during athletic activities are believed to contribute to the etiology of numerous knee joint injuries [1,2]. The single leg squat test is commonly used by practicing clinicians to identify individuals who display such abnormal mechanics. Presently, due to the restraints of typical clinical settings, analysis of this test is done qualitatively. However, quantification of a patient's performance on this test would facilitate accurate documentation of these mechanics as well as changes due to interventions. Two-dimensional images recorded by a digital camera during this test will reveal the frontal plane projection angle (FPPA) of the knee during this test. However, it is unclear to what extent the frontal plane projection angle determined using such methods is related to actual three-dimensional (3D) kinematics. Specifically, it would be beneficial to know to what degree tibiofemoral (TF) valgus, a widely accepted risk factor for injuries such as ACL rupture and patellofemoral pain, is represented by such images. Additionally, the extent to which performance on the single leg squat test is associated with lower extremity alignment during faster, more demanding tasks has not been determined.

The purpose of this study was to examine the correlation of the FPPA of the knee during single leg squats with hip and knee frontal and transverse plane kinematics. Second, we analyzed to what extent the FPPA of the knee during single leg squats reflects knee and hip kinematics during a single leg landing. We hypothesized that the FPPA during single leg squats would be significantly correlated with TF valgus during single leg squats and landings.

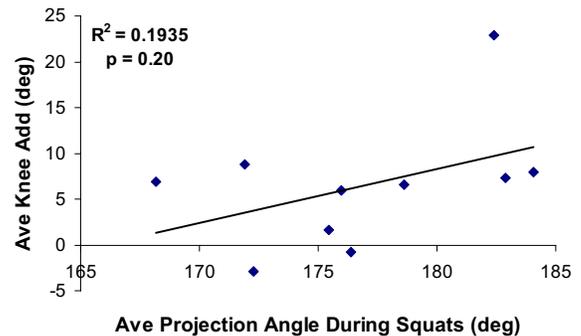

### METHODS

As part of an ongoing study, 10 healthy subjects performed five single leg squats and five single leg landings. All trials were collected for the dominant leg of each subject. Retroreflective markers placed on the lower extremity were tracked by a six camera Vicon motion analysis system collecting at 120 Hz. V3D software was used to determine lower extremity kinematics. Markers placed on the leg of each subject bisecting the frontal plane of the proximal thigh, TF joint, and malleoli at the ankle were used to determine the FPPA of the knee in each digital image (CorelDraw). Subjects performed each single leg squat to a cadence and a self-selected depth. Single leg landings were performed from a height of 23 cm. During each squat trial, a digital image was recorded by a camera placed 2m anterior to the subject, perpendicular to the frontal plane, and at the height of the knee

joint in single leg stance. Each image was recorded as the subject passed 45° knee flexion as determined by an electrogoniometer on the lateral aspect of the leg. To synchronize the digital camera with the motion analysis, a signal was delivered to the motion analysis workstation as the image was recorded. Pearson correlation coefficients were calculated between the FPPA and selected 3D kinematics during single leg stance and landing conditions.

### RESULTS AND DISCUSSION

The FPPA was significantly associated with transverse plane kinematics at the knee (Table 1). 3D TF valgus was weakly associated with the FPPA during single leg squats (Figure 1). During single leg landings, the FPPA was more highly correlated with peak TF internal rotation ( $r = .66, p = 0.04$ ) than peak TF abduction ( $r = .54, p = 0.11$ ). After ten subjects, it appears that interpretation of the FPPA should not neglect the influence of transverse plane motion on this measure. However, we are collecting additional subjects to sufficiently power the study.

**Figure 1: Knee abduction angle determined using rigid body analysis versus the FPPA during single leg squats.**

### CONCLUSIONS

Based on these preliminary data, the FPPA of the knee during single leg squats appears to indicate the degree of TF valgus to a limited extent. A greater correlation between knee transverse plane kinematics and FPPA has been identified. The FPPA during a single leg squat also appears to lend insight into the degree of knee internal rotation during a single leg landing.

## PREDICTION OF HUMAN WALKING BASED ON SIMPLE GAIT DESCRIPTORS

Lei Ren, Richard Jones and David Howard  
Centre for Rehabilitation and Human Performance Research, Salford University,  
Salford, United Kingdom; email: d.howard@salford.ac.uk

### INTRODUCTION

Gait prediction has many potential applications including the investigation of: motor control objectives in gait; the impact of musculoskeletal structure and injury on movement coordination; and the effect of assistive devices on locomotion performance [1]. Dynamic optimisation combined with the forward dynamics method offers a possible solution, however, it leads to very large computational burdens [2]. The inverse dynamics method, with its high computational efficiency, may provide an alternative means of gait prediction [3].

In this study, an inverse dynamics multi-segment model was combined with optimisation techniques to simulate normal human walking in the sagittal plane on level ground. Walking is formulated as an optimal motor task, subject to multiple constraints, with minimisation of mechanical energy consumption being the performance criterion. All segmental motions and ground reactions were predicted from only two simple gait descriptors: walking velocity and cycle period.

### METHODS

The human body is modelled as a dynamic coupled multi-segment system containing seven segments: the right and left thighs, shanks, and feet together with a HAT segment (head, arms and trunk). The segments are connected by frictionless hinge joints, and the model accounts only for segmental motions in the sagittal plane. The foot is modelled as a rigid body with a curved surface rolling on the ground without slipping.

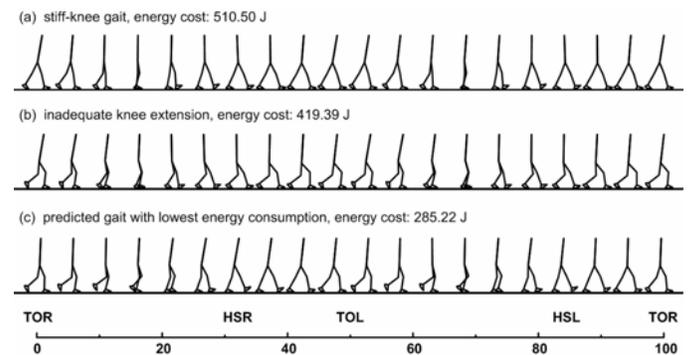

A set of kinematic variables (segmental angles) are used to define the motion of the model. During walking, the motion of the stance ankle can be determined by the shape of the plantar surface of the stance foot and its orientation. Thereafter, the motion of each body segment can be derived based on the topology of the model, the segmental angles and the stance ankle motions.

An inverse dynamics method is employed to calculate the joint kinetics and mechanical energy expenditure during walking. As the ground reactions are initially unknown, the inverse dynamics algorithm is based only on segmental motions [4], where a linear transfer assumption is used to solve the indeterminacy problem during the double support phase [4].

In this study, the gait prediction problem is formulated as an optimisation problem, which can be described as: find segment trajectories that achieve the specified gait parameters, whilst minimizing energy cost, and satisfying the constraints associated with a walking gait. Multiple constraints are implemented in the optimisation, which can be broadly categorized as: task constraints, biomechanical constraints and environmental constraints.

### RESULTS AND DISCUSSION

The optimisation scheme was implemented in the MATLAB (Mathworks, MA, USA) programming environment using the SQP (Sequential Quadratic Programming) optimisation algorithm. The two input gait descriptors (walking velocity and cycle period) were obtained from the gait measurement data of one subject (age: 38years, weight: 101.7kg, height: 178cm), where the averaged values from four repeated normal walking trials were used.

**Figure 1:** Some typical gait patterns (local minima) found during the random optimisation runs. The model (weight, 101.7 kg) walked at 1.50 m/s, with a cycle period of 1.0 s.

To find optimal solutions (local minima), the minimization was repeated with different random initial values. Due to the high non-linearity of human walking, several local minima were obtained (Figure 1). It was found that the solution with the lowest energy consumption (Figure 1(c)) yields the most realistic gait pattern.

Quantitative comparisons of the predicted ground reactions and segmental motions with gait measurements show that the model reproduced the significant characteristics of normal gait in the sagittal plane. The simulation results suggest that minimising energy expenditure is a primary control objective in normal walking. However, there is also some evidence for the existence of multiple concurrent performance objectives.

<sup>5</sup>Hebrew Rehabilitation Center for Aged Research and Training Institute, Boston, MA

### INTRODUCTION

The human balance control system relies, in part, on somatosensory feedback. In older adults, patients with diabetic neuropathy and patients with stroke, diminished somatosensation is associated with increased postural instability during standing and walking. Recently, it has been demonstrated that subsensory mechanical noise can improve somatosensation in healthy young individuals and older adults<sup>1</sup>. Moreover, it has been shown that subsensory mechanical noise applied to the soles of the feet via vibrating insoles can enhance balance control in healthy young<sup>2</sup>, elderly individuals<sup>2</sup>, patients with diabetic neuropathy<sup>3</sup>, and patients with stroke<sup>4</sup>. The goal of this study was to test the hypothesis that the amount of reduction of postural sway during the application of noise to the soles of the feet is directly correlated with the baseline postural sway of the individual.

### METHODS

The postural-sway data of twelve healthy elderly<sup>2</sup> (mean 73 years), 15 subjects with diabetic neuropathy<sup>3</sup> (mean 60 years) and 15 subjects with unilateral stroke<sup>4</sup> (mean 61 years) were pooled from three earlier studies. In each of these studies, subjects stood barefoot with eyes closed on gel-based vibrating insoles that applied subsensory random vibrations to the soles of the feet. With the application of noise, both traditional and random-walk postural sway measures, analyzed from the displacement of a shoulder marker, improved significantly across the groups. These results demonstrated promising improvements in balance control; however, they did not address the contributions that balance impairments have on the level of improvement seen in postural sway during the application of noise. To determine these factors across the three populations, we developed a linear regression model. We compared age, height, sensory threshold, and/or baseline sway of each subject to the difference measure (*difference measure = mean value of control condition - mean value of noise condition*) for each sway parameter of each subject, respectively. We hypothesized that increases in these independent variables would lead to an increase in the difference measure for each sway parameter (indicated by positive coefficient estimates for each sway parameter and  $p < 0.05$ ). With the linear regression model, we also analyzed if interactions were present between stimulation (control vs. noise) and condition (subjects with diabetic neuropathy vs. subjects with stroke vs. elderly) on postural sway.

### RESULTS AND DISCUSSION

As indicated in Table 1, all coefficient estimates for the mean value of baseline sway of each sway parameter versus the difference measure of each sway parameter, respectively, are

Parameters	Estimates	p-value
Mean Radius	0.2 ± 0.1	< 0.0001
Swept Area	0.2 ± 0.1	0.0038
Max Radius	0.3 ± 0.1	< 0.0001
Range AP	0.3 ± 0.1	< 0.0001
Range ML	0.4 ± 0.1	< 0.0001
$\langle \Delta r^2 \rangle_c$	0.1 ± 0.1	0.0339
$D_{rl} (s^{-1})$	0.6 ± 0.1	< 0.0001
$H_{rl}$	0.4 ± 0.1	< 0.0001

**Table 1:** Coefficient estimates of the traditional and random-walk sway parameters from the model of base-line postural sway versus the difference measure for each sway parameter of each subject, respectively.

statistically significant. Coefficient estimates for age, height and sensory threshold for each sway parameter versus the difference measure for each sway parameter, respectively, were not statistically significant; therefore, these independent variables were removed from the model. No interactions were found between stimulation and age in any of the parameters suggesting that there were no differential effects of mechanical noise in the elderly, patients with diabetic neuropathy and patients with stroke.

This study shows that reduction of postural sway during the application of noise to the feet is greater in individuals with larger baseline postural sway.

### CONCLUSIONS

Noise-based devices, such as randomly vibrating shoe insoles, may prove effective in enhancing performance of dynamic balance activities (e.g., walking) in individuals with balance deficits. Moreover, it may be possible to predict the magnitude of the stimulation effect by measuring the baseline performance of the individual.

## GENERALIZED APPROACH TO THREE-DIMENSIONAL MARKER-BASED MOTION ANALYSIS OF BIOMECHANICAL MULTI-SEGMENT SYSTEM

Lei Ren, Richard Jones and David Howard  
Centre for Rehabilitation and Human Performance Research, Salford University,  
Salford, United Kingdom; email: d.howard@salford.ac.uk

### INTRODUCTION

Three-dimensional motion analysis using photogrammetric techniques has been increasingly used in human movement studies recently. Although most 3D applications only focus on specific parts of the body with relatively simple structures (e.g. the lower limbs), real biomechanical systems are more complex as human and animal skeletons are composed of interconnected articulated links with hundreds of degree of freedom (DOF) and complicated topologies; moreover the environmental constraints are various.

This paper presents a methodology for 3D kinematic and kinetic analysis of general multi-body systems using marker-based photogrammetric devices, which can be used for a large range of biomechanical systems, whether human or animal. The proposed methodology is being implemented in a software package, SMAS (Salford Motion Analysis System).

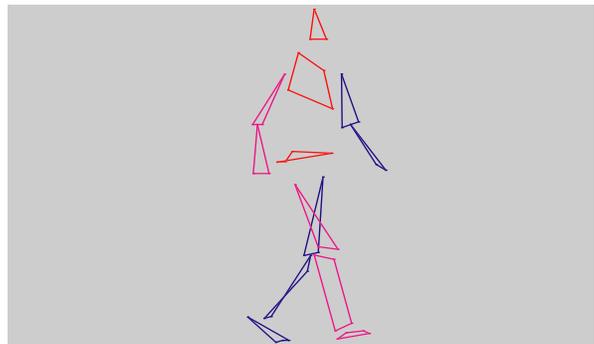

### METHODS

The biomechanical system is modelled as a set of rigid segments, connected by generic joints with up to six independent DOF. Three templates are employed to define the biomechanical system: the body template, marker template and force template. All definitions are generic, so that any biomechanical multi-body system can be described.

The body template represents the topology of the multi-body system, which includes the definitions of body segments, their adjacent segments, and interconnecting joints. The marker template defines two marker sets: technical markers and anatomical landmarks. Technical markers are attached to body segments to record their changing positions and orientations, and are associated with technical frames. Anatomical (or bony) landmarks are used to define bone-embedded local frames for each body segment. The force template describes the properties of the external force systems acting on the biomechanical system. These external forces can be set as known (e.g. measured by force plates) or as unknown.

For kinematic analysis, a least square method [2] is used to estimate the position and orientation of body segments from the technical marker coordinates. The CAST protocol [1] is employed, based on a set of calibration procedures, to establish the mapping between the technical and anatomical frames. The calibration procedure allows for the use of different landmark identification techniques (e.g. markers and/or wands). The joint centers can be identified using functional methods or directly from anatomical landmarks. The anatomical landmarks (derived or real) are then used to define anatomical frames and the orientations of body segments. Thereafter the joint kinematics can be described based on the topology defined in the body template.

For kinetic analysis, the inverse dynamics method is employed. However, this differs from the conventional approach where the calculations proceed sequentially, from distal to proximal segments. In SMAS, the calculation sequence depends on the system topology and the environmental constraints defined in the body and force templates. The algorithm starts from all solvable segments, calculates the forces and moments at their adjacent joints, and then runs iteratively until no solvable segment remains. Different approaches are used to derive joint forces and moments according to the determinacy of the system. In the under-determined case, inverse dynamics is used to derive all the solvable joint forces and moments, whereas, in the determinate case, all joint forces and moments can be calculated. If redundancy exists, a least squares method [3] is employed to improve the accuracy of the calculated joint kinetics.

**Figure 1:** A SMAS 3D model of whole-body walking. The polygons represent the body segments with anatomical landmarks at their vertices.

### RESULTS AND DISCUSSION

The methodology is being implemented as a MATLAB based software package, SMAS, which is now almost complete. Figure 1 shows a 3D whole-body SMAS model. The SMAS methodology applies to general biomechanical multi-segment systems, and makes best use of the available kinematic information. Moreover, unknown external forces and moments can be derived, as well as the internal joint forces and moments.

## HIGH RANGE OF MOTION ACTIVITIES OF DAILY LIVING: DIFFERENCES IN THE KINEMATICS BETWEEN HONG KONG AND CHENNAI, INDIA SUBJECTS

<sup>1</sup>Urs Wyss, <sup>1</sup>Heather Brown, <sup>1</sup>Andrea Hemmerich, <sup>2</sup>Tanya Packer, <sup>1</sup>Stacey Smith  
<sup>1</sup>Queen's University, Kingston, Ontario, Canada; e-mail: [wyss@me.queensu.ca](mailto:wyss@me.queensu.ca)  
<sup>2</sup>Curtin University, Perth, Western Australia

### INTRODUCTION

There are regions in the world where for cultural or religious reasons high range of motion (ROM) activities of daily living (ADL), such as squatting, kneeling and cross-legged sitting are common. When patients in these regions suffer from joint disease, it is more difficult for them to be treated with joint replacements, as not many of the current designs allow for a high ROM. Kinematic and kinetic data is limited (3), which is why it is necessary to study high ROM ADL. It was not known if high ROM activities would be following the same kinematic and kinetic patterns in different regions, which is why data was collected from more than one specific group. This study discusses data from subjects from Hong Kong and Chennai in India, and looks at differences between the two populations.

### METHODS

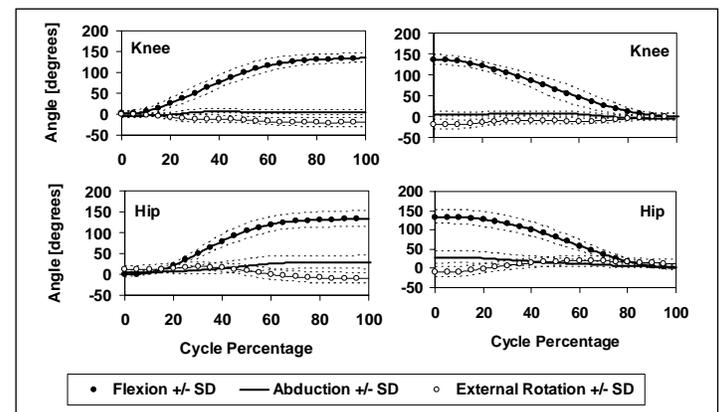

In Hong Kong there were 8 female and 3 male subjects assessed. Their mean age was 50.2 years (SD 7.8), the mean mass was 59.3kg (SD 9.9), and the mean height 158.4cm (SD 10.3). In Chennai there were 10 female and 20 male subjects. Their mean age was 48.1 years (SD 7.6), the mean mass was 57.1kg (SD 10.2), and the mean height 158.6cm (SD 7.3). The kinematics were recorded with a Fastrak system (Polhemus), and the ground reaction forces with a non-magnetic force platform (AMTI). The trials were split into a phase going with gravity into the posture, and against gravity out of the posture. Each phase was then normalized to 100%, so that the data can be compared (1).

### RESULTS AND DISCUSSION

The mean curves with the standard deviations (+/- 1SD) for the hip and knee angles of the squatting with heels down activity, is shown in Figure 1 for the Hong Kong subjects. It shows the flexion/ extension, abduction/ adduction and external-/ internal-rotation curves. The differences between the Hong Kong and Chennai subjects are mainly in the flexion/ extension movement, which is why only those are summarized in Table 1 for other activities. The kneeling data is not added here, since both groups indicated that it is not an activity that they would do frequently. This, of course would be a very important ADL in Muslim populations. The data in Table 1 shows that the Hong Kong subjects had a higher flexion maximum at the hip as compared to the Chennai subjects. There was, however, a large standard deviation, indicating big differences between subjects. It is interesting to see in Table 1 that the larger hip angles in the Hong Kong subjects are compensated somewhat by smaller maximum knee angles. Furthermore, the standard deviations at the knee of the Chennai subjects are smaller than for the hip angles, indicating much less variation between subjects.

### CONCLUSIONS

The kinematics of how the subjects in Hong Kong perform high ROM ADL are different from subjects in Chennai, India. Some of these differences are over 30 degrees. The Hong Kong subjects use less knee flexion, but more hip flexion. Reviewing the position of the sacral marker showed that the compensation of the lower hip angles is mostly taking place in the lower region of the back (2). It is important to be aware of the differences how high ROM ADL are performed in populations with different cultural and religious backgrounds when artificial joints are developed for these persons, so that the technical ROM of the implant is sufficiently large.

**Figure 1:** Hip and knee rotations for squatting heels down of Hong Kong subjects.

**Table 1:** Maximum hip and knee flexion angles for three ADL of the Hong Kong and Chennai subjects.

	Maximum Hip Flexion [degrees]		Maximum Knee Flexion [degrees]	
	Hong Kong	Chennai	Hong Kong	Chennai
Squatting Heels Down	133 (21)	95 (26)	135 (20)	152 (11)
Squatting Heels Up	108 (22)	91 (17)	142 (15)	155 (7)
Sitting Cross-Legged	128 (29)	85 (34)	126 (32)	149 (8)

## ONE-FOOT VERTICAL JUMP WITH APPROACH IN UNILATERAL TRANSTIBIAL AMPUTEES

Siobhan Strike and Matthew Taylor

School of Human and Life Sciences, Roehampton University, London, SW15 4JD, UK

Email: s.strike@roehampton.ac.uk

### INTRODUCTION

Jumping is a key skill in many team sports and sporting situations, for example a jump shot in basketball, a block in volleyball, an interception in netball or basketball and a jump in football are all common maneuvers in sport and recreation. While many types of jump (countermovement, approach, static etc) have been researched in some way for non-disabled performers [1,2] there is little evidence of research into the mechanisms, compensations and alterations made by disabled performers in similar situations. An understanding of the biomechanics of amputee jumping and the identification of the compensatory mechanisms employed by amputees to achieve controlled flight is justified.

The aim of the study was to assess the biomechanical technique used by transtibial amputees to reach maximum flight height in a 1-footed vertical jump with an approach from the sound and prosthetic sides. Through this assessment, alterations to jump biomechanics could be identified and compensatory mechanisms detailed.

### METHODS

Three male transtibial amputees were asked to perform maximal one-legged vertical jump with approach from their right and left limbs. Of the three, only two were comfortable completing the task and achieving height from the prosthetic side. One participant withdrew from the research. Both remaining participants were traumatic left-sided amputees and were healthy and active and free of musculoskeletal injuries. Participant one (P-1) had a mass of 69kg and height of 1.78m. The amputation had taken place 8 years prior to testing. Participant two (P-2) had a mass of 81kg and height of 1.77m. The amputation had taken place 12 years to testing. For the motion capture, a seven camera VICON 512 retro-reflective motion analysis system was used. The cameras were operating at a frequency of 120Hz. Thirty-three retro-reflective markers were placed with tape on the head, trunk, arms and legs. One-foot vertical jumps with an approach were analysed. The participants took a 2-3 step approach followed by a take off from the sound limb or the prosthetic limb. The instruction to the participants was simply to jump as high as possible.

Both participants warmed up for about ten minutes prior to data collection and they were allowed sufficient time to practice the jumps. At least 3 practice attempts were taken. Each participant then performed three jumps of each type and the best jump, defined by maximum height of the Centre of Mass (CoM) was selected for further analysis.

### RESULTS AND DISCUSSION

Outcome results for the subjects are presented in Table 1.

*Table 1 Outcome results for jump with approach*

	Participant 1			Participant 2		
	Sound	Pros	Diff	Sound	Pros	Diff
Max Height of CoM (m)	1.39	1.26	0.13	1.32	1.20	0.12
Flight Height of CoM (m)	0.19	0.10	0.17	0.17	0.15	0.02
Height of CoM @ TO (m)	1.20	1.16	0.04	1.15	1.05	0.1
Vv of CoM @ TO (m/s)	2.0	1.36	0.64	1.80	1.52	0.28
Min Height of CoM (m)	0.81	0.98	0.17	0.75	0.89	0.14
Last step length (cm)	31	14	17	61	47	14
Vy of CoM at end of approach (m/s)	0.51	0.20	0.31	1.13	0.80	0.33

For both participants the maximum height achieved was reduced on the prosthetic side compared to the sound side. For P-1 the flight height from the prosthetic limb was substantially lower than that from the sound limb, while for P-2 the flight height was similar from both. This is due to the varied joint angles at take-off.

A key aspect in a jump with an approach is the approach itself. The length of the last step prior to the jump was asymmetrical for both participants and P-2 took a longer step than P-1 on both sides. For both participants the step was longer from the prosthesis onto the sound limb. The horizontal velocity is lower in both cases for P-1 than for P-2. This indicates that P-2 has greater horizontal momentum as he begins the jumping action. However, as P-2 does not jump as high as P-1 it is probable that he cannot make full use of this momentum.

Table 2 Temporal characteristics associated with the approach and take-off phases of the jump

	Participant 1		Participant 2	
	Sound	Pros	Sound	Pros
Final approach (s)	0.57	0.72	0.44	0.40
Countermovement (s)	0.89	0.37	0.89	0.56
Push-off (s)	0.3	0.23	0.48	0.2

The timing of the phases for the jump was asymmetrical for both participants and different between the amputees. For both amputees the jump on the sound side took longer than on the prosthetic side, mainly due to the extended countermovement and push-off phases.

## PARASPINAL REFLEX BEHAVIOR AS A FUNCTION OF TRUNK POSTURE

Ellen Rogers,<sup>1</sup> Kevin Granata

Musculoskeletal Biomechanics Laboratory, Virginia Polytechnic Institute, Blacksburg, VA, USA

<sup>1</sup>E-mail: Granata@vt.edu

### INTRODUCTION

Prolonged use of flexed postures during manual materials handling is associated with high incidence rates of low back pain (LBP). Spinal instability has recently been considered a potential risk factor for LBP. Previous work indicates that spinal stability is influenced by posture. The ability to accurately assess and reposition the lumbar spine has been shown to decrease with trunk flexion angle<sup>1</sup>. The ability to sense and control spinal curvature is important to spinal stability. Total stability in flexed postures must take into account changes in neuromuscular control, these being important factors in preventing injury during unexpected loading. However, spinal reflex response has not been measured as a function of posture.

Position-dependent reflex behavior has been exhibited in the elbow and the ankle, but not in the trunk. Reflex behavior may depend on anatomical architecture and mechanical advantage of the joint as well as differences in tonic firing rates associated with changes in muscle length. Evidence suggests that a fully flexed spine results in a reduced moment arm for the trunk extensor muscles and load redistribution to passive tissues and deeper spinal muscles. We hypothesize that trunk flexion will reduce paraspinal reflex behavior. The specific aim of this project was to evaluate trunk reflex behavior using data recorded in various trunk flexion angles.

### METHODS

Paraspinal reflexes were assessed at four trunk angles (0°, 30°, 60°, and 90°) on twenty-six subjects with no history of low back pain. Subjects were attached to a servomotor via a harness and cable system such that anteriorly directed horizontal loads were applied at the T10 level of the trunk. The servomotor applied a constant isotonic preload. The subject maintained an unsupported upright trunk posture throughout the experiment with their pelvis restrained; trunk angle was achieved via an apparatus that rotated the lower body to the desired angle in order to reduce confounding factors due to changes in spinal load in flexed postures. Each trunk angle was maintained for approximately 3 minutes, to limit exposure to ligament strain. Superimposed on the preload were force perturbations of  $\pm 70$  N applied in a pseudo-random stochastic fashion with a flat bandwidth from 0-50 Hz. Lumbar paraspinal EMG were measured throughout the trial.

To quantify paraspinal reflex dynamics, the EMG response to a force perturbation was modeled as the closed loop transfer function of the system. Reflex gain was identified as the peak value of the impulse response function relating input force to EMG response using time-domain deconvolution analyses<sup>2</sup>.

### RESULTS AND DISCUSSION

Reflex gain decreased significantly ( $p < 0.0003$ ) with trunk angle. From upright posture (0° trunk angle)  $G_R$  decreased 13.4% at 30° ( $p = 0.36$ ), 24.2% at 60° ( $p < 0.02$ ), and 29.9% at 90° ( $p < 0.05$ ). A significant gender-by-trunk angle interaction indicates possible gender differences in position-dependent reflex behavior. From upright females exhibited a 24.7% reduction in  $G_R$  at 60° ( $p < 0.02$ ) and a 31.7% reduction in  $G_R$  at 90° ( $p < 0.0003$ ). However in male subjects there was no significant change in  $G_R$  due to trunk flexion (Figure 1).

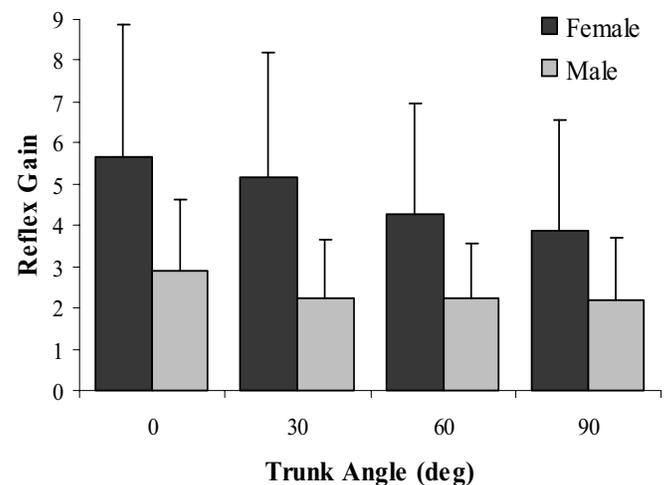

Figure 1. Reflex gain decreased significantly ( $p < 0.0003$ ) with trunk angle.

It has previously been demonstrated that paraspinal reflex gain is altered following prolonged static and cyclic flexion<sup>3</sup>. It is interesting that brief periods of trunk flexion caused an inhibition of reflexes similar to the effects of prolonged flexion. Baseline EMG was also found to decrease with trunk flexion. In response to a perturbation muscles are therefore less excitable and produce a smaller reflex gain.

### CONCLUSIONS

Reduced reflex response in flexed postures, even brief periods, can contribute to reduced stability, making unexpected loading events particularly risky. Prolonged flexed posture work is a known risk factor for LBP; possibly even brief flexed postures should be considered a risk factor.

## TRAINING AND PERFORMANCE OF ROBOTIC LAPAROSCOPY: ELECTROMYOGRAPHIC ANALYSIS TO QUANTIFY THE EXTENT OF PROFICIENCY

<sup>1</sup>Kenji Narazaki, <sup>2</sup>Dmitry Oleynikov, <sup>2</sup>Jesse J. Pandorf and <sup>1</sup>Nicholas Stergiou

<sup>1</sup> University of Nebraska at Omaha, Omaha, NE; <sup>2</sup> University of Nebraska Medical Center, Omaha, NE  
email: [knarazaki@mail.unomaha.edu](mailto:knarazaki@mail.unomaha.edu), web: <http://www.unocoe.unomaha.edu/hper/bio/home.htm>

### INTRODUCTION

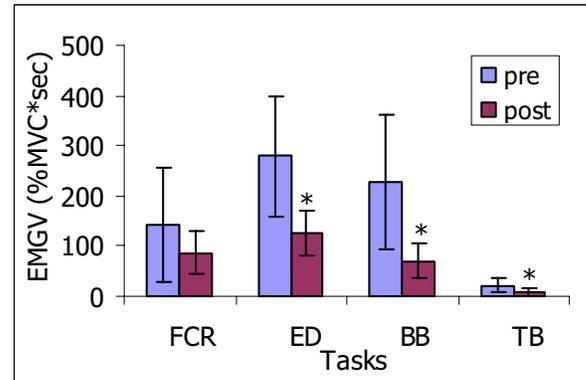

In recent years robot-assisted laparoscopy has been developed as a novel surgical procedure [1]. Although this technology promises ease of use and mechanical precision, little has been known about the learning strategies of this new technique [2, 4]. Evaluation of surgical performance and skill acquisition during training are limited in measuring only task completion time and number of errors occurred or a subjective evaluation by an expert [3]. To our knowledge, no studies have examined physiological measures (i.e. electromyography profiles) of the surgeons during performance of robotic surgical techniques. The purpose of this study was to assess changes in robot-based surgical performance through a designed training protocol using electromyography (EMG) in order to identify objective variables for the quantification of learning and dexterity.

### METHODS

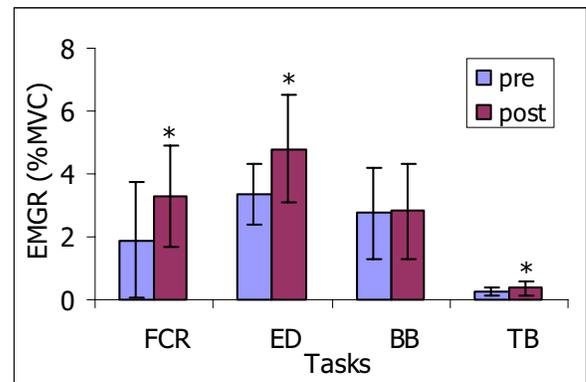

Seven right-handed medical students, novice users of the da Vinci<sup>®</sup> robotic surgical system, practiced three inanimate surgical tasks, bimanual carrying (BC), needle passing (NP) and suture tying (ST), with the robotic system for a total of six training sessions during a three weeks period. Before and after the training protocol, performance tests were conducted for all the tasks and muscular activation was monitored from the subject's right arm and forearm using a surface EMG system (DelSys; 1000 Hz). The muscles examined were: flexor carpi radialis (FCR), extensor digitorum (ED), biceps brachii (BB), and triceps brachii (TB). The relative EMG data, percent of raw EMG data relative to maximal EMG output (MVC), for each muscle and for each task were integrated for the entire task completion time (T) to obtain the total volume of muscular activation (EMGV). Moreover, the rate of muscular activation (EMGR) was calculated by dividing the EMGV by T. Mean values of the EMGV and EMGR were compared pre- and post-training using dependent *t*-tests ( $\alpha=0.05$ ).

### RESULTS AND DISCUSSION

The results revealed significant reductions in EMGV for all muscles in all three tasks; except for the FCR muscle in the BC and ST tasks (Figure 1). However, reductions in EMGV were observed even for the FCR (Figure 1). The relative decreases in EMGV between pre- and post-training testing ranged from 33.2% to 68.6%. These results indicated that less motor units were recruited to perform the same tasks after training which can probably result in decreased fatigue. Significant increases in the EMGR were found for the FCR and TB muscles in all three tasks and for the ED muscle in the ST task (Figure 2). The relative increases in the EMGR in the muscles examined ranged from 30.3% to 84.5%. The EMGR results indicated improvements in the way that motor units are recruited and probably superior efficiency.

**Figure 1:** The total volume of muscular activation in the suture tying task (\* $p \leq 0.05$ ).

**Figure 2:** The rate of muscular activation in the suture tying task (\* $p \leq 0.05$ ).

This study objectively demonstrated changes in robotic surgical performance in novice users through a designed training protocol using EMG profiles. The variables examined showed great promise as indicators of learning and dexterity for practical surgical tasks. Future studies will further validate these findings, as well as, incorporate the variables identified to establish valid criteria for the development of integrative surgical systems and virtual training tools.

## DEVELOPMENT OF THE PORTABLE POSTURE TRAINING DEVICE

Wen-Chieh Yang, Wei-Hsun Huang, Chih-Han Chang, Kao-Chi Chung  
 Institute of Biomedical Engineering, National Cheng Kung University, Tainan, Taiwan  
 E-mail: [cchang@mail.bme.ncku.edu.tw](mailto:cchang@mail.bme.ncku.edu.tw)

### INTRODUCTION

Clinically, an orthosis could be used to support and correct the spine mechanically when moderate abnormal curvature of the spine is detected. The conventional spinal orthoses have been confirmed to be effective in altering the natural history of adolescent idiopathic scoliosis (AIS) [1]. However, employing the orthosis requires the constant corporation from the patient and wearing the orthosis too long might induce muscle atrophy or motion incoordination by this passive correction approach [2].

The aim of this study was to develop a portable posture training system by applying an audio-feedback signal to promote the active correction of the abnormal posture from subject's muscle force [3] and to prevent continue deteriorated. This system could be used to detect a pre-set angle limitation of a joint and remind the patient adjusting to a suitable posture by audio warning when this angle limitation is violated.

### METHODS

In order to achieve the portable objective, this posture training system needs to be light weight and low-power consumption. Therefore, the designed system consisted only two components: a flexible bend sensors (FSR, FLX-01 and Images SI Inc, Figure 1) and a self-developed data logger. The bend sensor, stick on the skin by the sport tape, is used to monitor the rotation (bending) on the joint thus detecting the patient posture on his/her activities of daily living. The design chart of the data logger is shown in Figure 2. This data logger used MSP430F169 microprocessor (Texas Instruments) as the MCU which incorporated the A/D function.

In order to prevent constantly calibration and degeneration of the bend sensor, a setting button was built within the data logger. By pressing this setting button, current bend angle of the bend sensor would be recorded into the data logger and used as a pre-set angle limitation of the joint.

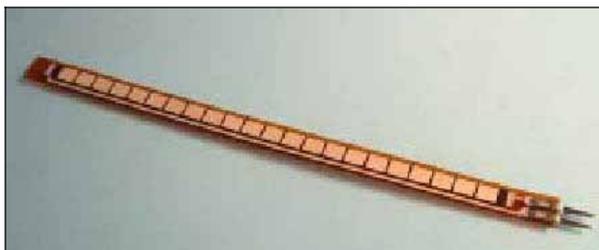

Figure1: Bend sensor

### RESULTS AND DISCUSSION

Figure 3 shown the final layout of the data logger circuit board. The weight of this data logger is less than 120g (including the box) and with two mercury batteries this system

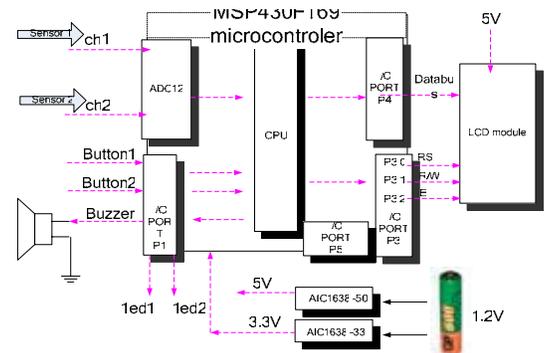

Figure 2: The Data logger design chart

could operate up to 400 hours. To use this system after the bend sensor was stick on the target joint, the user needs to posture the joint at the limitation of the correct angle and press the setting button. If later, the angle of the target joint is larger or smaller (depends on the setting) than this angle limitation, system would provide with an alarm sound. The device provided two modes for alarming: the static mode, if the angle violate the limitation for more than 10 second; the alarm sound will be sent out. The second mode, the dynamic mode, would send out the alarming once the violation of the angle is detected. The current angle sampling setting of this system is set as 10 HZ, and theoretically, with 12 bits of A/D converting, the resolution of this system could up to 2 degree.

Figure 3: The circuit board of the data logger

### CONCLUSIONS

A portable posture training system was developed with simple component design and easy to use. Clinical trails of this system are currently being evaluated.

## Modeling of solute Transport in cartilage under static and dynamic loading

Le Zhang and Andras Z. Szeri  
University of Delaware

email: [lzhang@me.udel.edu](mailto:lzhang@me.udel.edu), web: [www.me.udel.edu](http://www.me.udel.edu)

### INTRODUCTION

Articular cartilage consists mostly of chondrocytes and an extracellular matrix, the latter being composed of water, collagen fibers and proteoglycan. Since adult cartilage is avascular, the only way chondrocytes receive nutrient and get rid of waste is by diffusive/convective transport across the articular surface. During its daily routine, cartilage is subjected to a wide range of static and dynamic loading. Osteoarthritis is characterized by a deterioration of cartilage: it is believed that type and intensity of the mechanical loading play a major role in regulating transport activity and, therefore, degeneration. Previous theoretical studies of solute transport in cartilage assumed constant diffusion coefficient; in the present work we relax this assumption.

In this study, a mixture theory based, three dimensional formulation of neutral solute transport in soft tissue is presented [1]. By using Cohen-Turnbull-Yasuda's tortuosity model [2], the diffusion coefficient is made to depend on local deformation. Employing this model, we then study the effects matrix structure, solute size, and the type and intensity of mechanical loading have on the solute transport in soft tissue.

### METHODS

We model the tissue as a three phase mixture, consisting of an interstitial fluid, a hyperelastic solid matrix, and a neutral solute. The governing equations for neutral solute transport in cartilage are derived from the conservation of linear momentum, mass of each phase and the mixture. The conservation equations are complemented with the various constitutive equations.

Under appropriate circumstances, the governing equations reduce to the classical convection/diffusion equation and the equations of the biphasic cartilage model. The 3-D formulation is then implemented in the finite element code ABAQUS, following Ferguson[3]. Since convective diffusion is analogous to convection/diffusion of heat, the third equation in the formulation is solved by thermal analogy procedure in ABAQUS.

### RESULTS AND DISCUSSION

We validate our model for diffusion of solute in cartilage with Quinn's experimental data[4], as shown in Figure1. Curves represent our model, and symbols represent the experimental data. Quinn's experiments were performed on solute transport in cartilage under unconfined compression.

Confined compression tests are selected to show the application of our theoretical model (Figure2). 400Da and 400kDa dextran transport are investigated. Solute diffuses from the surface into the deep layer of the tissue. Figure2

shows concentration distribution of the solute in the cartilage (through the depth) after 1h diffusion into the tissue under 0%,10% and 20% static compression.

The Y coordinate represents the normalized reduction of concentration when the compression of the tissue varies from 0% to 10% or 20% of its intact thickness. For both solutes, the static loading inhibits their diffusion. 400kDa diffusion shows a higher reduction with increasing loading.

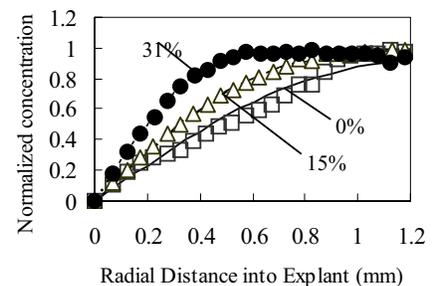

Figure 1. Concentration distribution of 40kDa under static loading (0%, 15%, 30% compressive strain)

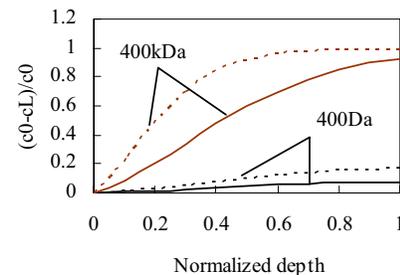

Figure 2: Concentration distribution, static loading :  
- 10%compressive strain---20%compressive strain

### CONCLUSIONS

We propose a three phase mixture model on a 3-D finite element platform to predict the diffusive and convective transport of different size solute in cartilage under different mechanical loading.

## RIB CAGE MOTION PATTERNS IN SWIMMERS DURING RESPIRATORY MANEUVERS

Karine Jacon Sarro, Amanda Piaia Silvatti, Angélica Lodovico Pachêco, Carla Maia Aguiar Loula,  
Ricardo Machado Leite de Barros

Laboratório de Instrumentação para Biomecânica – Faculdade de Educação Física, Universidade Estadual de Campinas,  
Campinas (SP), Brazil; e-mail: [ksarro@fef.unicamp.br](mailto:ksarro@fef.unicamp.br)

### INTRODUCTION

Breathing is a dynamic act in which the coordinate motion of the rib cage increases and decreases its volume. Studies show that lung volumes [1] and respiratory motion patterns [2] can be changed by the practice of exercises and respiratory techniques. This work aims to verify if the rib cage motion patterns are altered in swimmers during respiratory maneuvers.

### METHODS

The methodology is based on the kinematical analyses of 38 markers attached to the volunteer's trunk representing the rib cage (figure 1) using the DVideo system [3]. A group of 11 male swimmers (SG) was compared to a control group (CG) of 9 non-athletes volunteers during tidal volume (TV) and vital capacity (VC) maneuvers in sitting position. The rotation angles among the coordinate system associated to each pair of ribs and the coordinate system associated to the trunk were calculated in function of time (figure 2). The curves of rotation angle around the quasi-transverse axis were correlated. All combinations of two curves from the 2<sup>nd</sup> to the 10<sup>th</sup> ribs were tested. Considering that the correlation coefficient did not present a normal distribution, a transformation was applied according to Fisher (z-transformed correlation coefficient). In order to verify the statistical difference between groups t-tests ( $p < 0.05$ ) were performed.

### RESULTS AND DISCUSSION

No significant differences were found between the two experimental groups during TV breathings. The figure 3 shows the distribution of the transformed correlation during VC maneuvers using a Box-plot representation. Significant higher values were found in the SG correlating the ribs (2,3,4,6,7,8,9) to the 10<sup>th</sup> and correlating the 2<sup>nd</sup> with the 9<sup>th</sup> rib. It can be seen that the distribution of z-correlation coefficient of the 2<sup>nd</sup> with the 10<sup>th</sup> ribs presents significantly higher median values and reduced dispersion in SG. It is also remarkable that the median values of the z-correlation decrease with the increment of the distance between the two ribs considered. The 9<sup>th</sup> and 10<sup>th</sup> ribs are important as region of apposition between diaphragm and rib cage. The higher correlation values in SG suggest an optimized pattern and reinforce the idea that practicing swimming can promote positive changes in the respiratory pattern.

### CONCLUSIONS

The results obtained suggest that swimming practice lead to the formation of optimized breathing pattern when larger efforts are required from the respiratory system. This study also showed the viability of using the 3-D kinematical analysis to evaluate respiratory motion patterns.

## ALTERED ANKLE JOINT POSITIONING DURING JUMP LANDING IN SUBJECTS WITH FUNCTIONAL ANKLE INSTABILITY (FAI)

<sup>1</sup>Eamonn Delahunt, <sup>1</sup>Kenneth Monaghan, <sup>1</sup>Brian Caulfield  
<sup>1</sup>University College Dublin School of Physiotherapy, Republic of Ireland  
[eamonn.delahunt@ucd.ie](mailto:eamonn.delahunt@ucd.ie)

### INTRODUCTION

FAI, a subjective feeling of ankle instability or, recurrent symptomatic ankle sprains (or both), has been reported to be the most common and serious residual disability following ankle sprains. Single leg landings from a jump are one of the frequent mechanisms of injury to the lateral ligament complex of the ankle joint. To date, there have been no thorough investigations into the kinetic and 3D kinematic patterns of subjects with FAI during jump landing. The purpose of this study was to undertake a comprehensive analysis, of the kinetic and 3D kinematic patterns associated with jumping landing in a group of subjects with FAI, with the aim of determining whether changes in the neural control of movement and dynamic stability of the ankle joint exist in these subjects.

### METHODS

Eleven subjects with unilateral FAI (8male, 3 female) and 13 control subjects (5 male, 8 female) volunteered to participate. Inclusion criteria in the FAI group were based on the criteria used by Caulfield and Garrett [1].

CODA mpx 30 infrared light emitting diodes were attached to the involved lower extremity in the FAI group and the left lower extremity in the control group and were used to provide information pertaining to 3D segment angular displacement and angular velocity. Ground reaction force was measured by a Bertec force-plate. Subjects stood 1m in front of a force-plate with the test leg relaxed and non-weight bearing. The subject then used the contralateral leg to propel him/herself from the start position to land on the test leg on the centre of the force-plate. A jump was deemed unusable if the subject required any form of correction following landing such as touching the floor with the non-test limb or correcting their position on the force-plate. Each subject performed 10 single leg jumps onto the force plate.

Average values for hip, knee and ankle joint 3D angular displacements and velocities were calculated for each subject. Group mean time averaged profiles (500ms pre initial contact (IC) – 500ms post initial contact) were calculated. Differences in FAI and control group time averaged profiles were tested for statistical significance using independent two-sided t-tests. Magnitudes and timing of peak medial/lateral, anterior/posterior and vertical forces were identified for each jump and individual and group mean profiles subsequently calculated. One-way ANOVA was used to test for significant differences in timing and magnitude of peak forces. Furthermore, magnitudes of medial/lateral, anterior/posterior and vertical components of GRF were averaged over time following initial contact for each

subject and group mean profiles were calculated. Differences in FAI and control group time averaged profiles were tested for statistical significance using independent two-sided t-tests. The level of significance was set at  $p < 0.05$  for all analyses.

### RESULTS AND DISCUSSION

FAI subjects exhibited a significant increase in ankle joint supination during the period 70ms pre IC to 30ms post IC ( $p < 0.05$ ). They also exhibited a significant increase in knee joint flexion from the time period 95ms pre IC to 5ms post IC ( $p < 0.05$ ). No statistically significant differences were noted for angular velocities during these times ( $P > 0.05$ ). No statistically significant differences in the timing, magnitude or time averaged profiles for any of the components of GRF were noted post IC ( $P > 0.05$ ).

Prior to IC with the ground, the process of neuromuscular preparation for the subsequent ground contact is essential to the stability of the ankle joint [2]. Inappropriate positioning of the ankle joint prior to IC could increase the potential for injury. Following IC, the line of action of the GRF is dependent upon the position of the foot in relation to the centre of gravity and inertia [2]. If the ankle joint is held in a more supinated position when IC occurs, an external inversion load is placed upon the ankle joint, thus increasing the potential for a hyperinversion injury. If the evtor musculature of the ankle joint cannot counteract this external inversion load or if a poorly executed landing occurs, hyperinversion and subsequent injury to the lateral ligament complex of the ankle joint is likely to occur.

### CONCLUSION

The disordered positioning of the ankle joint observed in subjects with FAI is likely to result in repeated injury to the chronically unstable ankle, due to the potentially injurious external inversion load created by an excessive supinated position of the ankle joint upon IC.

## MAINTENANCE OF GAIT STABILITY IN CONCUSSED COLLEGE PATIENTS DURING DUAL TASKS

Robert D. Catena, Paul van Donkelaar, Tonya M. Parker, Louis R. Osternig, Li-Shan Chou  
Motion Analysis Laboratory, Department of Human Physiology, University of Oregon  
Eugene, OR; contact: [chou@uoregon.edu](mailto:chou@uoregon.edu)

### INTRODUCTION

According to Kahnemñ's [2] model of information processing, processing capacity in humans is limited. When two tasks are presented to an individual, the desired outcome(s) will occur so long as the capacity of the system has not been exceeded. Once the capacity has been reached, there will be a decline in performance in one or all tasks. It has been estimated that, between the ages of 15-24 years, 133 people out of 100,000 will receive a traumatic brain injury (TBI) each year [3]. This accounts for 31.7% of all concussions. The maintenance of dynamic stability while perturbed by different secondary tasks is crucial day by day. Motor perturbations have been previously described to have significant detrimental effects on a TBI population [1]. To date, there have been no studies measuring a simple reaction time, a cognitive, and a motor dual-task with level walking, specifically in a concussed population. Our study looked to determine how different secondary tasks affect dynamic stability of patients with concussion and how balance is maintained during each task.

### METHODS

Subjects (Conc),  $n=11$ , were identified as suffering a grade II concussion within 48 hours of collection. Controls (Norm),  $n=8$ , were matched by gender, age, and stature. The whole body motion data were collected with an 8camera motion analysis system (Motion Analysis Corp., Santa Rosa, CA) during gait. Twenty-nine reflective markers were placed on bony landmarks. A thirteen-link model was created, each with the segmental center of mass (CoM) defined according to Winter [4]. The whole-body CoM was calculated using the weighted sum of each segment [1]. Center of pressure (CoP) location was found with two force plates (AMTI, Watertown, MA). The collection was divided into three parts. The single task session (level) was walking without a concurrent task. The first dual task session (OB) required crossing an obstacle at 10% of body height midway down the walkway. The second dual task session (COG) added in a cognitive task (e.g. backward digit span, spelling backwards) to level walking. Then the 3rd dual task session added a simple reaction time test (RT on) that was imposed with random catch trials (RT off) while walking. During RT trials, the subject responds to an audio perturbation by pressing a button on a wireless remote.

Gait temporal-distance parameters as well as the maximum CoM-CoP separation distances and the time-corresponding CoM linear velocities in the anterior-posterior (A/P) and medio-lateral (M/L) directions were examined [1]. 2x5 ANOVA's with repeated measures were used to assess the differences between tasks and groups. If there was a significant difference ( $p<.05$ ), a post-hoc pairwise comparison was completed to find between which specific tasks there was significance.

### RESULTS AND DISCUSSION

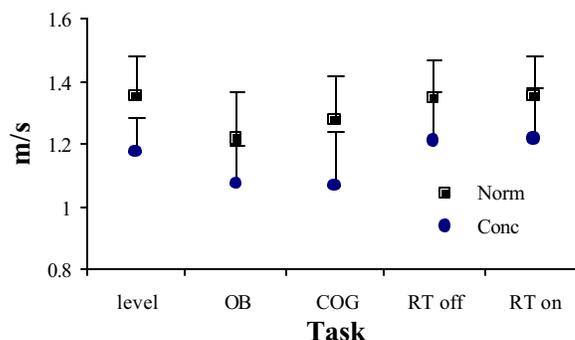

Figure 1. Average Gait Velocity in each task

Significant task effects between OB and level ( $p<.001$ ) and COG and level ( $p=.016$ ) were seen in gait velocity (Figure 1). A significant group effect was also seen ( $p=.018$ ). Norms showed task effects only between OB and level walking for A/P CoM-CoP maximum separation ( $p=.029$ ), and CoM velocity at A/P max separation ( $p=.015$ ). Concs showed significant effects between OB and level walking for A/P range of motion (RoM) ( $p=.001$ ), M/L RoM ( $p=.023$ ), A/P CoM-CoP max separation ( $p<.001$ ), and CoM velocity at A/P max separation ( $p<.001$ ). Concs also showed significant effects between COG and level walking for CoM velocity at A/P CoM-CoP max separation ( $p=.045$ ). Even more interesting is that there seem to be differences in Concs between COG and OB for some gait stability parameters. A/P CoM-CoP max separation ( $p=.002$ ) and velocity at M/L CoM-CoP max separation ( $p=.025$ ) are both greater in the OB task.

### CONCLUSIONS

Our study shows that a concussion has effects on normal gait regardless of single or dual tasks. Within both groups, only the more difficult tasks have shown to perturb gait stability, leading us to believe there is an attentional deficit in concussed patients. There also seems to be different compensatory actions taken by the individuals with a concussion to overcome these attentional deficits when faced with different types of dual-task situations.

## THE INFLUENCE OF SUBJECT CHARACTERISTICS AND JOINT KINEMATICS ON FUNCTION AND QUALITY OF LIFE IN PATIENTS WITH OSTEOARTHRITIS PRIOR TO TOTAL KNEE REPLACEMENT

<sup>1</sup> Marietta van der Linden, <sup>1</sup> Phil Rowe, <sup>2</sup> Paul Gaston <sup>2</sup> Richard Nutton  
<sup>1</sup> Queen Margaret University College <sup>2</sup> Royal Infirmary Edinburgh  
 email: mvanderlinden@qmuc.ac.uk

### INTRODUCTION

Osteoarthritis (OA) is associated with increased age, with pain and with functional limitation in joints. The rising proportion of elderly in our society means that optimal management of pain and functional loss in OA is of increasing importance. In this study the role of pre-operative patient characteristics such as passive knee flexion and muscle strength on knee motion during functional activities and common outcome measures of function were explored. Secondly, relationships between functional knee motion and quality of life measures and daily activity were investigated.

### METHODS

Thirty patients with osteoarthritis were assessed an average of 6 weeks before surgery. Fourty age-matched controls were also included in this study. Knee angle was measured using an electrogoniometer during level, stair and slope walking, getting in and out of a chair and getting in and out of a bath. Maximum passive knee flexion was measured in sitting with a manual goniometer. Muscle strength was measured using the MIE Myometer [1] and was normalized for body mass. Other outcome measures included the American Knee Society Score (AKS), the Western Ontario & McMaster University Osteoarthritis Index (WOMAC) and a quality of life questionnaire, the SF36. The patient's daily physical activity was recorded using an activity monitor (ActivPAL [2]). This monitor records the time spent lying/sitting, standing and stepping. In addition it will display the number of steps made.

### RESULTS AND DISCUSSION

Table 1 summarizes the most important patient characteristics. Except age and the SF36 mental score, all characteristics were significantly different between the most affected leg of the patients and the age matched controls ( $p < 0.01$ ). Knee flexion during all functional activities was significantly less ( $p < 0.01$ ) in the patient group. Further, the affected leg of the patients showed significantly less knee flexion than their contralateral leg in all functional activities except sitting and had significantly weaker knee extensor and flexor strength ( $p < 0.01$ ). Knee flexion strength of the affected leg was relatively less reduced (42%) compared the normal group than knee extensor

strength (52%) which corresponds to the findings by Hortobagyi [3].

Passive flexion correlated weakly to moderately ( $r = 0.41$  to  $0.55$ ) with the knee angle during most functional activities except sitting down and getting up from a chair and walking on a flat surface. A total score derived from the knee angle during the functional activities was moderately associated with the functional components of the AKS and the WOMAC ( $r = 0.56$  and  $r = -0.49$  respectively) but less with the SF36 ( $r = 0.44$  and  $r = 0.33$  for the Mental and Physical score respectively). Knee extensor and flexor strength were associated with WOMAC function ( $r = -0.51$  and  $r = -0.54$  respectively) but not or weakly with the AKS function ( $r = 0.14$  and  $r = 0.32$  respectively)

The daily amount of steps as measured by the ActivPAL was only associated with age ( $r = -0.51$ ) in the patient group. None of the measured characteristics in the control group showed correlations coefficients higher than 0.34 with any of the outcome measures of the ActivPAL. Interestingly, the mental component of the SF36 was more strongly associated with the function score of the WOMAC ( $r = -0.75$ ) than the physical component of the SF36 ( $r = -0.45$ ).

### CONCLUSIONS

This study shows that a score derived from the knee motion during functional tasks as measured by an electrogoniometer is associated with traditional outcome measures of function such as the WOMAC and the AKS. However, this score derived from electrogoniometry is more objective and sensitive than the traditional questionnaire based outcome measures of function and may therefore be more appropriate for the assessment of outcome after knee replacement surgery.

## THE FINITE ELEMENT ANALYSIS OF INTERFACE STRESSES BETWEEN THE FOOT AND ANKLE-FOOT ORTHOSES

Wei-Ching Hung, Chih-Han Chang and Chu-Lung Wu  
Institute of Biomedical Engineering National Cheng Kung University  
e-mail: [danaia826@yahoo.com.tw](mailto:danaia826@yahoo.com.tw), web: [www.bme.ncku.edu.tw](http://www.bme.ncku.edu.tw)

### INTRODUCTION

Ankle-foot orthosis (AFO) is often used to correct abnormal gait and maintain ankle and foot in neutral position during ambulation. Unsuitable prescription of AFO would cause the increasing of plantar pressure and even ulceration [1]. Currently, the design of AFO still relies on the orthotist's experience and subjective judgments. This often induced a costly "trail and error" approach to obtain an acceptable AFO. There are some studies to discuss the mechanical behavior in different types of the AFO. But interface stresses between foot and orthoses is seldom discussed especially the shear stresses [2]. The objective of this study was to investigate the interface stress between foot and AFO by establishing a 3D finite element model.

### METHODS

A female subject (aged 26) was selected as the modeling target. To setup the material property of the soft tissue, the load-displacement curves of the soft tissues in four regions of the foot were recorded and the Young's moduli were calculated from these curves. The contact pressure between the foot and AFO under foot flat condition were measured by the Novel Pedar (NOVEL GmbH Pedar) to valid the finite element results.

The finite element geometry of the foot-AFO structure was established based the CT images. To simplify the computational aspect, the bone structure was modeled as a single entity that is no joint is modeled. The surface-to-surface contact elements were placed between the foot and orthosis with a friction of coefficient 0.5. The proximal anterior surface of the leg was constrained in the anterior and posterior directions to model the strap constraint. The entire bottom area of AFO was fixed to simulate the foot flat condition. Besides, the heel and toe regions of the AFO bottom area were fixed respectively to simulate the heel strike and toe off stages. The loading was applied as a displacement on the superior surface of the leg bone. This displacement increased until the reaction

Figure 1: The finite element mesh of the foot-AFO structure.

fore reached the body weight for foot flat condition and 125% body weight for heel strike and toe off conditions.

### RESULTS AND DISCUSSION

The finite element mesh of the foot-AFO structure was shown in Figure 1. The differences of averaged contact pressures between the EMED measured results and finite element simulated outcomes were less than 10% which validated the finite element model.

For the foot flat condition the peak contact pressure occurred on the forefoot region which consistent with general biomechanical observation on foot (Figure 2). For the heel strike and toe off conditions, the peak interface stresses happened on the heel and toe regions respectively and this is due to the constrain conditions. Comparing with the foot flat mode, the interface stresses could be increased by more than 200% at toe off or heel strike modes, even though, the loading was increased by only 25%. Moreover, this large increasing of interface stress occurred on both the contact pressure and the shear stress.

### CONCLUSIONS

The results of this study indicated that not only the contact pressure but also the interface shear stress plays an important role in the biomechanical evaluation of AFO. Both the loading amount and boundary condition (postural) are vital in determining the interface stresses distributions. The loading and boundary conditions affect the interface stress distribution tremendously; therefore a more realistic loading is necessary for the evaluation of AFO and the modeling of joints might be required for loading conditions other than foot flat.

### INTRODUCTION

Compression Hip Screw (CHS) is one of the most widely-used prostheses for the treatment of intertrochanteric fractures because of its strong fixation capability[1]. Fractures at the neck and screw holes are frequently noted as some of its clinical drawbacks, which warrant more in-depth biomechanical analysis on its design variables. In this study, we investigated the effects of the changes in design variables to the strength of the CHS. Particularly, changes in the plate thickness and number of screw holes at the side plate were studied in relation to the strength of the implant.

### METHODS

#### Specimen Preparation

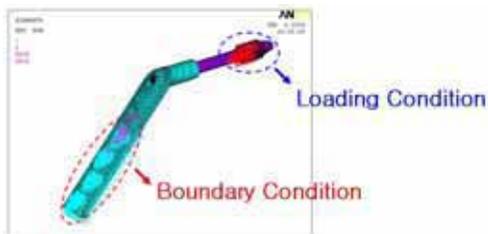

Twenty compression hip screws (Solco Biomedical Co. Ltd., South Korea) with an inclination angle of 135° between the barrel and the long axis of the side plate were used in this study. All side plates were made of Grade 2 titanium and the lag screws of Ti6Al4V. Specimens were classified into four groups (n=5 each): Group I was the control group with the neck thickness of 6-mm and 5 screw holes on the side plate, Group II 6-mm thick and 8 holes, Group III 7.5-mm thick and 5 holes, and Group IV 7.5-mm thick and 8 holes.

#### Mechanical Test

Each of the specimen(n=3 for each group) and the jig were mounted on the mechanical testing machine (MTS 858, MTS system Corp., MN, USA)[2]. Compressive load was applied at a rate of 0.17mm/sec with the maximum displacement set at 60mm for failure tests. The failure loads were determined by 0.2% offset method which is 0.2% of the lever arm length. Fatigue tests were done (n=2 for each group) to determine the fatigue life. Fatigue loads were applied at 5Hz with data acquisition rate of 20/sec. The 50% and 75% of the failure loads that was obtained earlier from the failure tests were used for each group. Maximum number of loading cycle was set at 1 million cycles according to ASTM[3].

#### Finite Element Analysis

Finite element models simulating each group were constructed to analyze the change in stress distribution due to changes in thickness and hole numbers.

**Figure 1:** Loading and boundary conditions of finite element models

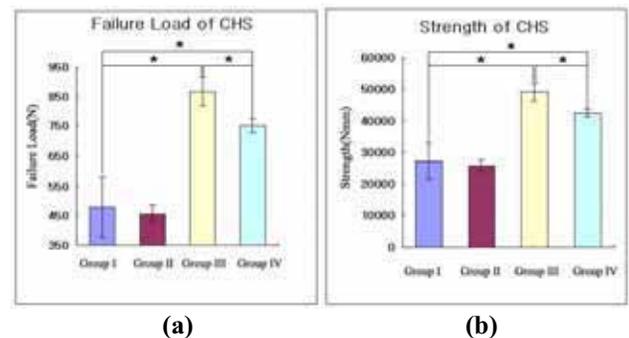

To reflect the same loading and boundary conditions as in the

mechanical test, a compression load of 300N and contact areas between side plate and the jig were restricted in all directions [4](Figure 1).

### RESULTS AND DISCUSSION

#### Experimental Results

Group III was found to be the strongest type with the failure strength of 867N and the bending strength of 49KN-mm, followed by Groups IV. Adding 1-mm of the plate thickness reinforce the CHS by 80% (480N in Group I vs. 867N in Group III) and it was statistically significant ( $p < 0.05$ ) (Figure 2). No fatigue failures were found in all specimen groups after 1 million cycles regardless the magnitude of fatigue loads 50% and 75% of the failure loads.

**Figure 2:** The results of the failure tests of the CHSs: (a) Failure loads, (b) Strengths (\*:  $p < 0.05$ )

#### Finite Element Analysis Results

Peak von-Mises stresses at the neck region are analyzed. Group I (175MPa) showed the highest stress but Group III (111MPa) had the lowest. Stresses were appeared to be more concentrated around the perimeters of the lag screw holes than at the junction between the barrel and the side plate. The highest peak von-Mises stresses were found at the most superior screw hole location.

### CONCLUSIONS

In this study, both biomechanical tests and finite element analyses showed that the thickness was a far more effective and sensitive design variable for the reinforcement of the CHSs than the screw hole numbers. It was also indicated that more screw holes on the side plate rather decreased the overall strength of CHSs.

<sup>2</sup>Department of Orthopedic Surgery, Mayo Clinic Rochester, MN.

### INTRODUCTION

Aseptic loosening and femoral neck fractures resulted in unpredictable survival of resurfacing arthroplasty in the past. Introduction of metal-on-metal bearing couples reduced aseptic loosening drastically. Improving prosthesis design in order to optimize load transfer can be an additional means to reduce implant failure. We tested various parametric design changes to explore their influence on the stress pattern in the anatomical and 'resurfaced' proximal femur.

### METHODS

Finite element analysis of the proximal femur was performed with a generic, hemispherical design. Parametric tests were performed for implant stiffness, stem length and shell size. Modeled elastic moduli were 110,000 MPa (titanium), 200,000 MPa (CoCr) and 350,000 MPa (ceramic). Stem length variations were: a) *conventional stem*, as currently is use, b) *half stem*, reaching till the neck, c) *short stem*, reaching till the center of the femoral head and d) *no stem*. Shell sizes, expressed as an angle, included 260°, 220° and 180°.

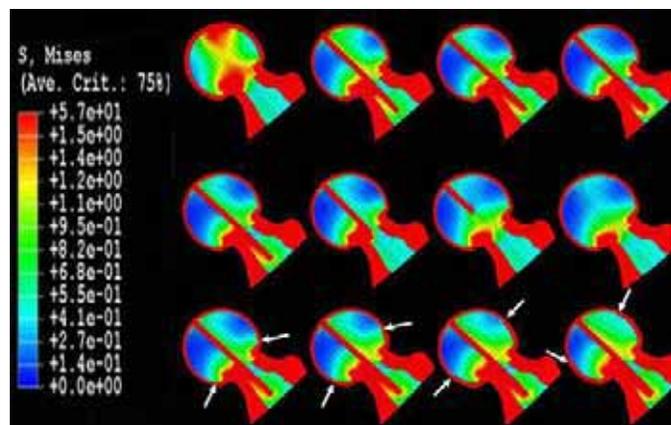

### RESULTS

**Cortex.** Peak stress concentration at the cortex was at the posterior-medial cortex of the neck, just under the posterior rim of the prosthesis. Surface replacement did not alter the cortical stress pattern of the cortex, independent of design.

**Cancellous bone.** Resurfacing caused stress concentration at the medial side of the neck. The antero-posterior part of the proximal half of the neck was slightly stress shielded, whereas a slight increase in stress was found at the distal half of the neck. In the femoral head especially the area of the primary trabecular system and the circumference were shielded. This shielding was profound even with the least stiff implants. The stiffer the prosthesis, the more distal the area of stress concentration extended distally. The shielding was independent on prosthesis stiffness. The *short stem* and *no stem* designs did not influence the stress pattern in the femoral neck. The length of the stem has no influence on the stress pattern in the femoral head. With decreasing shell size, the area of stress concentration at the medial neck extended more distally. The antero-posterior shielding slightly decreased, however that change was very small. In the femoral head a smaller prosthesis reduced stress shielding slightly.

### DISCUSSION

The shielding of the femoral head in our model showed a pattern similar to the resorption pattern found by Huiskes *et al.* [1]. They suggested prosthetic failure to result from a combination of progressive mechanical effects and interface bone resorption due to micromotion. Possibly, shielding

**Figure 1: Stress pattern at the proximal femur showing the effect of implants stiffness (top, left to right: anatomical hip, Ti, CoCr, ceramic), stem length (middle, left to right: conventional stem, half stem, short stem, no stem) and shell size (bottom, left to right: 260°, 220°, 180° and 140°). Arrows indicate the edge of the prosthesis. Stresses are Von Mises stresses.**

compromises bone quality, to make the femoral head more susceptible to these processes.

Watanabe *et al.* [3] related early fractures to stress shielding of the femoral neck in their finite element analysis. However, using DEXA scans, Kishida *et al.* [2] found bone mineral density in the femoral neck to be preserved after surface replacement. It likely is the stress concentration in the cancellous bone of the medial femoral neck that puts the neck at a greater risk for fractures.

### CONCLUSIONS

1. As yet reported, resurfacing arthroplasty leads to stress concentration at the cancellous bone of the femoral neck and stress resorption at the circumference of the femoral head.
2. Less stiff implants reduce stress shielding of the femoral head but lead to higher stress concentration at the neck.
3. Designs with a short stem preserve the stress pattern of the anatomical hip joint at the level of the femoral neck.
4. A smaller shell slightly reduces stress shielding in the femoral head.
5. Thus, designs with a short stem could possibly reduce the risk on stress fractures, while small shells could possibly be beneficial in preserving bone quality of the femoral head.

## BIOMECHANICAL APPROACH TO BALLET MOVEMENTS: A STUDY OF THE EFFECTS OF BALLET SHOE AND MUSICAL BEAT ON THE VERTICAL REACTION FORCES

Andreja Paley Picon<sup>1</sup>, Paula H. Lobo da Costa<sup>2</sup>, Isabel de C. N. Sacco<sup>3</sup>, Alberto Carlos Amadio<sup>1</sup>

<sup>3</sup>Department of Physical Therapy, Fonoaudiology e Occupational Therapy – Universidade de São Paulo – Brazil.

### INTRODUCTION

Biomechanical studies have tried to explain the loading characteristics of ballet dancing due to the *pointe shoes* and the extreme positions of the foot while standing *en pointe* [1]. Of great importance to the overall ballet performance is also the influence of musical beat, identified by the time signature of the musical tempo, responsible for the speed aspect and thus the correct dynamic of the dance movements and this aspect should also be considered while studying the ground reaction forces. The purpose of this study was to describe the external loads during a ballet movement, sauté - 1<sup>st</sup> position, while performed with two different footwears (slippers and *pointe shoes*) and two different time signatures (2/4 and 6/8) in order to identify the relative contribution of these two aspects on the loads measured by a force platform. The "sauté" is a vertical leap with both feet from the first position and is considered a basic movement performed in an Allegro tempo.

### METHODS

Six female ballet dancers (mean age 17 ± 2,1 years-old, mean mass 52 ± 8,4 kg) with at least six years of training volunteered to this study. All dancers practice at least eight hours per week with slippers and *pointe shoes* and had no musculoskeletal injuries at the time of this experiment. All participants signed an informed consent form before testing. While positioned on the force platform, the dancer performed two trials of eight consecutive sautés from the first ballet position with the slippers and the same trial with the *pointe shoes*.

The time signatures 2/4 and 6/8 are binary tempos and the time unit used in this study was the quarter note. Consequently, in the condition 6/8, the movements were performed in the eighth note. This reveals the speed aspect of the dancer performances during this study. Only the vertical components of the resultant ground reaction forces were studied, because it better reflect the external loads applied to the body during landing from a jump. Ground reaction forces (GRF) were measured by a piezoelectrical force platform (Kistler Instruments), sampled at 1000Hz, low pass filtered with a cut off frequency of 200 Hz. Each sauté were divided into three phases: initial position (*demi-plié* or knees flexion), jump and landing (*demi plié* or knees flexion). For each sauté, the selected variables for descriptive purposes were: peak vertical force during landing (Fy), stance time (ST), vertical force rate of increase (Rfy). The time signature was determined by edited extracts from classical pieces, specially prepared for ballet classes, which were played on a CD-player. The data were tested for normality with a Shapiro Wilks test, and differences among the

experimental conditions were tested with an analysis of variance one-way and a post-hoc Scheffe test.

### RESULTS AND DISCUSSION

The different footwears did not produce significant differences in the profile of the resultant curves. In accordance with typical curves of each condition, the 6/8 time signature produced two vertical peaks and the 2/4 time signature produced only one peak of vertical force. The mean values for Fy1 and Fy2 as well as for the stance time (ST) and the rate of increase of the vertical force (Rfy) for the four conditions studied are presented in TABLE 1.

TABLE 1: Mean values (± sd) for Fy1, Fy2, ST and Rfy for at least 90 sautes-1<sup>st</sup> position, with *pointe shoes* (2/4 and 6/8 beats) and slippers (2/4 and 6/8 beats).

	Fy1 (BW) (mean ± sd)	Fy2 (BW) (mean ± sd)	ST (s) (mean ± sd)	Rfy (mean ± sd)
<b>Pointe 2/4</b>	3,89 (± 0,75)	----	0,37 <sup>#</sup> (± 0,15)	35,14 (± 10,11)
<b>Pointe 6/8</b>	2,89 (± 0,95)	1,67 (± 0,38)	0,57 <sup>+</sup> (± 0,10)	31,74 (± 12,32)
<b>Slipper 2/4</b>	3,60 (± 0,70)	----	0,35 <sup>++</sup> (± 0,09)	33,11 (± 9,57)
<b>Slipper 6/8</b>	2,80 (± 0,82)	1,83 (± 0,34)	0,63 <sup>#</sup> (± 0,09)	26,98 (± 9,78)

With relation to the footwear type, it was observed that the resultant vertical forces measured were not statistically different between slipper and *pointe shoes* conditions. In this way, the results pointed out that the musical beat may be a factor of greater influence on the vertical GRF, compared to the footwear type, determining the different curves observed in this study. Significant differences were only found for the stance time for the different conditions. With respect to the vertical force rate of increase no differences were found for footwear and time signature conditions.

### CONCLUSIONS

The *pointe shoes* do not produce greater loads than slipper shoes when measured the GRF. The time signature 6/8 produced greater stance times when compared to 2/4 time signature, thus, it is likely that the musical beat influenced more the mechanical aspects evaluated in this study than the footwear types. There is a clear tendency to the fact that the faster the musical beat, the greater the attention should be payed to the landing technique, mainly that of foot positioning on the ground, independently of the ballet shoe used.

### INTRODUCTION

The cause of running injuries continues to elude scientists. While a number of factors have been examined, the role of gait asymmetry and limb dominance has received little attention. Gait asymmetry has been suggested to be both a cause and effect of injury [1]. In addition, previous literature reports that left dominant (LD) people tend to be more symmetrical than right dominant (RD) people [2]. However, the relationship between laterality and gait has not been explored.

Therefore, one purpose of this study was to examine the differences in kinetic asymmetry during gait between LD and RD runners. The difference in injury patterns between LD and RD runners was also examined. The study focused on the symmetry of loading parameters that have previously been linked to chronic running injuries [3]. It was hypothesized that LD runners would be more symmetrical and, as a result, have fewer injuries than RD runners.

### METHODS

This is an ongoing study in which, to date, there are 16 LD subjects and 16 age- and mileage-matched RD subjects enrolled. An *a priori* power analysis, based on a 10 point difference in symmetry and variability from previous literature, indicated that 24 subjects were needed per group. All volunteers were female, rearfoot strikers who ran at least 20 miles per week and were free of any lower extremity injuries at the time of data collection. Limb dominance was determined by the foot with which a subject would kick a ball.

Subjects ran along a 25 meter runway at a speed of 3.65 m/s ( $\pm 5\%$ ), striking a force platform (Bertec Corp., Worthington, OH) at its center. Data were sampled at 960 Hz. Five trials were collected for both the left and right sides. The kinetic variables of interest were peak vertical impact ground reaction force, average and instantaneous vertical loading rates, and peak vertical shock. For each subject, these variables were extracted from the individual trials and averaged across the five trials, within each side.

The symmetry index (SI) [4] was used to evaluate the symmetry of each runner with respect to each of the kinetic parameters:  $SI = (X_{dom} - X_{non-dom})/X_{dom} * 100$

Following the gait assessment, all running-related injuries were monitored for one year. Independent, two-tailed t-tests were performed to compare the kinetic variables and the number of injuries sustained by the LD and RD runners. A value of  $p < 0.05$  was considered significant for all comparisons.

### RESULTS AND DISCUSSION

While the SI values were not significantly different between the LD and RD runners (Table 1), instantaneous loading rate and peak shock were 24.9 and 32.5%, respectively, higher in the RD runners. These individuals also had 38.2% more injuries than LD runners. Based on the *a priori* power analysis, the current number of subjects does not adequately power the study. Therefore, the results may be strengthened as the study continues, and additional subjects are added.

In light of previous literature suggesting that LD people tend to be more symmetrical [5], the kinetic preliminary findings of this study are not surprising. LD people often cite the need to adapt to a "right-handed world." However, this has much less of an influence on lower extremity tasks. Therefore, the increased symmetry may not necessarily be a learned adaptation, but may be related to neurological control. The fact that the more asymmetrical, RD runners are so much more likely to become injured may lend insight into the role of symmetry in the mechanism of injury.

Future studies will focus upon examining how other gait mechanics (ie. kinematics) differ between LD and RD runners. The link between gait mechanics and the side on which a runner sustains an injury will also be studied.

Table 1: Comparison of SI Values and Number of Injuries between the LD and RD runners

	Impact GRF	Avg. LR	Instant. LR	Peak Shock	# of Injuries
LD	9.0	15.6	9.4	16.6	13
RD	8.0	17.1	12.5	24.6	21
p-value	0.68	0.69	0.30	0.22	0.26
% Diff	12.6	9.2	24.9	32.5	38.1

## LASR: A NEW ANALYTICAL TOOL TO INCREASE INFORMATION RETRIEVAL FROM COMPLEX IMAGES

K Bogie<sup>1,2</sup>, X Wang<sup>3</sup>, J Sun<sup>3</sup>

<sup>1</sup>Cleveland FES Center, <sup>2</sup>Departments of Orthopaedics & <sup>3</sup> Statistics, Case Western Reserve University. Cleveland, Ohio,

### INTRODUCTION

Interface pressure mapping has been used in research settings for many years, most commonly in the evaluation of seating pressure distributions. Over the past decade, improvements in pressure monitoring technology have led to increasing acceptance in clinical use. However, this brings with it other issues to be considered: evaluation conditions are not as closely controlled as in a research setting and repeated evaluations are often required. Current image analysis is often limited to subjective evaluation of pressure maps, with minimal numerical indices; and gives no objective indication of the significance of any pressure changes observed. Furthermore, intra-assessment comparison of pressure images may be complicated by relative subject movement between assessments. These factors thus limit the clinical utility of the information collected.

We have developed a novel multi-stage image analysis technique that employs data -mining approaches to maximize information retrieval [1]; The LASR (longitudinal analysis and self-registration) tool incorporates fast registration schemes with a customized false-discovery-rate (FDR) controlled statistical procedure.

### METHODS

The LASR tool was applied to data obtained from a longitudinal study of the effects on tissue health of using regular gluteal neuromuscular electrical stimulation (NMES) [2]. Repeated assessments of interface pressures were obtained using a Tekscan CliniSeat multi-cell sensor mat (Tekscan Inc., Boston MA). At each assessment, the interface pressure sensor mat was placed over the subject's cushion in the wheelchair prior to transfer. Seating interface pressures were evaluated with the subject sitting still, with no movement or pressure relief procedures, at a scan rate of 2Hz for a 200s period to give a 400 frame 'static data' movie.

The assessment protocol produced large volume data files for a relatively small number of subjects - a statistical challenge known as "huge-p, small-n" problem. In addition, a true reproduction of seating posture on each visit was not always feasible. The LASR algorithm uses a multi- stage procedure to sequentially address these challenges;

*Step 1:* Spatially register all images using customized self-registration scheme for images with no fixed landmarks.

*Step 2:* Create pixel-by-pixel (and frame-by-frame) difference images and movies.

*Step 3:* Filter difference images using local-polynomial smoothing.

*Step 4:* Create T image/maps and movies by computing test statistic  $T_x$  based on neighborhood weighted averages.

*Step 5:* Compute FDR-controlled P maps and movies with controlled global error rate.

The LASR output map gives a global representation of statistically significant pressure changes. In the clinical application presented, LASR indicates if NMES effectively alters seating interface pressures, with a FDR of <0.05.

### RESULTS AND DISCUSSION

Typical LASR analysis output is illustrated in the following case study: Pressure mapping assessment for subject Y showed poor spatial alignment, with both translation and rotation occurring between the baseline and post-treatment images (Figure 1a). Qualitative evaluation of longitudinal changes was difficult. After applying the LASR algorithm it could be seen that pressures were reduced bilaterally over time (Figure 1b). The left and right sacro-ischial regions were equally affected.

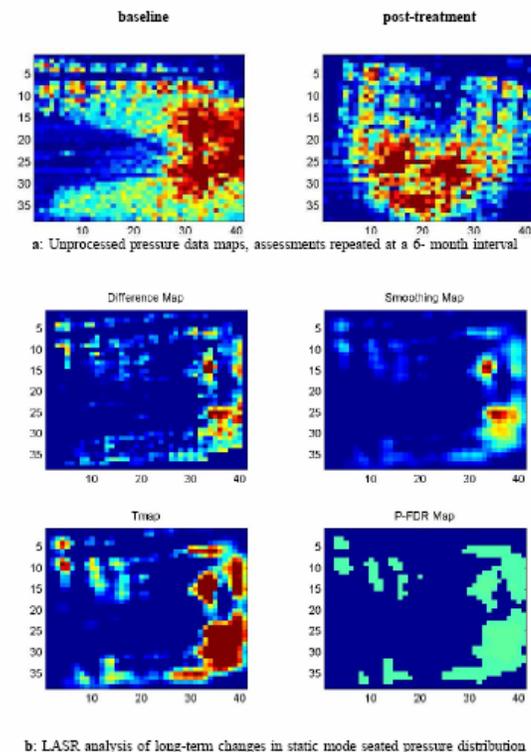

Figure 1: Pressure mapping analysis using LASR

### CONCLUSIONS

The LASR tool allows useful quantitative information to be derived from pressure mapping images. In the specific study, LASR analysis showed that statistically significant changes occurred in the ischial region over time. Using LASR we can confirm that NMES improves seating interface pressure distributions thus reducing the risk of developing pressure ulcers.

LASR is an analytical technique to compare 3-D images with no fixed landmarks with many potential applications in the field of image analysis and promises to become a powerful new tool for clinicians and researchers.

**MODELING THE BENEFITS OF TOWING DURING ADVENTURE RACING,  
 RUNNING WITH APPLIED HORIZONTAL FORCE**

Alena Grabowski and Rodger Kram  
 University of Colorado, Boulder; email: alena.grabowski@colorado.edu

**INTRODUCTION**

Adventure races are typically self-supported, multi-sport, team (3-5 people) races with a wilderness aspect. A team must stay together at all times; therefore, the slowest team member determines overall performance. Adventure racers have used towing as a technique to increase overall team speed during the running portions of a race. Mechanically, towing is accomplished by attaching an elastic cord from the waist of one racer (tow-er) to the waist of a teammate (tow-ee). In theory, the most aerobically fit racer should tow a less fit teammate so that the racers run at the same relative level of exertion (%VO<sub>2max</sub>), thus achieving a faster speed than the less fit runner could accomplish solo. Our purpose was to predict the optimal towing forces between two runners that would result in the best overall race performance.

**METHODS**

We used previously established equations [1,2] to model 10, 20, and 42.2 km race distances on a flat course, assuming a constant towing force and negligible aerodynamic drafting. We calculated towing forces and amount of time saved for different combinations of VO<sub>2max</sub> (ml/kg\*min) and body mass. The relationship between VO<sub>2submax</sub> and running speed established by Daniels and Gilbert [1] is:

$$VO_{2submax} \text{ (ml/kg*min)} = 0.3744V^2 + 10.93548V - 4.6$$

(V=velocity in m/sec)

The %VO<sub>2max</sub> that can be sustained for a defined time [1] is:

$$\%VO_{2max} = 80 + 18.94393 * e^{(-0.012778T)} + 29.89558 * e^{(-0.1932605T)}$$

(T=time in min)

We normalized the equation of Chang and Kram [2] to calculate changes in VO<sub>2submax</sub> due to aiding or impeding towing forces:

$$\% \text{ Change } VO_{2submax} = 0.155(AHF)^2 - 4.420(AHF) - 0.0000153$$

(AHF=Applied Horizontal Force in % body weight)

We determined theoretical time saving by combining equations, solving iteratively, and using curve-fitting techniques.

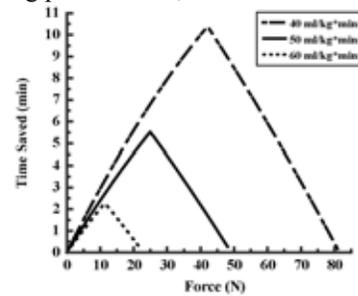

**RESULTS AND DISCUSSION**

Our model predicts that towing can improve overall running performance by more than 10min in a 10km race (Fig.1, Table1). The effectiveness of towing depends on differences in VO<sub>2max</sub>; a tow-er must have a higher VO<sub>2max</sub> than a tow-ee.

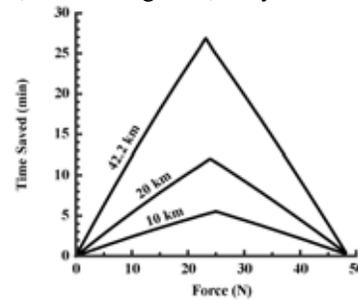

**Table 1:** Solo race times for 10km based on runners' VO<sub>2max</sub>. Optimal tow force, maximum time saved, & optimal race time based on tow-ees' VO<sub>2max</sub> & body mass. Tow-er always had VO<sub>2max</sub> = 70 ml/kg\*min, body mass = 70 kg.

VO <sub>2max</sub> (ml/kg*min)	Body Mass (kg)	Race Dist (km)	Solo Race Time (min)	Optimal Tow Force (N)	Maximum Time Saved (min)	Optimal Race Time (min)
40	70	10.0	50.01	42.1	10.4	39.61
50	70	10.0	41.33	24.9	5.5	35.83
60	70	10.0	35.37	11.4	2.3	33.07
<b>70</b>	<b>70</b>	<b>10.0</b>	<b>31.02</b>			

For a given VO<sub>2max</sub> difference, performance can be further improved when a tow-er has greater body mass than the tow-ee. However, with optimal towing force, performance may also improve when a tow-ee is heavier than a tow-er. Additionally, towing may improve relative performance more as the race distance increases (Fig.2). Optimal towing force for best overall performance during running depends on runners' VO<sub>2max</sub>, body mass, and distance. The strongest determinant of running performance due to towing is the VO<sub>2max</sub> of each runner. Body mass differences and race distance can also influence running performance, but have smaller effects.

**Fig. 1:** Time saved in 10km race due to towing force. Tow-er's VO<sub>2max</sub> = 70ml/kg\*min, body mass = 70kg; Tow-ee's VO<sub>2max</sub> = 40, 50, or 60 ml/kg\*min, body mass = 70kg.

**Fig. 2:** Time saved in 10, 20, & 42.2km races due to towing force. Tow-er's VO<sub>2max</sub> = 70ml/kg\*min, body mass = 70 kg; Tow-ee's VO<sub>2max</sub> = 50 ml/kg\*min, body mass = 70 kg.

## CUMULATIVE HEAD ACCELERATION IN COLLEGE FOOTBALL PLAYERS DIFFERS BY POSITION

<sup>1</sup> David McNeely, Sarah Manoogian, Stefan Duma, <sup>2</sup>Jeffrey Chu, Jonathan Beckwith, Richard Greenwald, <sup>3</sup>P. Gunnar Brolinson, <sup>4</sup>Mike Goforth

<sup>1</sup>Virginia Tech Center for Injury Biomechanics, <sup>2</sup>Simbex, Lebanon, NH, <sup>3</sup>Edward Via Virginia College of Osteopathic Medicine, <sup>4</sup>Virginia Tech Department of Sports Medicine; email: [dmcneely@vt.edu](mailto:dmcneely@vt.edu), web: [www.cib.vt.edu](http://www.cib.vt.edu)

### INTRODUCTION

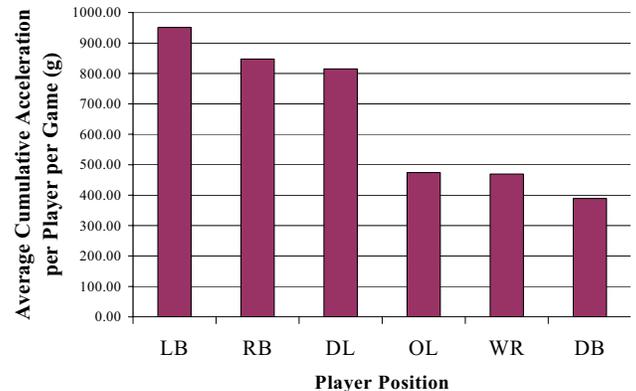

There are 300,000 incidences of sports-related concussions each year in the United States, with football having the most concussions of any sport [1]. In order to better understand these injuries, the impact event needs to be recorded and analyzed. Head accelerations were recorded during the 2004 Virginia Tech football season. A difference in the average amount of head acceleration per game is seen when comparing different playing positions in football.

### METHODS

*In-situ* linear head accelerations were recorded in real time using the Head Impact Telemetry (HIT) System (Simbex, Lebanon, NH) during practice and games during the 2004 football season. The HIT System measures linear head acceleration of the center of gravity of the head through an array of single-axis linear accelerometers [2,3]. Eighteen players were instrumented as part of a larger study, covering all playing positions. For this study, fifteen players were assessed. Game-only data was compiled from the entire 2004 season, and separated by player. The cumulative accelerations experienced by each player were tabulated and normalized by the number of games recorded for each player. Then, the players were grouped by playing position. Groups were receivers (WR), running backs (RB), offensive linemen (OL), defensive linemen (DL), linebackers (LB), and defensive backs (DB). The average of the cumulative head acceleration experienced by each player position per game played was calculated.

### RESULTS AND DISCUSSION

A total of 3,134 impacts were recorded during the 2004 season during games. Average acceleration per impact did not differ by player position. Figure 1 shows the average cumulative head acceleration experienced per game, grouped by position. Distinct difference can be seen throughout the different player positions. Defensive linemen's average cumulative accelerations per game were significantly higher than offensive linemen, wide receivers, and defensive backs ( $p < 0.05$ ). Linebackers exhibited significantly higher accelerations than offensive linemen and wide receivers, and

**Figure 1** Average cumulative acceleration per player per game, grouped by position.

running backs saw higher per-game averages than offensive linemen and defensive backs (Table 1).

### CONCLUSIONS

A better understanding of the head accelerations to which football players are subjected will lead to improved protective equipment and more effective treatment. Head accelerations are inevitable in the game of football. Players at all positions experienced similar average accelerations per impact. However, players at the running back, linebacker, and defensive lineman positions appear to experience higher cumulative accelerations each game than do players at the wide receiver, defensive back, or offensive lineman positions. A limitation of this study is the fact that some variability is introduced due to the fact that some of the players were active in a larger portion of the game than others.

## VIBRATION ALTERS PROPRIOCEPTION AND DYNAMIC LOW BACK STABILITY

<sup>1</sup> Maneesha Arashanapalli and <sup>1</sup> Sara E. Wilson

<sup>1</sup> Mechanical Engineering, University of Kansas, email: [sewilson@ku.edu](mailto:sewilson@ku.edu)

### INTRODUCTION

Whole body vibration has long been shown to be a risk factor for low back disorders. Vibration is associated with 1.5-39.5 fold increase in low back injury risk [1]. Vibration has been associated with a higher incidence of low back disorders in occupations such as pilots, tractor drivers and heavy equipment operators [2]. Although a number of investigators have studied the transmissibility of vibration, the mechanism by which vibration results in low back injury is not understood. One potential mechanism by which vibration may lead to low back injury is through changes in the dynamic stabilization of the spine. Muscle and muscle-tendon vibrations of 20 to 120 Hz are known to result in proprioceptive illusions in the extremities due to the stimulation of the muscle spindle organs [3]. After removal of vibration from the muscle, proprioceptive changes have been shown to persist [4]. In this experiment it was hypothesized that vibration-induced proprioceptive changes in the muscle both during and after vibration will correspond to changes in the dynamic stabilization of the low back.

### METHODS

Seven healthy subjects were recruited for the study, which was approved by the Human Subjects Committee, University of Kansas. Electromagnetic sensors were placed over the manubrium and the T10, T12, C7 and the S1 spinous processes. Lumbar curvature was defined as the angle between the T10 and S1 markers. Electromyographic sensors were placed on 8 trunk muscles (RA/ES/IO/EO) to measure their activity. The reposition sense protocol consisted of training trials followed by assessment trials. In the training trials, subjects were asked to match their current lumbar curvature with a target lumbar curvature. In the assessment trials, the subjects were asked to reproduce the target lumbar curvature without visual feedback. After two training trials, training and assessment trials were alternated. Reposition Sense Error (RSE) was defined as the absolute difference between the actual curvature assumed and the target lumbar curvature during the assessment trials. Directional error (DE) was defined as the difference between the actual curvature assumed and the target lumbar curvature during the assessment trials. In the sudden loading protocol, the subject wore a harness, which applied a small sudden forward impulse through a dropped weight mechanism. The time from impulse load to peak muscle response was assessed from the EMG data for the erector spinae muscle groups. Both the reposition sense test and sudden loading test were conducted before, during, immediately after, 15 minutes after, and 30 minutes after vibration.

### RESULTS AND DISCUSSION

In this experiment, two different effects were observed. First during vibration, kinesthetic illusions were observed resulting

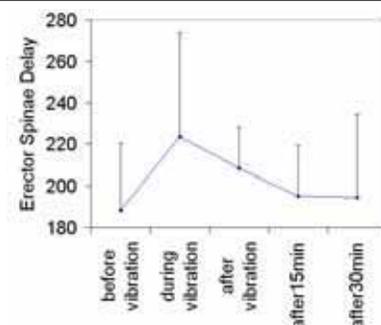

in increases in reposition sense error and directional error (Figure 2). Subjects tended to assume more lordotic postures during vibration, which is consistent with previous evidence of muscle lengthening kinesthetic illusions. After vibration, the reposition sense error remained increased while directional error returned to zero suggesting a habituation mechanism for altered position sense. Both during and after vibration, delay in muscle response during dynamic low back stabilization was increased suggesting that proprioceptive changes may indeed be a mechanism for altered low back stability and increased injury risk (Figure 1).

### ACKNOWLEDGEMENTS

This publication was made possible by support from the National Institute for Occupational Safety and Health (1R03 OH007995-01).

**Figure 1:** The delay between perturbation and peak initial muscle response was found to increase both during and after vibration returning to baseline after 15 minutes.

**Figure 2:** Reposition error was found to increase both during and after vibration, returning to baseline after 30 minutes. Directional error was found to be near zero except during vibration.

## VALIDATION OF A THREE DIMENSIONAL MODEL TO QUANTIFY PATELLOFEMORAL JOINT FORCES

Yu-Jen Chen<sup>1</sup>, Irving Scher<sup>1,2</sup>, Thay Q Lee<sup>3</sup>, Christopher M. Powers<sup>1</sup>

<sup>1</sup>Musculoskeletal Biomechanics Research Laboratory, University of Southern Calif., Los Angeles, CA. [yujensch@usc.edu](mailto:yujensch@usc.edu)

### INTRODUCTION

Although the patellofemoral joint is typically modeled as pulley system where the compressive force acting on the patella is created by the forces in the quadriceps tendon and patellar ligament, this assumption has not been validated. The purpose of this study was to validate a 3D model of the patellofemoral joint. To accomplish this goal, patellofemoral joint reaction forces (PFJRF's) that were directly measured from an in-vitro cadaveric set-up were compared to the PFJRF's, obtained from a computational model.

### METHODS

*In-vitro measurement of the PFJRF:* Seven fresh-frozen cadaveric knees were used in this study. Each was dissected to separate the individual heads of the quadriceps, the central tendon and the patellar ligament. The knee was mounted on a custom jig that was fixed to an Instron machine frame. Quadriceps muscle loads were accomplished using a pulley system and weights. Muscle forces were based on previously reported muscle cross-sectional area data (vastus medialis: 67 N, vastus lateralis: 98 N, rectus femoris and vastus intermedius combined: 111 N). The line of pull of each muscle was based on its 3D muscle fiber orientation. To quantify the magnitude and direction of the PFJRF, a six axis load cell was incorporated into the femoral fixation system so that a rigid body assumption could be made. Care was taken to distract the tibia (5 mm) and cut all soft tissue connection between the tibia and femur so that the only force acting on the femur was from the patella. Using this set-up, PFJRF's (magnitude and direction) were obtained at 0, 20, 40, and 60 degrees of knee flexion. In addition to the PFJRF data, 3D coordinates of the line of pull of each muscle, the orientation of the patellar ligament relative to the tibia, and the patella flexion angle was quantified using a Microscribe digitizer. The force in the patellar ligament was obtained using a buckle transducer. The alignment of the femur relative to the tibia in the frontal plane was measured using a goniometer.

*Computer-based estimation of the PFJRF:* Following in-vitro testing, computational models based on the three-dimensional coordinates obtained from each of the cadaver knees were created. SIMM modeling software was used to model the four quadriceps muscle force vectors and the patellar ligament force vector. The 3D coordinates of the muscle force vectors relative to the patella and the orientation of the patella and patellar ligament relative to the tibia were identical to that of the in-vitro set-up. In addition, the exact muscle loads and the measured force in the patellar ligament were used. Lower limb alignment also was matched to in-vitro measurements. Based on the unit vectors of each of the quadriceps muscles forces noted above, a resultant quadriceps force vector (relative to

the patella) was calculated. The magnitude and direction of the PFJRF was quantified as the resultant of the quadriceps force vector and the patellar ligament force vector. This calculation was repeated at 0, 20, 40 and 60 degrees of knee flexion.

### RESULTS AND DISCUSSION

On average, the resultant PFJRF's estimated by the computer model was consistently higher, but similar in magnitude, to the measured in-vitro PFJRF's at all knee flexion angles (9.2% difference at 0°; 10.0% at 20°; 13.4% at 40°; and 15.6% at 60°, Fig. 1). The PFJRF distribution in all three planes was similar between modeling methods across all knee flexion angles. The Pearson's correlation coefficient revealed a significant association between the resultant PFJRF's estimated from the computer model and the measured PFJRF's from the cadaver specimens ( $r^2=0.89$ ;  $p < 0.001$ )(Fig. 2)

### SUMMARY

These results suggest that good estimates of the magnitude and direction of the PFJRF can be obtained using a computer-based model. Accurate modeling of PFJRF's is needed to define the biomechanical environment of the patellofemoral joint and to identify the factors contributing to abnormal patellofemoral joint loads during functional activities.

## A COMPARISON OF HIP EXTENSION TORQUES IN CONVENTIONAL AND SPLIT SQUAT EXERCISES

Ben Meyer and Jesús Dapena  
Biomechanics Laboratory, Indiana University  
email: bwmeyer@indiana.edu

### INTRODUCTION

Conventional two-leg squats are considered an important part of lower extremity strength training programs, as they serve to exercise the hip and knee extensor musculature. However, the exertion of a large hip extension torque requires a large load and/or a large forward lean of the trunk. In turn, this requires the exertion of large torques by the lumbar extensor musculature, and thus increases the risk of spinal injury. As an alternative to conventional squats, some athletes use split squats as part of their training (Figure 1). The exercise is focused on the forward leg.

The purpose of this study was to examine the relationship between load and hip extension torque in the conventional and split squat exercises, and to draw inferences in regard to the risk of injury for the lumbar spine.

### METHODS

Ten male athletes (standing height =  $1.76 \pm 0.07$  m; mass =  $88 \pm 14$  kg) volunteered for the study. The subjects performed conventional squats at 60, 70, and 80% of their raw one-repetition maximum (1-RM), and split squats at 20, 25, and 30% of their raw conventional squat 1-RM. (Raw lifts are those performed without the use of knee wraps or squat suits.) At the low point, the thigh was approximately parallel to the ground.

Each trial was recorded with a Vicon 370 motion analysis system, and the ground reaction forces and torques exerted on the right foot were measured with an AMTI OR6-7-1000 force platform. The sampling rate was 60 Hz for both. Joint torques were computed using the method proposed by Andrews [1,2]. Lifted mass was defined as the sum of the masses of the trunk, arms, head, and barbell. Trunk angles were expressed relative to the vertical. Data were calculated for the low point of the lift, defined as the instant of minimum thigh angle.

### RESULTS AND DISCUSSION

Figure 2 shows that the split squat required less lifted mass than the conventional squat to attain any given amount of hip extension torque. In addition, the subjects used a smaller amount of forward lean of the trunk in the split squat ( $25 \pm 12^\circ$ ) than in the conventional squat ( $35 \pm 6^\circ$ ). The combination of a smaller lifted mass and a smaller forward lean of the trunk in the split squat for any given amount of hip extension torque implied smaller lumbar extension torques. In turn, this implied a smaller risk of injury for the lumbar spine when the split squat is used.

### CONCLUSIONS

The results of this project indicate that athletes who wish to focus their efforts on the hip extensor musculature should perform the split squat. The use of the split squat reduces the

risk of lumbar spine injury by reducing the forward lean of the trunk and the lifted mass in relation to the conventional squat.

## MUSCULAR STABILISATION OF THE HEAD IN CAR COLLISIONS

Lars Janshen

Humboldt-University Berlin, Institute of Sport Science

email: [lars.Janshen@rz.hu-berlin.de](mailto:lars.Janshen@rz.hu-berlin.de) web: [www.sportbiomechanik.de](http://www.sportbiomechanik.de)

### INTRODUCTION

Frontal and rear-end collision with low speed are common accident mechanisms in situations with dense city traffic. During a rear-end collision the car occupant of the struck vehicle is pushed forward by the seat-back. Due to its inertia the neck is forced to an extension-flexion movement commonly called 'whiplash'. To improve car safety mainly anthropometric test dummies (ATD) e.g. Hybrid III are used. Although there is an ongoing development of ATD, such as the BioRID P3, and of specific components like the TRID-neck studies in which dummies or cadaver models are used do not reveal neuromuscular control strategies to adjust neck stiffness and to stabilize head position. However: muscular activation is presumably essential for postural control and head stability especially during trunk linear acceleration as they occur in car collisions [1].

The purpose of this study was to investigate differences in muscular coordination patterns of car occupants in frontal and rear-end collisions of small vehicles with low speed.

### METHODS

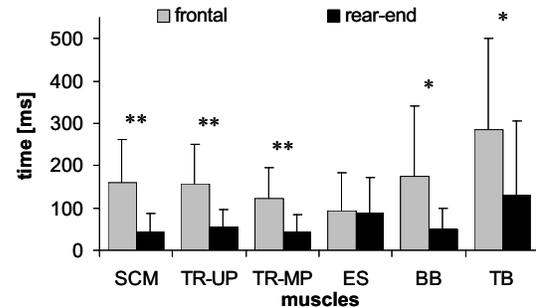

Six male subjects performed five frontal and rear-end collisions with a bumper car (speed = 2.6 m/s) in a randomized order. The instant of car collision and head movement of the occupant were recorded by accelerometers (1000 Hz). Kinematic data was collected using side view high-speed video (1000 Hz). Body motion was related to car motion. In a 2D-model angular amplitude and angular velocity of defined joints located at the cervical spine (C4), between head and neck, neck and shoulder and at the elbow were analyzed in the sagittal plane.

Myoelectric activity of specific neck, upper trunk and arm muscles of either body side was recorded using surface EMG. The signals were pre-amplified and digitized (1000 Hz) to a PDA. After online verification using W-LAN the signals were stored on a PC. EMG-Signals were rectified and filtered using the moving average (MA) method. The analyzed EMG parameters included time, mean amplitude (RMS) and integrals (iEMG) of pre-activation (prior to relative body motion) and main-activation (during relative body motion). RMS and iEMG were described relative to the maximum MA values of the respective muscles and subjects.

In the statistical analysis a MANOVA was performed for the independent factors "subject", "collision type" and "body side". The dependent variables were defined by the measured parameters in the kinematic and EMG analysis.

### RESULTS AND DISCUSSION

Within the series of collision types no significant differences between trials were observed. Kinematic data during the frontal and rear-end collisions showed that the complex motion of the head, neck and torso of the car occupant consists of mostly horizontal translational and rotational movements. During

**Figure 1** Activation times [ms] of the muscles sternocleidomastoideus (SCM), upper (TR-UP) and middle trapezius (TR-MP), erector spinae (ES), biceps (BB) and triceps brachii (TB) prior to relative head movement (N = 6).

frontal collisions all defined joints except the head-neck joint demonstrated significantly higher flexion compared to the rear-end crashes. During the rear-end collisions a nearly stationary head position observed in the first  $70 \pm 6$  ms of the crash could be attributed to head inertia [2]. This caused significantly higher and earlier maximum flexion in the head-neck joint and higher maximum extension in the other joints compared to frontal crashes.

In frontal collisions all muscles except the erector spinae showed significantly longer activation times prior to relative head movement compared to rear-end crashes (Figure 1). Together with significantly higher mean amplitudes representing the activation intensity this can be attributed to the visual anticipation of the frontal crash. This probably enabled a muscular induced neck stiffness to interlink motion of head and torso. In rear-end collisions EMG showed reflex induced activation time of about 50 ms prior to relative head movement with low intensity for all muscles. This seemed to be insufficient to interlink the head to the forward motion of the trunk.

### CONCLUSIONS

In this study a significant difference of the muscular activation during frontal and rear-end collisions was observed. In contrast to currently used passive structures like crash test dummies or human cadavers, the muscular activity seems to play an important role during crashes and therefore should be more considered in future crash-models. Especially the results of the frontal collisions may help to improve occupant safety in the ongoing development of airbag concepts and help to prevent injuries.

## A BIOMECHANICAL STUDY OF THE PULLOUT STRENGTH OF THE SELF-TAPPING BONE SCREWS IN OSTEOPOROTIC BONE MATERIAL INSERTED TO DIFFERENT DEPTHS

<sup>1</sup>Suneel Battula, <sup>1</sup>Glen O. Njus and <sup>2</sup>Andrew Schoenfeld

<sup>1</sup>The Department of Biomedical Engineering, The University of Akron,

<sup>2</sup>The Department of Orthopedic Surgery, Akron General Medical Center; email: bsuneel@uakron.edu

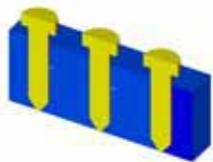

### INTRODUCTION

Bone screws are commonly used implants for fixation of fractures and are also for stabilizing bone transplants [1,2]. The failure of osteosynthesis is determined by the maximum load that can be transferred between a screw and the bone [3]. This maximum load is referred to as the pullout strength (PS) and can be assessed by axial pullout tests. PS becomes a crucial factor in osteoporotic bone. It is a common practice in orthopaedic surgery to insert the self-tapping bone screws (STS) 2mm past the far cortex to prevent the cutting flutes from remaining in the far cortex.

The purpose of this study was to determine PS of the screws inserted to different depths in the osteoporotic bone material and to evaluate if there is a significant difference in the PS of the STS of different manufacturers.

### METHODS

Ninety Stainless Steel (SS) self-tapping cortical bone screws (40mm length, 3.9mm cutting flute length and 3.5mm diameter) from three manufacturers, Zimmer (Warsaw, IN), Synthes (Monument, CO) and Stryker (Mahwah, NJ), were evaluated. These screws were inserted into bone coupons representing osteoporotic bone material. The bone coupons were bicortical with polyurethane foam (density of 0.24 grams/cc and tensile modulus of 143 Mpa) for cancellous bone and E-Glass-filled epoxy sheets (1.7 grams/cc density and tensile modulus of 12.4 GPa) for cortical bone.

**Figure 1:** Layout of the bone coupons and the screws.

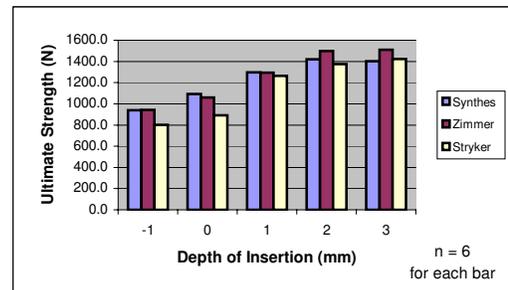

The screws were subdivided into five groups of six screws per depth per manufacturer. They were inserted -1mm, 0mm, 1mm, 2mm and 3mm relative to the far cortex. Three screws were inserted per coupon (Fig 1) based on the St. Venant's principle.

The axial pullout was performed in agreement with the *ASTM F 543-02* specifications for the metallic medical bone screws. Uniaxial load to failure was applied under displacement control at a rate of 0.1 mm/s using an Instron 8511 materials testing machine.

### RESULTS AND DISCUSSION

Fig. 2 shows comparison of the PS of the screws of different manufacturers at different depths of insertion. It may be observed that the PS of the screws inserted 1, 2 and 3mm past the far cortex were significantly higher than the other groups.

Loading energy (LE) was computed as the area under the load displacement curve up to maximum load (PS). Table.1

**Figure 2:** Pullout Strength of Bones screws from different manufacturers inserted to different depths

summarizes the results of the LE at different depths and also for all manufacturers. Two-factor ANOVA and SNK tests were performed to determine the effect of the depth of insertion and manufacturer on the PS.

The statistical results indicate that the PS of the screw when inserted to 2 and 3mm past the far cortex is significantly different ( $P < 0.05$ ) from the other depths of insertion. The results failed to indicate any significant difference between the PS of the screws manufactured by different companies.

**Table 1:** Means  $\pm$  standard deviation of the Loading energies (N-mm) of the screw pullouts at different depths.

DOI (mm)	Manufacturer		
	Synthes	Zimmer	Stryker
-1	294 $\pm$ 60.6	271 $\pm$ 83.4	211 $\pm$ 31.1
0	344 $\pm$ 83.6	337 $\pm$ 74.4	251 $\pm$ 35.5
1	416 $\pm$ 99.9	441 $\pm$ 109.3	421 $\pm$ 104.4
2	561 $\pm$ 87.2	636 $\pm$ 83.6	535 $\pm$ 51.5
3	560 $\pm$ 101.1	616 $\pm$ 50.1	628 $\pm$ 44.4

### CONCLUSIONS

It has been confirmed with the help of biomechanical testing that the optimum depth of insertion for a bone screw in osteoporotic bone material is 2mm past the far cortex. It can also be concluded that the PS of the self-tapping bone screws made by different manufacturers are not statistically different from each other.

## A SYNTHETIC MODEL FOR MECHANICAL EVALUATION OF VERTEBRAL BONE

Amy Johnson and Tony S. Keller  
 University of Vermont, Burlington VT  
 email: [ajohnson@uvm.edu](mailto:ajohnson@uvm.edu), web: [www.emba.uvm.edu/~keller/mrl](http://www.emba.uvm.edu/~keller/mrl)

### INTRODUCTION

Biomechanical studies of vertebral compression fractures and cement augmentation typically rely on cadaver vertebrae, which exhibit highly variable structural and material characteristics depending on the age and degeneration of the samples. Moreover, cadaveric specimens are increasingly difficult to obtain in sufficient numbers for statistically valid studies. The goal of this project was to create and mechanically test a synthetic vertebral body using commercially available open-cell foam, which is marketed as a structural analog to human cancellous bone. The open-cell structure allows for cement injection making it a desirable testing material for vertebral cement augmentation studies.

### METHODS

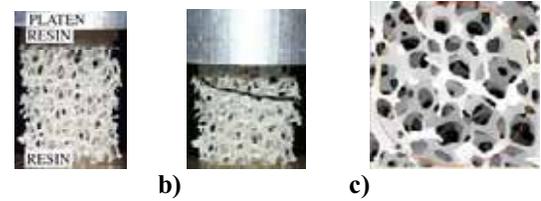

Blocks of open cell foam (apparent density,  $\rho_a = 0.12 \text{ g/cm}^3$ ) were obtained from Pacific Research Laboratories, Inc. (Vashon Island, WA). A 9mm foam cube was digitized using a  $\mu$ CT scanner (36 micron voxels). Volume fraction (BV/TV), three-dimensional (3-D) material anisotropy, and standard morphology (Tb.N, Tb.Th, Tb.Sp) were characterized using a proprietary program based on the parallel plate model method [1]. Ten samples of open cell foam were cut into cylindrical cores (12.8 mm diameter by 19.8 mm height) using a brass-coring tool. Using a servo-hydraulic test machine, the cylindrical foam samples were initially subjected to non-destructive uniaxial compression tests under displacement control. Foam specimens were preloaded to 0.5N, preconditioned for 5 cycles to 0.4% strain using a 1Hz sinusoid, and ramp loaded at 0.016 mm/s to 0.8% strain. 1.5 mm thick fiberglass resin end-plates were molded to the top and bottom surfaces of the foam samples (Fig. 1a). The fiberglass resin end-plate was representative of the cortical bone endplate present in vertebral centrum, and served to reinforce the damaged (cut), load-bearing surface of the foam cylinders. Foam+endplate samples were non-destructively tested as described previously, followed by a failure ramp at a rate of 0.016 mm/s.

Stress-strain data were used to obtain the apparent modulus ( $E_a$ ), 0.2% offset yield stress ( $\sigma_y$ ), 0.2% offset yield strain ( $\epsilon_y$ ), ultimate stress ( $\sigma_{ult}$ ), and ultimate strain ( $\epsilon_{ult}$ ). The apparent elastic modulus was determined over a 0.5% strain range for the non-destructive tests. A paired-observations t-test (POTT) was used to compare the apparent modulus of foam vs. foam+endplate samples.

**Table 1:** Apparent modulus (mean  $\pm$  standard deviation) of foam vs. foam+endplate test specimens.

	Open Cell Foam	Foam + Endplates
Modulus $E_a$ (MPa)	$4.97 \pm 2.13$	$6.62 \pm 3.04^*$

\*no significant difference (POTT,  $p > 0.05$ )

**Figure 1:** a) Foam sample with fiberglass endplates prior to compression; b) Post-yield crush zone (highlighted) is visible ( $\epsilon \sim 15\%$ ); c)  $\mu$ CT 3-D rendering (9 mm x 9 mm).

### RESULTS AND DISCUSSION

The foam specimens consisted of an interconnected network of rods similar in morphology to vertebral trabecular bone (Fig. 1c). Foam samples were characterized as transverse isotropic with a BV/TV, Tb.N, Tb.Th, Tb.Sp of 0.106,  $0.280 \text{ mm}^{-1}$ , 0.378 mm, and 3.20 mm, respectively. Human vertebral cancellous bone is transverse isotropic with similar morphology and has an apparent density ranging from 0.05–0.30  $\text{g/cm}^3$  [2]. The latter corresponds to a volume fraction ranging from 0.03 – 0.156 (assuming a bone tissue density  $\rho_t = 1.9 \text{ g/cm}^3$ ). The foam+endplate specimens exhibited a crush or fracture consolidation typical of open-celled materials (Fig. 1b). Addition of the endplate increased the stiffness of the foam cores 33%, but this was not statistically significant (Table 1). Mean  $\pm$  standard deviation for  $\sigma_y$ ,  $\epsilon_y$ ,  $\sigma_{ult}$  and  $\epsilon_{ult}$  were  $0.231 \pm 0.033 \text{ MPa}$ ,  $3.44 \pm 0.72 \%$ ,  $0.241 \pm 0.029 \text{ MPa}$  and  $3.78 \pm 0.74 \%$ , respectively. The ultimate apparent strength and stiffness of similar density vertebral cancellous bone is 0.745 MPa and 12.4 MPa, respectively [2]. The lower values obtained for the foam samples (most likely) reflect the 40% lower tissue density of the foam compared to bone tissue ( $\rho_t = 0.12 \text{ g/cm}^3 / 0.106 = 1.13 \text{ g/cm}^3$ ). Strain values,  $\epsilon_y$  and  $\epsilon_{ult}$  were also lower than lumbar trabecular bone, which are reported as 6.0% and 7.4%, respectively [3].

### CONCLUSIONS

Our results indicate that the synthetic open-cell foam exhibits morphology similar to human vertebral cancellous bone, but has a lower density and concomitant lower strength and stiffness in comparison to human bone. Future work will focus on creation of a synthetic foam wedge fracture and cement augmentation model to study vertebral kyphoplasty.

**POSTURAL CONTROL STRATEGIES IN PEOPLE WITH AND WITHOUT PERIPHERAL NEUROPATHY  
- A NEURAL NETWORK APPROACH**

Ge Wu<sup>1</sup>, Marc Sarnow<sup>2</sup>, Larry Haugh<sup>3</sup>, Juvena Hitt<sup>1</sup>

<sup>1</sup>. Department of Physical Therapy, <sup>2</sup>. Department of Orthopaedic Surgery, <sup>3</sup>. Department of mathematics  
The University of Vermont, Burlington, VT 05405, USA

**INTRODUCTION**

Postural control strategies (PCS) during perturbed, upright stance depend on the integration of multiple sensory feedbacks by the central nervous system. People with peripheral neuropathy (PN) have decreased mechanoreception in the foot. This sensory change may lead to modified PCS when their balance is disturbed. The goal of this study was to use an Artificial Neural Network (ANN) model to quantify the motor-sensory relationship during a dynamic, human postural control task in elderly people with PN and without PN (NPN).

**METHODS**

Five PN (73.6±3.2 yrs) and seven NPN (80.1±8.5 yrs) elderly subjects participated in the postural perturbation experiment – maintaining an upright balance when the supporting base is suddenly rotated toes-up-down around the ankle joints (maximum rotation of 12° in each direction, maximum speed of 50°/s). All subjects signed a consent form approved by the IRB at the University of Vermont.

Following measurements were done: the electromyography (EMG) of the tibialis anterior (TA) and gastrocnemius (GAS) muscles of both legs, the distance between the eyes' center to a gaze target in front of the subjects; the head linear and angular accelerations; the ankle rotation; and the normal and shear forces under the feet. All signals were properly low-pass filtered, synchronized, and sampled by a data acquisition system (Bioengineering Technology Systems). Trials 11-25 were collected for each subject, five seconds each trial.

A two layer ANN model was constructed with seven inputs (head angular and linear accelerations (P<sub>1</sub> and P<sub>2</sub>), eye-target distance (P<sub>3</sub>), ankle rotation (P<sub>4</sub>), ankle velocity (P<sub>5</sub>), normal and shear forces under the feet (P<sub>6</sub> and P<sub>7</sub>)), two outputs (i.e., EMG envelopes of TA (y<sub>1</sub>) and GAS (y<sub>2</sub>) muscles).

The ANN model was trained based on the Back-Propagation algorithm. For every trial, the ANN model was trained 120 times, 10,000 epochs each, and a goal error of 0.001. For each training, a set of weights was determined and was used to calculate a set of 14 Q values (one for each of the 14 input-output pairs) to estimate the contribution of each sensory stimulus to each leg muscle activity [1]:

$$Q_{ki} = \frac{cp_{ki}^1 \int_T P_i \cdot y_k dt}{4 \int_T y_k^2 dt} \times 100\% \quad (k=1,2, i=1-7) \quad (1)$$

$$cp_{ki}^1 = \sum_j W_{jk} \omega_{ij} \quad (k=1,2, i=1-7, j=1-50) \quad (2)$$

where Q<sub>ki</sub> is the Q value between the i<sup>th</sup> input variable (P<sub>i</sub>) and the k<sup>th</sup> output variable (y<sub>k</sub>), ω<sub>ij</sub> and W<sub>jk</sub> the first and second layer weights, respectively, and T the total time duration of the platform movement. The group means of each Q value were compared with a two-sample, unequal variance t-test.

**RESULTS**

The time trajectories of the input and output variables were consistent, and there were no significant group differences in the peak-to-peak values except for the normal force, shear

force and EMG of the GAS muscle (significantly smaller in PN group, p < 0.009).

For the Q values, there were marginally significant group differences (p<0.10) for each muscle (Table 1). For TA muscle, the PN group had a higher Q value for ankle angle and head linear acceleration than the NPN group (p<0.06). For GAS muscle, the PN group had a higher Q value from head angular acceleration than the NPN group (p=0.075).

Table 1. Group means and standard deviations of Q values

Outputs	Inputs	NPN	PN	P value
TA	Head ang acc	1.4 ± 1.1	1.4 ± 1.6	0.499
	Head linear acc	0.2 ± 0.1	1.3 ± 1.3	0.061
	Vision	2.4 ± 1.8	1.3 ± 1.1	0.107
	Ankle angle	1.4 ± 0.6	3.3 ± 2.1	0.057
	Ankle velocity	2.8 ± 1.4	2.7 ± 1.2	0.449
	Shear force	3.6 ± 2.9	4.3 ± 2.0	0.267
	Normal force	1.6 ± 1.4	1.0 ± 0.8	0.114
GAS	Head ang acc	0.3 ± 0.2	0.6 ± 0.3	0.075
	Head linear acc	0.6 ± 0.6	0.4 ± 0.3	0.193
	Vision	7.5 ± 11.2	3.5 ± 2.3	0.197
	Ankle angle	1.2 ± 0.6	1.7 ± 1.6	0.294
	Ankle velocity	1.6 ± 1.4	2.5 ± 1.6	0.183
	Shear force	1.7 ± 1.8	2.9 ± 3.4	0.161
	Normal force	2.0 ± 2.4	2.3 ± 1.4	0.310

**DISCUSSION AND CONCLUSION**

This study examined the quantitative relations between each of the seven mechanical stimuli to the visual, vestibular and somatosensory systems and each of the two leg muscle activities during a sudden toes-up-down rotation of the supporting base among elderly people with and without severe loss of cutaneous mechanoreception in the feet. There were two main findings. First, people with PN have increased dependence on vestibular system or ankle joint receptors. Second, the primary sensory contribution to both muscle activities remains from the somatosensory system in the PN group. It is possible that these subjects still maintain the use of this afferent information from the ankle joint, but with increased assistances from other sensory systems.

These findings are supported by the notion that when portions of the somatosensory receptors are eliminated, there are increased contributions from other sensory systems [2-4]. This study demonstrates the potential of the ANN model in quantitatively studying motor-sensory relationship in human postural control.

## CONTROL OF CENTER OF PRESSURE DURING TAI CHI MOVEMENT

Ge Wu, Juvena Hitt

Department of Physical Therapy, University of Vermont, Burlington, VT, 05401, email: ge.wu@uvm.edu

### INTRODUCTION

Tai Chi Chuan (TCC) is shown to be an effective form of balance exercise for elders [1]. However, its mechanisms in improving balance are not yet clearly understood. The purpose of this study was to examine the control of body center of pressure (COP) during single stance of the TCC movements.

### METHODS

A total of ten young subjects (age  $27 \pm 4$  years) participated in this study. All subjects had practiced TCC daily for at least two weeks before testing, and signed an Informed Consent Form approved by the University of Vermont Institutional Review Board.

The kinematics of the trunk and limbs were measured using a marker-based Motion Analysis System (BTS). Surface electromyography (EMG) was recorded from tibialis anterior (TA), soleus (SOL), peroneus longus (PL), rectus femoris (RF), semitendinosus (ST), and tensor fasciae latae (TFL) muscles. The ground contact characteristics were recorded by two force plates (AMTI) and one pressure plate (Tekscan).

Subjects were asked to perform, five times, with bare feet, one basic Yang-style TCC movement, parting the wild horse mane, over a walkway covered by the force and pressure plates. The distances between these plates were adjusted so that subjects could land with the left foot first on the force plate, followed by the right foot on the pressure plate, and the consecutive left foot on the second force plate. The signals from the force and pressure plates, the Motion Analysis System, and the integrated EMG were collected at 50Hz, 15 seconds each trial.

The single stance time was determined based on the force and pressure plate measurement. Following parameters were computed over the single stance phase: spatial position and angular motion of the ankle, knee, hip and shoulder joints, the RMS value of EMG signals of both stance and swing legs, and the foot COP displacement in the medial-lateral and anterior-posterior directions, normalized by foot width (FW) and foot length (FL), respectively.

The mean and standard deviation of each variable, as well as the temporal features of both SW and TCG were calculated for each subject and compared using two-tailed t-test. They were considered statistically different when the p value was less than 0.05.

### RESULTS

The foot COP maintained fairly stationary and centered mainly in the center of the foot (Fig. 1). The maximum range of motion was  $14 \pm 6\%$ FW and  $7 \pm 2\%$ FL, as compared to  $64 \pm 8\%$ FW and  $72 \pm 7\%$ FL over the complete TCC movement. The stance leg remained fairly stationary, while the swing leg went through a large amount of hip adduction and flexion (Table 1), and the shoulder had a large range of displacement ( $\sim 25$ cm) in the transverse plane. All six muscles in the stance leg were activated at or above 20%MVC, and remained active for more than 50% of the single stance time (Table 2).

### DISCUSSION AND CONCLUSION

These results suggest that TCC movement involves the precise control of body COP. The fact that the foot COP is centered in the midfoot region with minimal movement during single stance is by no means a coincidence. Earlier studies have shown that during quiet, upright stance, body weight is located more towards the heel region, resulting in more plantar pressure in the rearfoot than in the forefoot region [2,3]. Moreover, the large amount of leg and trunk movement during single stance tends to shift the body center of mass. Thus, maintaining foot COP in the midfoot region requires a conscious and precise control of the neuromuscular system. It is perhaps the practice of this precise control of the neuromuscular system that helps improve the stability of upright stance.

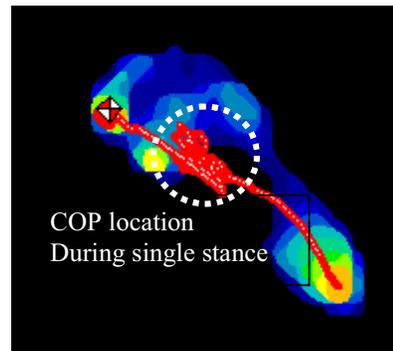

Fig 1. Illustration of foot COP location during single stance.

Table 1. Means and stds of joint ROM (deg)

Joints	Stance leg	Swing leg
Ankle flexion/extension	$6 \pm 3$	$14 \pm 10$
Knee flexion/extension	$8 \pm 8$	$74 \pm 6$
Ankle inversion/eversion	$2 \pm 5$	$4 \pm 9$
Hip flexion/extension	$7 \pm 3$	$48 \pm 6$
Hip abduction/adduction	$6 \pm 8$	$20 \pm 9$

Table 2. Means and stds of stance leg muscle EMG features

Muscles	RMS (%MVC)	On time (% single stance)
TA	$38 \pm 11$	$91 \pm 19$
PL	$33 \pm 10$	$80 \pm 24$
SOL	$20 \pm 9$	$57 \pm 31$
RF	$39 \pm 15$	$77 \pm 37$
TFL	$42 \pm 16$	$87 \pm 27$
ST	$21 \pm 12$	$59 \pm 38$

## DIFFERENCES BETWEEN OPERATED AND NON-OPERATED SHOULDER MUSCLE ACTIVATION PATTERNS RECORDED DURING THE DRAGON BOAT “LONG AND HARD” STROKE

<sup>1</sup>Linda McLean, Ellen Keeves, Jen Wolfe, Karen Filion, Anna Smith, Tierney Bowen, Degen Southmayd  
<sup>1</sup>Queen’s University School of Rehabilitation Therapy,  
Email: mclean@post.queensu.ca

### INTRODUCTION

Surgery for breast cancer often results in muscle weakness, loss of shoulder motion, and pain (Blomqvist et al., 2004). Many women begin to participate in dragon boat training and racing post-operatively as a form of fitness and as a source of social support. Changes in the force couples at the shoulder joint may predispose women who dragon boat to develop shoulder overuse and/or impingement syndromes.

We hypothesized that women who had undergone partial or complete mastectomy with lymph node dissection would demonstrate differences in muscle activation patterns during the performance of the dragon boat stroke on their operated as compared to their non-operated side.

### METHODS

Nine experienced female dragon boaters and breast cancer survivors from the Kingston Region participated in this study. Participants were required to have undergone a unilateral partial or complete mastectomy with lymph node dissection.

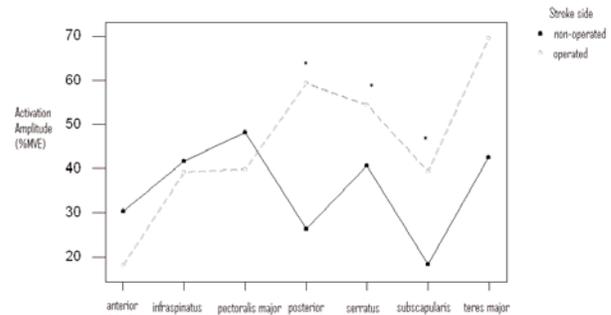

Delsys™ DE2.1 electrodes were used to record electromyographic (EMG) activity from seven muscles bilaterally, including the anterior deltoid, serratus anterior, pectoralis major, posterior deltoid, teres major, infraspinatus, and supraspinatus based on positioning described by Decker et al.(1999) and Hintermeister et al. (1998). Bipolar fine wire electrodes were used to record the activity of the subscapularis muscle. Each subject performed a series of three repetitions of a maximal voluntary isometric contraction (MVIC) for each muscle. She then performed ten repetitions of the “long and hard” dragon boat paddle stroke on each side, using a water trough and regular dragon boat paddle to simulate the activity.

Maximum voluntary electrical activation (MVE) was determined by using the highest root mean square value (RMS) computed over 200ms moving windows across each data set. The MVE was compared between the operated and non-operated sides for each muscle using a one-way repeated measures ANOVA ( $\alpha = 0.05$ ). The maximum activation amplitudes achieved during paddling were tested using a three-way repeated-measures ANOVA including muscle, recording side (operated vs. non-operated) and paddling side (operated vs. non-operated) as factors, and all two-way interactions ( $\alpha = 0.05$ ).

### RESULTS AND DISCUSSION

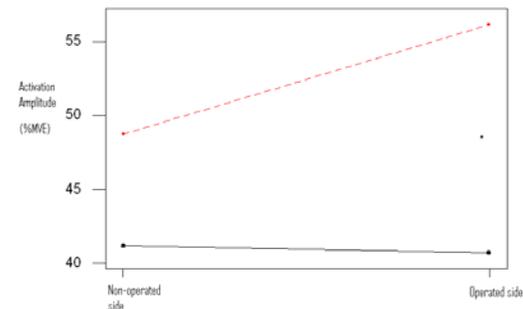

Four subjects had been operated on their dominant side, while five had been operated on their non-dominant side. Four subjects consented to having fine wires inserted bilaterally.

There were no significant differences between the operated and non-operated sides in terms of the MVE generated during the MVIC at any of the eight muscles studied.

**Figure 1:** Mean peak muscle activation amplitude on the operated side when paddling on the operated vs. the non-operated side. (\* denotes statistically significant differences)

During performance of the dragon boat stroke, there were significant muscle by side (operated and non-operated) and muscle by paddling side interactions ( $p < 0.0005$ ). As such the data for each muscle were analyzed separately. Post-hoc analyses revealed that the posterior deltoid, serratus anterior and subscapularis muscles on the operated side worked significantly harder than those same muscles on the non-operated side, particularly when paddling on the operated side.

**Figure 2:** Activation amplitude of serratus anterior muscle on the operated and non-operated side during the “long and hard” stroke. (Solid line denotes paddling on the non-operated side; dotted line denotes paddling on the operated side, \* denotes statistical significance at  $\alpha = 0.05$ )

### CONCLUSIONS

Due to differences in force couples at the shoulder induced by these muscle activation differences, these results may explain why women who participate in dragon boat training often develop shoulder pain on their operated side.

## VALIDATION OF CALIBRATION TECHNIQUES FOR TEKSCAN PRESSURE SENSORS

<sup>1</sup>Jill M. Brimacombe, <sup>1</sup>Carolyn Anglin, <sup>1</sup>Antony J. Hodgson and <sup>2</sup>David R. Wilson  
<sup>1</sup>Dept. of Mechanical Engineering, <sup>2</sup>Dept. of Orthopaedics,

### INTRODUCTION

Thin, flexible pressure sensors are often used in orthopaedic biomechanics to measure loads in the knee joint. Prior to using sensors in cadaver and clinical studies, it is important to show that the results they provide are accurate under the proposed testing conditions. Other investigators have previously validated Tekscan I-Scan pressure sensors (Tekscan, Inc., Boston, MA) for accuracy and repeatability of force and force distribution measurements [1]. The current validation study aims to demonstrate that user-defined calibration algorithms provide more accurately calibrated force measurements than the Tekscan built-in calibration routines.

### METHODS

Three new, identical I-Scan pressure sensors (model #5051-2500) were loaded using a materials testing machine (Instron 8874, Canton, MA). To simulate the loading in a prosthetic knee joint, each sensor was compressed between a flat disk of UHMWPE (D = 3.82 cm) and a larger aluminum plate. To reduce shear loads at the sensor surfaces, sensors were coated with K-Y lubricant (Johnson & Johnson, Montreal, Canada).

Sensors were conditioned four times at a load of 20.0 kN (120% of the maximum expected pressure). Four different calibration methods were used: a Tekscan linear calibration (performed at two different scales), a Tekscan power calibration, a user-defined 10-point cubic calibration and a user-defined 3-point quadratic calibration. The Tekscan linear calibrations were performed at 20% and 80% of the maximum applied load; the Tekscan power calibration was performed using both of these loads. All Tekscan calibrations pass through (0,0). The user-defined polynomial algorithms used a least squares curve-fitting technique.

Following conditioning and calibration, each sensor was subjected to 3 loading cycles consisting of 10 loads between 0 and 16.7 kN applied in a random order. Throughout conditioning, calibration and loading, forces were ramped up over 10s, held for 5s, and decreased over 10s. Sensors remained unloaded for 120s between load applications. Force data were saved as raw (uncalibrated) values; each calibration algorithm was applied to the same output. Force measurement error was defined as the difference between calibrated Tekscan output and Instron load cell measurements.

### RESULTS AND DISCUSSION

Figure 1 shows the typical calibrated output for one sensor using the 5 calibrations. Of the 3 Tekscan calibrations tested, the power calibration was the most accurate (Figure 2); the root mean square (RMS) errors of the measured forces for the 20% linear, 80% linear, and power calibrations were  $4.07 \pm 0.21$  kN,  $1.75 \pm 0.09$  kN, and  $0.447 \pm 0.16$  kN, respectively, corresponding to 24.4%, 10.5% and 2.7% of the tested sensor range. The user-defined polynomial calibrations were markedly more accurate; the quadratic and cubic

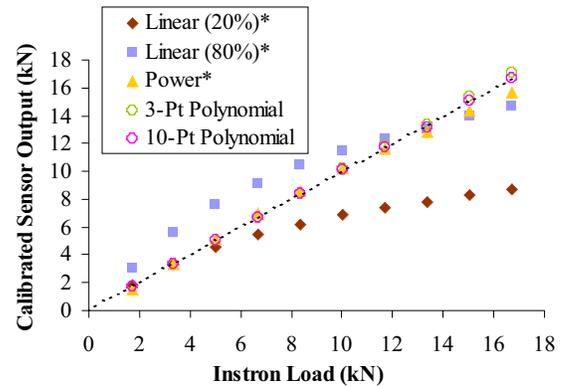

Figure 1: Typical sensor output calibrated using Tekscan (\*) and user-defined algorithms.

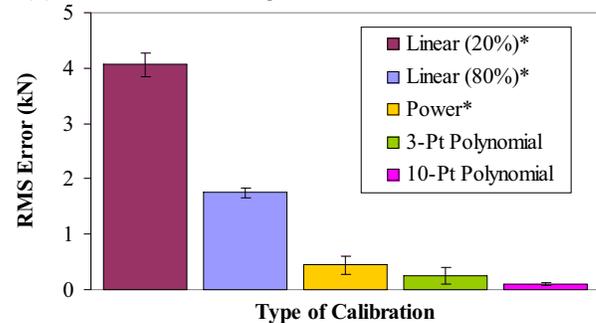

Figure 2: Average RMS errors of Tekscan (\*) and user-defined calibration techniques.

calibrations had RMS errors of  $0.24 \pm 0.15$  kN (1.5%) and  $0.10 \pm 0.03$  kN (0.6%), respectively. While most studies do not report their calibration procedure, the previous study which used the Tekscan power calibration found a higher, but comparable, RMS error of  $6.5 \pm 4.4\%$  [1].

### CONCLUSIONS

I-Scan force measurements may be accurate to within 0.6% when calibration algorithms use a least squares minimization technique. Although the 10-point cubic polynomial was the most accurate algorithm, the loading process is considerably more time-consuming. The 3-point quadratic calibration requires only one additional calibration load compared to the Tekscan power calibration and decreases the error in force measurement from 2.7% to 1.5%. Since it is straightforward to export sensor output and calibrate data externally, it is recommended that investigators design their own calibration curves. Since output is dependent on experimental protocol (sensor type, interface materials, sensor range in use, etc.), sensor behaviour must be investigated for each application.

### INTRODUCTION

Surgical treatment of late stage childhood spinal deformities is successful but invasive. With the goal of creating early, minimally invasive surgical methods, preclinical studies on prototype implants have shown that spine growth may be slowed unilaterally [1]. Spine curvatures were associated with histomorphometric structural gradients of vertebral physes[2]; the mechanism is presumed to be compressive stress gradients across the intervertebral joint, comprised of disc and two growth plates. A clinically successful implant design would require the application of compression levels sufficient to inhibit growth without significantly affecting disc viability.

Many studies have measured spinal pressures in the fluidic disc nucleus. However, to determine side-to-side compression differences in the annulus, thin, flat transducers are required, with sensor faces oriented transversely. The purpose was to design and develop a MEMS transducer capable of measuring compressive stress in the annulus of the intervertebral disc.

### METHODS

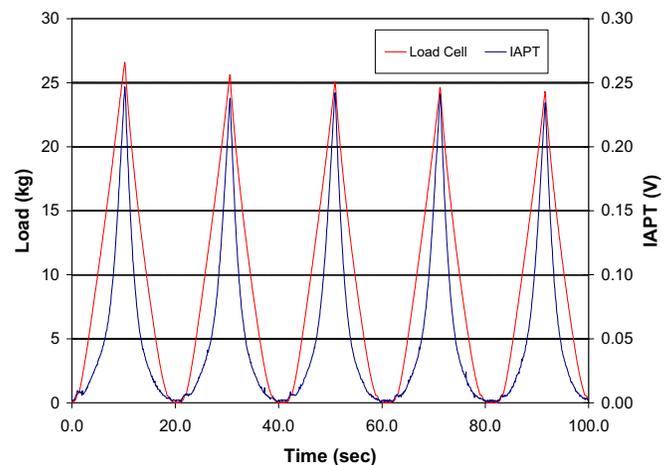

Piezoresistive sensors were chosen for size, range, and ability to be placed remotely from signal conditioning circuitry. Commercial sensor dies in a full Wheatstone bridge configuration (SM5108: 0.65 mm<sup>3</sup>, Silicon Microstructures Inc., Milpitas, CA) permitted absolute pressure measurements at physiological levels. Carriers of various lengths and pad sizes were tested to define the thinnest functional device. Dies were electrically connected in a clean room complex (Class 10) using photolithography, micro-machining, and wire-bonding techniques [3]. The sensors were designed into a small, thin, metallic package (2.5 mm width, 12.5 mm length, 0.8 mm thickness) to withstand dynamic *in vivo* stresses and to allow for firm attachment to vertebrae (Fig. 1).

**Figure 1:** Packaged sensors were small, thin, and rugged.

Packaged sensors were calibrated under both fluid and solid contact conditions by first using a dynamic nitrogen pressure chamber (0-1.6 MPa) with commercial reference pressure

sensor, and then using solid contact confined compression tests [3]. Sensors were then placed into the annulus of porcine vertebral motion segments that had been mounted into a materials test system. The segment was tested in cyclic compression (0.05 Hz) with simultaneous acquisition of load and pressure.

**Figure 2:** Intra-annular pressure transducer followed load cell.

### RESULTS AND DISCUSSION

Intra-annular pressure transducers (IAPT) were successfully connected and packaged to withstand compressive stresses to at least 1.6 MPa. Calibrations performed in fluid versus solid contact tests did not differ significantly; sensors performed consistently with linear output and small offset voltages. Preliminary *in situ* tests indicated that applied loads and sensor response (IAPT) were well-correlated (Fig. 2), and that the sensor is likely to withstand the physiological environment. Testing continues to determine the effects of shear and torsional loading, dynamic range, and long-term reliability prior to their intended application *in vivo*.

### CONCLUSIONS

Novel subminiature (MEMS) compression sensors were successfully fabricated, packaged, and calibrated as isolated transducers as well as *in situ* in the annulus of the intervertebral disc. Further characterization and consideration for *in vivo* and other biomechanical uses are warranted.

## GENDER DIFFERENCE IN CARPAL TUNNEL COMPLIANCE

Zong-Ming Li

Hand Research Laboratory, Department of Orthopaedic Surgery

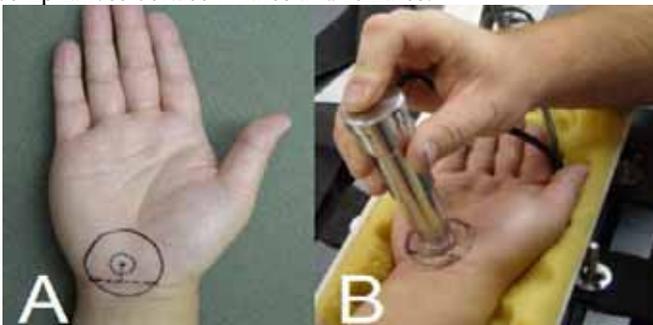

University of Pittsburgh, Pittsburgh, PA 15213, USA. [zmli@pitt.edu](mailto:zmli@pitt.edu); [www.pitt.edu/~zmli/handlab/](http://www.pitt.edu/~zmli/handlab/)

### INTRODUCTION

The carpal tunnel is formed by the carpal bones and the transverse carpal ligament, and is unaccommodating for the expansion of its contents. The detrimental mechanical limitation by the ligament is exemplified by carpal tunnel release, a universal surgical procedure to release the transverse carpal ligament for the treatment of carpal tunnel syndrome. Previous studies have shown that myofascial release manipulation applied to the carpal tunnel caused tunnel enlargement and improvement of carpal tunnel symptoms [1]. The stretchability of the transverse carpal ligament was also demonstrated in cadaver studies [2]. In addition, hypertrophy of the transverse carpal ligament has been proposed as one of the pathogenesises of carpal tunnel syndrome [3]. To date, little is known about the mechanical properties of the carpal tunnel. The purposes of this study were (i) to characterize the force-displacement relationship resulting from indentation applied to the palmar aspect of the wrist overlying the transverse carpal ligament, and (ii) to study gender difference in carpal tunnel compliance as determined by the indentation test.

### METHODS

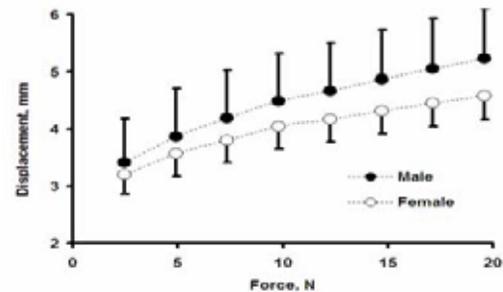

A hand-held Myotonometer (Neurogenic Technologies, Inc) was used to measure force and displacement during indentation testing. The indentation probe has a flat end with a diameter of 10 mm. To standardize indentation location on the skin overlying the transverse carpal ligament, a line was drawn to connect the palpable pisiform and scaphoid. A point 10 mm distal from the connection line on the bisector was marked as the center of indentation (Figure 1A). During the testing, the hand was placed in an arm holder with the palmar side facing upward (Figure 1B). The probe was manually pressed down perpendicular to the skin surface. The device took measurements from 0.25 to 2.00 kg at an increment of 0.25 kg. Twelve males (age  $29.3 \pm 6.6$  years) and twelve females (age  $26.2 \pm 4.3$  years) who had no neuromusculoskeletal disorders to the upper extremity participated in the study. Effective compliance was defined as the slope of the linear regression line of a set of force-displacement data. Repeated measures 2-way ANOVAs were used to compare the displacement differences. An independent t-test was used to compare the effective compliances between males and females.

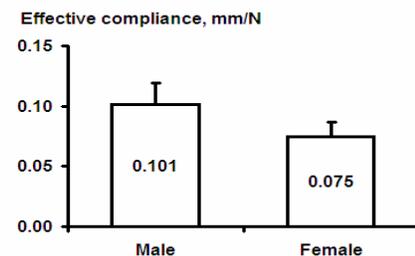

**Figure 1.** Center of indentation above the transverse carpal ligament (A), and manual indentation testing (B).

### RESULTS

In the tested force range, the displacement increased linearly with applied force for either male or female group (Figure 2,  $R^2$  ranges from 0.936 to 0.981). Females showed significantly smaller displacements than males ( $F = 30.4, P < 0.001$ ). Force increases from 0.25 to 2.00 kg caused average indentation displacements of  $1.82 \pm 0.30$  mm and  $1.38 \pm 0.25$  mm for males and females, respectively. The effective compliance of females,  $0.075 \pm 0.012$  mm/N, was 24.5% lower than that of males,  $0.101 \pm 0.018$  mm/N ( $P < 0.005$ , Figure 3).

**Figure 2.** Force and displacement from indentation testing.

**Figure 3.** Effective compliance (mm/N).

### DISCUSSION

An indentation testing was performed non-invasively to the palmar wrist overlying the transverse carpal ligament. A linear force-displacement relationship was shown in the tested force range. The results confirmed the hypothesis that females have less compliant carpal tunnels than males. This finding may partially explain the higher prevalence of carpal tunnel syndrome in women than in men [4]. Future studies are needed to investigate the material and structural properties of the transverse carpal ligament, the relationship of the ligament to the carpal tunnel pressure, and the biological and biomechanical adaptations of the ligament to repetitive hand use.

## SKILL ACQUISITION OCCURS DURING FALL-PREVENTIVE MOTOR REPOSE TRAINING

Karrie L. Hamstra-Wright, Karen L. Reed-Troy, and Mark D. Grabiner

Musculoskeletal Biomechanics Laboratory, University of Illinois at Chicago; email: khamstl@uic.edu

### INTRODUCTION

Older adults have a high incidence of trip-related falls that contribute to significant morbidity and mortality. A surrogate treadmill task has been proposed as a potential fall-preventive training tool for older adults. Successful motor response training must elicit stepping strategies as similar as possible to those evoked during actual trips and must demonstrate motor skill acquisition. Differences in the foot trajectories after an actual trip compared to those during the treadmill task have been attributed to the presence of an obstacle [1]. Recent work has shown that the addition of an obstacle to the surrogate treadmill task increases step height and step length to more closely approximate stepping responses elicited during an actual trip [2]. Older adults have demonstrated the ability to modify failed stepping strategies and successfully recover on the subsequent trial during the treadmill task without the obstacle [3], but little is known about the underlying motor control mechanisms regulating the acquisition of this skill.

The purpose of our study was to assess motor skill acquisition while participants successfully stepped over an obstacle during the surrogate treadmill task. We hypothesized that step height, trunk flexion, and trunk angular acceleration would decrease as subjects acquired the skill.

### METHODS

Ten healthy young adults (7 females, 3 males) participated in the study ( $26.9 \pm 5.04$  yrs,  $171.2 \pm 6.47$  cm). A surrogate trip was induced through sudden treadmill acceleration (maximum speed of 2.5 mph). Subjects were instructed to recover equilibrium and continue walking after the treadmill was unexpectedly activated. Fifty randomized stepping trials, 25 without an obstacle on the treadmill and 25 with a 5 cm obstacle placed 2.5 cm in front of the toes, were conducted. Whole body 3D kinematics were collected with an eight-camera motion capture system (Motion Analysis, Santa Rosa, CA). Maximum step height of the recovery (first leg to step) and trail limb (second leg to step), peak trunk flexion, and peak trunk angular acceleration in flexion and extension were compared between conditions (with, without obstacle) and between trials (trials 1-5 average, trials 20-25 average).

### RESULTS AND DISCUSSION

A repeated measures MANOVA revealed a significant reduction in step height, trunk flexion, and trunk angular acceleration in flexion and extension between trials. In the

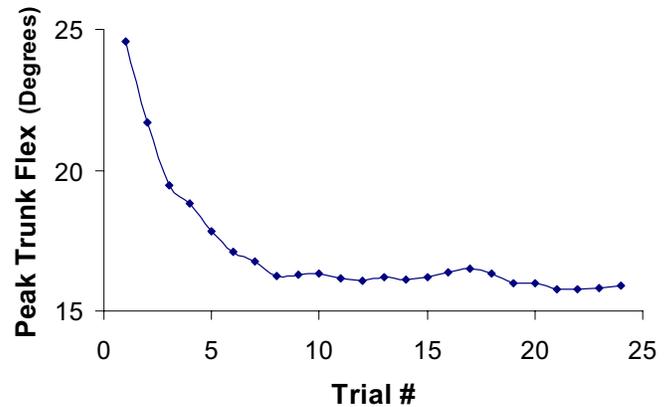

Figure 1: Running mean of peak trunk flexion versus trial number for a typical subject

obstacle condition, recovery and trail step height decreased from trials 1-5 (recover:  $30.75 \pm 5.85$  cm; trail:  $34.79 \pm 5.77$  cm) to trials 20-25 (recover:  $27.31 \pm 6.88$  cm; trail:  $30.22 \pm 5.13$  cm). Regardless of condition, participants demonstrated considerable decreases in trunk flexion and trunk angular acceleration with repetition illustrating skill acquisition of this novel task (Table 1). When subjects stepped over the obstacle, peak trunk flexion reached a steady state whereby further repetition did not result in less trunk flexion (Figure 1). This progressive reduction in peak trunk flexion indicates greater trunk control as trial number increases.

### CONCLUSIONS

Twenty-five trials using the surrogate treadmill task with the addition of an obstacle appears to be a more than adequate number of trials to illustrate improvements in foot and trunk control as a measure of skill acquisition. Decreased trunk flexion during tripping events may contribute to successful trip recovery [3] making it a desirable outcome of a fall-preventive training protocol. This work provides further direction in the design and development of a treadmill training protocol as an expedient and effective tool in training older adults how to avoid falling after large postural disturbances.

**WRIST KINETICS DURING IMPACT ARE AFFECTED BY HAND SYMMETRY**

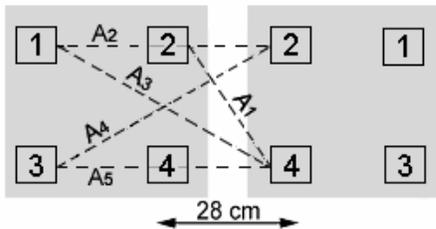

Karen L. Reed-Troy and Mark D. Grabiner

Musculoskeletal Biomechanics Laboratory, University of Illinois at Chicago email: klreed@uic.edu

**INTRODUCTION:** Falls onto the outstretched hands are the most frequent cause of upper extremity injury, and it has been estimated that older adults experience wrist fractures at a rate of 8 to 10 per 1000 person-years [1]. Previous work has quantified impact forces during symmetrical simulated falls [2,3], and several groups have shown that cadaver wrists fracture when loaded with 1.5 to 3.6 kN [4]. There is evidence that many falls result in temporally and spatially asymmetrical hand impacts [5], however no experimental studies have examined the sensitivity to wrist kinematic and kinetic measures to asymmetry.

The present study was undertaken to quantify wrist kinetics during asymmetrical impacts, and specifically to address three questions. How is spatial asymmetry at impact related to temporal asymmetry? Do asymmetrical impacts result in larger resultant forces than symmetrical impacts? How is loading direction affected by asymmetry?

**METHODS:** Nine adults participated in this institutionally reviewed and approved experimental protocol. Each subject performed 15 forward falls from a kneeling position onto two force plates. Five asymmetrical combinations of four targets, A<sub>1</sub> through A<sub>5</sub>, were selected (Figure 1), based on hand dominance. Each subject performed three consecutive trials at each combination. Force plate data were captured at 2400 Hz. Motion data were captured at 240 Hz (Motion Analysis, Santa Rosa CA).

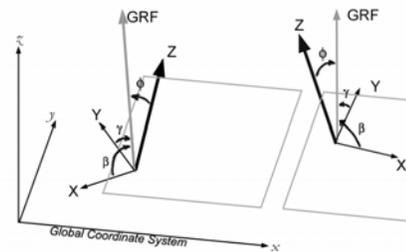

**Figure 1** Force plates showing the locations of the four targets. Combinations A<sub>1</sub> through A<sub>5</sub> for a right-handed individual are shown with dotted lines.

The instant of force-plate contact was determined as the time at which each plate measured  $\geq 5\%$  body weight (BW). The instant of peak force was measured when the maximum resultant force was reached on each plate. Temporal offset (dtime) between hand-hits was determined for each subject (dtime>0, dominant hand hit first). Force direction for each arm was determined relative to the axis of the forearm (from wrist center to elbow center, Figure 2) and expressed in directional cosines.

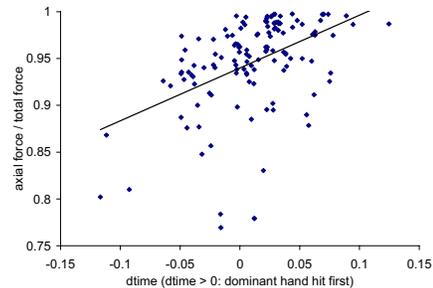

**RESULTS AND DISCUSSION:** Spatial asymmetry caused a temporal offset abs(dtime) between hand-hits of 33±25 ms. On average, 25±9 ms elapsed between the instant of contact and the instant of peak force. In contrast, symmetrical falling data collected with the same set of targets resulted in significantly smaller temporal offsets of 12±11 ms [5].

Asymmetry did not influence peak resultant force magnitude (symmetrical: 92 ± 38 %BW, asymmetrical 94 ± 30 %BW).

**Figure 2** Arm-specific coordinate systems with direction cosines. The z-axis of each system is aligned with the axis of the forearm at the instant of peak force. The axes are mirror-images of each other such that a positive x-value indicates laterally directed force, relative to the forearm (i.e. the left hand coordinate system has left-handed axes). Direction cosine angles are defined such that  $\beta$  is the angle from the x-axis,  $\gamma$  is the angle from the y-axis, and  $\phi$  is the angle from the z-axis. A force is directed along the axis of the forearm when  $\beta=90^\circ$ ,  $\gamma=90^\circ$ , and  $\phi=0^\circ$ . Note that in all cases  $\cos^2\beta + \cos^2\gamma + \cos^2\phi = 1$ .

However, at the same target location (1 through 4), asymmetry significantly influenced force direction. In targets 1, 2, and 4, asymmetry caused the resultant force to be more axially directed. The 95% C.I. for peak force direction across all asymmetrical positions ranged from 100% axially loaded to  $\beta=82.5^\circ$ ,  $\gamma=70.4^\circ$ ,  $\phi=29.5^\circ$  (87% axially loaded).

**Figure 3** Dominant hand axial force versus temporal offset.

Larger temporal offsets were associated with axially directed resultant ground reaction forces in the first hand to hit (i.e. dominant axial/total force  $\sim$  dtime,  $r = 0.454$   $p < 0.001$ , non-dominant axial/total force  $\sim$  dtime,  $r = -0.335$   $p < 0.001$ , Figure 3). When the ground is contacted asymmetrically, the first hand may be used to reduce the downward and forward velocity of the body, while the second hand may play a more important role in preventing body rotation and in reducing shear.

Although asymmetry doesn't appear to affect peak force magnitude, it does cause more axially directed forces. This appears to be modulated by the magnitude of temporal offset. The extent to which fracture mechanics of the radius are affected by loading direction is still unknown. Furthermore, spatial asymmetry has been shown to cause temporal asymmetry, even for this self-initiated falling task.

## RECOVERY RESPONSES TO SURROGATE SLIPS ARE DIFFERENT THAN ACTUAL SLIPS

Karen L. Reed-Troy and Mark D. Grabiner

Musculoskeletal Biomechanics Laboratory, University of Illinois at Chicago

email: klreed@uic.edu

**INTRODUCTION** Slipping and slip-related falls are a common and potentially dangerous problem, especially for older adults. We believe that it is possible to train corrective responses of older adults to reduce the incidence of slip-related falls. However, such an approach requires further understanding of the causal biomechanical distinctions between a successful and an unsuccessful recovery effort. Surrogate tasks are often used to study complex biomechanical events associated with large postural perturbations [1,2]. Although surrogate tasks enhance experimental control over one or more elements of a generally more complex event, such control may change the task of interest by imposing biomechanical constraints that reduce the validity of the surrogate. The purpose of the present study was to quantify the differences in lower extremity and trunk kinematics following a simulated slip versus an actual slip. We hypothesized that the simulated slips would result in significantly different (and less realistic) recovery kinematics, and that individuals who fell on either surface would have larger and faster trunk extensions, and more rapid slipping foot acceleration.

**METHODS** Twenty-two healthy young adults were each subjected to two types of unexpected slips during a single laboratory visit. Slips were induced in random order using a custom slipping platform and also using artificial ice [3]. The slipping platform consisted of three raised plywood platforms laid end-to-end to create a 7.2 m long walkway. The middle platform had two surfaces (31 x 122 cm), one for each foot, which could be locked in place or move along linear bearings. Each surface could slide a maximum distance of 62 cm in the direction of walking. During trials in which a slip was to be induced the middle platforms were unlocked remotely. The artificial ice consisted of a 1.2 x 1.2 m Plexiglas sheet, the surface of which was coated with a film of mineral oil prior to a slipping trial. Subjects were slipped on the artificial ice after 10 control trials (with no threat of a slip) were collected; they were unaware of the oil. Data from the first slip on the platform were compared to data from the slip on the oil.

From motion capture data (Motion Analysis, Santa Rosa, CA) the onset of the slip and the instant of recovery (the instant the non-slipping foot contacted the surface) were identified. The following variables were quantified for each subject: slip displacement (forward and mediolateral directions), peak slipping foot forward and mediolateral velocities and accelerations, slipping foot internal/external rotation, time to rear foot ground contact, distance the foot was placed behind the body center of gravity, peak trunk extension, and peak trunk extension velocity during the slip. Paired t-tests were used to compare responses during platform slipping and artificial ice slipping.

**RESULTS AND DISCUSSION** Four subjects (three female) either fell or grabbed the safety harness rope to avoid falling on the artificial ice. Fallers had significantly larger peak lateral flexion angles (30° vs. 13°, p=0.01) and more trunk rotation about the spine (24° vs. 14°, p=0.003). There were no significant differences in trunk extension between fallers and non-fallers. However, the peak slipping heel velocities were larger (214 cm/s vs. 148 cm/s, p=0.04), the slipping displacements were larger (55 cm vs. 30 cm, p=0.02), and the internal/external ankle rotation during the slip was larger (14° vs. 7°, p=0.02) in slips that resulted in a fall.

Four subjects (two male, two female) fell or grabbed the safety harness rope to avoid falling on the slipping platform. Subjects who fell or required rope assistance had significantly larger peak trunk extension angles (38° vs. 17°, p=0.002) but there were no differences in lateral flexion or rotation. Peak heel accelerations were larger (1000 cm/s<sup>2</sup> vs. 602 cm/s<sup>2</sup>, p=0.04) and internal/external leg rotation was larger (14° vs. 7°, p=0.008) in those who fell compared to those who recovered.

Recovery from slips on the artificial ice appears to be biomechanically different than recovery from slips on the slipping platform (Table 1). Specifically, on the artificial ice the slipping foot's forward displacement and acceleration were 32% smaller and 85% larger than on the platform, respectively, despite nearly identical pre-perturbation walking velocities (127 cm/s on the platform, 126.7 cm/s on the ice) Slips induced on the slipping platform resulted in smaller slipping foot accelerations than those on the artificial ice. Furthermore, slips on the platform elicited a less conservative recovery response, despite nearly identical pre-perturbation walking speeds in both trials. A conservative response would include rapid placement of the rear foot far behind the center of mass to help prevent excessive trunk extension and reestablish the base of support.

Since several of the variables of interest are influenced by the methodology, providing a realistic perturbation is of great importance. Four of the ten measures that were significantly different between slipping surfaces were the same that distinguished fallers from non-fallers on those surfaces. Simulated slips may be an appropriate vehicle to investigate specific variables associated with sudden postural perturbations, however constraining the direction and displacement of the slip and the additional friction between the slipping foot and the surface, appear to influence the elicited recovery response.

## DOES FREE MOMENT PREDICT THE INCIDENCE OF TIBIAL STRESS FRACTURE?

<sup>1</sup>Clare E Milner, <sup>1,2</sup>Irene S Davis and <sup>3</sup>Joseph Hamill

<sup>1</sup>University of Delaware, Newark, DE, <sup>2</sup>Drayer Physical Therapy Institute, Hummelstown, PA, <sup>3</sup>University of Massachusetts, Amherst, MA; email: [milner@udel.edu](mailto:milner@udel.edu), web: <http://www.udel.edu/PT/davis/Lab.htm>

### INTRODUCTION

Stress fracture injuries are common in distance runners, and occur most frequently at the tibia. Female runners are twice as susceptible to stress fracture as males. While multiple factors probably lead to the development of stress fractures, biomechanical factors such as loading are considered to play a role. Free moment (FM) is the torsional force about a vertical axis due to friction between the foot and the ground during stance. While FM has been linked to pronation, its potential role in running injuries has not been investigated widely. The relationship of FM to the loads experienced by the lower extremity makes it worthy of further investigation in relation to stress fracture injury. The spiral nature of some stress fractures indicates that torsional stresses on the lower extremity may be involved. If this is the case, the magnitude of the load may be more important than its direction. Furthermore, since FM is calculated directly from a force platform, it may have some value as a simple tool for predicting tibial stress fracture (TSF) in runners.

Preliminary work in our laboratory showed an increase in peak positive FM (resistance to toeing out), and trends towards higher FM at peak braking force and net angular impulse in 13 runners with a history of TSF, compared to runners with no previous lower extremity bony injuries. These trends suggest that there might be significant differences in FM variables between the groups if a larger subject pool were analyzed. Furthermore, the preliminary study did not consider the absolute magnitude of peak FM. An absolute measure (peak regardless of direction) may better represent the size of the torsional force acting on the lower extremity.

The purpose of this study was to investigate the relationships between FM variables and the occurrence of TSF in female distance runners. We hypothesized that maximum positive FM (POSBM), FM at peak braking force (FMBRAK), net angular impulse (IMP) and absolute peak FM (ABSFM) would be greater in runners with a history of TSF compared to uninjured controls. In addition, ABSFM would be predictive of group membership.

### METHODS

A group of uninjured female distance runners with a history of tibial stress fracture ( $n = 25$ , age =  $28 \pm 10$ y, weekly mileage =  $116 \pm 39$  miles) and an age- and mileage-matched control group ( $n = 25$ , age =  $26 \pm 9$ y, weekly mileage =  $117 \pm 47$  miles) ran at 3.7m/s on a 25m runway containing a force platform sampling at 960Hz. Data from five trials were scaled to body weight and height and values for each variable averaged for statistical analysis. Differences between the TSF and control groups were examined using independent t-tests ( $p \leq 0.05$ ). All t-tests were one-tailed, as only higher values in the TSF group were of interest. The utility of ABSFM in

predicting group membership was investigated using binary logistic regression.

### RESULTS AND DISCUSSION

Generally, FM was greater in the TSF group (Table 1). While the magnitude of FM was significantly higher in the TSF group for POSFM and FMBRAK, the highest values in both groups were found in ABSFM. ABSFM also had a larger effect size (0.93, large) than POSFM (0.76, moderate). The higher value of ABSFM, compared to POSFM, indicates that in some runners negative FM (resistance to toeing in) is greater in magnitude than positive FM (resistance to toeing out). This is supported by our observations that some runners have a negative bias in their free moment curve. Therefore, POSFM does not always reflect the highest torsional force experienced by these subjects.

Further support for the importance of ABSFM in TSF was provided by the binary logistic regression. Regression results suggest that increased ABSFM is related to an increased likelihood of being in the TSF group. The model indicated that for every  $1.0 \times 10^{-4}$  increase in ABSFM, the likelihood of having a history of TSF increases by a factor of 1.354 (95% confidence interval 1.086 to 1.688),  $p = 0.007$ . According to the model chi-square statistic, the model is significant ( $p = 0.001$ ). It also predicted group membership correctly in 66% of the cases. The Nagelkerke R square value was 0.251, suggesting that 25% of the variance between the two groups is explained by ABSFM.

These data suggest a relationship between FM and a history of TSF in distance runners. However, further prospective studies are needed to determine whether ABSFM can be used to predict the occurrence of TSF in female distance runners.

**Table 1:** Free moment variables in TSF and Control groups.

	POSBM	FMBRAK	IMP (s)	ABSFM
<b>TSF</b>	$7.5 \pm 4.5$	$4.0 \pm 5.7$	$6.2 \pm 5.7$	$9.0 \pm 4.3$
<b>Controls</b>	$4.7 \pm 2.5$	$1.6 \pm 3.7$	$1.6 \pm 5.5$	$5.9 \pm 2.1$
<b>Effect size</b>	0.76	0.49	0.83	0.93
<b>P</b>	0.023	0.043	0.781	0.001

All variables are  $\times 10^{-3}$ , except IMP which is  $\times 10^{-4}$ .

### CONCLUSIONS

Peak positive FM, FM at peak braking force and absolute peak FM were significantly higher in the TSF group. This suggests an association with history of TSF in female distance runners. The magnitude of absolute peak FM successfully predicted a history of TSF in this group in 66% of cases.

## THE INFLUENCE OF MUSIC ON KINEMATIC AND DYNAMIC GAIT PATTERNS

Wolfgang I. Schöllhorn, Henrike Kokenge, Karina Fölling, Meike Alichmann, Christiane Bohn  
 Institute for Sport Science; University of Münster  
 email: [schoell@uni-muenster.de](mailto:schoell@uni-muenster.de)

### INTRODUCTION

For the optimization of therapeutic processes different learning strategies have been suggested. From a neurophysiological point of view cognitive processes such as learning and memory are affected by emotions [1]. Beside psychological interventions music can lead to emotional responses [2]. The aim of this study was to investigate the influences of music on everyday movement with extremely individual characteristics [3].

### METHODS

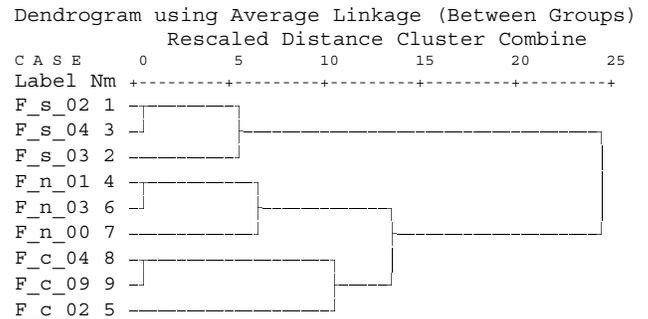

Kinematic and dynamic gait patterns were recorded from 16 subjects within three conditions: Stimulating (s), comfort (c), and no (n) music. In all trials headphones were worn. In each condition subjects had to pass in a randomly assigned order three times a 5m zone within which one double step was video recorded (25 Hz). Gait velocity was self determined (0.86-1.49m/s) and measured by means of two pairs of light bars. Subjects were recorded three dimensionally with 2 video cameras (JVC), one in front, and one on the right side of the subject. Angles and angular velocities of the main joints (ankle, knee, hip, shoulder, elbow, trunk) were determined via DLT within SIMI-Motion-Software. Ground reaction forces were measured via Kistler force platform (1000Hz). The time courses of all variables and groups of variables during three right ground contact phases were classified by means of hierarchical cluster analysis. The groups of variables were a) all angles and angular velocities, b) all angles, c) all angular velocities, d) all variables of the lower extremities, e) the ankle angle, and f) ground reaction forces. Assessment rates were

$$\text{determined by } AR = \frac{1}{n} \sum_{i=1}^n \frac{m_i}{r_i} 100\%,$$

with n = number of subjects, m = number of trials clustered in the largest cluster, and r = number of trials per subject. All subjects had to answer a questionnaire about the personal music preferences.

### RESULTS AND DISCUSSION

The cluster analysis on the basis of all trial and all variables reveals an AR of 90%, which increases up to 93% when only the angular variables are included. Both ARs with respect to the number of subjects and trials provide strong evidence for the individuality of gait patterns according to [3]. On the background of the ground reaction forces the AR decreases to 70%. Obviously, the angular variables, as the most differentiated type of data, lead to the highest AR. The cluster analyses within single subjects show a strong influence of music in the gait pattern of only two subjects. Most intriguingly some subjects who stated to have no musical or rhythmical sense in the questionnaire displayed fairly good ARs for each type of music. Two subjects achieved a 100% separation by the type of music which they were listening to

**Figure 1:** Dendrogram of a single subject (F) based on all kinematic variables with a disjunct separation of gait patterns by type of music (s, n, c).

during gait (figure 1). Very often the single- subject- cluster-analysis leads to a separation of the gait pattern with stimulating or with calming music. When the stimulating music mode was separated the calming and no music mode was merged. When the calming music condition was separated the stimulating and no music condition was clustered together. Whether this provides insight into fundamental personal moods or into situational personal music preferences demands further research.

### CONCLUSIONS

Although the applied linear pattern recognition approach is not considered as the most differentiated one[4], the results verify relevant consequences. This study shows a twofold support for emphasizing research, particularly in clinical applications, on individuals rather than on groups. Firstly, a strong individuality of gait patterns was diagnosed. Secondly, evidence for individual motor reaction when listening to music was shown. However, the presented approach provides a supplementary and sensitive tool for interdisciplinary problems towards more complex or holistic questions.

## COMPARING THE GAIT OF BIPEDAL ROBOTS WITH THAT OF INFANTS

Christopher L Vaughan, Victoria Mendel, Nazir Karbanee  
MRC/UCT Medical Imaging Research Unit, Department of Human Biology, University of Cape Town,  
Observatory 7925, South Africa; email: [kvaughan@cormack.uct.ac.za](mailto:kvaughan@cormack.uct.ac.za)

### INTRODUCTION

There has been renewed interest in the capabilities of bipedal robots in the past decade. They may be classified as *active*, (having their own power supply and actuators) or *passive* (driven by the effects of gravity), and *static* (the centre of gravity is always within the base of support) or *dynamic*, where the CG sometimes falls outside the support base [1].

Just as a bipedal robot needs to trade off balance and propulsion, so too does the human infant need to master these two factors when learning to walk [1]. In this paper we compare our recent data for an active and a passive robot with our prior data for young children [2].

### METHODS

We based our active robot on the “drunken sailor” design [3], in which two actuators were incorporated, one to drive the legs and the other to tip the robot from side-to-side in order to clear the swinging leg (Figure 1). The robot had adjustable leg lengths (of 122, 137 and 152 mm), a mass of 0.72 kg and a programmable controller, allowing different cadences and step lengths to be implemented. A six camera Vicon system was employed to capture images at 120 Hz from four retro-reflective markers attached to the hip joints and feet of the robot. The 3D data files enabled us to calculate cadence, stride length and velocity, from which dimensionless velocity – the square root of the Froude Number – was derived [4].

Figure 1: Powered bipedal robot driven by two motors.

Our passive robot was based on the design of Garcia *et al.* [5] and implemented in both a physical and computer simulated form. We present here our simulated data. The robot had

adjustable leg lengths (520, 770 and 1160 mm), a mass of 3.46 kg and we varied the angle of the inclined slope from 1.0 to 4.5 degrees. The temporal-distance parameters, which enabled us to calculate the dimensionless velocity, were a direct output of the simulation.

### RESULTS AND DISCUSSION

Our active robot used a static pattern of movement to maximize stability (Figure 1) and hence sacrificed velocity, having dimensionless velocity values between 0.031 and 0.043 (Figure 2). In contrast, our passive robot used a dynamic gait pattern, achieving dimensionless values up to 0.3 for shorter leg lengths and a slope of 4.5 degrees (Figure 2). With increasing leg lengths, however, stability was critical and the dimensionless velocities dropped off to 0.1. These data are in good agreement with the literature: Collins *et al.* [6] built and tested a 3D passive dynamic walker, while Honda’s ASIMOV robot [7] has an active dynamic pattern (Figure 2). The dimensionless velocities for children [2, 4] increase from 0.25 for an 18 month-old up to a value of 0.45 for teenagers and adults.

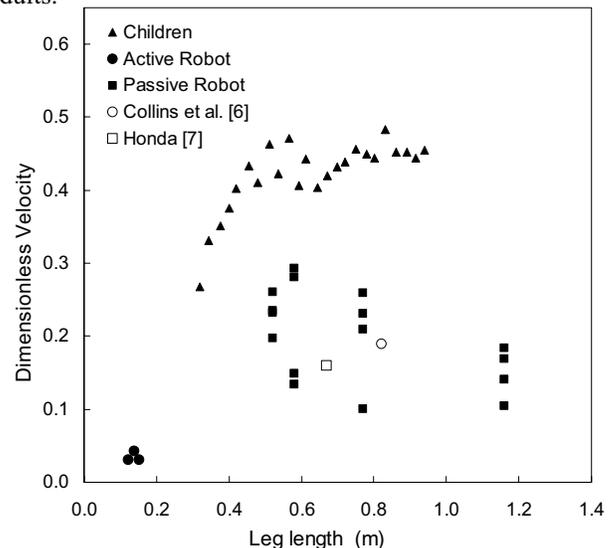

Figure 2: Dimensionless velocity as a function of leg length.

### CONCLUSIONS

From a developmental point of view, the gait of sophisticated bipedal robots is just beginning to approach that of infants.

## KINEMATICS OF MOUSE SCROLLING

U. Chris Ugbole, Thomas H. Christophel, Nancy A. Baker, Zong-Ming Li  
Hand Research Laboratory, Departments of Orthopaedic Surgery, Bioengineering, and Occupational Therapy  
University of Pittsburgh, Pittsburgh, PA 15213, USA. [zmli@pitt.edu](mailto:zmli@pitt.edu); [www.pitt.edu/~zmli/handlab/](http://www.pitt.edu/~zmli/handlab/)

### INTRODUCTION

One of the most common computer peripherals is a two-button scroll mouse. Studies have shown that the risk of upper extremity musculoskeletal disorders can be increased by intensive mouse use such as clicking and dragging, wheel scrolling, cursor movement, and awkward wrist posture [1-2]. Previous studies on mouse use have focused on finger forces [3-4], wrist positions [5] and hand motion [6] during pointing and dragging. The purpose of this study was to examine the joint kinematics of the index finger during mouse wheel scrolling.

### METHODS

Five subjects aged  $26 \pm 3$  years without any musculoskeletal disorders of the upper extremity participated in the study. All subjects were familiar with using a computer mouse. Five reflective markers of 5 mm diameter were placed on the index finger: the center of the nail, distal and proximal interphalangeal (DIP and PIP) joints, metacarpophangeal (MCP) joint, and the midpoint of the 2nd metacarpal bone. A motion capture system (VICON 460, Oxford, UK) was used to collect the marker motion data. Each subject comfortably gripped a two-button scroll mouse (Microsoft® Intellimouse®, Redmond, WA) with their right hand with the index finger over the wheel. They were instructed to maintain a neutral wrist posture. The subjects performed full forward and backward scrolling tasks at 1 cycle/second following a metronome. Ten cycles of scrolling data was collected at 60 Hz. The range of motion and the coefficients of correlation for the DIP, PIP, and MCP joints were calculated. A two-way ANOVA was used to examine the difference in joint range of motion (ROM).

### RESULTS

During backward scrolling, the DIP, PIP and MCP joint movements were highly correlated (Figure 1). The DIP and PIP joint moved in phase with correlation coefficient of  $0.996 \pm 0.025$ . The MCP joint was correlated in anti-phase with the PIP or DIP joint. For example, the correlation coefficient between the MCP and PIP joint movements was  $-0.916 \pm 0.066$ . Each backward scroll cycle began with the minimal flexion of the DIP and PIP joints ( $5.3 \pm 2.5^\circ$  and  $14.6 \pm 7.4^\circ$  respectively) and maximum flexion of the MCP joint ( $21.9 \pm 6.9^\circ$ ) and ended with maximum flexion of the DIP and PIP joints ( $38.1 \pm 8.8^\circ$  and in  $57.2 \pm 8.5^\circ$  respectively) and minimal flexion of the MCP joint ( $8.4 \pm 6.1^\circ$ ). A similar, but reverse, pattern was observed during forward scrolling. In backward or forward scrolling the PIP joint ROM was greater than the DIP joint ROM and was more than twice the MCP joint ROM ( $P < 0.05$ , Figure 2). The scrolling direction did not significantly affect the ROMs of the DIP, PIP or MCP joint.

### DISCUSSION

Mouse use requires controlled and stereotypical movements of the DIP, PIP and MCP joints. The negative correlation between the MCP joint and the interphalangeal (IP) joints (i.e.

IP joint flexion with MCP joint extension) is advantageous as it prevents excessive muscle shortening or lengthening, preserving optimal muscle lengths for effective force production. On the other hand, our results show that the DIP, PIP and MCP joints move in the ranges of  $5-38^\circ$ ,  $15-57^\circ$ , and  $8-22^\circ$ , respectively, during a typical mouse scroll. These motions comprise approximately 40% (DIP), 50% (PIP), and 15% (MCP) of their respective full ROM (see also [7]). In addition, these motion ranges do not surround the functional neutral positions of these joints, which may place these joints under more-than-minimum stress throughout mouse use. Mouse use can account for over 20% of computer use time and more than 78 uses per hour [3]. This repetitive stresses on finger joints could lead to musculoskeletal disorders of hand muscles and finger joints. Further biomechanical studies of mouse usage could help design ergonomic mice to minimize musculoskeletal strain.

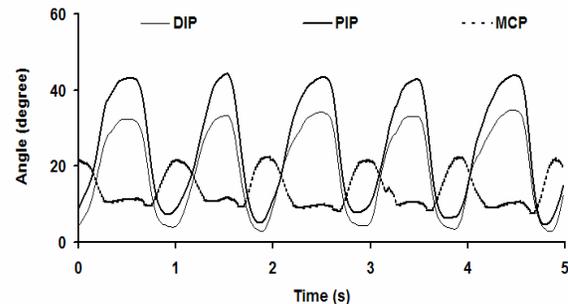

Figure 1. Representative joint angular motion during 5-cycles of backward scrolling.

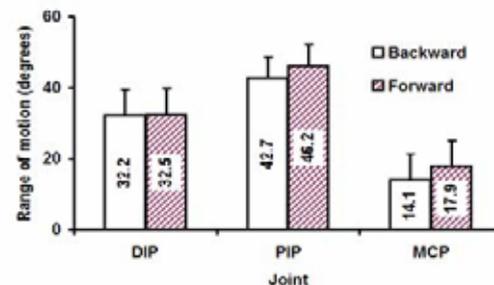

Figure 2. Range of motion of individual finger joints during backward and forward scrolling.

## KINEMATICS OF THUMB OPPOSITION

Jie Tang, Thomas Christophel, Zong-Ming Li

Hand Research Laboratory, Departments of Orthopaedic Surgery and Bioengineering  
University of Pittsburgh, Pittsburgh, PA 15213, USA. [zmli@pitt.edu](mailto:zmli@pitt.edu); [www.pitt.edu/~zmli/handlab/](http://www.pitt.edu/~zmli/handlab/)

### INTRODUCTION

One of the most important hand functions is thumb opposition, which results from flexion, abduction and axial rotation at the carpometacarpal, metacarpophalangeal and interphalangeal joints [1]. The thenar muscles, innervated by the median nerve, are critical for coordinated thumb movements. It is commonly observed that thumb opposition is impaired with median neuropathy [2]. The clinical method to assess thumb motion capability is to measure the distance between the thumb tip and the fingertip, or between the thumb tip and distal palmar crease [3]. Goniometric measurement quantifies thumb range of motion in isolated planes, but does not provide information of the dynamic relationship between flexion and rotation. The purpose of this study was to examine the 3D movement of the thumb during opposition.

### METHODS

Three young male subjects aged  $25.6 \pm 3.2$  years without any musculoskeletal disorders of the upper extremity participated in the study. Six markers with diameters of 5 mm were attached to the hand (Figure 1). Three markers (1, 2 and 3) affixed to a small triangle plate were attached to the thumb nail. Three markers (4, 5, and 6) were placed on the outstretched fingers to establish a local coordinate frame (OXYZ). A motion capture system (VICON 460, Oxford, UK) was used to collect marker motion data. A normal vector (N) was defined from the three markers on the plate, pointing in the dorsal direction. The forearm was supinated so that the palm was in parallel to the horizontal plane and faced upward. All fingers were at full extension in parallel with the palm.

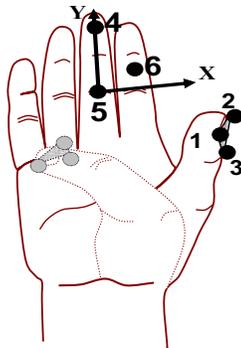

Figure 1: Marker placement on the right hand.

The subjects were instructed to perform thumb opposition, starting with the thumb at full extension in the palm plane, and then moving the thumb tip to the distal palmar crease of the little finger, and then returning to the starting position. Ten cycles of this movement were performed at self-selected paces. The thumb tip was approximated by calculating the middle point between markers 1 and 2. The flexion and pronation angles were determined by computing the projection angles of the vector N in the XY and XZ planes, respectively.

### RESULTS AND DISCUSSION

In the XZ plane, the thumb tip moved in a parabola trajectory during opposition (Figure 2). The thumb tip moved palmarly in the beginning phase and then dorsally as the tip approached the palmar crease. The movement magnitudes in the X and Z directions were  $124.8 \pm 8.6$  mm and  $54.2 \pm 10.9$  mm, respectively. The distal phalanx changed its orientation constantly during opposition, as shown by the non-parallel normal vectors (Figure 2). This change in orientation was produced by concurrent angular movements in flexion and pronation (Figure 3). The angle-angle curves showed piecewise coordination patterns. Thumb pronation was mainly produced in the beginning phase of opposition, perhaps contributing from the movement at the carpometacarpal joint. Flexion motion dominated at the later phase of opposition, likely resulting from movements at the metacarpophalangeal and interphalangeal joints. The ranges of motion in flexion and pronation were  $166.7 \pm 14.4$  degrees and  $144.0 \pm 16.5$  degrees, respectively. These kinematic analyses potentially allow for quantification and discrimination of abnormal motion patterns by hands with neuromuscular disorders such as carpal tunnel syndrome.

## THE EFFECT OF FOOT PLACEMENT ON SIT-TO-STAND WITH AND WITHOUT WALKER ASSISTANCE

Shashank Raina, Catherine A. Stevermer, and Jason C. Gillette

Department of Health and Human Performance, Iowa State University, Ames, Iowa, USA; email: sraina@iastate.edu

### INTRODUCTION

Moving from a sitting to standing position is a transfer that is essential to perform activities of daily living. Individuals having dysfunctional or weak lower extremities may have difficulty performing sit-to-stand movements and may depend on others for assistance. For example, frail elderly and those who have suffered a spinal cord injury may struggle with sit-to-stand movements. If leg strength is insufficient, the upper extremities play an important role in the standing up process. Greater arm assistance reduces maximum hip and knee joint torques by up to 50% [1]. Janssen et al. concluded that repositioning of feet influenced the strategy of the sit-to-stand movement and required lower extension moments at the hip [2]. The present study is aimed at finding how foot placement with or without walker assistance alters the biomechanics of sit to stand in healthy adults.

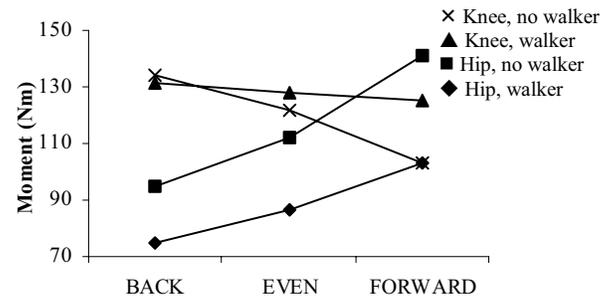

### METHODS

Four subjects (2 male/2 female, age  $25 \pm 5$  yr, height  $173 \pm 20$  cm) participated in this experiment. The subjects did not have any musculoskeletal disorder that would hinder their sit-to-stand performance. An eight-camera video System (Peak Performance, Englewood, CO) was used to track ten reflective markers placed on both sides of the subject's body. The subjects sat on a bench (height 45 cm) with their feet on two separate force platforms (AMTI, Watertown, MA). A Guardian Easy Care adult folding walker was used as an assist device for sit-to-stand. Two triaxial force sensors (Kistler, Amherst, NY) were used for measuring the hand forces applied on the walker.

The subjects sat with their feet shoulder width apart. The protocol involved two independent variables. The first independent variable compared standing with and without the assistance of a walker. The second independent variable that was tested involved three different initial postures: the feet anterior with respect to the knees (foot-forward) at an angle of  $80^\circ$  of knee flexion, the feet even with the knees (foot-even) at an angle of  $90^\circ$  of knee flexion, and the feet posterior with respect to the knees (foot-back) at an angle of  $100^\circ$  degrees of knee flexion. Hand support forces and joint moments were calculated during sit-to-stand movements for these six conditions. Each subject performed three repetitions of the six sit-to-stand conditions for a total of 18 trials.

### RESULTS AND DISCUSSION

Maximum hip extension moments increased from foot-back to foot-forward (Fig.1). The hip extension moments without walker assistance were higher than when using a walker for all foot positions. Maximum knee extension moments without walker assistance decreased from foot-back to foot-forward. Knee extension moments with the walker did not show as much of a change with foot positioning. Knee extension moments for foot-forward were higher with walker assistance

**Figure 1:** Hip and knee joint moments for alternative foot placements with and without walker assistance.

than without. Maximum ankle plantar flexion moments for foot-back (46Nm) were greater than foot-forward (23Nm) with the walker. The hand forces also showed a consistent trend. The vertical, anterior, and lateral forces increased gradually from foot-back to foot-forward. The average vertical forces were 18% body weight for foot-forward and 11% body weight for foot-back.

The results suggest that if a person has weakness in the hip, a foot-back placement will help reduce the moment requirements on the hip. Walker support in combination with a foot-back placement will facilitate lowering the hip moment requirements even further. This combination will also reduce the hand forces required on the walker, which is important because elderly individuals may have low upper body strength. The knee moments were substantially lower without walker assistance for the foot-forward placement. This may be due to the restricted range of motion of the upper body that reduces the amount of momentum generated. However, there was little difference between knee joint requirements with or without walker assistance when using the foot-back placement.

In addition, the results suggest that the net moment requirements of the body are reduced at the foot-even placement if standing with the help of a walker and the foot-back position if standing without any external support. These results can be used to help optimize stimulation patterns for paraplegics using functional neuromuscular stimulation systems to perform sit-to-stand. They can also be used to choose an appropriate foot placement to help reduce the force requirements for people with weakness in specific joints.

### INTRODUCTION

Osteoarthritis (OA) can lead to pain, disability, and loss of range of motion in the knee. The pre-operative condition of the knee has been shown to influence the functional outcome of treatments for OA [1]. A greater understanding of how motion of the knee is affected by OA may facilitate the assessment of the efficacy of potential treatments. We used a computer-assisted navigation system to study the passive kinematics of osteoarthritic knees intra-operatively and answer two questions: 1) Does the varus or valgus malalignment of the knee measured in full extension persist with flexion of the knee? and 2) Do “femoral rollback” (posterior translation of the femur on the tibia with flexion) and “screw-home” (external rotation of the femur with flexion) motions seen in a normal knee remain in an OA knee?

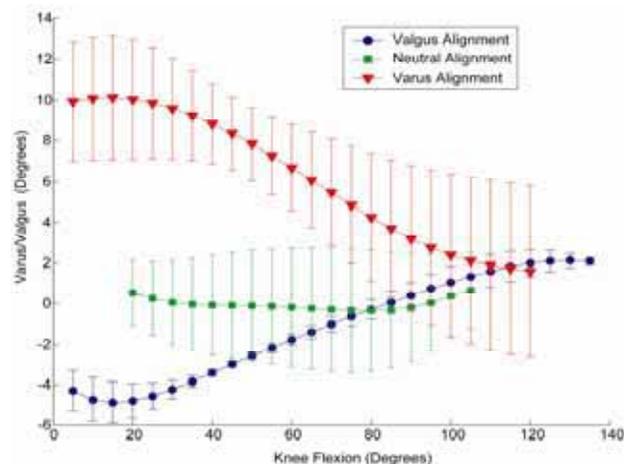

### METHODS

Twelve patients undergoing a primary total knee arthroplasty for treatment of OA gave informed consent to participate in this study. Patients were grouped by limb alignment: mechanical axis varus alignment (six patients), neutral alignment (four patients), and valgus alignment (two patients).

After exposure of the knee joint at the beginning of the operation, the surgeon attached passive optical reference frames from the navigation system onto the medial side of the distal femur and proximal tibia. He circumducted the femur and used a calibrated optical stylus to identify landmarks on the patient’s distal femur, proximal tibia, and ankle to establish anatomic reference frames in the femur[2] and tibia[3]. While supporting the leg with an open palm so as to avoid applying external loads to the limb, the surgeon then manipulated the subject’s leg through two full cycles of knee flexion and extension. The navigation system recorded the position and orientation of the femur and tibia throughout the motion pattern. We measured the displacement of the origin of the femoral reference frame (OFRF) with respect to the origin of the tibia reference frame to assess translation and determined the flexion, varus/valgus, and internal/external rotations of the knee[4]. Repeated measures analysis of variance (ANOVA) was used to evaluate the differences in kinematics between the three OA groups from 20° to 105° of flexion, the range of motion common to all subjects.

### RESULTS AND DISCUSSION

The varus/valgus malalignment measured in full extension did not persist with flexion of the knee, but the neutrally aligned limbs generally maintained their neutral alignment (Figure 1). All groups trended towards a slightly varus alignment in deep flexion, resulting in overall significantly different patterns of varus/valgus rotation between groups ( $p < 0.001$ ).

**Figure 1:** Mean varus (+)/valgus (-) angles for 3 OA groups. Error bars represent 1 standard deviation.

A very limited “screw-home” motion was present in all OA groups. In varus knees, the femur externally rotated by an average of  $3.0^\circ \pm 4.4^\circ$  over the common range of knee flexion. In the neutral and valgus groups, we observed an average of  $5.0^\circ \pm 6.9^\circ$  and  $1.0^\circ \pm 2.6^\circ$  of external rotation, respectively. No differences existed between the groups ( $p > 0.6$ ). These magnitudes of rotation are all less than what has been observed in normal knees, where as much as  $25^\circ$  of rotation has been reported [5].

The expected “femoral rollback” was present in the varus and valgus groups. In varus knees, the OFRF translated posteriorly an average of  $10.7 \pm 3.0$  mm. Similarly, in valgus knees, the OFRF translated posteriorly and average of  $8.0 \pm 0.9$  mm. However, the motion of the neutral knees was significantly different than the other two groups ( $p < 0.001$ ). In neutral knees, the OFRF translated anteriorly an average of  $7.0 \pm 5.8$  mm before translating posteriorly  $7.7 \pm 5.0$  mm from the most anterior point.

This study represents the first intra-operative characterization of the in-vivo passive kinematics of advanced osteoarthritic knees. Computer-assisted navigation systems, in which reference frames are directly and rigidly attached to bone, are a valuable research tool and represent a safe and reliable means of collecting intra-operative kinematic data.

## THE RELIABILITY AND REPRODUCIBILITY OF FOOT MEASUREMENTS USING A MIRRORED FOOT PHOTO BOX COMPARED TO CALIPER MEASUREMENTS

Nathan A. Mall, W. Mack Hardaker, James A. Nunley, MD, and Robin M. Queen, PhD  
 Michael W. Krzyzewski Human Performance Laboratory, Duke University  
 Division of Orthopaedic Surgery, Duke University Medical Center

### INTRODUCTION

It is widely believed that the height of the medial longitudinal arch (MLA) is a predisposing factor to various types of lower extremity injuries. Discrepancy exists in the literature as to which foot morphologies predispose individuals to certain injury patterns, and whether MLA height plays a role in injury prevention. The controversy surrounding the importance of MLA height and foot morphology could result from inconsistencies in these measurements in the literature. The purpose of this study is to determine the reliability of intertester, intratester, and foot photo box (FPB) versus caliper measurements

### METHODS

This study was comprised of 30 subjects (15 male, 15 female) between the ages of 18 and 30 years old. Both feet were tested (n=60) in a 90% weight bearing (WB) stance. First, each foot was palpated and marked for the following bony landmarks in a 90% WB posture: navicular, calcaneus, head of the first metatarsal, and shaft of the first metatarsal. Using a caliper and goniometer, foot length (FL), truncated foot length (TFL), navicular height (NH), height of the dorsum of the foot at 50% of FL (DH), and the angle of the first ray (FRA) were measured. A digital photograph was taken of both feet individually in a 90% weight bearing stance. The mirrored FPB allowed visualization of the posterior, anterior, medial, and plantar aspects of the foot from one picture.

Once the first rater completed measuring and photographing both feet, the marks were erased and the second rater repeated the protocol. The bony landmarks were then digitized and FL, TFL, NH and FRA were measured from the digital photos using the SigmaScan Pro software (Richmond, CA).

The subjects were then asked to return for a second day of testing approximately one week later. Intertester and between measurement condition (FPB versus calipers) reliability were determined using the intraclass correlation coefficient (ICC) (2,k) model and intratester reliability was determined using the ICC (2,1) model.

### RESULTS AND DISCUSSION

Preliminary results for the mean, intratester, and intertester reliability for the foot photographs, as well as the FPB to caliper comparisons for the right foot of 15 subjects (7 male, 8 female) are shown in Table 1. While the intratester reliability was slightly higher using caliper measurements, the intertester reliability was higher using the FPB.

Comparing the FPB to the caliper measurements shows good reliability (0.993-0.858), indicating that the FPB could be used

in place of caliper measurements with similar reliability. Caliper measurements have already been shown to be valid to radiographic measurements [3], the FPB measurements should also correlate well with radiographic measurements. The FPB values reported are similar to those in the literature from radiographic measurements[1]. The highest between condition reliability was NH/FL and NH/TFL.[3]

	Mean	SD	Intratester	Intertester	Conditions
FL	250.26	21	0.9909	0.9945	0.993
TFL	186.46	14.92	0.9773	0.9774	0.9922
NH	36.8	5.31	0.8644	0.8405	0.9451
DH	60.1	5.76	0.8862	0.9203	0.8897
FRA	24.2	4.39	0.4911	0.5964	0.9197
NH/FL	0.1475	0.0235	0.8885	0.882	0.9282
NH/TFL	0.1984	0.0317	0.8941	0.9011	0.9176
DH/FL	0.2401	0.0172	0.8499	0.8366	0.8601
DH/TFL	0.3232	0.0223	0.7757	0.7448	0.8578

**Table 1:** Foot Photograph Measurements and ICC values.

The FPB offers several advantages over the caliper measurements; including, speed of measurement, visualization of rearfoot angle, measurement of various footprint indices, and the ability to have the pictures assessed by foot and ankle specialists for a clinical assessment of foot morphology. From the plantar view, various footprint indices[2] were measured, with intratester and intertester ICC values ranging from 0.975 to 0.923 and 0.969 to 0.928, respectively. The average photo took  $51.3 \pm 19.6$  seconds per foot while the caliper measurements took more than 4 times as long with an average of  $227.4 \pm 68.9$  seconds.

### CONCLUSIONS

The mirrored FPB is at least as reliable as caliper measurements, and offers better intertester reliability. The speed of testing is faster with the photograph, and also allows calculation of footprint indices. Previously, caliper measurements have been shown to correlate well with radiographic measurements. Our results are similar to results from previous studies which reported caliper and radiographic measurements. [1, 3] Future studies will determine the validity of the FPB to radiographic measurements.

## CARDIAC CATHETER WITH VARIABLE HEAD CURVATURE ACTUATED BY IPMC (IONIC POLYMER-METAL COMPOSITE)

### INTRODUCTION

The technically difficult part in a catheter surgery is to push a catheter ( $\sim\phi 2\text{mm}$  below) through the crotched vessels by using guide wires with different curvatures. The above-mentioned process takes a lot of time and also raises the risk of surgery due to numbers of guide-wire changes.

IPMC (Ionic Polymer-Metal Composite) consists of an electrical active polymer layer sandwiched by metal electrode layers. When a driving voltage is provided, the IPMC membrane bends toward anode direction because the hydrophilic positive ions move toward cathode direction [1-3]. During the design of an IPMC actuator, there are four technical problems to be overcome: (1) how to glue electrode layers on the polymer membrane; (2) how to drive under a wet condition; (3) how to prevent electrolysis when higher driving voltage ( $>1.23\text{V}$ ) is to be applied and (4) how to increase the force output of the actuator (mN order).

The purpose of this study is to develop an active guide-wire by using IPMC membrane and to overcome above technical problems.

### METHODS

According to the actuation principle of IPMC, a two segment IPMC actuator is designed. Two pairs of electrodes are joined to the polymer membrane and form a two-segment actuator. While two different phase voltages are applied on the two pairs of electrodes respectively, the actuator can perform a variable S-shape deformation. This design will offer an opportunity to solve the problem that a traditional catheter with a single fixed curvature can not overcome.

The size of the IPMC actuator is decided based on the constraint of the catheter and the length is 20 mm, the width is 1 mm and the thickness is 0.2 mm. The diameter of the whole active guide-wire is constrained to less than 1 mm.

The nafion<sup>®</sup> is one kind of ion exchange polymers, and a 20% nafion solution is used to make a membrane in this study. In order to attach the electrode layers to the membrane, we mix the nano silver powder with a 5% nafion solution and spread on a glass slide. After drying the solution, a membrane is formed (the electrode layer,  $\sim 30\mu\text{m}$ ), and a 20% nafion solution is spread on it and cured to form a film. The film was cut into two halves and glued together by using nafion solution. The electroless silver plating process was applied at the final step and nickel layer was electroplated on two spots as the contacts for electric conduction.

To demonstrate the feasibility of the IPMC actuator, a performance test system was set up and a prototype of IPMC

actuator is fabricated and tested. Finally, the IPMC actuator was assembled to form the head of a guide-wire.

### RESULTS AND DISCUSSION

The IPMC (length of 20mm, width of 5 mm & thickness of 0.3 mm) driven by 2.8V could perform an approximately 90 degree bending (Fig. 1) and the force was about 0.25gf. The sheet resistances are 0.12 ohm/mm and 0.15 ohm/mm. The elasticity of the IPMC is 3.5GPa (Dry) or 1.16GPa (Wet). According to the test results, the deformation and force output were proportional to the driving voltage, and we found that the oxidations on IPMC surface electrodes made the resistance too high, so its performance was deteriorated under long-term actuation (Fig. 2).

### CONCLUSIONS

The active guide wire with the IPMC actuator could change the head curvature according to the magnitude of the applied voltage. Reducing the surface resistance and maintaining the humidity of IPMC can further improve the performance of the active head, and to accurately control the tip position of the IPMC actuator is an on-going work.

### INTRODUCTION

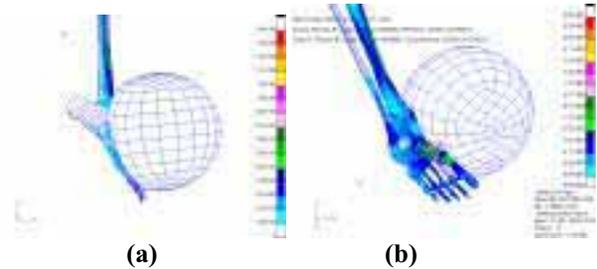

The motion analysis of kicking in football has been studied by several investigators. However, there are few studies that analyzed the interaction of the kicking foot and ball at impact in football. The purpose of this study is to clarify the relation between the stress distribution, the deformation and the impact point on the foot using a finite element skeletal foot model.

### METHODS

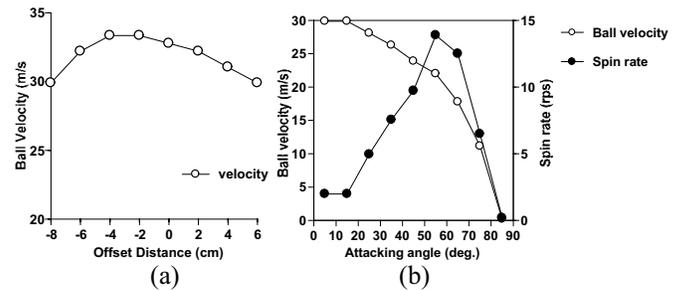

The basic shape of the finite element skeletal foot joint model was described using a commercial foot skeletal model for computer graphics and anatomical data, and the solid model was defined after simplifying that model (Fig. 1). The Young's modulus of hard tissue parts was 15GPa and the Poisson's ratio was 0.3 [1], The Young's modulus of soft tissue parts was 1500 MPa and the Poisson's ratio was 0.3 [2]. In the analysis of the ratio of restitution on the foot complex at impact using the instep kick model, the impact point was defined from the axis of the ball -80 to +60 mm at intervals of 20 mm in the vertical direction. The ball velocity and the direction of the ball trajectory after impact were compared by each vertical offset distance. In the curve kick analysis, the generation of spin depends upon the attacking angle and the impact point of the foot on the ball in relation to the axis of the ball. The simulations were carried out with a fixed coefficient of friction of 0.4 with attacking angles from the axis of the ball 5 to 85 degrees at intervals of 10 degrees.

### RESULTS AND DISCUSSION

In the instep kick analysis using the finite element skeletal foot model, high intensity stress (about 50 MPa) was seen in metatarsal, cuneiform, navicular and tibia at impact. The ball velocity after impact with an offset distance of -20 mm was 33.4 m/s, and that for the offset distance of +20 mm was 32.2 m/s. The maximum ball velocity after impact in this simulation was for the offset distance of -20 mm and -40 mm, while the minimum ball velocity was for the offset distance of +60 mm and -80 mm (Fig. 2(a)). These was a tendency that the deformation of the foot joint in the lower impact case was greater than that of the higher impact case. It is suggested that the energy dispersion of the foot for the lower impact case is greater than that for the higher impact case. The direction of the ball trajectory after impact (shoot angle) in each case indicated a nonlinear trend. The maximum shoot angle was 16

**Figure 1:** The instep kick model (a) and the curve kick model (b) using finite element skeletal foot model.

**Figure 2:** The relation between offset distance and ball velocity (a) and the relation between attacking angle and ball velocity (b).

degrees for the offset distance of -20 mm. It seems that the shoot angle was influenced by the location and the deformation of the foot complex and the ball. The relation between attacking angle and ball velocity and the relation between attacking angle and spin rate are shown in Fig. 2(b). It was found that the spin rate of the ball generally increases as attacking angle is increased, but the spin rate falls rapidly in the case of the attacking angle being 75 degrees or greater. The ball velocity simply decreases as the attacking angle is increased. Hence it is considered that, for the infront curve kick, a foot orientation at impact, with the attacking angle between the face vector and the swing vector generates the optimum moment with which to generate ball spin.

**INTRODUCTION**

Scoliosis is a disease of spinal deformity accompanied by deformation of costal bones. Some researchers[1] suppose that the difference between left and right costal bones lengths cause the scoliosis in some case of AIS (Adolescent Idiopathic scoliosis). This paper measured the lengths of left and right ribs of 5 scoliosis subjects and 3 healthy subjects. These geometrical data are gotten by 3-D reconstruction of CT images. CAD software executed the measurement of 3-D length of the ribs.

**METHODS**

CT images including thoracic vertebrae and their costal bones were used. The images were reconstructed by the software, 3D-DOCTOR (Able Software corp. MA, USA). The 3-D data were converted to CAD data. For the measurement of the length of 3-D costal bone, CAD software, Rhinoceros (Robert McNeel & Associates, WA, USA) was used. Figure 1 is an extracted spinal centerline and the illustration of its curvature. Table 1 shows the Cobb angles and locations of apex vertebrae of curvature of scoliosis on each patient.

**RESULTS AND DISCUSSION**

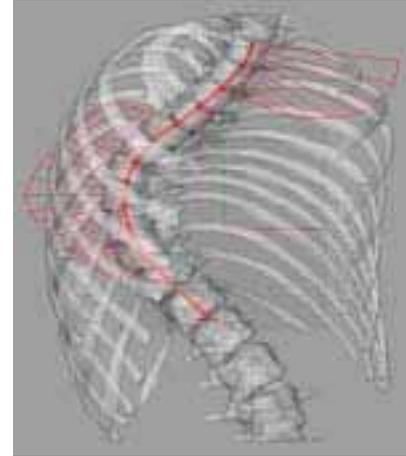

The result shows that in scoliosis subjects the difference between the left and the right rib lengths was a little larger than that of healthy subjects. And the average percentage difference to the rib length was 2.2% (SD: 1.5%) in scoliosis subjects ( $n=5$ ) whereas it was 1.1% (SD: 0.1%) in healthy subjects ( $n=3$ ). (Figure 2) Each patient's correlation coefficient of CCS (Concave Curvature of Spine) and  $\Delta CV$  (Difference between the rib length of concave side of spine and that of the convex side, that is the value subtracted rib length of the convex side of spine from that of the concave side) is shown in Figure 3. The average correlation coefficient of all patients was 0.24 (SD: 0.33) assuming the tendency that the rib of concave side is longer than that of convex side.

**CONCLUSIONS**

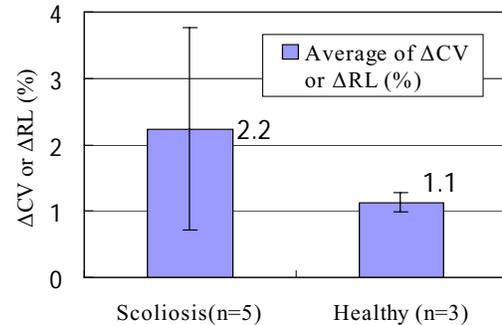

From the measurement of five scoliosis patients, it was suggested that rib of concave side of spinal curvature is longer than that of convex side or that there is no difference between both lengths of the rib.

**Table 1:** Cobb angle and apex vertebral location of five scoliosis subjects

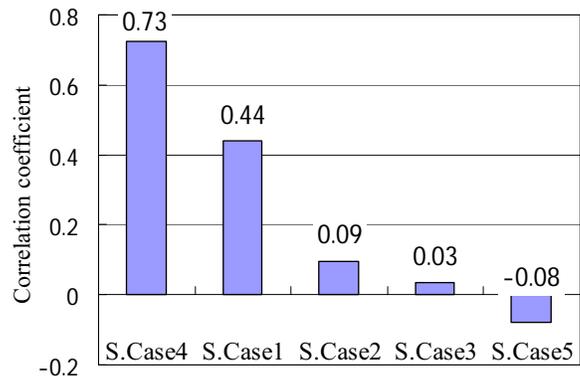

Case	Cobb angle (deg.)	Location of apex vertebra of the lateral curvature

## THREE DIMENSIONAL FINITE ELEMENT ANALYSIS OF MAXILLARY PALATE WITH A UNILATERAL CLEFT

Linping Zhao<sup>1,3</sup> P. K. Patel<sup>1,2,3</sup>

<sup>1</sup>Shriners Hospitals for Children, 2211 Oak Park Avenue, Chicago, IL 60707 Email: [lzhao@shrinenet.org](mailto:lzhao@shrinenet.org)

<sup>3</sup>The Cleft Lip and Palate Institute, Westchester, IL 60154

### INTRODUCTION

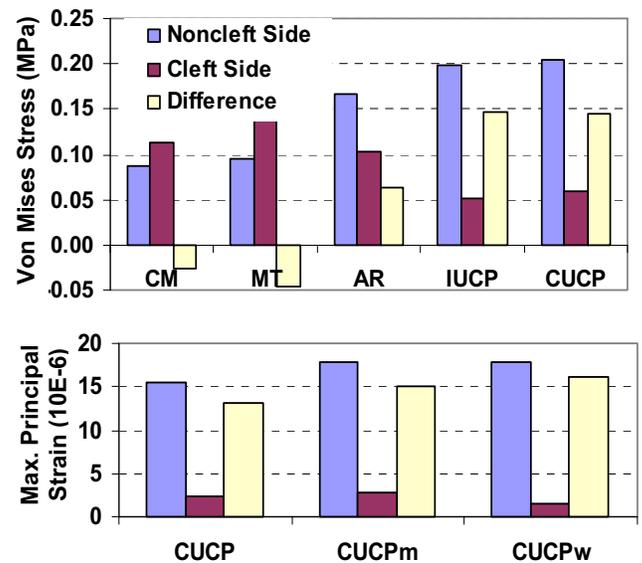

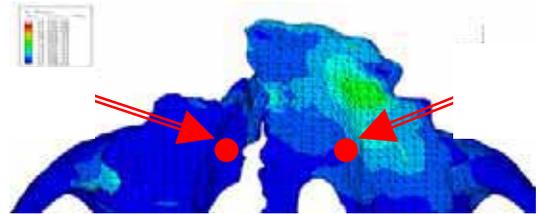

Cleft lip and palate is the most common congenital craniofacial deformity. Up to 80 % of this population has a skeletal defect. While the surgical procedures for reconstructing the skeletal defects in children with facial clefts is well established [1, 2], it remains unclear how the cleft leads to the alteration in the stress/strain distribution within the maxillary palate, the alveolar arch and the midfacial skeleton. Our preliminary study revealed that unilateral cleft leads to non-uniform, asymmetric stress/strain distribution within the maxillary skeleton during functional tasks [3]. The aim of the current study was to verify such hypothesis that the size (depth and width) of unilateral cleft affects the severity of the non-uniform stress/strain distribution within the mid-facial skeleton.

### METHODS

Subject-specific CT scans were obtained following a protocol for clinical examination. Using ANALYZE AVW 4.0 (Biomedical Imaging Resource, Mayo Foundation, Rochester, MN), the maxilla was separated from the mandible and skull, and its surface was modeled with triangular patches. This surface model was imported into ABAQUS/CAE (ABAQUS Inc., Pawtucket, RI). After manually editing, that is, cleaning, repairing, and smoothing, a volumetric mesh was generated using tetrahedral elements. This model acted as a control model (CM). Four models were established to simulate the unilateral cleft with various depths: 1) absent second right incisor (MT), 2) alveolar ridge defect (AR), 3) incomplete unilateral cleft palate (IUCP), and 4) complete unilateral cleft palate (CUCP). Three models were used to simulate complete unilateral cleft with various widths: 1) 1.0 dental unit (CUCP), 2) 1.5 dental units (CUCPm), and 3) 2.0 dental units (CUCPw). For all FE models, the maxilla was modeled as a linear elastic object with elastic modulus of 12.7 GPa and Poisson's ratio of 0.3. Both the inferior and posterior ends of the maxilla were fixed while forces (100 N in total) perpendicular to the occlusal plane were added to the teeth. The FE analysis was conducted using ABAQUS STANDARD v. 6.4 (ABAQUS Inc., Pawtucket, RI).

### RESULTS AND DISCUSSION

The severity of non-uniform stress/strain distribution, indexed using the peak value of Von Mises stress at the paranasal region, increased when the unilateral cleft size (depth and width) increased. The severity was also indexed using the difference in parameters between two sites that were picked up from cleft and non-cleft sides, respectively. Along with the increase of the cleft depth and width, parameters such as Von Mises stress (Fig. 1 middle) and maximum principal strain (Fig. 1 bottom) increased on the non-left side while decreased on the cleft side. This led to an increase in the difference, or in severity of the non-uniform stress/strain distribution.

**Figure 1:** The severity of the non-uniform stress/strain distribution within the maxillary palate indicated in Von Mises stress as a function of unilateral cleft depth (middle), and in maximum principal strain as a function of unilateral cleft width (bottom).

### CONCLUSIONS

The existence of unilateral cleft leads to non-uniform stress/strain distribution on the maxillary palate and midfacial skeleton. The size of the unilateral cleft affects the non-uniformity: the larger the depth and width of the unilateral cleft, the more severe the non-uniform stress/strain distribution within the maxillary palate and midfacial skeleton. This has the clinical implication that earlier skeletal reconstruction would restore symmetrical growth and development of the facial skeleton.

## Muscle coordination in stroke patients' upper limbs

<sup>1</sup>Zhen-Wei Wu, <sup>1</sup>Ming-Shaung Ju, <sup>2</sup>Chou-Chin K. Lin

<sup>1</sup>Department of Mechanical Engineering, National Cheng Kung University, Tainan, Taiwan; web:  
<http://myweb.ncku.edu.tw/~msju/mml>,

<sup>2</sup>Department of Neurology, National Cheng Kung University Hospital, Tainan, Taiwan

### INTRODUCTION

Robot-aided rehabilitation is getting popular in the rehabilitation of the strokes. Compared with conventional therapies, a major benefit of rehabilitation robot is that it is able to offer stroke patients repetitive rehabilitation exercise with high intensity and steady quality. Furthermore, sensors deployed on the robot provide abundant information on patient's motor functions. Physiological data such as EMG and biomechanical signals such as joint torque and ROM can be utilized for motor function assessments on stroke patients.

With a laboratory-made rehabilitation robot [1], motion data of patient's upper limb was recorded throughout the treatment [2]. In this work, analyses of load sharing by model simulation were utilized to characterize variation in muscle coordination and improvement of patient's motor function. Model validation was prerequisite for further studies and was the primary topic in this abstract to ensure that the model does reflect faithfully the interaction between patients and the robot to an extent.

### METHODS

All the recruited patients were asked to perform horizontal circular tracking motion at shoulder level with visual cues and under resistance applied by the rehabilitation robot. The patients were requested to perform the tracking motion as accurate as possible. A 6-axis load cell and electro-goniometer were fixed to the end-effector of the robot and the patient respectively to measure the force and motion data.

To estimate the muscle force/neural excitation in patient's upper limb during treatment, a neuromuscular model of human upper limb [3] were modified by adding five muscles [4,5]. The kinematic structure of the shoulder was also modified to fit the treatment movement. An optimization was employed to solve the force distribution problem and the neural excitation distribution which could be utilized to characterize the coordination in affected muscles. In the present study, a widely accepted objective function as following [6] was employed for solving the load sharing problem:

$$J = \sum_{j=1}^9 \left( \frac{F_j}{PCSA_j} \right)^2$$

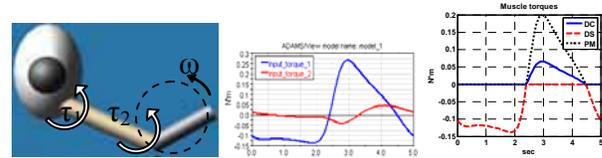

where  $F_j$  is muscle force of the  $j^{\text{th}}$  muscle. When solve the inverse dynamics problem, only the steady state muscle forces were considered to generate the required muscle activations. When the muscle activations were known, neural excitations could be obtained from the following equation:

$$\dot{A}_j = C_j(u_j - A_j)$$

where  $u_j$  was neural excitation,  $A_j$  was muscle activation and  $C_j$  was a time constant of the  $j^{\text{th}}$  muscle.

### RESULTS AND DISCUSSION

A simplified human upper limb (Figure 1) was utilized to validate correctness of the optimization procedure. It was

**Figure 1:** A simplified human upper limb for validation of optimization procedure for the load sharing problem. On the middle, estimated joint torques are depicted. On the right, the torques applied at shoulder joint by DC, DS and PM are depicted.

assumed that the limb was performing horizontal circular motion with a constant angular velocity ( $\omega = 2\pi/5$  rad/sec) at shoulder level. For simplicity, only parts of deltoid and pectoralis major muscles were used to generate the required torque at shoulder joint to validate the optimization procedure. In the first 2.3 sec, muscle DS was activated to horizontally extend the shoulder joint and DC and PM were silent. Conversely, during 2.3~4.3 sec, DC and PM were co-activated to horizontally flex the shoulder joint and DS was silent. The resultant torque of these three muscles was equal to the estimated torque. Due to physiological differences, the torque contribution between DC and PM were different. Results of validation showed that the optimization procedure could determine the load sharing condition under the given objective function, the antagonist remained silent while the agonists were both activated.

### CONCLUSIONS

The biomechanical model of human upper limb coupled with the optimization procedure was suitable for analyzing load sharing of stroke patient's upper limb. By modeling interaction among muscles, it provided a feasible way for further investigation on various possibilities of a patient's muscle coordination before and after the robot-aided treatment.

## BIOMECHANICAL FEATURES OF NORMAL PATELLAR TENDONS AND THOSE WITH PATELLAR TENDINOPATHY

Andrew Simons, Tim Wrigley, Kay Crossley, Ben Metcalf  
 Centre for Health, Exercise and Sports Medicine (CHESM), University of Melbourne, Australia  
 email: timw@unimelb.edu.au      web: http://www.physioth.unimelb.edu.au/chesm/

### INTRODUCTION

The aetiology of patellar tendinopathy commonly suffered by recreational and higher level athletes in jumping sports ('jumper's knee') is uncertain. Currently there is controversy as to whether the most often affected posterior fibres of the patellar tendon (PT) at the patella inferior pole are subjected to greater or lesser stress [1,2]. Particular gross features of PTs that may predispose them to tendinopathy have not been found. Symptomatic PTs are commonly seen to be thickened on MRI [3], however no clear differences in absolute AP width between symptomatic and asymptomatic PTs have been found. Cross-sectional area (CSA) in PTs has not been studied along the entire PT length, with or without tendinopathy. The aim of this study was to characterise this CSA, and determine if tendinopathy resulted in differences in CSA, or PT stress during a maximal contraction, compared to normal PTs.

### METHODS

16 symptomatic patients (12M/4F, 27.3±6.6 yr) and 22 asymptomatic controls (15M/7F, 23.0±4.7 yr) were studied. Symptomatic subjects had a PT lesion detected on ultrasound, a stereotypical history of patellar tendinopathy symptoms sufficient to affect exercise activity for 6 months or more, with no previous knee surgery or signs of other knee pathology. Both groups participated in jumping sports at least once a week.

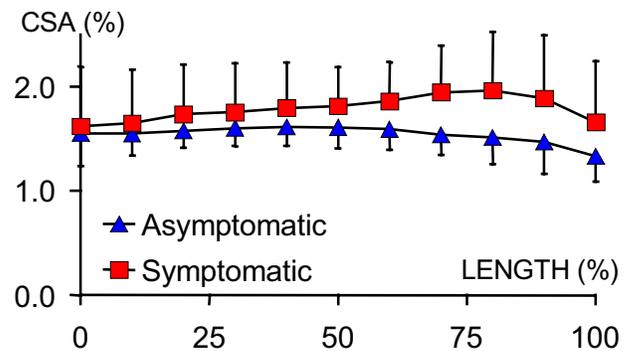

MRI was performed in a 1.5T magnet (GE Sigma Horizon LX) and extremity array coil, on the symptomatic knee in patients and the 'jumping' knee in controls, in full extension. Multiple 3.5 mm PD images (512x384 matrix) were obtained in the sagittal and axial planes. As a proportional indication of the likely moment to which the knee extensor mechanism including the PT might be exposed in jumping sport activities, the maximum isometric knee extension moment was recorded on a Kincom 125-AP dynamometer at 60 degs flexion, with correction for gravitational torque.

The PT was outlined in each axial slice and CSA calculated using Image-J software (NIH). The PT moment arm was measured from the tibiofemoral contact point to the mid-PT in the sagittal plane [4] and adjusted to account for the difference between full extension and 60 degs flexion. Force and stress in the PT were estimated as follows:

$$F_{PT} = M_{KE} / r_{PT} \qquad \sigma_{PT} = F_{PT} / A_{PT}$$

Where:  $F_{PT}$  = PT force (N)  
 $M_{KE}$  = knee extension moment (N.m)  
 $A_{PT}$  = PT CSA (mm<sup>2</sup>)  
 $r_{PT}$  = PT moment arm (mm)  
 $\sigma_{PT}$  = PT stress (MPa)

### RESULTS AND DISCUSSION

**Figure 1:** Scaled PT CSA (% tibial width<sup>2</sup>) vs PT length (0% = tibial tuberosity; 100% = patella inferior pole).

**Table 1:** Measured and calculated variables for asymptomatic and symptomatic subjects; mean (SD)

	Asymp.	Symp.	p
Height (cm)	177.9 (7.9)	178.5 (8.2)	.808
Body mass (kg)	70.9 (10.2)	82.9 (15.7)	.007*
Peak isometric moment (N.m)	152.9 (42.9)	163.6 (56.5)	.503
Peak isometric moment (N.m/kg)	2.16 (0.42)	2.00 (0.64)	.356
Max PT CSA (mm <sup>2</sup> )	103.1 (24.1)	126.6 (32.8)	.014*
Min PT CSA (mm <sup>2</sup> )	72.6 (20.0)	77.3 (29.4)	.557
Mean PT CSA (mm <sup>2</sup> )	89.6 (19.0)	103.7 (25.5)	.055
Max scaled PT CSA <sup>1</sup> (%)	1.76 (0.22)	2.18 (0.51)	.007*
Min scaled PT CSA <sup>1</sup> (%)	1.25 (0.25)	1.35 (0.52)	.479
Mean scaled PT CSA <sup>1</sup> (%)	1.54 (0.16)	1.79 (0.41)	.034*
Peak PT force (N)	3588 (991)	3966 (1278)	.305
Stress for max PT CSA (MPa)	35.8 (9.6)	33.3 (12.5)	.481
Stress for min PT CSA (MPa)	54.2 (28.6)	67.5 (65.2)	.392
Stress for mean PT CSA (MPa)	40.9 (10.7)	40.5 (15.7)	.936

<sup>1</sup>scaled to % tibial width squared

\* p < 0.05

PT force and CSA in these young adult PTs (Table 1) were higher than has been reported for elderly PTs, while PT stress (based on mean CSA) was similar [5]. CSA did not increase at the distal insertion (Figure 1) as in the Achilles tendon [6]; in fact PTs tended to *decrease* CSA at the *opposite* end, the patella inferior pole. Maximum PT CSA was greater in the symptomatic group, but PT stress was not significantly different. Greater CSA is consistent with pathological thickening often seen on MRI, although this was highly variable. Future longitudinal studies will be required to identify any differences prior to symptom onset.

## PREDICTED GAIT MODIFICATIONS TO REDUCE THE PEAK KNEE ADDUCTION TORQUE

<sup>1,2</sup>Benjamin J. Fregly, <sup>2</sup>Kelly L. Rooney, and <sup>1</sup>Jeffrey A. Reinbolt

<sup>1</sup>Department of Mechanical & Aerospace Engineering, University of Florida,

<sup>2</sup>Department of Biomedical Engineering, University of Florida; email: [fregly@ufl.edu](mailto:fregly@ufl.edu), web: [www.mae.ufl.edu/~fregly](http://www.mae.ufl.edu/~fregly)

### INTRODUCTION

High tibial osteotomy (HTO) is a more conservative surgical procedure than is total knee replacement for treating medial compartment knee joint osteoarthritis (OA). Following HTO surgery, patients with a low peak knee adduction torque during gait tend to have the best long term clinical outcome [1]. As an alternative to HTO surgery, this study uses inverse dynamic optimization of a patient-specific full-body gait model to predict gait modifications that could reduce the peak knee adduction torque.

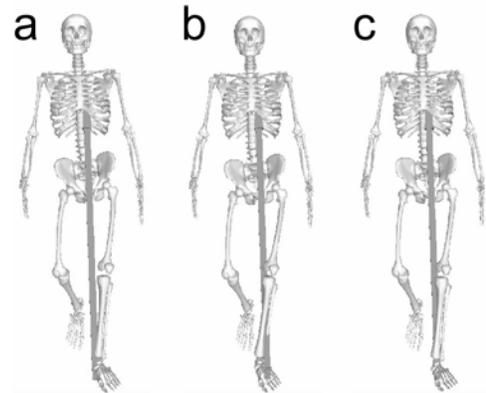

### METHODS

Kinematic and kinetic gait data were collected from a single highly functional knee OA patient with 5° varus alignment and grade 2 medial OA in both knees. The subject walked at a speed of approximately 1 m/sec and also performed isolated joint trials to determine the position and orientation of each lower extremity joint [2]. One complete gait cycle (left heel strike to left heel strike) with clean surface marker and ground reaction data was selected as the nominal data set for the optimization study.

A dynamic, three-dimensional full-body gait model was developed using SIMM. The model possessed 27 degrees of freedom (DOFs) composed of gimbal (3 DOFs), universal (2 DOFs), and pin (1 DOF) joints. External forces and torques acting on the pelvis were calculated from a 6 DOF joint between the ground and pelvis. Since no external loads act on the pelvis in real life, non-zero external force or torque components at any time frame represent error in the model and/or experimental data.

Joint and body segment parameters in the model were tuned via optimization to match the nominal gait data as closely as possible. The cost function simultaneously minimized errors between model and experimental marker locations in the laboratory reference frame, external pelvis forces and torques, and changes in body segment parameters away from their initial values. Design variables were joint positions and orientations in the body segments, body segment parameters, and parameters defining joint translations and rotations (see below). Final root-mean-square (RMS) errors were 1.9 cm in surface marker positions and 3.6 N and 2.8 Nm in external pelvis forces and torques, respectively.

Inverse dynamic optimizations were performed to predict novel gait motions that minimized the left knee adduction torque subject to several reality constraints: follow the prescribed path of each foot, follow the experimental trunk orientation, eliminate external forces and torques on pelvis, and keep the center of pressure under each foot. The 500 design variables were motion and ground reaction torque curves parameterized using a combination of a cubic

**Figure 1:** a) Experimental gait motion, b) gait motion predicted without control torque tracking, and c) gait motion predicted with control torque tracking. Arrows indicate line of action of ground reaction force vector.

polynomial and eight Fourier harmonics [3]. Ground reaction forces, shoulder and elbow rotations, and pelvis horizontal translations were prescribed to match the experimental data. The optimizations were performed with and without penalty terms to minimize changes in the leg control torques.

### RESULTS AND DISCUSSION

The optimizations predicted realistic gait motions that reduced the peak knee adduction torque by 72% without control torque tracking and 45% with it (Fig. 1). The optimizations drove the left knee inward in part through increased hip, knee, and ankle flexion, causing the ground reaction force vector to pass more laterally to the knee center than in the experimental situation. These kinematic changes were produced primarily by an increase in knee extension and ankle inversion torque. Predicted changes with control torque tracking were similar but decreased in amplitude compared to those found without control torque tracking.

The optimization results suggest that gait modifications may be able to reduce the peak knee adduction torque by as much as HTO surgery, which has been reported to produce an average 34% reduction [1]. Due to their synergistic effects, even small gait modifications had a large influence on the peak knee adduction torque. If the predicted gait modifications can be achieved in practice, they could help define new rehabilitation strategies for knee OA patients either apart from or in conjunction with HTO surgery.

## Effects of passive repeated plyometric training on specific kicking performance of elite Olympic Taekwondo player

<sup>1</sup>Hsiang-Hsin Wang, <sup>1</sup>Chiang Liu and, <sup>1</sup>Mu-Yen Chu, <sup>2</sup>Wei-Hua Ho, <sup>2</sup>Tzyy-Yuang Shiang

<sup>1</sup>Institute of Coaching Science, National College of P.E & Sports, Taiwan,

<sup>2</sup>Institute of Sports Equipment Technology, Taipei P.E College, Taiwan; email: mystarmailbox@yahoo.com.tw

### INTRODUCTION

Sporting activities involved striking, kicking, jumping, or high frequency rapid acceleration movements require a high power output of the involved muscles (Newton, et.al 1996). Coaches and athletes have modified training method in an attempt to develop explosive power, because velocity of movement is an important factor to reach perfect performance. Therefore, The Passive Repeated Plyometric Training Machine (PRP Training Machine) was designed in order to reach the best power training effect. PRP movement has been shown consisted of many characteristics that set them distinctly apart from other types of movement such as high velocity, high frequency movement and isokinetic contraction during entire range of motion under passive contraction (Wang, et al 2001). Many researches indicated that PRP training could improve neuromuscular system of general players. However, it is not clear how much training effect can beneficial to elite players. Hence, the aim of this study was to determine the effects on specific kicking performance of a 6-wk PRP training program of elite Olympic Taekwondo player.

### METHODS

**Subject:** The subject was an elite athlete who won a gold medal of Taekwondo event in 2004 Athens Olympic games. The subjects' age, height, and weight was 22 years, 173 cm, and 58 kg, respectively.

**Specific kick test:** Subject chose kicking movements according to his special skills and necessary of competition. The test movements include right leg turning kicking (RTK), left leg turning kicking (LTK), left leg slide step turning kicking (LSTK), right leg axe kicking (RAK), left leg axe kicking (LAK), right leg back kicking (RBK), and left leg 5 continuous kicking (LCK). An accelerometer was attached on the back of dummy to catch time and impact acceleration of dummy. When the movement test begins, subject standing in front of dummy and chose a suitable distance. Subject has to kick the target of dummy as rapidly as possible while trigger was flashed red light. The kicking velocity was displacement divided by movement time (m/sec). Besides, total time of 5 kicks (sec) was used to calculate kicking velocity of LCK. The kicking power was the square root of 3 dimensional impact accelerations of the tri-axial accelerometer while the dummy was kicked by subject. The kicking power of LCK was calculated total power of 5 kicks (g).

**Training program:** PRP machine can control the frequency of pedal and monitor training load during entire movement in passive and repeated form. Training duration was three times a week for six weeks before the pre-competition of Athens Olympic Games. The training load was between 60%MVC to 70%MVC; the frequency of pedal was between 1.5Hz to 3Hz. Exercise duration was set 10 seconds to 15 seconds. The

training program was 8 sets a time, and took three minutes rest between each set.

### RESULTS AND DISCUSSION

The results indicate that velocity of RTK was significantly increased after PRP training ( $p < 0.05$ ). Besides, the kicking power of LAK and RBK were also significantly increased after PRP training ( $p < 0.05$ ). The velocity and power of most movements were increased after PRP training, but no significant change occurred (Table 1). The subject of this study was elite Taekwondo player who won three times gold medal of international championship during 2002 to 2004. Therefore, breakthrough of physical strength and specific kicking performance was difficult for top athlete. Thus, even very little progress of velocity and power was valuable to an elite player and excited everyone who joined this training project.

**Table 1:** Training effect of PRP after 6-wk. (n = 3)

Variable	Pre-training M ± SD	Post-training M ± SD	p
<b>Velocity (m/sec)</b>			
RTK	3.496 ±0.167	3.666 ±0.161	.04*
LTK	3.606 ±0.205	3.906 ±0.442	.33
LSTK	2.646 ±0.213	2.630 ±0.160	.81
RAK	3.190 ±0.180	3.436 ±0.211	.11

\* p-value significantly less 0.05

### CONCLUSIONS

The results indicate that a PRP training program could improve the velocity and power of kicking of elite Taekwondo player in a sport specific kicking performance. Based on the results of this study, we believe that PRP training is an efficient method of training for elite players to improve strength and power. Therefore, PRP training could be used for those sports activities that involve high muscle speed and power such as Taekwondo, soccer and volleyball etc.

## JOINT KINETICS AND POSTURE CONTROL DURING DROP LANDINGS

Yasuyuki Yoshida and Takeo Maruyama  
Graduate School of Decision Science and Technology,  
Tokyo Institute of Technology, Tokyo, Japan

### INTRODUCTION

Landing movement from vertical direction has been investigated in biomechanics since force platforms were developed to measure ground reaction forces. In drop landing studies, control of rotary stability based on the net effect of the three joint moments has not been investigated, previously. Devita & Skelly [1] investigated the relationship between knee joint flexion and kinetic parameters during stiff and soft drop landings. However, this study did not consider rotary stability. Ashby & Heegaard [2] quantified rotary stability in standing long jump study by using the moment about center of mass by ground reaction force ( $M_{CM}$ ). The purpose of the present study is to investigate the relationship between lower extremity joint kinetics and posture control during drop landings.

### METHODS

Ten healthy male subjects (mean±SD: age 22.9±0.99 years; body mass 68.2±7.00 kg; height 174.5±3.57 cm) participated after providing written informed consent. All subjects wore tight fitting shorts and a T-shirts, and were tested in bare feet. A force platform (Kistler type 9287BA Kistler Instruments, Switzerland) was used to measure the ground reaction force (GRF) at 1kHz. The left sagittal view was recorded using two high-speed cameras (FASTCAM Photoron, Japan) at 0.25kHz. The motion capture and recording GRF were synchronized using a synchronized pulse generator (PH-1460, DKH, Japan).

Soft and stiff drop landing conditions from a 0.48m height was tested. In soft landing (SOFT), the subjects were instructed to land as soft as possible by using joint flexion. On the other hand, in stiff landing (STIFF) the subjects were instructed to land with minimum joint flexion. Subjects placed their hands on their hips, pushed off from the platform with one leg, closed their legs in midair, and landed on the force platform and dummy platform by each foot simultaneously.

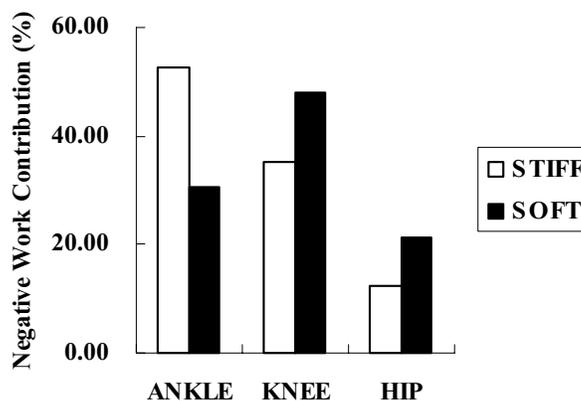

The ankle, knee and hip joint moments were calculated using inverse dynamic analysis combining anthropometric, kinematic, and kinetic data. The segmental masses, the mass center location of the lower extremity, and their moment of inertia were estimated using a four segmental mathematical model [3]. In this study  $M_{CM}$  was also calculated

### RESULTS AND DISCUSSION

Figure 1 shows a typical example of joint negative work contribution at ankle, knee and hip during STIFF and SOFT. In STIFF, joint negative work contribution was 52.48%, 35.24% and 12.29% in ankle, knee and hip. In SOFT, joint negative work contribution was 30.62%, 48.05% and 21.33% in ankle, knee and hip.

The pattern of power curve was different between STIFF and SOFT. In STIFF after touchdown negative ankle power increased dramatically. On the contrary, in SOFT knee joint negative power decreased slightly after the middle of movement.

In  $M_{CM}$  two style landings started with a forward moment, then the moment decreased and became backward. The peak of backward of STIFF was greater than that of SOFT. While  $M_{CM}$  is in backward direction, knee flexion moment and hip extensor moment appeared.

**Figure 1:** Typical example of ankle, knee and hip joint negative work contribution during STIFF and SOFT.

### CONCLUSIONS

In conclusion, these findings indicate that ankle and knee joint contributed shock absorption. Hip joint did not much contributed shock absorption, however, contributed posture control during drop landings.

### INTRODUCTION

Tennis scientist and players dream of finding the excellent racket that will immediately transform them improving high performance and reduce occur sports injury (Brody, 1995). Haake, et al. (2003) advocate several biodynamical properties of tennis racket such as vibratory characteristics. Rackets general are made of new material high strength carbon or graphite composite. Carbon fibre used most often and it is usually combined with high strength carbon fibre. The purpose of this study was to investigate the vibration of various tennis rackets, which were composed by the mixture of high strength carbon fibre and general carbon fibre.

### METHODS

There were five different kinds of tennis racket, composed by high strength carbon fibre and general carbon fibre in the ratio of 1 to 0, 3 to 1, 1 to 1, 1 to 3 and 0 to 1. All of them had the same string tension, weight, balance point and moments of inertia. The experiments of the study were to collect their vibration amplitudes and to find damping ratio. One tri-axial accelerometer (range 50 g) was fixed on the racket handle and Bio PAC MP100 AcqKnowledge system (2000Hz) were used to acquire the vibratory signals. The ball speed was controlled to be  $15 \pm 2$  m/s by a Lobster ball machine. The selected variables in the experiments were tested by one-way ANOVA  $\alpha = .05$  significant level.

### RESULTS AND DISCUSSION

The results of this study indicated that the carbon fibre made racket had a lower damping ratio on the center location (0.026) and off-center location (0.038; 0.064) impact (Table 1). The

damping ratio was significantly decreased as the content of high strength carbon fibre in the racket was getting increased.

Comparing the results with prior damping ratio showed that the pure carbon fibre racket had a higher damping ratio on the center and off-center impact. And the damping ratio was decreased significantly as the content of high strength carbon fibre in the racket increased. Thereby, based on the vibratory analysis among the various material compose of tennis rackets, it was concluded that by increasing the content of high strength carbon fibre in the racket, it would be decreasing the damping effect of the racket. In other words, it would increase the vibratory wave after impact. Therefore, based on the vibratory analysis among the differential material composition of tennis rackets, it concluded that by increasing the content of glass fibre in the racket, it would be increasing the load in the tennis player's arm.

### CONCLUSIONS

These results suggest that the forearm can be easily fatigue in such a high-impact power tennis players. This high-frequency vibration caused much greater stress on the joint of the hand and arm. Then, indirectly, this phenomenon might affect the athlete's performance.

## THE STABILITY OF ACETABULAR CUP UNDER SCREW FIXATION

<sup>1</sup>Jui-Ting Hsu, <sup>1</sup>Chih-Han Chang, <sup>1</sup>Heng-Li Huang, <sup>1</sup>Guan-Liang Chang, <sup>2</sup>Kuo-An Lai, <sup>3</sup>Weng-Pin Chen

### INTRODUCTION

The total hip replacement is a common surgical procedure in orthopaedics. However, the acetabular cup loosening is one of the major failure modes of cementless acetabular cup. Many researches point out that an unstable cup would induce a large micromotion under dynamic loading. This large micromotion would reduce the bone ongrowth on the cementless cup surface and prohibit the osseous integration [1, 2]. Besides the press fit fixation, the screw-fixation is a widely employed approach. However, how to achieve a better fixation effect with screw is still unclear. The objective of this study was to evaluate the effects of screw numbers and position on the initial stability of acetabular cup.

### METHODS

Three dimensional finite element model of pelvis was established from the saw bone.(model and brand names) which included the cancellous bone, cortical shell and subchondral bone. The Osteonic Omnifit (Allendale, New Jersey) acetabular components (including five screw holes, titanium cup, polyethylene liner and ceramic head) were also modeled (Figure 1). The interface of cup and pelvis was simulated with surface-to-surface contact elements with coefficient of friction 0.5 [3]. All the other component interfaces were assumed to be bonded.

To evaluate the fixation, loadings of the five stages of a gait cycle [4] were applied at the center of the femoral head while the cup was fixed on the pelvis with one, two, three, four or five screws respectively. (To simplify the computational aspect, each screw was modeled as a cylinder.) The nodes on sacroiliac joint and pubic symphysis were fixed in all degree of freedom as the boundary condition. The maximum relative micromotion between cup and pelvis was used as the evaluation index for stability. All the finite element analyses were performed using the ANSYS (Swanson Analysis Inc., Huston, PA, USA) software package.

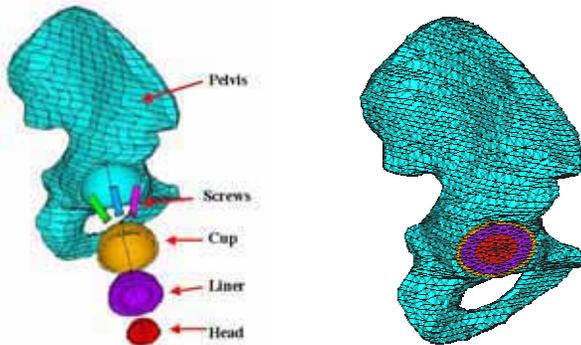

Figure 1: (a) Solid model (3 screws) and (b) Mesh model

### RESULTS AND DISCUSSION

In general the maximum relative micromotions between cup and pelvis occurred at the inferior edge of the acetabular cup; that is the opposite side of the screw fixation region (Figure 2). For the same number of fixation screw, different combinations (e.g., five different choices of one-screw fixation) produced various stability effect and the differences could be large. For different number of fixation screw, the five-screw fixation, most stable one, only reduced 16% of peak relative micromotion compared with the best one-screw fixation (Figure 2). What this indicated is that screwing position is more important than screw number and inserting several screws closely together is unnecessary. However, the selection of screw position depends on both absolute location (relative to the loading location) and relative location (area size covered by multiple fixation-screws).

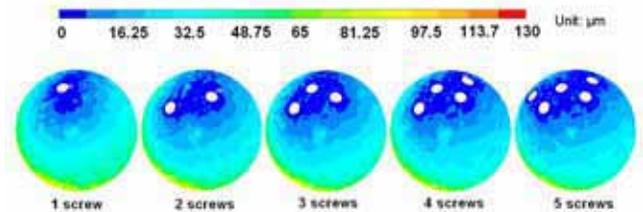

Figure 2: The micromotion distributions of different location screw fixation.

### CONCLUSIONS

This study suggests that selection of screwing location for acetabular cup is an important factor to achieve better cup stability. The selection of better screw location depends mostly on the loading modes of the cup (the activities of the patient). The general principle is to spread the screw as far as possible so that it can cover most loading cases. However, the bone quality and anatomic consideration were neglected in this research.

## A MICROMECHANICAL MODEL OF THE PERIODONTAL LIGAMENT

<sup>1</sup> Mikhail Perelmuter, <sup>2</sup> Francesco Genna, and <sup>2</sup> Angelo Carini

<sup>1</sup> Institute for Problems in Mechanics, pr. Vernadskogo 101-1, 119526, Moscow, Russia (perelm@ipmnet.ru)

<sup>2</sup> Dept. of Civil Engineering, University of Brescia, Via Branze, 38 - 25123 Brescia, Italy (genna@bscivgen.ing.unibs.it)

### INTRODUCTION

A micromechanical model of the periodontal ligament (PDL), a thin layer existing between a root of a tooth and the alveolar bone is considered. The PDL is considered as a nanocomposite material comprising corrugated collagen fibrils and viscous gel-like ground substance. The individual cell of the composite material, with the effective properties reflecting the properties of the fibrils and ground substance, is considered.

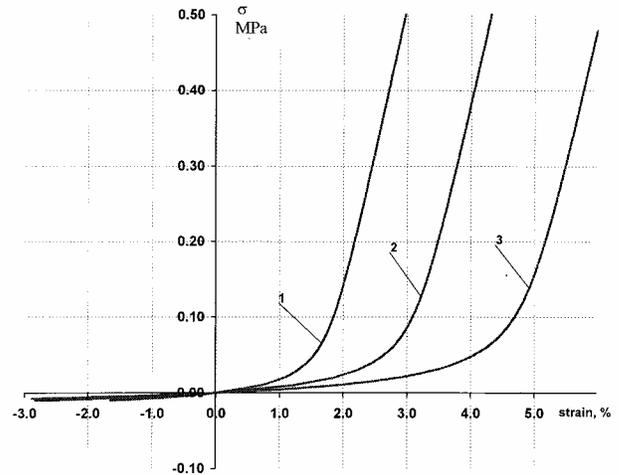

### MECHANICAL MODELLING

It is supposed in the model that the collagen fibrils and the ground substance form a two-layer coaxial cylinder with curvilinear axis. The diameter of the external cylinder is chosen according to the volume fraction of the collagen fibrils. The general equations for the bending/tension strain states of this composite beam are written in the frame of geometrically nonlinear Reissner's beams, supposing that (i) the constituent materials (fibril and matrix) are linearly elastic and isotropic; (ii) there is no mechanical interaction among the fibrils; (iii) each subunit bears the normal and bending loading; (iv) the absence of shear strains; (v) the absence of distributed loads and moments. By assuming a small undulation of the fibrils axis it is possible to get an approximate analytical solution of the governing equations, from which stress-displacement curves can be obtained, showing the dependence of the apparent strain on the external stress, and, thus, the dependence of the PDL elastic modulus on the load level. To model at least the initial locking effect in the PDL under compressive loading we change the Young modulus of the ground substance to its bulk modulus.

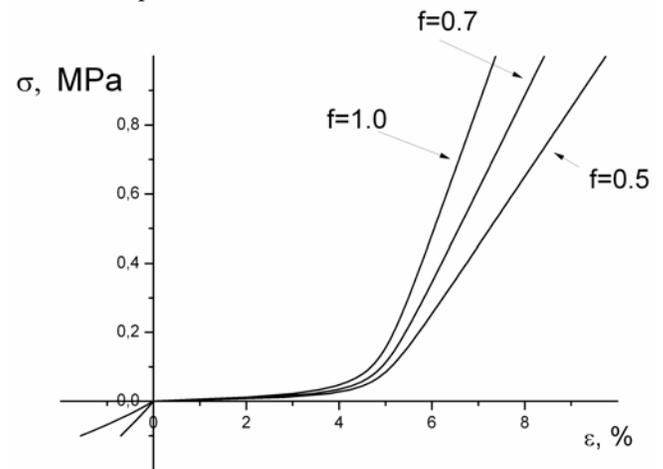

### RESULTS

Some results are presented for the following values of the mean parameters of the PDL: wavelength of the undulation  $\lambda=10, 16, 24 \mu\text{m}$ , maximal angular deflection of the fibril from the straight axis,  $\theta_0=15^\circ, 20^\circ, 25^\circ$ , average radius of the fibril cross section  $r_f=150 \text{ nm}$ , Young's modulus of the collagen fibrils  $E_f=40 \text{ MPa}$ , Young's modulus of the ground substance  $E_m=2 \text{ MPa}$ , fibrils' volume fraction  $f=0.3-0.7$ .

The dependency of the normal stress in a single fibril on the apparent strain is given in Figure 1. The variation of the maximal undulation angle has a strong influence on the stress-strain distributions. A similar dependency, accounting for the ground substance influence, is given in Figure 2. For strains larger than 6%-7% we can consider the PDL layer as a solid shell with Young's modulus approximately equal to the modulus of the fibrils. The value of the Young modulus at zero strain is the effective modulus of the wavy fibrils.

**Figure 1:** External stress vs. apparent strain in a single fibril: wavelength  $\lambda=16 \mu\text{m}$ ,  $E_f=40 \text{ MPa}$ ,  $r_f=150 \text{ nm}$ , lines 1, 2 and 3 correspond to  $\theta_0=15^\circ, 20^\circ$  and  $25^\circ$ .

**Figure 2:** External stress vs. apparent strain,  $\lambda=16 \mu\text{m}$ ,  $\theta_0=25^\circ$ ,  $r_f=150 \text{ nm}$ ,  $f=0.5$  and  $0.7$  including compression,  $f=1.0$  without ground substance.

### CONCLUSION

The proposed micromechanical model is based on a physical-mechanical ground, and its material parameters are physical quantities that can be experimentally determined; it offers a direct way to determine the influence of the problem parameters on the stress state of the tooth-PDL-bone system.

## COMPARISON OF THE EFFECTIVENESS OF ORTHOSES VERSUS PROPRIOCEPTIVE EXERCISES FOR THE PREVENTION OF ANKLE INJURIES IN BASKETBALL PLAYERS

Dieter Rosenbaum, Ralf Schröter, Eric Eils  
 Movement Analysis Lab, Orthopaedic Department, University Hospital Münster, Germany  
 email: [diro@uni-muenster.de](mailto:diro@uni-muenster.de), web: [www.motionlab-muenster.de](http://www.motionlab-muenster.de)

### INTRODUCTION

Ankle injuries frequently occur in ball games like basketball [1] and may lead to prolonged absences from practice and games. Ankle stabilizing devices such as tape or orthoses are highly recommended as preventive measures against inversion traumata [2]. Alternatively, physiotherapy with exercises addressing a wide variation of strengthening and proprioception has been suggested [3] even though the effectiveness is still under discussion. Furthermore, it has never been shown whether both approaches are equally effective or have a different impact on injury prevention. The aim of the present study was the prospective randomized investigation of the effect of these two alternative approaches to prevention of ankle injuries in a large sample of active basketball players from various levels of expertise.

### METHODS

A total of 337 athletes from 12 women's teams and 23 men's teams of level 1 (Bundesliga) through level 5 (Kreisklasse) leagues participated. All players were actively involved in regular practice sessions and official games in their respective league. 95 athletes were assigned to the orthoses group and were wearing either the AirGo orthosis (Aircast) or their previously used orthosis. Another group of 115 players participated in a proprioceptive training that was carried out in addition to their normal basketball practice session (2 circuits with 6 stations, 15 min duration). The remaining 125 athletes served as a control group and continued their customary practice. All teams were followed for one games season (October 2003 to April 2004) and were asked to report all incidences that involved a basketball related injury that occurred either during practice or in official games and lead to the cessation of active participation. The frequency of injuries was expressed in relation to the amount of participation in basketball activities that were registered in a diary.

### RESULTS AND DISCUSSION

A total of 107 reported injuries was located in 54% in the ankle joint, 12% the knee, 10% each the fingers and the head (Fig. 1). There were 28% primary ankle injuries and 68% recurrent injuries. The situations that lead to the injuries were equally distributed between practice sessions and official games and mostly involved direct contact with an opponent. The injuries resulted in a rehabilitation period of 2.5 weeks on average.

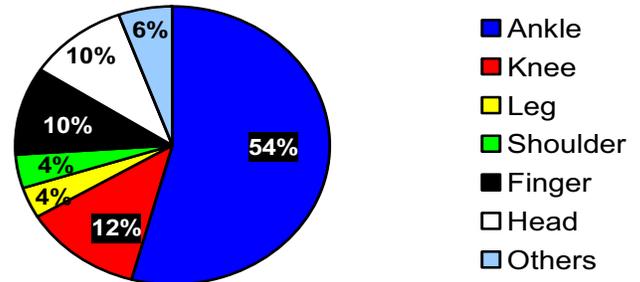

Figure 1: Distribution of the location of injuries (n=107)

Intervention	Control Group (n=125)	Proprio. Group (n=115)	Brace Group (n=95)
Basketball injuries/ 1000 participations	3.37	1.97*	1.00*

Tab. 1: Relative injury frequency for different interventions methods (\*=significantly different from control group)

In the control group, the relative injury frequency was determined as 3.37 injuries per 1000 sports participations. In the proprioceptive training group it was significantly reduced to 1.97 injuries per 1000 sports participations. The least injuries occurred in the orthosis group with only 1.00 injury per 1000 sports participations (Tab. 2).

The injury statistics of the control group of active basketball players supports previously reported ankle injury frequencies in basketball [1]. Significant differences between the experimental groups underline the positive effect of both preventive measures with an even more pronounced effect of the ankle stabilizing orthoses.

### CONCLUSIONS

Both preventive measures, i.e. multi-station proprioceptive exercises as well as ankle orthoses may be recommended for the prevention of primary and recurrent ankle injuries.

## PEDOGRAPHIC ASSESSMENT OF CLINICAL AND FUNCTIONAL OUTCOME AFTER HALLUX VALGUS SURGERY – COMPARISON OF 32 PATIENTS BEFORE AND AFTER SCARF OSTEOTOMY

<sup>1</sup>Timo J. Lorei, <sup>2</sup>Christian Kinast, MD, <sup>1</sup>Hans Klärner, MD, <sup>1</sup>Dieter Rosenbaum, PhD  
<sup>1</sup>Movement Analysis Lab, Orthopaedic Department, University Hospital Münster, Germany  
<sup>2</sup>Zentrum für orthopädische Fusschirurgie, München, Germany  
email: [diro@uni-muenster.de](mailto:diro@uni-muenster.de), web: [www.motionlab-muenster.de](http://www.motionlab-muenster.de)

### INTRODUCTION

The Scarf osteotomy has become a standard surgical treatment of pre-arthritis hallux valgus deformities. Several reports evaluated short and long term results but focused on subjective, clinical and radiographic results [5,6]. More recent studies also applied pedographic measurements for a functional evaluation of foot loading characteristics after surgery [1,7]. However, few studies investigated the relationship between subjective, clinical and radiographic outcome with pedographic results and only one study reported also about the behavior of the, contralateral foot in comparison to the operated foot [1].

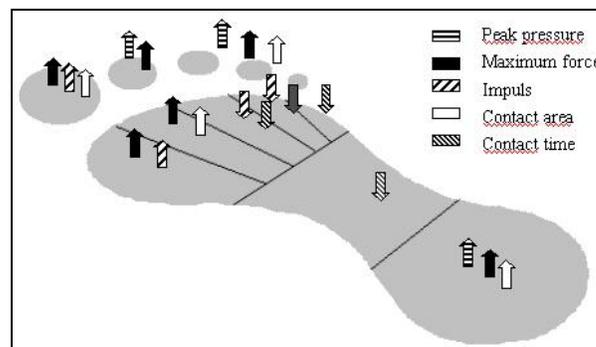

The aim of this study was to evaluate patient satisfaction, clinical, radiographic and pedographic parameters in order to determine the subjective and functional outcome after surgery.

### METHODS

32 unilateral hallux valgus patients that had been treated with a Scarf osteotomy performed by one surgeon (C.K.) were investigated after a mean follow-up of 33 months. Patients reported subjective satisfaction with the surgical outcome, cosmetic appearance, and pain. For the clinical evaluation, the AOFAS score was applied [2]. Hallux valgus and intermetatarsal angles were determined from weight-bearing x-rays. Pedographic measurements were performed before surgery and repeated at follow-up with a capacitive pressure distribution platform (emed ST-4, novel Munich). Foot prints were subdivided into ten regions and plantar pressure patterns were analyzed with respect to peak pressure, maximum force, and impulse values.

### RESULTS AND DISCUSSION

28 of the patients (87.5%) described the result of the operation as excellent or good, one patient (3.1%) as fair and three (9.4%) as poor. The AOFAS Score reached 89 out of 100 points after surgery. The hallux valgus angle improved significantly from 32.5° to 6.6° ( $p < 0.0001$ ) and the intermetatarsal angle from 15.5° to 6.6° ( $p < 0.0001$ ). Maximum force and impulse decreased under the lateral forefoot ( $p < 0.038$ ) and increased under the medial forefoot ( $p < 0.001$ ). Loading also increased significantly under the hallux (maximum force  $p < 0.0001$ , impulse  $p < 0.001$ ) indicating that the hallux became more actively involved in the rollover process. Comparison of the operated and contralateral foot revealed a good restoration of loading symmetry. Correlation analyses demonstrated an influence of postoperative pain ( $r = 0.549$ ) and hallux valgus angle ( $r = 0.443$ ) on patient satisfaction: Patients were more satisfied with lower hallux valgus angles.

**Figure 1:** Summary of the significant changes of the operated foot before and after surgery.

The results indicate that the Scarf osteotomy achieved a high rate of subjective patient satisfaction, good restoration of foot function. A good symmetry between affected and contralateral feet was demonstrated. These results are reflected in the patient satisfaction. The correction of the hallux valgus angle is more pronounced than in comparable reports [4,8]. A significant relationship was seen between the postoperative hallux valgus angle and patient satisfaction as well as the extent of medial load shift. This load shift has been described after a follow-up of 20 months [1] and 18 months following Scarf osteotomy [7]. The present results showed a similar load transfer with an off-loading of the first ray before surgery that can be reversed with successful surgery to achieve a more physiologic loading. However, this may take up to one year. The loading changes are not confined to the affected foot but the contralateral foot may also show discrete changes as a consequence of the deformity as well as after surgery. Gait symmetry appeared well restored in the present population after surgery.

### CONCLUSIONS

The Scarf osteotomy appears to be a well suited procedure for correction of severe hallux valgus deformities. Pedographic analyses offer an objective evaluation of the complex changes after surgery.

## A NEW PORTABLE 3-D GYROSCOPE SYSTEM FOR THE EVALUATION OF UPPER LIMB FUNCTION

A.M.A. Chan and A.C. Nicol  
Bioengineering Unit, University of Strathclyde (Glasgow, UK)  
Email: [anita.chan@strath.ac.uk](mailto:anita.chan@strath.ac.uk)

### INTRODUCTION

The shoulder joint is extremely important for the positioning of the hand in order to interact with the environment and interest in the restoration of good function to the upper limb is becoming increasingly important. Current clinical methods for functional assessment are limited to subjective pain questionnaires and physical examination which relies largely on the experience of the clinician. While motion analysis techniques have become widely used in research environments, they are not suitable for use in a clinical environment due to their requirement for long and complex testing procedures. The use of kinematic sensors have shown great promise in gait analysis [1, 2] but these systems have tended to be heavy and bulky.

This study aims to develop a lightweight, portable and cost effective system for 3D motion analysis of the upper limb which can be readily applied within a clinical environment.

### METHODS

The 3D gyroscope system consists of three identical units (figure 1a) and uses a total of 9 single axis gyroscopes (Murata ENC 03JA). Each gyroscope unit holds three single axis gyroscopes securely at right angles to one another within a rigid plastic housing to allow the recording of angular velocity in three dimensions. The plastic housing (figure 1b) consists of an inner core to which the gyroscopes are mounted, a circular base, and a conical shaped lid.

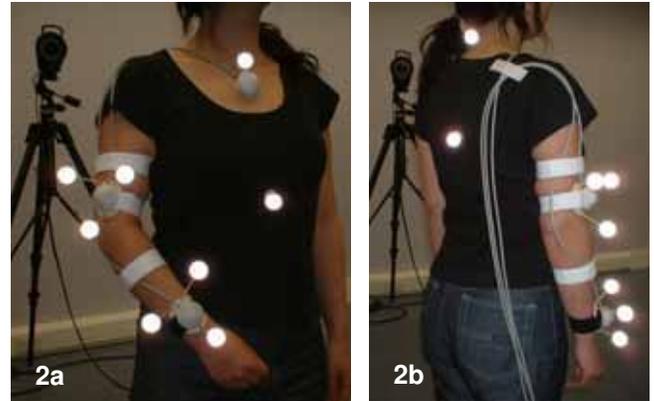

**Figure 1:** (a) one 3D gyroscope unit, (b) components of the plastic housing.

Each 3D gyroscope unit is small (40mm diameter by 25mm high) and lightweight (20g approximately) and is mounted onto the body independently of other system components, thereby minimising size and weight so as not to affect the production of movement when attached to the upper limb of the subject.

Figure 2a and 2b shows the 3D gyroscope system mounted onto the chest, upper arm and forearm. Data from the 3D gyroscope system were sampled simultaneously with an 8 camera Vicon 612 motion analysis system while the subject performed a variety of movements including maximal flexion

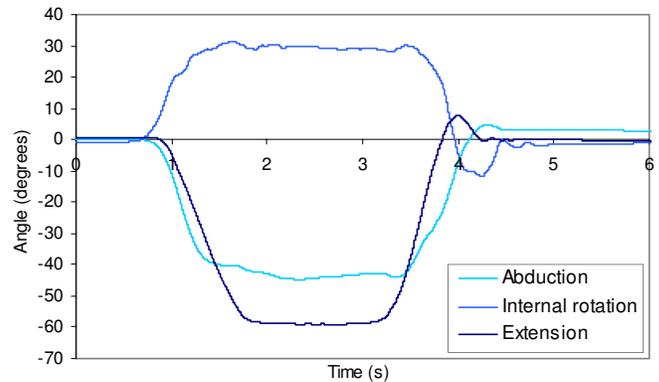

and extension, and movements to simulate activities of daily living such as brushing hair and dressing.

**Figure 2a and 2b:** Front and rear view of 3D gyroscope system and retroreflective markers mounted onto healthy subject.

### RESULTS AND DISCUSSION

Angular velocity data were filtered and integrated to obtain angle data. Figure 3 shows angle data for the upper arm 3D gyroscope unit during a 'reach up back' activity.

**Figure 3:** Upper arm 3D gyroscope output for 'reach up back' activity.

The results of this research indicate that the 3D gyroscope system shows potential for use within a clinical setting as a portable motion analysis system for the upper limb.

## RUNNING DOES NOT PROTECT AGAINST AGE-RELATED GAIT ADAPTATIONS

<sup>1</sup>Hans H.C.M. Savelberg, <sup>1</sup>Lex B. Verdijk, <sup>1</sup>Paul J.B. Willems and <sup>2</sup>Kenneth Meijer

<sup>1</sup>Department of Health Sciences, Maastricht University, The Netherlands; email: [hans.savelberg@bw.unimaas.nl](mailto:hans.savelberg@bw.unimaas.nl)

<sup>2</sup>Department of Biomedical Engineering, Technische Universiteit Eindhoven, The Netherlands.

### INTRODUCTION

Age effects on human gait have been shown in many studies. DeVita and Hortobagyi [1] argued that a redistribution of joint moments is a most characteristic aspect of age-related gait changes. Elderly were found to increase hip joint extensor torques to compensate for reduced plantar flexion torques. It has been argued that reduced muscle force underlies these age-associated gait adaptations. Physical activity is known to improve muscle function. Combining these observations brings us to the hypothesis that physical active can be applied to prevent gait related retardation of gait function. If anything, running induced adaptations might be most suited to counterbalance the effect of ageing on gait stability.

### METHODS

Four groups of subjects were included: young-active, young-inactive, elderly-active and elderly-inactive. All physical active subjects were selected from a group of runners. The inactive participants had not exercised more than once a week for more than one year. Moreover admission to either of the activity groups was based on a physical activity questionnaire.

The subjects were asked to walk over a 12m level walkway, both at a self-selected speed and at a test speed of 1.5m/s. For each trial 2D segmental positions in the sagittal plane from video images (50Hz) of reflective markers and vertical and horizontal ground reaction forces (Kistler type 9281A) were obtained. Inertial properties of the lower limb segments were based on a regression model, using subjects' measures. Inverse dynamic analysis was applied to calculate net joint torque moments of the ankle, knee and hip joint. Only when  $GRF_z$  exceeded 300N, the point of application of the GRF-vector was determined accurately. Consequently only joint torques between 10 and 90% of the stance phase are presented. Peak values of joint torques and powers were statistically analyzed.

### RESULTS AND DISCUSSION

Spatio-temporal characteristics in both the self-selected and the test speed differed between ages not between activity groups. Under both condition elderly walked slower and with shorter step lengths. This resembles previous studies.

Also for joint torques differences between groups occurred as an effect of age not of activity level. In the ankle joint torque elderly displayed a gradual increase from low plantar flexion torques at heel contact to large plantar flexion torques at toe off (Figure 1a). Young subjects were characterized by a rapid initial increase, followed by a plateau phase at midstance and a subsequent final rise of plantar flexion moment. Maximal plantar flexion torques were significantly larger in young subjects (152Nm vs 132Nm). Elderly had reduced knee extensor torques (Figure 1b) and increased hip extensor torques (Figure 1c) at the initial part of the stance phase. These age-related changes match exactly those presented earlier [1]. No changes in joint torque due to differences in activity were found.

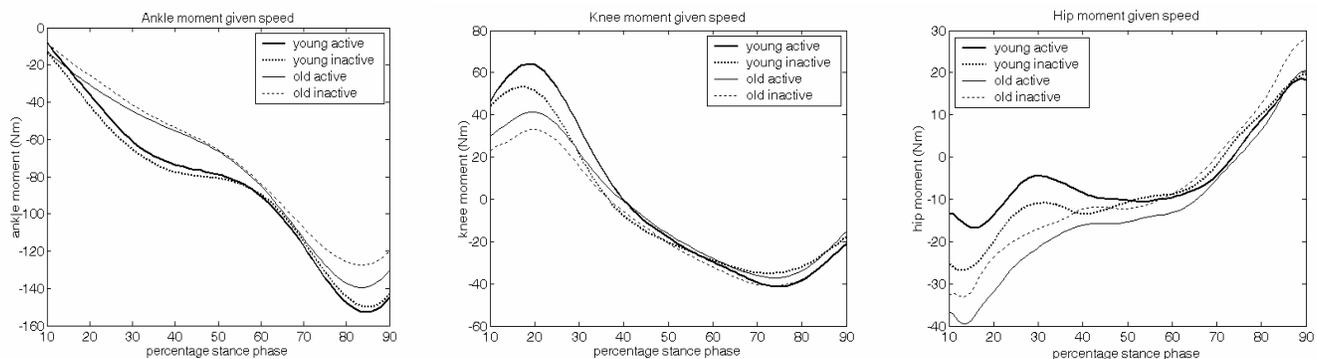

For the same population also function of knee joint extensor and flexor muscle has been reported [2]. An age-associated reduction of knee flexor function was found within the joint angle range used during running and walking. In that study also no effects of activity could be found.

### CONCLUSIONS

Based on this study and the previous study evaluating muscle function in the same population [2] it can be concluded that running does not protect against age-associated muscle wasting. Moreover, it is once again suggested that gait changes result from reduced muscle function.

### INTRODUCTION

Impulsive loading of the knee joint caused by heel strike has been suggested to participate in the development and progression of degenerative joint diseases, such as osteoarthritis (OA) [1,2].

Joint pain is one of the cardinal symptoms of OA and is one of the primary aims in conservative treatment of the disease. As pain can be considered a protective mechanism, pain relief may have the potential to increase the impulsive knee joint loads during walking and thus accelerate the degeneration through increased mechanical loads.

Accordingly, the aim of the study was to investigate the effect of local knee joint analgesia on the impulsive knee joint loads during walking in patients suffering from knee joint OA.

### METHODS

Ten subjects with painful knee joint OA were included in the study (average age 67.8 (SD 5.0), height 164.2 (SD 4.5), weight 74.0 (SD 12.3)).

Intra-articular lidocain injections (10 cc) were performed using ultrasound guidance to ensure proper placement of the bolus within the joint cavity. The injection was performed in the most affected/painful knee.

Linear accelerations were measured at the tibial tuberosity and sacrum, using a piezoresistive accelerometer, in synchrony with a 3D gait analysis. Acceleration measurements and gait analyses were performed before and immediately after the injections. The subjects were instructed and trained to walk at 4.0 km/h (~1.1 m/s) both pre- and post injection.

Knee joint pain during walking was scored using a 100 mm Visual Analogue Scale after the initial measurements (before injections) and again after the post injection measurements.

Impact attenuation (IA) was quantified using a ratio between the peak accelerations at heel strike measured at the tibia tuberosity ( $P_{tibia}$ ) and sacrum ( $P_{sacrum}$ ):

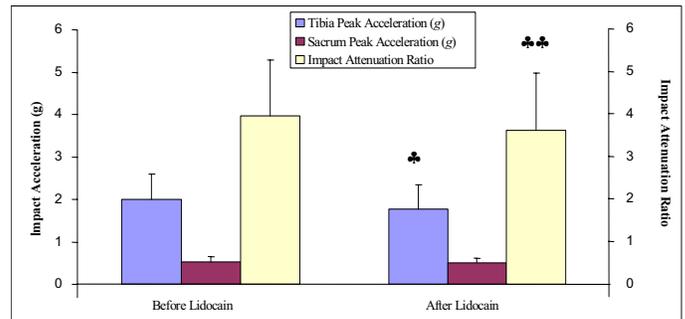

$$IA = P_{tibia} / P_{sacrum}$$

To explain the any changes in acceleration patterns kinematic data were extracted from the 3D gait analysis.

### RESULTS

One subject was excluded due to misplacement of the lidocain bolus. All remaining subjects showed a significant decrease in pain during walking ( $p=0.005$ , see table).

Impact attenuation significantly decreased after lidocain injections ( $p=0.01$ ), caused primarily by a decrease in tibial accelerations ( $p=0.002$ ). Sagittal joint kinematics showed a

**Figure:** Peak accelerations (g) and impact attenuation ratios before and after lidocain injections. Significant reductions in tibial accelerations ♣ ( $p=0.002$ ) and impact attenuation ♣♣ ( $p=0.01$ ) were found.

more extended leg after injections. Both hip and knee joint angles at initial contact turned toward extension after injections ( $p=0.03$  and  $p=0.0005$  resp.). Vertical velocity of the shank prior to impact decreased significantly ( $p=0.02$ ).

### DISCUSSION

Pain relief affected impact attenuation in a paradoxical way and caused the impact attenuation during walking to decrease, although the impact acceleration at tibia decreased. Extended hips and knees make the leg functionally longer, which could be a possible explanation of the decreased tibial acceleration. Changing knee joint angle at initial contact into more flexion has proved to be highly effective in regulating impact transmissibility [3]. Our results endorsed this, as both knee and hip joint angles changed significantly together with a decreased vertical shank velocity before impact.

### CONCLUSION

Local knee joint analgesia may affect the impact attenuation negatively, and this may have clinical implications on the treatment of knee OA in the future.

**INTRODUCTION**

Excessive loading of the knee joint during walking in patients suffering from knee joint osteoarthritis (OA) has been hypothesized to participate in development and progression of the disease [1].

Joint pain is one of the cardinal symptoms of OA and is one of the primary aims in conservative treatment of the disease. As pain can be considered a protective mechanism, pain relief may have the potential to affect the knee joint loading pattern during walking and thus accelerate the degeneration through increased mechanical loads.

Accordingly, the aim of the study was to investigate the effect of local knee joint analgesia on knee joint loading patterns during walking in patients suffering from knee joint OA.

**METHODS**

Ten subjects with painful knee joint OA were included in the study (average age 67.8 (SD 5.0), height 164.2 (SD 4.5), weight 74.0 (SD 12.3)).

Intra-articular lidocain injections (10 cc) were performed using ultrasound guidance to ensure proper placement of the bolus within the joint cavity. The injection was performed in the most affected/painful knee.

Three dimensional gait analyses were performed pre- and post injection. Force plate and movement data was combined to calculate net muscle moments about the joints of the lower extremities. The subjects were instructed and trained to walk at 4.0 km/h (~1.1 m/s) both pre- and post injection.

Knee joint pain during walking was scored using a 100 mm Visual Analogue Scale (VAS) after the initial measurements (before injections) and again after the post injection measurements.

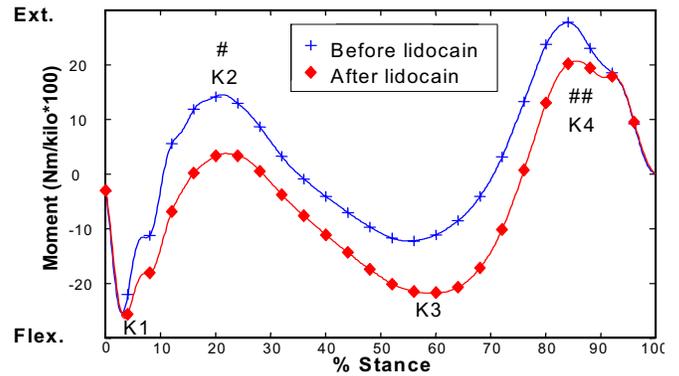

**RESULTS**

One subject was excluded due to misplacement of the lidocain bolus. All remaining subjects showed a significant decrease in pain during walking (p=0.005, see table).

A significant reduction of the peak extensor moments was found (K2: p=0.04, K4: 0.04) together with a significantly reduced knee flexion angle in early stance (p=0.003). Mid-stance peak flexor moments showed a tendency toward increase (p=0.06). No changes in abduction moments were found.

**DISCUSSION**

Pain relief caused the peak extensor moments to decrease, which may be interpreted as an unloading of the knee. A

**Figure:** Knee joint moments during stance before and after intra-articular lidocain injections. Significantly reduced peak extensor moments (K2 and K4) were found (both p = 0.04.). A tendency toward increased flexor moments in mid-stance was observed (p = 0.06).

decreased knee flexion angle makes it possible to walk with lower extensor moments [2] and thus decrease joint loads in early and late stance. All together this suggests a quadriceps avoidance pattern following lidocain injections. Decreased extensor moments and knee flexion angles together with unchanged abduction moments have been suggested to result in a dynamically unstable knee joint [3]. We hypothesised that pain relief would remove the protective mechanism of pain and thus increase joint loads, but surprisingly we found the opposite. Increased co-contractions of the hamstring muscles could be a possible explanation, but no EMG data was available in the present study.

**CONCLUSION**

We surprisingly found that OA patients walked with a quadriceps avoidance-like pattern following pain relief, which represents a paradoxical unloading of the knee joint. The observed changes may suggest an unstable knee following lidocain injections.

## PRINCIPAL COMPONENT ANALYSIS OF LIFTING WAVEFORMS

<sup>1</sup>Allan T. Wrigley, <sup>1</sup>Wayne J. Albert, <sup>2</sup>Kevin J. Deluzio, and <sup>3</sup>Joan M. Stevenson

### INTRODUCTION

In a previous investigation [3] we demonstrated the utility of a Principal Component Analysis (PCA) to discriminate between a group of healthy workers; 50 of whom remained healthy (CON) and 56 of whom developed low back pain (LBP) over a two-year assessment period [2]. This discrimination was done on the kinematic and kinetic waveforms associated with individual lifting patterns of a 15kg load performed when all worker were healthy. The purpose of this study is to determine if the PCA approach is robust enough to discriminate the clinical status of the workers when a confounding factor of load is introduced.

### METHODS

One kinematic (box velocity) and five kinetic (S1, L1, and T1 extension moments; trunk compression; trunk shear) waveforms describing the 2D motion of the trunk and box of 106 healthy male workers performing sagittal lifts of 5kg, 15kg, and 25kg box loads were analyzed. PCA [1] was applied to matrices consisting of each of the 6-waveform variables from both groups. All waveform data was transformed into principal components (PC)s using an eigenvector analysis of the covariance matrix. By orthonormalizing the covariance matrix (S), the eigenvector matrix (U) is determined. The eigenvalues are extracted by taking the diagonal components of Equation 1.

**Equation 1:** Calculation of Eigenvalues

$$L = U^T \times S \times U, \text{ where } L = \text{diagonal eigenvalues matrix}$$

The number of PCs retained for comparison (k) was determined using parallel analysis (Jackson, 1991). PC scores were calculated by projecting the original data points (X) into the new coordinate space defined by the k PCs (Equation 2).

**Equation 2:** Calculation of Principal Component Scores

$$Z = X \times U^T, \text{ where } Z = \text{the matrix of PC scores}$$

The k PC scores for each variable were used as the dependent measures in a two-way MANOVA in order to determine if there were any significant group differences.

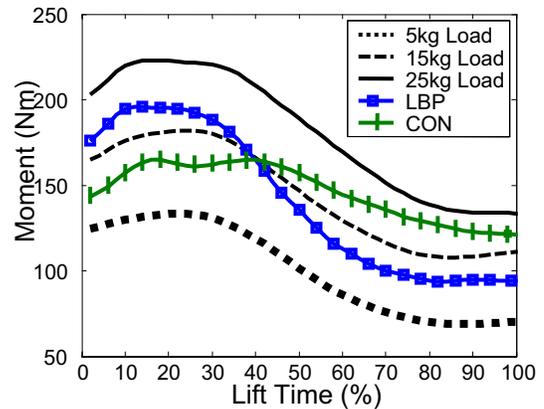

### RESULTS AND DISCUSSION

The MANOVA results (Table 1) revealed that the PCA was insensitive to confounding load effects as the same clinical status effects that were identified from our previous study [3] were identified again (Figure 1). Furthermore, significant load differences for the first PC of every kinetic variable (Figure 1)

indicates that magnitude effects account for the greatest amount of variation in the waveform data sets.

**Table 1:** MANOVA results for group differences and interaction for the PC scores of each waveform variable.

Effect	F	P	$\eta_p^2$
Clinical Status	3.006	0.001	0.147
Load	54.527	0.001	0.758
Clinical Status * Load	0.519	0.990	0.029

**Figure 1:** A significant load effect is illustrated with the three lines —, ---, and ... representing the mean of the trunk extension moment waveforms for each load. Two more lines (+ and □) were plotted to illustrate a clinical status effect based on waveforms that illustrate the PC score and PC coefficient relationship. The differences in load represent a magnitude effect while the differences in extension moment between the CON and LBP group show a change in the trunk loading pattern throughout the lift.

### CONCLUSIONS

The PCA technique was able to identify important biomechanical differences between the groups, and was insensitive to confounding load effects. This research has been able to relate differences in lifting technique prior to the development of LBP, and has identified that these differences are not load dependent.

## BIMANUAL MOTOR CONTROL: BIOLOGICAL AND ROBOTIC SYSTEM LEARNING VIA SIMULTANEOUS MOVEMENT REQUIREMENTS

Pete B. Shull and Roger V. Gonzalez

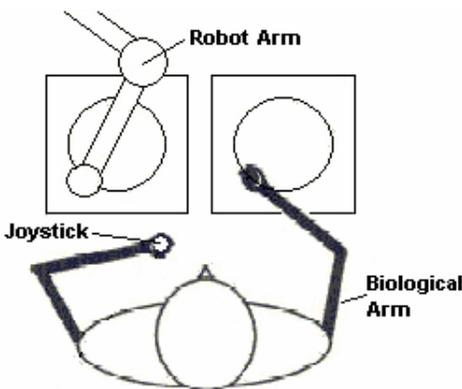

LeTourneau University; email: [RogerGonzalez@letu.edu](mailto:RogerGonzalez@letu.edu), web: <http://www.letu.edu/people/rogergonzalez/>

### INTRODUCTION

Bimanual human motor control learning studies have demonstrated that adaptation occurs while using both biological arms to conduct tasks of varying difficulty [1]. Unimanual learning has also been shown to occur when using a robotic system [2]. Though humans can perform tasks of varying complexity, bimanual learning using two contrasting input/output (I/O) systems simultaneously is not well understood. This study tested our hypothesis that humans can adapt spatially and temporally to a bimanual tracing task using both their biological arm and a robotic system simultaneously.

### METHODS

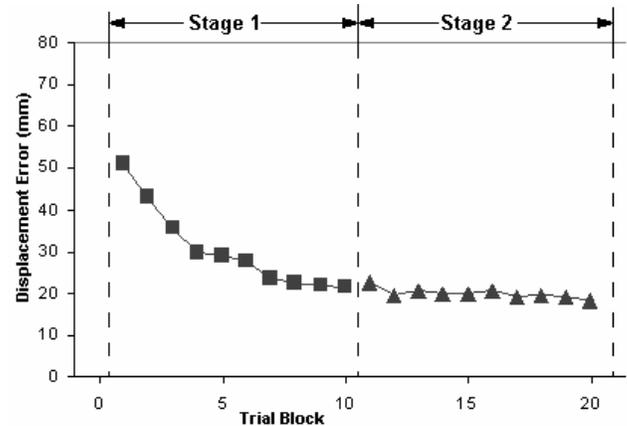

Four female and six male subjects (ages 19-29) voluntarily participated in this experiment. All subjects were right-handed by self-report and were tested during the same time each day ( $\pm 2$  hrs) for four consecutive days. Each subject was given the task of tracing 15 cm circle(s) clockwise at 3.2 second intervals using their biological and/or a robotic arm (Figure 1). XY digitizing tablets recorded two-dimensional spatial position every 100ms, and each trial lasted approximately 50 seconds. Subjects traced two circles using both biological arms for the first and last five trials of the experiment to examine normal bimanual performance before and after testing. During stage one of testing, subjects traced one circle with a robotic arm by applying forces and torques to a rigid joystick with their dominant arm. During stage two, subjects used the robotic arm and their non-dominant biological arm to trace both circles simultaneously. The control strategy for the actuation of the robotic arm was intentionally designed to be difficult and non-intuitive so that possible learning could be observed over time.

**Figure 1:** Experimental setup. Subjects traced 15 cm circles on digitizing tablets with the robotic arm by applying forces and torques to the joystick and/or with their biological arm.

### RESULTS AND DISCUSSION

Data was analyzed in blocks of five trials. Performance was based on spatial and temporal accuracy in tracing the circle(s).

**Figure 2:** Subject spatial performance using the robotic arm. During stage 1 subjects used only the robotic arm. Stage 2 required using both robotic and biological arms simultaneously.

Spatial accuracy was calculated by averaging the distance from the circle (in millimeters) at each point during the trial. Temporal accuracy was the average of the differences in desired and actual angle (in degrees) at each point of the trial. Compiled results of all subjects show that subjects learned to control the robotic arm by demonstrating spatial learning curves (Figure 2) and temporal exponential learning curves. Biological arm spatial and temporal scores were constant throughout testing and were statistically lower than robotic arm scores since controlling the biological arm was more natural than controlling the robotic arm.

It would seem that moving from stage 1 of testing to stage 2 would be a difficult task because the subject would be controlling two distinct I/O systems simultaneously and that the initial performance of stage 2 would be worse than the final performance of stage 1. However, neither the spatial nor the temporal learning curves were adversely affected when subjects moved from stage 1 to stage 2 of testing.

### CONCLUSIONS

Testing indicates that humans can learn to use two distinct parallel I/O systems simultaneously to conduct two-dimensional tracing tasks. It also appears that humans can transition from using one I/O system to using two distinct I/O systems without a decrease in performance in either system.

## UPPER EXTREMITY KINEMATICS DURING FLY-CASTING

<sup>1</sup>Joshua R. Allen, <sup>1</sup>Katie B. O’Keefe, <sup>2</sup>Timothy J. McCue, and <sup>1</sup>Michael E. Hahn  
<sup>1</sup>Movement Science Laboratory, Montana State University, Bozeman, MT, USA  
<sup>2</sup>Fly Casting Institute, Missoula, MT, USA  
 email: [mhahn@montana.edu](mailto:mhahn@montana.edu)

### INTRODUCTION

Fly fishing has long been a popular form of recreation among outdoor enthusiasts, and is increasing in popularity internationally. A recent study revealed shoulder and elbow pathologies associated with repetitive, high velocity, overhand movements common to fly-casting [1]. However, no study has formally documented the upper extremity movement patterns during fly-casting. The aim of this study was to determine kinematic patterns of the fly-casting stroke. Documenting the movement patterns common to fly-casting will allow greater understanding of the underlying mechanisms of upper extremity pathologies.

### METHODS

Seven subjects (6 male, 1 female; mean age 30.9) participated in the study after signing an informed consent. Subjects ranged from novice to expert, with a number of the subjects being professional fly-fishing guides. Twenty five reflective markers were placed on bony landmarks of the upper body (adapted from Rab et al. [2]). A 6-camera Vicon® 460 system (Vicon Motion Systems Inc., Lake Forest, CA, USA) collected marker position data at a frequency of 200 Hz.

Shoulder motion was calculated with respect to the trunk segment. The order of rotation for the shoulder was sagittal, frontal and transverse. The elbow was modeled as a single-axis pin joint and the wrist as a two-axis pin joint. Range of motion (ROM), peak angular displacement and time to peak displacement were examined for phase patterns, focusing on the following motions: shoulder flex/extension, ab/adduction, ext/internal rotation; elbow flex/extension; wrist flex/extension, radial/ulnar deviation.

Each subject performed multiple casting trials of their preferred casting style. Subjects were instructed to perform a series of “false casts” (usually 2-3), followed by the actual “shooting” cast. Three shooting casts were analyzed from each subject’s casting session.

### RESULTS AND DISCUSSION

It was determined that the fly-casting motion may be divided into three primary phases. The first phase, the “back cast,” is a movement from anterior to posterior, displacing the fly line behind the caster. Primary motions during phase 1 included flexion, abduction, and external rotation about the shoulder. At the end of the back cast, there is a pausing phase (phase 2) in which the caster waits for the line to load the rod prior to the forward cast. Phase 3, the “forward cast,” serves to move the rod anteriorly, sending the line to the desired target. Primary motions during phase 3 included shoulder internal rotation and extension, combined with elbow extension.

Average time spent in each phase 1-3 was as follows:  $0.72 \pm 0.07$ sec;  $0.36 \pm 0.09$ sec; and  $0.64 \pm 0.12$ sec, respectively. The greatest ROM for all joints occurred during phase 3, followed by phase 1. Phase 2 showed little motion ( $<7^\circ$  per joint) for all joint actions. The greatest ROM during phase 1 and 3 was for external rotation of the shoulder, followed by elbow flexion. Shoulder flexion and abduction also exhibited substantial ROM during the forward cast. Average ROM values are presented in Table 1.

**Table 1:** ROM during each phase (deg); mean  $\pm$  SD.

	Motion	Phase 1	Phase 2	Phase 3
<b>Shld</b>	Flex/Ext	$26.1 \pm 3.1$	$3.6 \pm 2.3$	$27.9 \pm 17.1$
	Ab/Ad	$19.2 \pm 9.6$	$6.9 \pm 5.3$	$22.1 \pm 21.0$
	ER/IR	$63.4 \pm 11.8$	$6.6 \pm 3.7$	$53.0 \pm 17.7$
<b>Elbow</b>	Flex/Ext	$31.0 \pm 6.1$	$3.4 \pm 2.2$	$41.1 \pm 17.0$
<b>Wrist</b>	Flex/Ext	$21.9 \pm 5.8$	$3.6 \pm 1.8$	$21.9 \pm 12.4$
	R/U Dev	$12.7 \pm 1.5$	$5.1 \pm 3.7$	$11.9 \pm 6.5$

The time to peak angular displacement within each phase is presented in Table 2. In general, large variation was seen in the timing of peak displacements. However, two distinct patterns showed consistency. Peak shoulder external rotation of  $71.6^\circ (\pm 17.0^\circ)$  occurred at  $4\% (\pm 6\%)$  of phase 3, and peak elbow flexion of  $101.7^\circ (\pm 14.6^\circ)$  occurred  $19\% (\pm 22\%)$  into phase 3. The early external rotation in phase 3 may indicate the effect of anterior trunk motion and inertial delay in the arm and rod segments, similar to the acceleration phase of a baseball pitch.

**Table 2:** Time to peak displacement (% phase); mean  $\pm$  SD.

	Motion	Phase 1	Phase 2	Phase 3
<b>Shld</b>	Flex/Ext	$22 \pm 25$	$42 \pm 30$	$64 \pm 29$
	Ab/Ad	$59 \pm 27$	$38 \pm 33$	$52 \pm 28$
	ER/IR	$78 \pm 25$	$46 \pm 36$	$4 \pm 6$
<b>Elbow</b>	Flex/Ext	$65 \pm 29$	$38 \pm 34$	$19 \pm 22$
<b>Wrist</b>	Flex/Ext	$54 \pm 42$	$50 \pm 38$	$35 \pm 25$
	R/U Dev	$56 \pm 39$	$53 \pm 34$	$55 \pm 24$

### CONCLUSIONS

Findings from this initial study indicate that there is moderate consistency of basic movement patterns between subjects during fly-casting. Parallel analyses are currently focusing on segmental coordination and joint dynamics, with emphasis on injury prevention. Future work will also quantify the effects of professional instruction on these variables.

**THE INTERACTION BETWEEN SURFACE GRADE AND EXERCISE DURATION FOR SERIAL SARCOMERE ADAPTATIONS FOLLOWING TREADMILL RUNNING IN RATS**

Timothy A. Butterfield, Walter Herzog  
 Kinesiology Research Centre, University of Calgary, Calgary, Alberta, Canada T2N 1N4  
 email: [walter@kin.ucalgary.ca](mailto:walter@kin.ucalgary.ca), web: [www.kin.ucalgary.ca](http://www.kin.ucalgary.ca)

**INTRODUCTION**

It is well accepted that eccentric exercise results in muscle injury and adaptation. *In-vivo* studies, aimed at quantifying the magnitude of muscle injury, have shown that several extensor muscles of the hindlimb of the rat experience varying degrees of muscle injury following chronic downhill walking [1], illustrating that the damage to these muscles is not uniform. Subsequently, a significant increase in serial sarcomere number (SSN) has been reported in the same knee extensor muscles following long-term downhill walking [2], leading to the hypothesis that eccentric exercise-induced damage results in this cellular adaptation. However, recent studies have shown that one extensor muscle of the hindlimb of the rat undergoes active lengthening during uphill walking [3], which would be expected to result in injury and sarcomere number increase. However, this has not been reported [2]. Recently, we have shown that not only can sarcomere number adaptations differ within a muscle, but can also occur between synergistic muscles, indicating a differential adaptation that may not be damage dependent [4].

**METHODS**

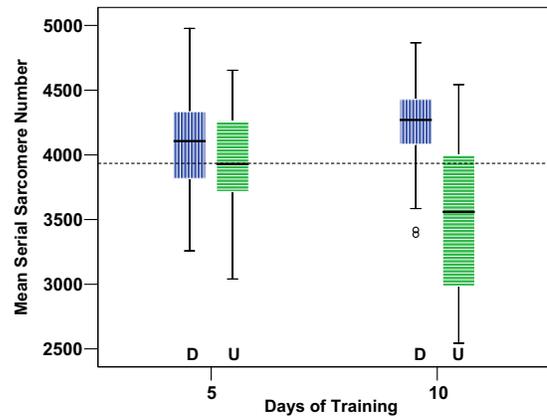

*Protocol I:* 24 male Long-Evans rats (age = 150 days) were randomly assigned to one of three groups: uphill (U) group (n=8), downhill (D) group (n=8) and a control (C) group (n=8). All groups were trained in five minute sets, with 1.5 minutes rest between sets for 5 days at 16 meters/min.

*Protocol II:* 16 male Long-Evans rats (age = 150 days) were randomly assigned to one of two groups: uphill (U) group (n=8), and a downhill (D) group (n=8). All groups were trained in five minute sets, with 1.5 minutes rest between sets for 10 days at 16 meters/min. Total training durations for each group are given in table 1.

*Tissue analysis:* 72 hours following the last training bout, the rats were killed, and the hindlimbs removed and fixed with the knee maximally flexed. Fascicle and sarcomere lengths of the vastus intermedius were measured using computer software and laser diffraction respectively. A two-way ANOVA was used to assess the differences in SSN with respect to surface grade and time.

**RESULTS AND DISCUSSION**

There were no significant differences in serial sarcomere number after only five days of exercise in either group, when compared to the control group. However, there was a significant interaction between exercise duration and surface

**Figure 1.** Interaction box plots for the uphill (U) and downhill (D) walking rats of 5 and 10 day duration, for the vastus intermedius muscle. Note the quantitative interaction of grade and duration on serial sarcomere number.

grade with respect to the serial sarcomere number in the vastus intermedius muscle ( $p < .001$ ), illustrating that the adaptation in serial sarcomere number over time was significantly greater in the uphill group compared to the downhill group (Fig. 1).

**CONCLUSION**

Serial sarcomere number changes in the vastus intermedius muscle can be predicted by surface grade only as a function of time. Although a previous study has shown that serial sarcomere numbers may vary depending on surface grade, the lack of a control group in that study does not allow the quantification of a gain or loss of sarcomeres compared to normal [2]. In addition, since knee extensor muscles have been shown to undergo lengthening contractions during uphill walking [3], the loss of sarcomeres in the uphill exercise group questions the role of muscle injury in the process of cellular adaptation.

## EFFECTS OF KNEE AND HIP JOINT MOTIONS DURING THE LANDING OF A STOP-JUMP TASK

Cheng-Feng Lin and Bing Yu,  
 Center for Human Movement Science, University of North Carolina at Chapel Hill  
 E-mail: feng1368@email.unc.edu

### INTRODUCTION

Performance of landing tasks in sports is important for the prevention of lower extremity injuries. Literatures have shown that stiff landing characterized by great impact forces may be a risk factor for knee injuries [1, 2]. Increased hip extensor and knee flexor moments at the initial contact have been found in stiff landing in which the knee flexion angle is less than 90 degree [3]. Female recreational athletes also showed increased knee resultants forces and decreased knee flexion angle during landing compared to the male [1]. However, five degrees increased did not significantly affect the magnitudes of ground reaction forces in stop-jump task [4]. This presentation will show that how the motions of knee and hip affect the ground reaction force.

### METHODS

Thirty male and thirty female healthy college students without known history of knee disorder were recruited for this study. Up to five steps approach run followed by stop-jump task was collected. Reflective markers were placed on bilaterally on ASIS, lateral malleolus, upper and lower anterior aspect of tibia. One marker was placed between the lumbar vertebrae 4 and 5. The videographic and ground reaction force (Bertec Corporation, Worthington, OH) signals were recorded by the Peak Performance Motus videographic and analog data acquisition system (Peak Performance Technology, Inc., Englewood, CO). The collected 3-D coordinates of the markers during each stop-jump trials were filtered through a Butterworth lower-pass digital filter at estimated optimum cutoff frequencies. All signal processing and data reduction were performed using MotionSoft 3-D motion data reduction program package version 5.5 (MoitonSoft, Inc., Chapel Hill, NC).

Linear regression analysis was performed to determine the relationships of knee and hip kinematics with the ground reaction forces. A type I error rate of 0.05 was chosen to indicate statistical significance in each analysis. A stepwise selection procedure was used to determine the best regression equation for each couple of dependent and independent variables. All statistical analyses were performed using the SYSTAT computer program package, version 5.0 (SYSTAT, Inc., Evanston, IL).

### RESULTS AND DISCUSSION

The results are shown in the Table 1. These results indicate that what affect the landing stiffness of the stop-jump task was hip and knee joint motions instead of configurations. A large hip and knee flexion angles at the initial foot contact with the ground do not necessarily make the landing soft, but active hip and knee flexion motions do. Hip joint motion at the initial foot contact with the ground mainly affects the ground reaction force and in the anterior-posterior direction during landing of the stop-jump task. Knee joint motion at the initial foot contact with the ground mainly affects the ground reaction force in vertical direction during landing of the stop-jump task. Hip joint motion at the initial foot contact with the ground appears to be an important technical factor that affects ACL loading during the landing of the stop-jump task.

## BONE MINERAL DENSITY OF THE PROXIMAL FEMUR IS NOT RELATED TO DYNAMIC JOINT LOADING DURING LOCOMOTION

Mary Lou Bareither, Karen L. Reed-Troy and Mark D. Grabiner

Department of Movement Sciences, University of Illinois at Chicago, Chicago, IL, USA.

E-mail: mbareith@uic.edu

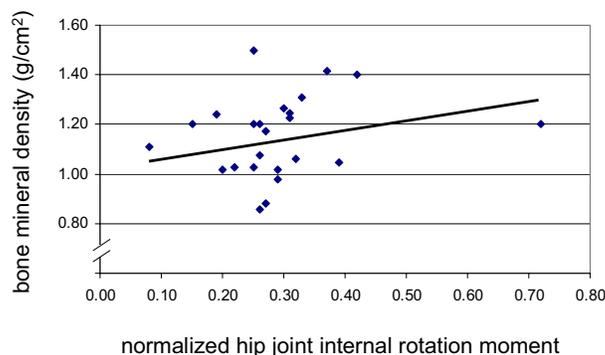

**INTRODUCTION** Load bearing provides the most potent influence on bone mass and architecture (1). In 2004 Moio et al. (2) reported that nearly 40% of the variance of proximal femur bone mineral density (BMD) was associated with peak hip joint moments during walking. This result implies that joint moments acquired using gait analysis during a single session conveys meaningful information regarding daily stress and loading history. We considered the possibility that the result could be an analytical artifact, as the relationships reported were based on joint moment calculations that implicitly included the influence of body mass.

We have previously reported the influences of body size variables on bone mineral density (3, 4). In each of these studies we found a significant relationship between muscle strength variables and bone mineral density of the proximal femur in older adults. However, after accounting for the influence of body size on muscle strength variables, the relationship between muscle strength and bone mineral density was reduced to zero. Based on this work we anticipated that the relationship between joint moments measured during locomotion and bone mineral density would be similarly affected.

The purpose of the present study was to characterize the extent to which body mass influences the relationship between hip joint moments during locomotion and bone mineral density of the proximal femur in a homogeneous sample of healthy young women. We hypothesized that BMD would not be significantly associated with hip joint moments during locomotion independently of body mass.

**METHODS** Twenty-five women (age and mass:  $22.96 \pm 2.05$  years,  $66.8 \pm 18.04$  kg) participated in this institutionally approved study. The BMD ( $\text{g}/\text{cm}^2$ ) of the non-dominant femur was determined by Dual Energy X-ray Absorptiometry (DXA) (Hologic QDR 4500 Elite). Subjects performed 10-15 trials during which they walked at a self-selected velocity along a path of approximately 10 meters. An eight-camera motion capture system (Motion Analysis Corporation, Santa Rosa, CA) and two AMTI force plates operating at 60 Hz recorded gait kinematics and kinetics. Univariate Pearson correlations were calculated to determine the relationships between hip joint moments, body mass, and proximal femur BMD. Significant correlations between hip joint moments and proximal femur BMD were subsequently investigated using an allometric scaling procedure (3,4) to determine the extent to which body mass influenced the relationship between hip joint moments and the BMD of specific regions of interest.

**RESULTS AND DISCUSSION** A potentially important relationship was discovered between only one of the measures of hip joint moment and one of the regions of interest of proximal femur BMD. Specifically, the peak internal rotation moment and the BMD of the intertrochanteric region were

**Figure 1:** BMD vs. normalized internal rotation hip moment. After removing the influence of body mass on the hip joint moment, the relationship with BMD was not significantly different than zero. The regression equation characterizing the relationship between the peak internal rotation moment normalized to body mass and intertrochanteric BMD:  $\text{BMD} = 1.071 + (.284 * \text{normalized internal rotation moment})$  was not significant ( $p=0.337$ ). The figure reveals the presence of an apparent outlier on the x-axis. A *post hoc* regression conducted without this data point resulted in an equation that was not significant ( $p=0.25$ ) and accounted for only 6.3 percent of the shared variance.

significantly correlated ( $r = 0.475$ ,  $p = 0.019$ ). The magnitude of the peak internal rotation moment was  $19.77 \pm 2.2$  Nm. The average BMD of the intertrochanteric region was  $1.15 \pm 0.03$   $\text{grams}/\text{cm}^2$ . However, the relationship between the allometrically scaled peak internal rotation moment and intertrochanteric BMD was not significant (Figure 1). Prior to scaling, the peak internal rotation hip joint moment (unscaled) was strongly associated with the BMD of the intertrochanteric region; accounting for more than 20 percent of the shared variance. However, scaling of the hip joint moments to account for the influence of body mass reduced the relationship between hip joint moment and bone mineral density to essentially zero. As expected, body mass accounted for a significant proportion of the shared variance of proximal femur BMD

In summary, the relationship between bone mineral density of the proximal femur in a sample of young healthy women and peak hip joint moments during locomotion was found to be dependent on the influence of body mass on both variables. After this influence was accounted for, the BMD-hip joint moment relationship disappeared. The results suggest that the dynamic hip joint moments during walking are not independently informative of daily stress stimulus and loading history in young women.

## HIGH SHEAR STRESS INDUCES P53 EXPRESSION AND APOPTOSIS IN CARTILAGE EXPLANTS

James Martin, Anneliese Heiner, and Joseph Buckwalter

Department of Orthopaedics and Rehabilitation, University of Iowa, Iowa City, IA, 52242

### INTRODUCTION

Joint injuries leading to articular surface incongruities (e.g., step-offs) can cause excessive mechanical shear stress, which promotes cartilage destruction and post-traumatic osteoarthritis (OA). Here we test the hypothesis that excessive shear stress induces chondrocyte stress responses that lead to apoptosis. We cultured human cartilage explants in a mechanically active bioreactor, the Triaxial Compression Vessel (TCV), which is capable of modulating shear stress at physiologically relevant loading levels. This device was used to test the effects of shear stress on chondrocyte viability, apoptosis, and expression of p53, a protein that is involved in the early stages of apoptosis.

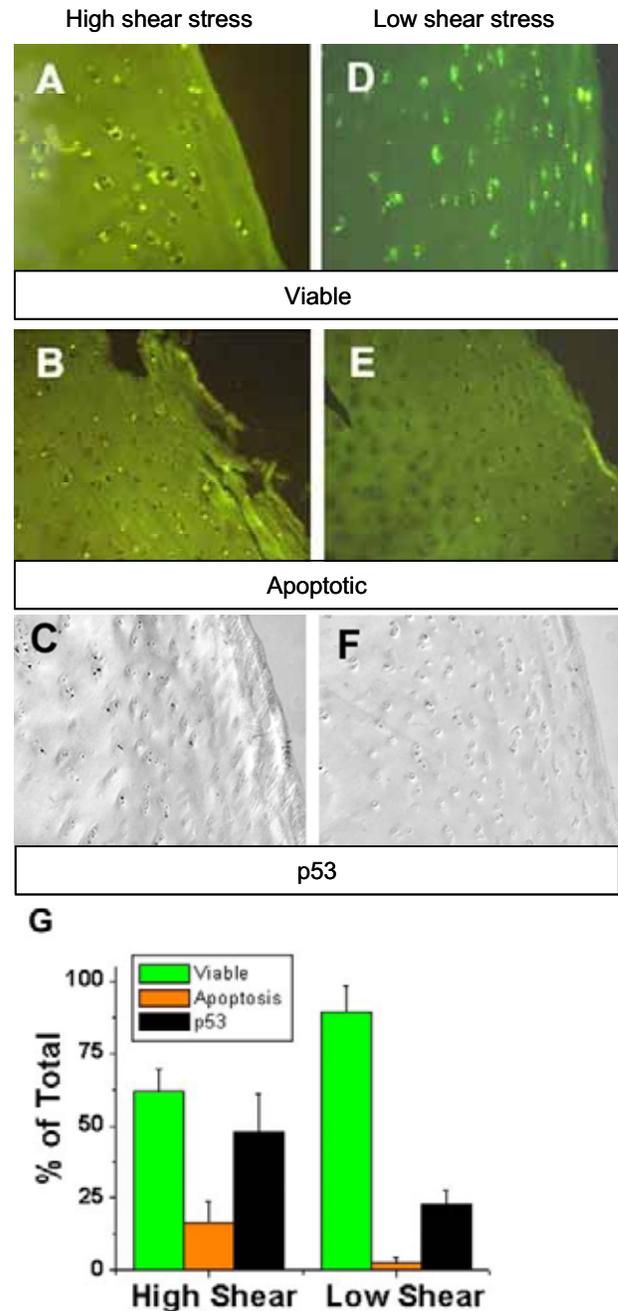

### METHODS

Cartilage explants harvested from non-osteoarthritic ankle joints from 2 donors were placed in the TCV for mechanical stress treatment. The TCV imposes variable shear stress states at quasi-physiologic levels by applying transverse compression and axial compression simultaneously. The interplay between axial and transverse compression determines shear stress levels. In this study, 2 different treatments (900 cycles, 1 Hz) were applied: 1) 5 MPa axial compression only (high shear stress), 2) 5 MPa axial + 5 MPa transverse compression (minimal shear stress). Treated explants were incubated overnight in calcein AM to stain viable cells (green signal), then were cryoembedded and sectioned. Replicate sections were stained for apoptosis by TUNEL assay using TMR-red-labeled nucleotide (orange signal) or with an anti-p53 antibody using HRP/NBT detection (black signal). Whole sections were scanned using a 10x objective to generate composite images composed of 10-20 frames. Composite images were analyzed by scoring the number of cells stained with calcein AM, TUNEL assay or p53 antibody as a percent of total cells present. At least 3 entire sections from each explant were analyzed for each stain. Student's t-test was used to evaluate statistical significance.

### RESULTS AND DISCUSSION

Chondrocyte viability in the superficial and transitional zones of cartilage explants declined from 89% in low shear stress to 62% in high shear stress. Apoptosis increased from 2.4% in low shear stress to 16.7% in high shear stress, while p53 expression increased from 23% to 48% (Figure 1). Differences in viability, apoptosis and p53 expression were significant ( $p < 0.05$ ). No significant changes were seen in the deep zone (data not shown) staining results.

Exposure to high shear stress induced chondrocyte death *via* apoptosis. High shear stress also induced p53 expression, indicating that cell death was imminent. This suggests that high shear stress causes chondrocyte depopulation that could contribute to cartilage degeneration in post-traumatic OA.

**Figure 1:** Effects of high and low shear stress on cartilage explants. (A,D) Calcein AM staining for viable cells (green). (B,E) TUNEL reaction for apoptosis (red-orange). (C,F) Immunostaining for p53 (black). (G) High shear stress decreases cell viability, increases apoptosis, and increases p53 expression, as compared to low shear stress.

## THE NEUTRAL ZONE IN HUMAN LUMBAR SPINE SAGITTAL PLANE MOTION: A COMPARISON OF IN VITRO QUASISTATIC AND DYNAMIC FORCE DISPLACEMENT CURVES

<sup>1</sup> Ralph E. Gay, <sup>2</sup>Brice Ilharreborde, <sup>2</sup>Lawrence J. Berglund, <sup>2</sup>Kristin Zhao, <sup>2</sup>Kai-Nan An

<sup>1</sup>Department of Physical Medicine and Rehabilitation, and <sup>2</sup>Biomechanics Lab, Mayo Clinic, Rochester, Minnesota  
email: [rgay@mayo.edu](mailto:rgay@mayo.edu)

### INTRODUCTION

The neutral zone (NZ) of a spinal motion segment has been defined as “that part of the range of physiological intervertebral motion, measured from the neutral position, within which the spinal motion is produced with a minimal internal resistance.” (1) The size of this region of laxity or high flexibility has been considered an indicator of the stability of a motion segment. The NZ has traditionally been measured in degrees of motion using a quasistatic technique that subjects the segment to pure moments that increase incrementally. The ends of the neutral zone are defined by the positions of the motion segment just before beginning the 3<sup>rd</sup> cycle in each direction (30 seconds after unloading the 2<sup>nd</sup> cycle). Thus, the NZ is a measure of residual deformation. Thompson et al suggested that the quasistatic NZ may be an artifact of the testing procedure (2). Using dynamic motion, they proposed a definition of NZ which used derivatives of a 4<sup>th</sup> order polynomial fitted to both the loading and unloading curves. The region most compatible with the NZ concept was confined by a slope of + or -0.05 Nm/degree. They found an area of laxity around the neutral position in a sheep model only during flexion/extension. *The objective of this study was to compare quasistatic and dynamic force-displacement curves from the same motion segments in regard to ROM and characteristics of the NZ region.*

### METHODS

Three human cadaveric lumbar motion segments (L1-2, L2-3, L4-5) aged 40-82 were harvested and dissected in the standard fashion leaving bone, ligament and disc tissue. Each segment was wrapped in saline moistened toweling to retard drying and mounted in custom fixtures (upper and lower) using dental plaster and K-wires. Motion segments were then placed in a custom testing device. Dynamic flexion and extension motion was induced using a counter-weighted stepper-motor mounted on a low friction bearing platform in the sagittal plane. The motor was controlled by a LabView program. Pure flexion/extension moments were transferred from the motor to the upper vertebra of the motion segment through low friction sliding bearings to allow lateral flexion to occur. Moments were applied at a rate of 1 degree/second up to 5 Nm then the motor reversed and applied a moment in the opposite direction. Force data were measured by a 6DOF load cell. Displacement was measured in degrees by CXTA tilt sensors. Four dynamic preconditioning cycles were completed then a 5<sup>th</sup> cycle was used for analysis (1 degree/second). Immediately after dynamic testing, the upper specimen mounting was attached to pneumatic cylinders via a cable and pulley system and pure moments were applied in 1 Nm increments from 0 load to 5 Nm. Force-displacement points were taken as the position after 30 seconds was allowed for viscoelastic creep after each new load and after removal of the load. The region between the points taken after load removal (representing residual deformation in both flexion and extension) was defined as the quasistatic NZ.

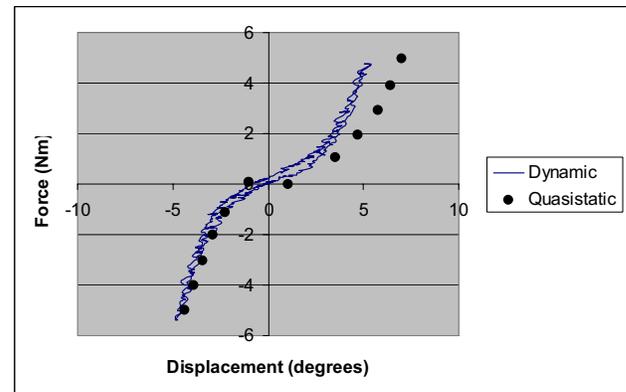

### RESULTS AND DISCUSSION

The ranges of motion attained in both techniques as well as size of neutral zone (degrees) are listed in Table 1. Using 4<sup>th</sup> order polynomials we found no discrete area with a slope near 0 as did Thompson et al. The region of the dynamic curves prescribed by the quasistatic NZ (centered on 0 load) was isolated and the slopes calculated. Figure 1 shows the two force-displacement curves superimposed for the motion segment with the largest quasistatic NZ (L2-3).

**Table 1.**

Spec	Q-ROM	D-ROM	Q-NZ	D-slope
L1-2	10.90	11.20	0.78	0.37
L2-3	11.35	10.23	2.11	0.28
L4-5	8.20	9.90	1.43	0.38

Q=quasistatic, D=dynamic, NZ=neutral zone (degrees), D-slope=slope of curve in dynamic NZ region

**Figure 1:** Quasistatic and dynamic force-displacement curves of an L2-3 motion segment superimposed.

### CONCLUSIONS

The dynamic force-displacement curves produced by a 1 degree/second moment did not demonstrate an area of laxity about the neutral position as was suggested by the quasistatic curves. This may be due to lack of sufficient relaxation during the dynamic motion despite the low load rate. Alternatively, a true NZ may not exist in these human specimens and the characteristics of motion about the neutral area may be better described by the slope or other functions. Although our results represent only a few specimens, the relevance of the quasistatic NZ, which represents residual deformation after the application of significant load, should be re-examined.

**EXPERIMENTALLY DERIVED MODEL OF HUMAN BODY GROWTH**

Maria K. Lebieadowska, Steven J. Stanhope,  
 Physical Disabilities Branch, National Institutes of Health, Bethesda, MD 20892\*  
 email: lebieadowskam@cc.nih.gov

**INTRODUCTION**

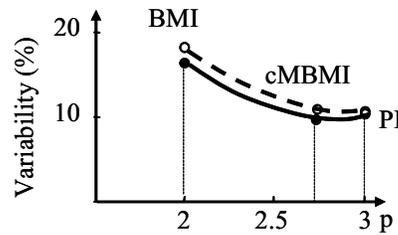

The proportion between body mass and body height serves as a general description of human body shape (HBS). Different indexes have been used to describe HBS. The most common is Quetelet's body mass index (BMI) that is the ratio between body mass and the second power of body height. The ability of BMI to detect obesity in children is limited by its relatively high level of unexplained variance. Ponderal index (PI) is a geometrically based index (the ratio between body mass and the third power of body height) of HBS. PI is based on a geometrical model, which follows the rules of allometry [1] and scaling of biomechanical parameters [2]. The growth (an age related increase in body height and mass) in children 6-18 years is often considered as geometrically similar, because the body proportions remain almost unchanged. It is unclear how close human growth follows the model of geometrically similar growth. The aims of this study were to (1) explore the assumption of geometrical growth by developing an experimentally derived model of human body growth; (2) to establish a modified body mass index (MBMI) that is invariant of the effect of growth; and (3) to compare variability of different indexes in a sample population of 6-18 year old children.

**METHODS**

We used the demographic data collected in able-bodied children age 6-18 years [3] (444 girls and 403 boys). To model growth, the best fit between the body height (H) and body mass (BM) was calculated separately in boys and girls with the function  $BM = m_i H^p$ . The modified body mass index (MBMI) was calculated as  $MBMI = BM / H^p$  in boys and girls separately. In addition an average body height power across the genders was used to calculate the common modified body mass index (cMBMI) in all children. The BMI ( $BMI = BM / H^2$ ) and PI ( $PI = BM / H^3$ ) were also calculated. The means, standard deviation and variability (standard deviation expressed as a percentage of the mean value) of all indexes were calculated. The correlation coefficients and regression lines were used to assess the relationship between indexes and body height. Statistica, StatSoft Inc. software was used in the analysis at  $p < 0.05$ .

**RESULTS AND DISCUSSION**

The best mathematical fit between body mass and body height found in girls was  $BM_G = 13.6 H^{2.71}$  ( $R^2 = 0.89$ ) and in boys  $BM_B = 13.9 H^{2.65}$  ( $R^2 = 0.91$ ). The difference between the

**Figure 1** The variability of different body mass indexes in girls (dashed line) and in boys (solid) as a function of p in the equation  $BM = m_i H^p$

experimentally obtained powers and the third power of body height reflected the discrepancy between the experimental and geometrically similar model of the human body growth. The different powers obtained in girls and boys may reflect the gender specific differences in body build. There were no statistically significant correlations between indexes and body height, except for BMI, which also exhibited the largest variability (18 % in girls and 17.7 % in boys) (Fig.1). The MBMI, cMBMI and PI exhibited similar variability (12.2%-13.9%) (Table 1). The increase of BMI with the body height in children requires an application of age charts and a z-score or percentile analysis. The fact that the other indexes are independent of body height sanctions a characterization of population with one mean and one standard deviation. Future studies should include the development of models of growth in various populations and in individual subjects.

**CONCLUSIONS**

Human growth in children 6-18 years old does not follow the geometrically similar growth model. Using variability as a guide, MBMI and PI appear to be superior to BMI in reflecting the relationship between the body height and geometry. Based on the differences in the coefficients cMBMI is superior to PI in the context of the differences due to growth in children 6-18 years old.

**INTRODUCTION**

Obesity is a major risk factor for knee, but not hip or ankle osteoarthritis (OA). Knee varus malalignment and an increased knee adduction (varus) moment are key variables linked to OA progression. We are studying gastric bypass surgery (GBS) patients with and without knee pain to evaluate gait biomechanics in obese subjects before and after a 100-pound weight loss.

**METHODS**

Twenty-one subjects were studied, including 18 females and 3 males. The pre-surgery age of the subjects was  $49.86 \pm 6.81$  years and the pre-surgery body mass index (BMI) was  $47.15 \pm 7.01 \text{ kg/m}^2$ . Weight-bearing, semi flexed anterior-posterior radiographs were taken to access radiographic knee OA (rOA). Eighteen (85%) subjects reported knee pain, and of those 18, 14 (78%) had rOA and 4 (22%) had no rOA. Normalized Western Ontario McMaster Arthritis Questionnaire (WOMAC) pain scores were less than 13 for the 3 subjects without pain and ranged from 16 to 73.2 for those with pain. Subjects were able to walk without the use of assistive devices.

Spatial-temporal, kinematic, and kinetic data were collected during natural cadence gait with a 7-camera Vicon 370E system. Peak knee flexion during swing, peak ankle plantarflexion for push-off, peak knee varus moment, and peak ankle plantarflexion power for push-off were determined to be the parameters of interest. Twenty-one subjects completed pre-surgical gait analysis sessions and 6 subjects completed post-surgical sessions. Weight loss for the 6 subjects was  $48.41 \pm 12.78 \text{ kg}$ , for a post-surgical BMI of  $29.40 \pm 5.78 \text{ kg/m}^2$ . Four of the subjects with pre-surgery knee pain reported no knee pain after weight loss. Subjects were compared to published normal control populations, using two-sample t-tests. For pre- and post-surgical assessments, subjects served as their own controls and paired t-tests were used to access significance.

**RESULTS AND DISCUSSION**

Five sets of comparisons were made for the 4 key parameters: 1) all obese subjects (n=21) versus control, 2) the no pain group (n=3) versus control, 3) the pain group (n=18) versus control, 4) the pain group versus the no pain group, and 5) the 6 post-surgical subjects versus their pre data, as shown in **Table 1**. Control values for peak knee flexion during swing, peak ankle plantarflexion for push-off, and peak ankle plantarflexion power for push-off were taken from Winter [1]. Peak knee varus moment was taken from Gok [2] since Winter only reported on sagittal plane kinematics and kinetics.

	Obese		Control		Significance

**Table 1:** Means, standard deviations, and p values for each of the 4 key parameters for the 5 sets of comparisons.

**CONCLUSIONS**

There were significant differences between the normal controls and the pre-surgical obese group for all 4 of the key parameters. Pain-free subjects demonstrated fewer differences in comparison with normal controls than did subjects with pain. Differences in ankle plantarflexion and ankle power between the pain and pain-free groups were statistically significant. Weight loss is associated with knee pain relief, which can account for improvement in gait biomechanics. The 6 subjects who completed pre- and post-operative evaluations exhibited a significant improvement in peak knee flexion during swing and 4 of these individuals became pain-free post-GBS. We plan to further investigate changes in gait biomechanics due to obesity, OA, or pain by completing post-operative tests after weight loss in all subjects.

## ASSESSING SHOULDER KINEMATICS IN A SUBJECT WITH A SPINAL ACCESSORY NEUROPATHY

Duane A. Morrow, Brian R. Kotajarvi, Alexander Y. Shin, Kai-Nan An, and Kenton R. Kaufman  
Biomechanics and Motion Analysis Laboratory, Division of Orthopedic Research, Mayo Foundation, Rochester, MN  
email: [kaufman.kenton@mayo.edu](mailto:kaufman.kenton@mayo.edu) web: [mayoresearch.mayo.edu/mayo/research/biomechanics](http://mayoresearch.mayo.edu/mayo/research/biomechanics)

### INTRODUCTION

Kinematic assessment of the upper extremity, particularly the shoulder joint, remains troublesome. Due in part to the technical difficulties in quantifying scapula movement, some investigators choose to report shoulder kinematics as the relative motion between the humerus and trunk [1]. Others, using the method proposed by Karduna [2], report shoulder motion as the angle between the humerus and scapula [3]. A previous report from our laboratory pointed to some of the discrepancies that exist between thoracohumeral pseudo-joint motion and glenohumeral joint motion [4], even in a normal subject. The purpose of this abstract is to report our clinical experience using this technique, examining the results of both methods of UE motion analyses.

Figure 1. Subject with the scapula tracker resting on the scapular spine.

### METHODS

UE kinematics were collected on a 17 year old patient with a right spinal accessory nerve palsy which resulted from the biopsy of an enlarged lymph node in the posterior triangle of her right neck. Sixteen retroreflective markers were used to define the head, trunk, scapula, upper arm, forearm, and hand in a six-segment biomechanical model. The three markers used to track the scapula were on a tracker [4] which was attached to the skin using double-sided tape and rested on the scapular spine (Fig. 1). Data was collected at 60-Hz using a 10-camera RealTime Motion Analysis System (Motion Analysis Corp., Santa Rosa, CA). The patient was asked to perform an UE kinematic exam consisting of moving her shoulder throughout her available Flexion/Extension (FE) and Ab/Adduction (AB) ranges of motion as well as reaching across her chest to her opposite shoulder (OS). The patient's elbow and wrist were held in their neutral alignment for the FE and AB trials, but allowed unconstrained motion during the OS trials. Three trials of each motion were collected.

Rotation matrices were calculated between anatomically-defined segment axes constructed using the guidelines established by the International Society of Biomechanics [5]. These rotation matrices were decomposed into clinically relevant coordinates using Woltring's helical-axis method [6].

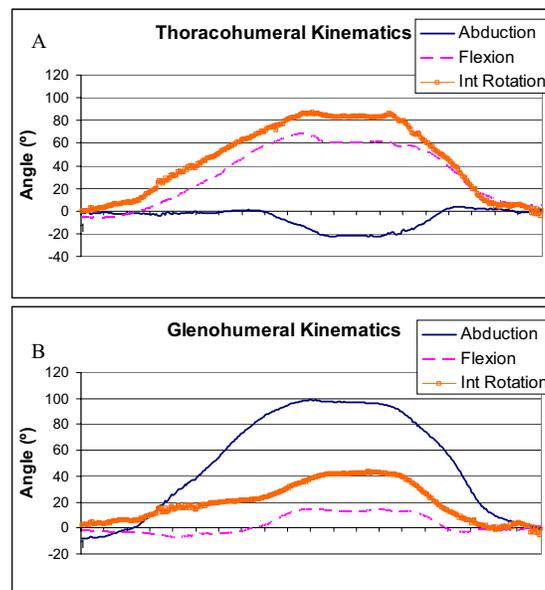

Figure 2. Thoracohumeral (A) and Glenohumeral (B) kinematics of a cross-shoulder reach.

### RESULTS AND DISCUSSION

Thoracohumeral and glenohumeral joint kinematics for this subject vary widely using the two techniques. Using only trunk and humerus markers to analyze shoulder motion, it would appear that reaching to the opposite shoulder consists mainly of shoulder flexion and internal rotation (Fig. 2A). However, consideration of the scapula in examination of glenohumeral motion reveals a large contribution of shoulder abduction and substantively less internal rotation (Fig. 2B). The palsy in the spinal accessory nerve lead to weakness in the upper and lower trapezius muscles which are used to keep the scapula retracted. As a result, the patient's scapula was rotated upwards over 52° and protracted by more than 48° (Fig. 1), accounting for the large discrepancy in the kinematics results. Similar results were found for the FE and AB motions.

### CONCLUSIONS

Great attention must be paid in the application of UE models used to study patients with clinical pathologies.

**PATELLAR DEFORMATION PATTERNS FROM A PRE-CLINICAL PATELLAR COMPONENT TEST**

<sup>1</sup>Mariana Kersh, <sup>1</sup>Heidi-Lynn Ploeg  
<sup>1</sup>University of Wisconsin – Madison, Department of Mechanical Engineering  
 E-mail: [mekersh@wisc.edu](mailto:mekersh@wisc.edu), web: [www.engr.wisc.edu/groups/BM](http://www.engr.wisc.edu/groups/BM)

**INTRODUCTION**

More attention is being given to the role of patellar components in total knee arthroplasty (TKA) as it is continually cited as a primary cause for TKA revision [1]. Various studies have documented the failure of patellar components [2-4], and as advances in TKA devices are made, it is important to ensure that the history of patellar failure is understood. This information can be used to develop pre-clinical tests to aid the design of clinically successful components. The goal of this study was to compare the polyethylene (PE) deformation of patellar components tested according to a new test protocol [4] against clinical results as one method for test validation.

**METHODS**

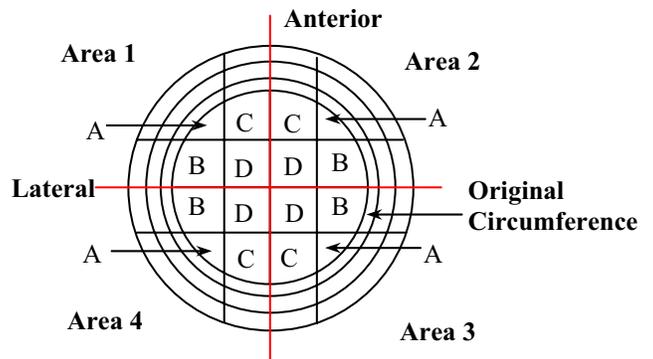

Five metal-backed (Component A) and five all-polyethylene (Component B) patellae were tested using an AMTI knee simulator. All components were fixed with bone cement and tested in bovine serum. A deep knee flexion cycle from 60° to 120° was simulated using a saw tooth waveform developed in a previous study [5]. The femoral component was initially displaced 1.2mm medially with an initial load of 1177N and then translated a total of 6.4mm medially as the load increased to 4258N. Components were tested at 1Hz to 50,000 cycles (20 years of deep knee bending activities), photographed before and after testing, and visually examined.

PE deformation defined as burnishing, creep, and polyethylene transparency, was quantified according to a 4-level scale for each deformation trait: none (0), minimal (1), moderate (2), and extreme (3). This scale was used to evaluate each section of a sixteen-area grid (Figure 1). Each section was assigned a score based on the amount of deformation present. Creep was measured by evaluating circumferential area changes.

**RESULTS AND DISCUSSION**

The average scores for each area and each component type are found in Table 1. There was no significant difference in the scores for Areas 3 and 4 of Component A or B for any deformation trait and were omitted from overall scores.

Overall, burnishing was more evident in the metal-backed components (score = 2.0) compared to the PE components (1.7). In both components, burnishing scores were higher on the lateral aspect (Area 1) of the patella compared to the medial (Area 2). A more pronounced difference was found in

**Figure 1.** Segmentation of Patella For Evaluation

the evaluation of creep: Component A had an average score of 2.0 compared to 0.8 for Component B. PE transparency was only found in Component A.

In a review of TKA revisions, Baech [4] documented asymmetrical wear patterns in metal-backed components. Andersen also found the presence of lateral edge wear [2]. Stulberg noted similar patterns of failure between the metal-backed and all-polyethylene components noting that both groups deformed at the lateral aspect of the component [3].

Regarding test survival, Component A averaged 5200 cycles before excess deformation required the test to be stopped. In contrast, all of the PE components survived 50,000 cycles. Studies have reported an average time to revision range of 11-18 months [2, 4]. The deformation results presented, as well as time to failure results, are similar to those documented in clinical literature indicating potential for the new test protocol to be used as a clinically relevant design tool.

## THE EMG/TORQUE RELATIONSHIP OF THE KNEE EXTENSORS DURING ACUTE FATIGUE

Tyler Brown and Michael E. Hahn

Movement Science Laboratory, Montana State University, Bozeman, MT USA  
 email: mhahn@montana.edu

### INTRODUCTION

Fatigue has been defined as a transient decrease of performance capacity of muscles during physical activity [1]. Response of knee musculature to acute fatigue may dictate adaptations to knee function during high impact activities, which may result in injury. One technique for assessing muscular adaptation to fatigue is to analyze the ratio of electromyographic magnitude (EMG) to torque production [2]. The purpose of this study was to determine the EMG/torque relationship of the vastus lateralis during acute fatigue.

### METHODS

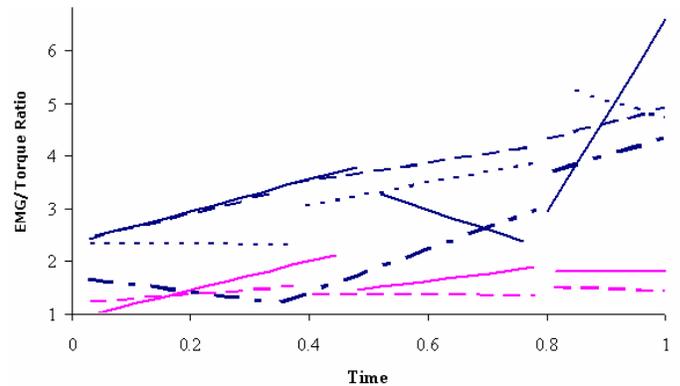

Six male subjects (mean age 24.3) participated in the study. All subjects signed an informed consent before participation. Subjects performed three isometric maximum voluntary (MVC) knee extension (KE) contractions at 45° before performing a fatigue protocol. The fatigue protocol consisted of subjects performing isokinetic KE contractions (concentric and eccentric) at 60°/s through their functional range of motion until acute fatigue was reached. Acute fatigue was defined as when the subject performed two consecutive contractions where the peak concentric torque was below 50% of MVC. All contractions were performed using the subjects' dominant leg.

Knee extensor torque during the isometric and isokinetic contractions was measured using a strain-gauge dynamometer (KIN-COM, Rehab World, Hixson, TN, USA). A passive bipolar surface EMG recording system (Myopac Jr., Run Technologies, Mission Viejo, CA, USA) was used to collect vastus lateralis (VL) activation magnitudes at a sampling frequency of 1000 Hz. EMG signals were bandwidth filtered (10-10,000Hz), full-wave rectified and smoothed with a 4<sup>th</sup> order Butterworth filter (low-pass cutoff = 5Hz) before analysis.

For analysis, torque production was normalized to body weight, processed EMG was normalized to maximal isometric activation and the ratio of EMG amplitude to torque production was calculated during each phase of the fatigue protocol. The change of torque produced during each phase was also determined.

### RESULTS AND DISCUSSION

It was determined that peak torque production during the fatigue protocol could be broken into three phases. The first phase ("initial") consisted of the first 12 to 15 cycles of the fatigue protocol where subjects maintained roughly 80 to 90%

**Figure 1:** EMG/torque ratio during the fatigue protocol. Time is listed as a proportion of the entire protocol.

of the torque produced during the isometric MVC. During the second phase ("decline") subjects' torque production dropped from 80% of MVC to below 50% in 12 to 15 repetitions and in the third and final phase ("fatigued"), declines in torque production leveled off and subjects maintained slightly less than 50% of MVC. The change of each subjects' torque production for each phase is shown in Table 1. Torque production during the initial phase increased slightly, in the decline phase there was a dramatic decrease and for the fatigued phase it leveled off with minimal declines.

Examination of the EMG/torque ratio indicates that responses to the fatigue protocol can be divided into two groups (Fig. 1). One group's EMG/torque ratio essentially doubled as a result of acute muscular fatigue, while a second group responded to fatigue without increasing their EMG/torque ratio. These results indicate that a group of subjects did not need to activate more fibers to sustain torque production of 50% MVC when fatigued. The other subjects needed to increase activation levels in an effort to maintain torque production during acute fatigue. Whether this signal increase resulted from increased recruitment or rate coding is undetermined.

### CONCLUSIONS

Further research is needed into the effects of acute muscular fatigue on the knee extensors. Future work will focus on whether the varied responses of the EMG/torque ratio to acute fatigue are due to group-specific training.

**DEVELOPMENT OF HUMAN PELVIC BONE FE MODEL  
 BY CONSIDERING PELVIC ANTHROPOMETRY**

<sup>1</sup>Cheolwoong KO, <sup>1</sup>Atsuhiro KONOSU, <sup>2</sup>Yukihiro YUKITA and <sup>2</sup>Jiro SAKAMOTO  
<sup>1</sup>Japan Automobile Research Institute, <sup>2</sup>Kanazawa University;  
 email: [kcheol@jari.or.jp](mailto:kcheol@jari.or.jp)

**INTRODUCTION**

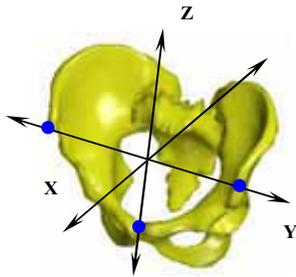

In collisions between pedestrians and road vehicles, the incidence of pelvic injuries resulting in serious wounds or death ranks high, following knee and head injuries. In light of this fact, the development of a human pelvis FE model with high bio-fidelity is required for reliable human injury analysis.

Thus far, several human pelvis models have been developed and modified in order to investigate the pelvic injury mechanism due to impact loadings [1,2,3]. However, detailed studies for pelvic anthropometry have been minimal. Therefore, it is necessary to consider pelvic anthropometry in pelvis FE model construction.

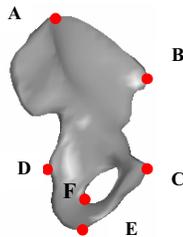

**METHODS**

In this research, a new human pelvic bone FE model (called the JK-model) was constructed on the basis of the CT image data of a Japanese adult. Anthropometry of the JK-model based on anatomical information was investigated by a comparison of measurement data obtained from cadaver pelvic bones.

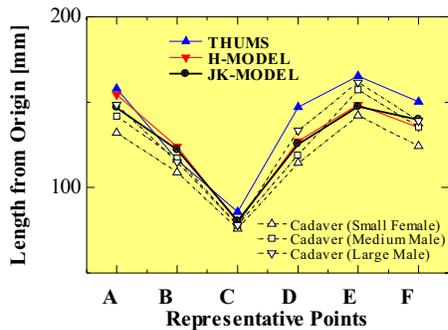

Figure 1 depicts the reference coordinate of the human pelvis, defined by Reynolds et al., in order to measure anatomical points of cadaver pelvises of Americans [4]. In this research,

**Figure 1:** Coordinate System of Pelvis [Reynolds, et al.]

**Figure 2:** Representative Points

**Figure 3:** Comparison of Pelvic Anthropometry

six representative points from A to F (A:Iliocristale, B:Left Iliospinale, C:Symphision, D:Ischio-Spinale, E:Inferior Turbersity point, F:Inferior Obturator Foramen Point) were selected, as shown in Figure 2. The length from the origin of the reference coordinate to each selected point was defined as a comparison parameter in order to investigate the pelvic anthropometry of the JK-model. In addition, the result was compared to the pelvic anthropometry of commercial pelvis FE models (for example, THUMS and H-model).

**RESULTS AND DISCUSSION**

The comparison parameters were summarized as presented in Figure 3. It was found that the lengths from the origin to D, E and F points of THUMS are greater than those of the H-model. The overall anthropometrical feature of the JK-model was close to that of the H-model. Also, the comparison parameters of the JK-model lie in the corridor of American measurement data; thus, the JK-model could be used as a standard model for human injury research in the crash safety field.

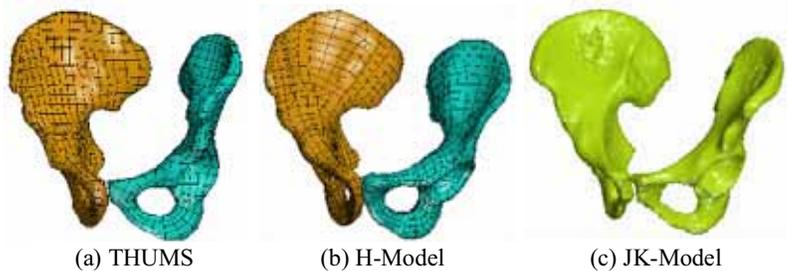

The appearance of pelvis models is depicted in Figure 4. It was considered that the JK-model has relatively higher bio-fidelity than those of commercial pelvis models with regard to pelvis shape.

**CONCLUSIONS**

In this research, a new human pelvic bone FE model was constructed on the basis of the CT image data of a Japanese adult. Its pelvic anthropometry was investigated with the use of anatomical information. It is considered that anthropometry study is important and necessary in FE model construction in order to obtain reliable analysis results.

## In-vivo measurement of the compressive force under the coraco-acromial arch

<sup>1, 2</sup>Toshimasa Yanai and <sup>3</sup>Franz K. Fuss

<sup>1</sup> Chukyo University, Japan; <sup>2</sup> University of Otago, New Zealand; email: [tyanai@life.chukyo-u.ac.jp](mailto:tyanai@life.chukyo-u.ac.jp)

### INTRODUCTION

Shoulder impingement is a widely recognized mechanism of chronic shoulder pain. With this mechanism, the shoulder pathology is explained as the consequence of repeated impingement, or compression, of the subacromial structures under the coraco-acromial arch. It has not been confirmed, however, if the compressive force that impinges the subacromial structures is sufficiently large to cause micro-trauma that leads to the pathological condition. The purpose of this study was to determine in-vivo the magnitude of the compressive force developed under the coraco-acromial ligament at selected shoulder configurations.

### METHODS

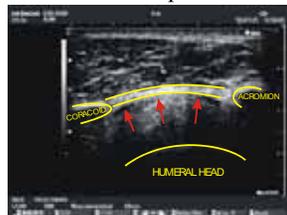

Five males with no history of shoulder pain volunteered to participate in this study. After having provided written informed consent, each subject was asked to actively maintain his arm in specified positions: (1) Anatomical (neutral) position, (2) 90° abduction + maximum external rotation, (3) 90° abduction + neutral rotation and (4) 90° abduction + maximum internal rotation. In addition, (5) the subject's shoulder was passively and forcibly configured to form the position for the Hawkins impingement test.

An ultrasound unit (EUB-6500, Hitachi Medico, Japan) was used to visualize and record the shape of the coraco-acromial ligament at each shoulder configuration. The probe was positioned carefully, so that the shape of the ligament's long-axis could be visualized. The contour of the upper, and also lower, surface of the coraco-acromial ligament were identified from the recorded images and digitized manually. The best-fit polynomial equation was determined to express the shape of the ligament mathematically for each shoulder configuration.

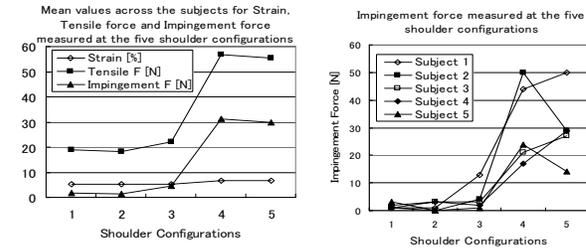

The ligament was modeled to have: (a) a uniform elastic property throughout the length between the insertions (Young's modulus = 290 MPa [2]); (b) smooth (no friction) surfaces; (c) a uniform cross-sectional area of 8 mm<sup>2</sup> throughout the length [2]; and (d) the length of a coraco-acromial ligament *in situ* was 5% (pre-strain) longer than the resting length of the ligament [2]. With this model and the measured length, the tensile force acting across the cross-sectional area of the ligament at its attachments and a single resultant of the distributed normal forces that caused the ligament to change its shape were determined. The latter force balances the two tensile forces and compresses the subacromial structures as a reaction (impingement force).

### RESULTS

The ultrasound images showed that the coraco-acromial ligament that was flat initially at the anatomical position was pushed, and deflected, upward by the subacromial structures

to form a curved shape when the arm was elevated and internally rotated. The extent of the deformation exhibited at the maximum internal rotation was found similar to that provoked at the Hawkins test position. This observation was confirmed with the determined impingement forces (below).

### DISCUSSION

The study demonstrated that the impingement force developed under the coraco-acromial ligament increased with the active shoulder internal rotation and that the magnitude of the impingement force recorded during active motion attained similar values to that recorded with the Hawkins test. The first result was consistent with the in-vivo study conducted by Nobuhara [1] in which the impingement force under the coraco-acromial ligament was measured directly from 260 patients during open surgery. The second result indicates that the subacromial structures during active shoulder motions are subject to a compression at the intensity similar to the "impingement sign (localized pain)."

The validity of the present methodology was tested with a cadaveric study in which known amounts of forces applied to ten specimens of coraco-acromial ligament were compared with the corresponding forces determined with the model approach used in the present study. The correlations were found high (0.925-0.986) although the absolute values of the forces were found to involve large error due to the individual variability in the Young's modulus of the ligament. These results suggest that the present methods provide sufficient accuracy in determining the relative magnitude of impingement force and that the ligament Young's modulus needs to be individualized to improve the accuracy in determining the absolute magnitude of the impingement force. It is also important to scan the ligament immediately after the subject has moved his arm into the required shoulder position, in order to keep stress-relaxation and creep to a minimum.

### INTRODUCTION

Ultra-stiff carbon fiber composites are now being placed in the outsole of both road and mountain cycle racing shoes. They are intended to transfer energy more efficiently from the legs and feet to the pedals. This is based on the belief that higher the stiffness of the outsole, the greater plantar pressure may be produced in the forefoot [1]. In this study, both finite element (FE) analysis and biomechanical experiment were done to assess the performance of the cycle racing shoes in relation to the material properties of the outsole.

### METHODS

Three types of outsole FE models outsole were generated for this study (Fig. 1-a). Type I was entirely made of a carbon composite based on the commercially available model (Shimano R-215, Japan); Type II, with a nylon outsole and the carbon composite insert (50 v/o); Type III, of a 100% nylon outsole. Thus, Type I was the stiffest outsole followed by Type II, and then Type III. Also, a foot model was generated from the CT data of a normal person with material properties from literature [2] (Fig. 1-b). The outsole was directly attached to the plantar surface of the foot. The insole part of the shoe was omitted in modeling for the sake of focusing on the outsole only and also to reflect the riding preference of many professional athletes. The material properties of the carbon composite were computed based on the classic lamination theory [3], which allowed us to convert the material properties of carbon composites from anisotropic to isotropic. Bending test of the carbon composite outsole was done to validate with the FE model results. Here, the cleat region of the outsole was held firmly while the heel part was pushed down until bending failure. Displacements under 30kg·f(294N) and 50kg·f(490N) that were within the elastic region were compared with the corresponding FE results.

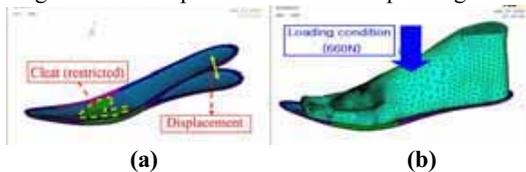

Figure 1: The FE models: (a) outsole. (b) with foot

To obtain the loading conditions for FE analysis, a healthy subject (male, 28 years of age, 735N) rode on a stationary cycle set up (SRM, Germany). In-shoe foot plantar force and pressure were measured with F-scan system (Tekscan Inc., South Boston, USA) while keeping RPM and torque constant during pedaling based on the protocol suggested in the literatures [4]. Maximum force of 660N was recorded and was applied to FE analysis as a loading condition. Performance in relation to different shoe types were assessed by comparing plantar stresses in the

forefoot region based on the literature findings on the relationship between the stress-strain and the load transmission and energy absorption at forefoot and heel regions[1, 4]. After applying appropriate loading and boundary conditions based on the experimental data, resulting stresses and displacements were assessed in foot plantar regions of FE models.

### RESULTS AND DISCUSSION

The bending test results were in good agreement with the predicted displacements with the FE model, suggesting the validity of our model. The stress at the forefoot was highest with Type I shoes (i.e., the stiffest), followed by Type II and then Type III. It was found that 50 % reduction in carbon composite from Type I resulted in decrease in maximum stress by only 10% in Type II (Fig. 2-a). Corresponding displacement at the heel regions were very small in both Types I and II (Fig. 2-b). However, importance of the carbon composite was clearly shown with significant drop in the maximum stress at the forefoot and leaping increase in the displacement at the heel from Type II to Type III.

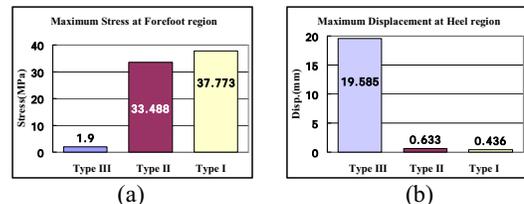

Figure 2: FEA results: (a) Stresses at forefoot, (b) Displacements at heel

### CONCLUSIONS

Our results demonstrated that the inclusion of ultra-stiff material such as carbon composite was very crucial for transferring the energy to the pedal through the outsole. More studies on the optimum amount and locations of the carbon composite material will follow using the FE model constructed from this study.

## Factors affecting lunate's sagittal alignment

Ajay Gupta

G.T.B.Hospital and University College of Medical Sciences, Shahdara, Delhi, India.

email: [drjaygupta@hotmail.com](mailto:drjaygupta@hotmail.com)

### INTRODUCTION

The lunate classically is described to have tendency to rotate dorsally under the capitate compressive force due to its shape of a wedge with apex towards the dorsum[1]. However no correlation could be demonstrated between the shape of the lunate and the radiolunate angle (RLA)[2]. The sagittal axis of the midcarpal joint lies parallel and dorsal to that of the radiocarpal joint, creating a force couple tending to rotate the lunate dorsally [1,3]. Despite this, lunate is found to maintain an attitude of flexion in most individuals [4].

The dorsal placement of the lunato-triquetral articulation on the lunate provides extension torque to the triquetrum causing lunate to rotate dorsally and balancing the scaphoid's flexion torque. Magnitude of such extension torque should presumably vary among various lunates depending upon inclination and extent of the triquetral's articulation on the lunate and triquetrum's alignment in sagittal and axial plane.

Review of literature failed to provide a study quantifying dorsal orientation of the midcarpal axis. Moreover, there has been no definite description also of how to measure and exactly draw the midcarpal (MCA) and the radiocarpal axes (RCA). It was felt that identifying MCA and RCA accurately on CT, quantifying their displacement with each other and establishing correlation among various parameters might be able to throw some light on the lunate's ambiguous behavior.

### METHODS

Database from our earlier studies [5] was utilized to provide material for the present study and included CT wrist of 70 healthy volunteers who never had any symptoms pertaining to their wrist joint. The mean age was 34 years with a range of 19-55 years. There were 49 males and 21 females.

Sagittal section through the middle of the capitate head was used to measure volar tilt of the distal radial articular surface (VT), lunate's sagittal axis (LSA) and the wedge ratio (WR) for the shape of the lunate[2]. Sagittal cuts were also measured for the axis of the triquetrum (TSA) and the midcarpal (MCA) and the radiocarpal axes (RCA). The distance between the two axes was measured and taken as positive value if MCA was found posterior to the RCA while anteriorly placed MCA measured as negative value. The axial sections were reformatted and measured for the lunate axis (LA), triquetro-hamate axis (THA) and luno-triquetral angle (LTA).

### RESULTS AND DISCUSSION

The midcarpal axis was found to be dorsal to the radiocarpal axis in 21 patients (30%), volar in 29 patients (41%) while the two axes were nearly collinear in 20 patients (29%). The mean distance between the two axes was 1.6 mm (S.D. 0.87) in the former group and -1.3 mm (S.D. 0.71) in the later. The distance between the two axes showed a strong correlation

**Figure 1:** Lunate is seen not to rotate towards its thinner side. It is rather rotating in the opposite direction in b, & c.

with the LSA ( $p<.001$ ) and mild correlation with WR measurements ( $p<.005$ ) while it showed no correlation with the VT. The LSA demonstrated significant correlation with TSA and LTA while no correlation was seen with the WR measurements, VT and the LA.

One out of every three persons is reported to have a lunate with shapes not favoring the tendency to dorsiflex. The whole proximal carpal row including the lunate was found to flex, radially deviate and supinate under the axial loading [6]. Elimination of the physiological axial load in anaesthetized patients with complete muscle relaxation reported producing extension of the lunate and the scaphoid and concluded that axial loading due to the normal tone of the forearm muscles tends to flex the scaphoid and the lunate[7]. Despite this, it is rare to find lunate maintaining an attitude of flexion in patients with scapholunate dissociation. The CT measurements of most lunates failed to classify them into the described three shapes since many lunates showed dissimilar typing on the various chosen sagittal sections of the same lunate[5]. It is thus not surprising that lunate's alignment failed to conform to its shapes (Fig.1).

### CONCLUSIONS

Relationship between MCA and RCA in terms of the dorso-volar displacement has key role in determining the lunate's sagittal alignment while the lunate's shape may be affecting it secondarily only. The other important factors are scaphoid's flexion torque and extension torque from the triquetrum, with TSA, LTA and THA in turn influencing the latter.

## ROTATIONS IN REARFOOT JOINTS AT END OF RANGE WEIGHT BEARING

### INTRODUCTION

Physiological end of range in the rearfoot joints while under body weight represents a normal functional scenario, as for example in squatting. However, the relative contributions of the relevant joints are unknown. From in-vivo, quasi-dynamic experiments using radiostereometric analysis (RSA) [1], we know: that between 10% and 41% of total foot plantarflexion during ankle joint plantarflexion is due to motion in the joints of the medial longitudinal arch, in particular the talonavicular joint; that during inversion-eversion motion of the foot, frontal plane motion occurs primarily at the talonavicular joint, rather than at the subtalar joint, as is commonly believed. Indeed, from a bone motion study of living subjects, the contribution of talocrural joint to inversion-eversion during the weight bearing phase of walking, has been calculated as 30% [2,3].

Undoubtedly, individual joints will have differing amounts of congruity in different loading circumstances and contribute differently to specific weight bearing functions. In the current study we sought to determine:

- Total rotations required for normal function.
- Joint kinematics during two different approaches to achieving maximal voluntary dorsiflexion.

### METHODS

In this descriptive study of joint kinematics of the foot, radiostereometric analysis (RSA) was employed to identify 3D rotation and translation of the joints of the rearfoot (talotibial, talocalcaneal, calcanealcuboid and talonavicular joints) in three normal subjects. Each of the relevant bones had been previously implanted with between 3 and 4 (radio opaque) tantalum markers under local anaesthetic utilising standard surgical procedures. Ethical approval for the study was obtained from the Karolinska University Hospital local ethics committee. Synchronised double X-ray exposures were taken to calculate the relative positions of the segments relative to a calibration coordinate system defined by a cage with tantalum markers.

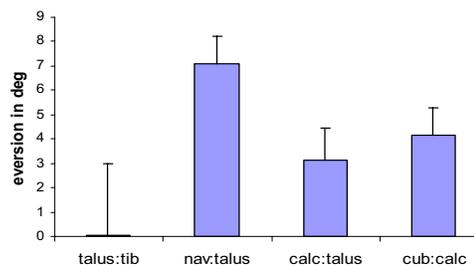

The subject stood with the examined foot within the calibration cube. X-ray exposures were taken in the following positions: (i) neutral: a neutral (reference) position with the subject standing straight and relaxed with their weight even between both feet, (ii) inversion (foot turned in), (iii) eversion (foot rolled out), (iv) plantarflexion (demi-pointe position), (v) active full dorsiflexion, (vi) lunge (passive dorsiflexion). Individual joint rotations relative to the reference position were calculated using RSA. Rotations about the X-axis (mediolateral axis) were calculated for the two dorsiflexion

and the plantarflexion positions, while Y and Z rotations were calculated for the inversion and eversion positions.

### RESULTS AND DISCUSSION

The total range of motion at the talus-tib joint between a foot position of maximum plantarflexion and one of maximum dorsiflexion (lunge) was 60°. Whilst plantarflexion was greatest at the talus:tib joint (30°), there were 10° at the nav:talus joint. Not unexpectedly, the lunge position induced more talus-tib dorsiflexion than did active dorsiflexion (30° versus 18°), and therefore more useful in the clinical setting.

Between the positions of maximum eversion and inversion, there were the following total amounts of inversion-eversion: 42° at the nav:talus, and 17° at each of the calc:talus and cub:calc. These figures confirm the nav:talus as the joint that is most important to these end of range foot movements, as indicated previously [1-3]. Interestingly, whilst rotations for both the calc:talus and cub:calc were even between inversion and eversion rotations, eversion motion was only 7° for the nav:talus (Figure 1), compared to 35° for the inversion motion. Associated with this end of range foot inversion, was a notable amount of vertical axis rotation (adduction), especially at the nav:talus joint (28°).

**Figure 1.** Eversion joint motion (Y axis rotation) for maximum foot eversion.

There was little variability across the 3 current subjects, perhaps indicating that individual joints contribute similarly.

## MORPHOLOGICAL MUSCLE AND JOINT PARAMETERS FOR MUSCULOSKELETAL MODELLING OF THE LOWER EXTREMITY

### INTRODUCTION

To assist in the treatment of gait disorders, an inverse and forward 3D musculoskeletal model of the lower extremity will be useful that allows to evaluate *if-then* scenarios. However, in the current anatomical datasets no sufficiently accurate and complete information is available to construct a sufficiently valid model (e.g. [1]).

The aim of this project was the collection of a complete and consistent anatomical data set. This can be achieved by collection of the three-dimensional location of the rotation centre of the hip and rotation axes of the knee and ankle for joint modelling. For muscle modelling parameters are collected such as optimum length, PCSA, tendon/belly length, and force application parameters such as attachment sites described as point, line, or plane and wrapping surfaces for estimation of curved lines of action.

### METHODS & MATERIALS

One lower extremity, taken from a male embalmed specimen (age 77, height 1.74m, weight 105 kg), was studied. Position and geometry were measured with a 3D digitizer. Optotrak was used for measurement of rotation axes of joints. Sarcomere length was measured by laser diffraction [2].

The following steps were taken:

- Collection of anthropometric data of body segments for estimation of mass and moments of inertia.
- Placement of reference screws in 6 body segments (pelvis, femur, tibia, calcaneus/talus, midfoot and phalanges) for the definition of technical coordinate frames.
- Measurement of bony landmarks with respect to screws for definition of anatomical reference frames.
- Dissection of the muscles and ligaments.
- Measurement of attachment sites and underlying geometries.
- Estimation of kinematic axes and centres of rotation for the hip, knee and ankle. Therefore instantaneous helical axes and their optimal pivot point were determined for each joint using the recorded motion data of the associated segments.[3]
- Measurement of macroscopic and microscopic muscle parameters. Pennation angle and the actual length of muscle fibre and tendons were measured with the digitiser.

Optimal fibre length determined by multiplying the actual fibre length with the ratio of optimal and actual sarcomere length.

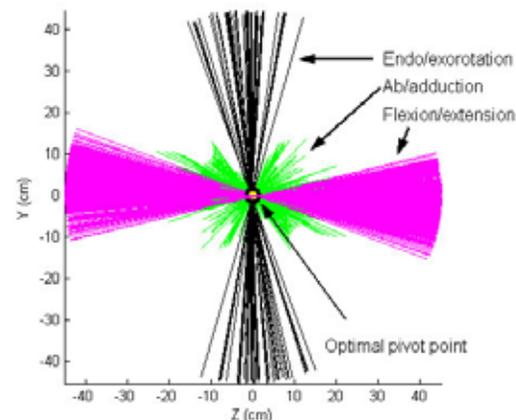

PCSA at optimal muscle length is calculated as the muscle mass divided by the density (assumed to be 1.056 g/cm<sup>3</sup>), resulting in muscle volume and subsequently multiplied by the cosine of the pennation angle divided by optimal fibre length.

### RESULTS

A total of 40 muscles were measured. Each muscle was divided in different muscle lines of action based on muscle morphology. For muscles with large attachment areas (such as the gluteus maximus) up to twelve muscle lines of actions were defined. In case of a curvature around an underlying contour, a geometric shape (sphere, cylinder, ellipsoid) was defined, representing the underlying structure. In the model, the shortest distance between origo and insertion over the surface will describe the curved force path of the muscle.

13 Ligaments of the hip, knee and ankle were included and will be modelled as a straight line between point origin and insertion.

Kinematic joint center and axes were constructed from motion data. A reconstruction of the hip joint rotation center by calculation of the optimal pivot point is shown in Figure 1. The mean distance of each helical axis to the pivot point is 9.12 mm.

**Figure 1:** Frontal view of hip rotation centre, defined as the optimal pivot point, calculated with instantaneous helical axes of recorded hip rotations around three anatomical axes.

### DISCUSSION

We have now available a unique anatomical dataset comprising all necessary data for modelling. Implementation of these data into an (existing) model of the lower extremity is likely to significantly improve the estimation of muscle forces and will thus make the use of the model as a clinical tool more feasible.

## VALIDITY OF THE NEW POWERTAP POWERMETER AND AXIOM CYCLE ERGOMETER WHEN COMPARED WITH AN SRM DEVICE

### INTRODUCTION

It is common to use laboratory tests in order to evaluate the performance of competitive cyclists. The difference between the winner and the second placed cyclist for track cycling is very small. In this condition it is very important to use a valid and reliable ergometer for tracking small changes in performance.

The aim of this study was to compare two new cycle ergometers, Axiom (Elite, Italy) and PowerTap (CycleOps, USA) with the SRM reference ergometer during maximal intensity exercise (sprint) and during sub maximal intensity exercise (only PowerTap vs SRM). The Axiom is an stationary electromagnetically ergometer which permits utilisation of the cyclist personal bicycle. The PowerTap is a mobile cycling powermeter that measures the power output with strain gauges localised in the hub of the rear wheel. The SRM system is a crankset that measures power output from torque and angular velocity continuously. The torque is thereby calculated by strain gauges (depending on the model 4, 8 or 20 strain gauges) that are located between the crank axle and the chainring.

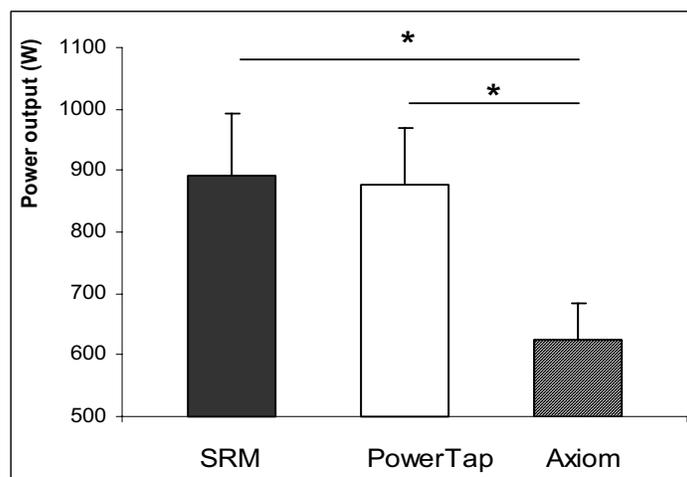

### METHODS

Ten male competitive cyclists (age  $25 \pm 3$  years, height  $180 \pm 5$  cm, body mass  $70.2 \pm 4.7$  kg) participated in the study. The study comprised two sprint tests in seated position on the Axiom ergometer. Tests were performed on the race bicycle equipped with the PowerTap and SRM ergometers against a 0.6 N/kg resistive loads. The exercise at sub maximal intensity (50 to 400 W) was performed on a treadmill (S 1830, HEF Tecmachine, Andrézieux-Bouthéon, France).

The three ergometers sampled (1 Hz) and stored the power output and the pedalling cadence (rpm). The maximal performance was determined by the maximal power output value. After testing our data for normality and homogeneity of variance, a correlation coefficient, bias, limits of agreement and 95% confidence interval (95% CI) (Bland and Altman, 1986) were calculated to quantify the differences between PowerTap and SRM power output. The analysis of mean differences between the Axiom, PowerTap and SRM power output were assessed with paired Wilcoxon tests, and significant difference was set at  $P < 0.05$ .

### RESULTS AND DISCUSSION

During maximal power output test, the results indicate that the Axiom values were significantly lower ( $p < 0.05$ ) compared with SRM and PowerTap values. Axiom ergometer underestimates the SRM and PowerTap values by 29 and 30 %, respectively (Figure 1). During exercise at sub maximal intensity, the regression analyses between the PowerTap and

**Figure 1** SRM, PowerTap and Axiom maximal power output values during sprint tests.

\* : significantly different ( $p < 0.05$ ) compared with Axiom

SRM power output indicate a high correlation ( $r = 0.99$ ,  $p < 0.001$ ). The mean differences power output measurement lay between 2.61 and 3.51 W. The mean bias for power output between PowerTap and SRM was  $3.1 \pm 3.4$  W.

These results indicate that the PowerTap device does provide a valid measure compared with SRM at sub and maximal exercise intensity. The lower bias value indicates that the mean SRM overestimation was only  $3 \pm 3$  W. However, the Axiom was not a valid ergometer when the maximal power output was tested. This result is in accordance with Bertucci et al. [1] who have tested the Axiom validity that shown the Axiom was not valid compared with the SRM during sub maximal intensity exercise. The difference between the SRM and the Axiom device can be explained by the difference between the power output calculation mode. The Axiom power output was calculated from the dubious polynomial equation on the software (taking into account the roller velocity and the braking torque) whereas the SRM and PowerTap ergometer measure the power output from the stain gauges technology.

### CONCLUSIONS

This study suggests that the PowerTap mobile cycling powermeter is valid (contrary to Axiom device) for performed scientific studies in the laboratory or in the actual cycling locomotion.

**INTRODUCTION**

Muscle contraction induces tendon elongation<sup>1</sup>). Repetitive muscle contractions are known to induce tendon creep<sup>2</sup>), but the presence of concurrent changes in mechanical properties of the tendon has not been elucidated. The purpose of this study was to investigate changes in the muscle-tendon complex mechanical properties during and after repetitive muscle contractions.

**METHODS**

Six men (mean ± SD for the age, body mass and height was 23.5 ± 1.2 years, 68.3 ± 7.1 kg, 172.7 ± 5.6 cm) performed 15 repetitive isometric ramp contractions. The subject was seated with the knee extended, and the ankle joint was attached to the foot plate at the right angles to the tibial axis. Preceding the experiment, MVC torque was measured, and the target torque was determined based on MVC. Before and after repetitive contractions, the following flexibility test was performed. The subject was seated with the knee extended, and the ankle joint was attached to the foot plate at an angle of 30° plantarflexion. The foot plate was connected to a dynamometer (VINE, Japan), by which the ankle joint was passively dorsiflexed with torque gradually increasing from zero to a value at which the passive loading to the ankle joint was just tolerable for each subject. The dorsiflexion angle and passive torque generated by plantar flexor muscles were measured during the test. During the passive loading, real-time ultrasonogram (SSD-6500, Aloka, Japan) was taken to track the movement MTJ (muscle-tendon junction of the gastrocnemius medialis and Achilles tendon). The movement of MTJ with dorsiflexion was assumed to be equal to the elongation of muscle belly (dMus). According to the estimated Achilles tendon moment arm<sup>1</sup>). The change of MTC (muscle-tendon complex) length (dMTC) during the passive dorsiflexion was estimated from changes in ankle joint angle. Tendon elongation (dTen) was calculated by subtracting dMus from dMTC. Tendon force (TF) was estimated from the torque and moment arm length<sup>3</sup>).

**Figure 1:** The relation between tendon force and dMus during 15 repetitive contractions, just only the 1<sup>st</sup>, 9<sup>th</sup> and 15<sup>th</sup> contractions are shown.

**RESULTS AND DISCUSSION**

The changes in dMus during 15 repetitive contractions are shown in Figure 1. The first contraction showed a different pattern compared with other contractions (p<0.05), dMus shifted proximally during repetitive contractions. This result indicates that repetitive contractions induced tendon creep. The flexibility test showed dMTC which involved an increase in dTen (p<0.05), but dMus did not change significantly. The elongated tendon changed its passive length-force curve, especially at the toe-region. Altered toe-region of the tendon length-force curve suggests structural changes of tendon as a result of repetitive contractions.

### INTRODUCTION

Biomechanical studies of human beings in a seated position to mimic the driver attitude have increased our knowledge of the effect of the shock on the body structure [1] for accidentology perspective. Potential injuries are generally indirectly estimated from dummies or PMHS paradigms. By consequence, resulting numerical models are limited due to the absence of consideration of potential modifications of functional response of the musculo-skeletal system [3]. This study was conducted to establish the influence of muscular activation of the lower limb prior the impact (pre-activation) on impact loading and on the resulting shock wave.

### METHODS

Ten young male adults volunteered in this study. The experimental protocol was approved by the human ethics committee of the University.

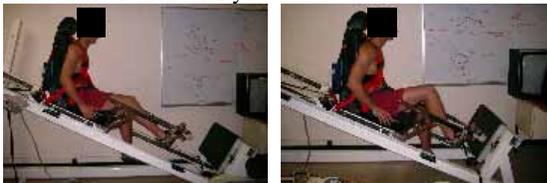

Figure 1. Experimental set : sledge ergometer [2].

The sledge ergometer (Figure 1) was associated to a lower limb guiding device (strain gauge sensor based) which allow the measurement of the overall force exerted by the impacting lower limb before the contact with the force plate. EMG activity of 4 lower limb muscles were monitored and 2 miniature accelerometer measured shank and thigh accelerations of the impacting leg. Three conditions, 25%, 50% and 75% of the maximal force input exerted on the guiding device, were tested in blocks of 3 consecutive trials. Each seated volunteer was dropped from a distance corresponding to 200% of maximal rebound off the force plate he could performed. EMGs, reaction force, displacement of the seat and force before impact were simultaneously recorded at a 2 kHz frequency. ANOVAs tests were run on the averaged measured parameters.

**Table 1:** Peak force (PF), peak shank (PS) and peak thigh (PT) accelerations, and calculated acceleration ratio (PS-PT) are reported for the 3 experimental conditions i.e. 25 %, 50% and 75% of maximum force pre-impact.

% maximum force	25%	50%	75%
PF (N/kg)	46 ± 3.7	48 ± 9.3	50 ± 7.3
PS (g)	13 ± 3.45	6.4 ± 4.70	6.4 ± 4.03
PT (g)	8.9 ± 1.10	4.5 ± 1.56	4.8 ± 1.63
PS/PT ratio (a.u)	1.46	1.42	1.33

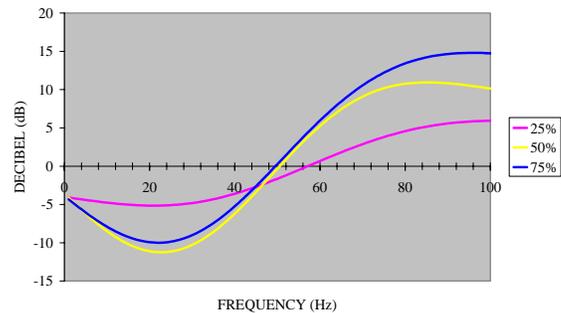

Figure 2. Gain/Attenuation profiles.

### RESULTS AND DISCUSSION

On average (Table 1), the lowest pre-activation condition generated highest acceleration peak associated with highest shock transmission ratio and lowest peak force. At the opposite highest condition revealed lowest amplitude peak associated with lowest shock transmission ratio and highest peak force. The computation of gain/attenuation (Figure 2) showed that attenuation was realized by the human system for the frequency content below 50-60 Hz. The best attenuation was provided for the highest pre-activation conditions.

### CONCLUSION

In accordance with recent studies [4] our results showed significant positive relationships between myoelectric input and shock cushioning. Additionally, increasing preactivation would play a role in the damping of the soft tissues.

## IMPROVING EMG BASED MUSCLE FORCE ESTIMATION USING PRINCIPAL COMPONENT ANALYSIS ON A HIGH-DENSITY EMG ARRAY

Didier Staudenmann, Idsart Kingma, Andreas Daffertshofer, Dick F. Stegeman and Jaap H. van Dieën  
 Institute for Fundamental and Clinical Human Movement Sciences, Faculty of Human Movement Sciences, Vrije  
 Universiteit, Amsterdam, The Netherlands; [d.staudenmann@fbw.vu.nl](mailto:d.staudenmann@fbw.vu.nl)

### INTRODUCTION

The reliability of EMG amplitude measurements when predicting muscle activation is an important issue in EMG based force estimation. Theoretically, two important factors influence the EMG signal. First, the location of the electrode arrangement in relation to the muscle fibre architecture and second, the amount of detected motor units (MUs), contributing to both the EMG and the muscle force. High-density EMG arrays allow the collection of monopolar signal to which also deep MUs are contributing. Principle component analysis (PCA) is a method to classify multidimensional datasets and to detect redundant information [1].

The aim of this experimental study is to analyze whether PCA techniques can improve force estimation from EMG collected with a high-density array.

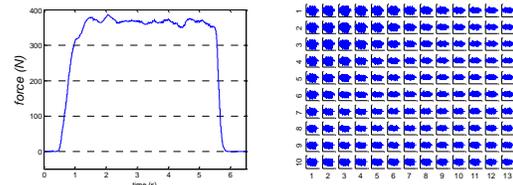

### METHODS

Eleven healthy subjects (age  $28.3 \pm 4.7$  years) performed isometric block-shaped extensions (Figure 1, left panel) with the right-arm at different conditions: Three elbow angles ( $60^\circ$ ,  $90^\circ$  and  $130^\circ$ ) and three levels of maximum voluntary contractions (20%, 50% and 80% MVC). During efforts subjects had online feedback of the contraction level.

Surface EMG of the triceps brachii and force output were measured simultaneously. The EMG was measured with an active monopolar electrode array of  $13 \times 10$  electrodes (BioSemi, biomedical instrumentation, Amsterdam, NL) [2].

EMG based force estimation from monopolar signals (1), PCA (low eigenvalues) (2) optimally aligned bipolar electrodes (3), Laplacian configuration (5) and conventional bipolar electrodes (5) were compared.

To quantify force estimation quality over the entire contraction pattern (Figure 1) we computed the root mean square difference (RMSD) between normalized EMG and normalized arm extension force.

**Figure 1:** Left panel: Block-shaped contraction pattern with a mean force over the plateau of 370 N. Right panel: raw monopolar  $13 \times 10$  EMG-signals (at  $130^\circ$  / 80% MVC).

To assess to what extent minor force fluctuations over the plateau were predicted we calculated the correlation coefficient between estimated and measured force.

### RESULTS AND DISCUSSION

The EMG processing procedures (Table 1) significantly affected RMSD and correlation (both:  $p < 0.01$ ). The two highest RMSD was found for the conventional bipolar electrodes (5) and the monopolar signals (1). PCA reduced RMSD by about 40% compared to conventional bipolar electrodes (5) and by about 12% compared to optimally aligned electrodes (3). In addition, the highest correlations over the plateau were obtained with the PCA procedure.

### CONCLUSIONS

High-density EMG is a powerful tool for the prediction of force output of a muscle but its value depends strongly on the EMG signal procedures. PCA can be used as an alternative to spatial filtering with different electrode configurations (3-5). Apparently, any order of spatially filtering electrodes (3-5) suffers from a biased choice of the configuration direction relative to the direction of the underlying muscle fibers. PCA appears to be a valuable tool, extracting the physiologically relevant information independent from the muscle structure and thereby improving the quality of muscle force estimation.

Correlation (r)	$0.3 \pm 0.2$	$0.5 \pm 0.2$	$0.4 \pm 0.2$	$0.4 \pm 0.2$	$0.3 \pm 0.3$

## The three dimensional load transfer characteristics of the wrist during maximal gripping.

<sup>1</sup>M.K. Gíslason, <sup>1</sup>N.K Fowler and <sup>2</sup>D.H. Nash.

<sup>1</sup> Bioengineering Unit, University of Strathclyde; email: [magnus.gislason@strath.ac.uk](mailto:magnus.gislason@strath.ac.uk)

<sup>2</sup> Department of Mechanical Engineering, University of Strathclyde

### INTRODUCTION

Wrist instability is a common problem post trauma or through arthritic changes and this can have a profound effect on hand function. With the increasing number of surgical treatments available for the painful wrist, there is a demand for more detailed information on the normal load transfer characteristics of this complex joint. Previous cadaveric studies have measured intra-carpal pressure using pressure sensitive films or conductive rubber [1]. Surface mounted strain gauges have also been used to measure strain levels on a limited number of carpal bones. Both these methods require invasive disruption of the materials under study. A limited number of computational models have been developed but due to the complexity of the wrist joint, many of these have been a two dimensional approach to what is in reality a three dimensional problem. In addition they do not include all 15 bones involved in load transmission or use theoretical/arbitrary loading conditions rather than measured data [2].

The aim of the current study was to develop a fully-representative three-dimensional finite element model of the entire wrist joint in order to study the transmission of force through the carpus during a functional activity. Real biomechanical data were used to define the boundary conditions and the contributions from cartilage and ligaments were incorporated into the model.

### METHODS

High resolution 3 Tesla MRI sequences were obtained from a single male subject, with in-plane (axial) resolution of 250x250µm and a slice thickness of 750µm. The MR images were imported into Mimics [3] software where solid models of 15 bones were created (distal sections of radius and ulnar, 8 carpal bones and proximal sections of 5 metacarpals). Physical material properties were assigned according to the pixel grayscale values of the different regions of the MR-image. Regions of cartilage, cortical bone and cancellous bone were defined with transition zones between the different layers. A finite element mesh was created in Abaqus [4] from 10-node tetrahedral brick elements (figure 1). Ligaments were modelled with non-linear spring elements and their origin and insertion points were evaluated manually according to previous anatomical studies.

A series of biomechanical trials were conducted to obtain subject specific loads during a whole hand maximal grip activity. Five six degree-of-freedom force transducers in a grip device were used in conjunction with VICON motion analysis to define the three dimensional load systems applied to each metacarpal according to its coordinate system. These data were applied as loading/boundary conditions in the finite element model to simulate the grip activity.

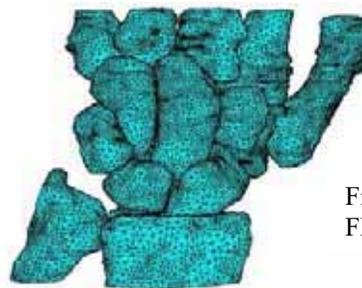

Figure 1: Dorsal view of the FE mesh.

### RESULTS AND DISCUSSION

Model results showed that 95% of the load applied to the metacarpals was distributed through the radius and only 5% through the ulna. Previous studies have shown the same ratio to be 90%-radius, 10%-ulna [5]. This discrepancy is consistent with the fact that the current wrist modelled had a negative ulnar variance and the force distribution was determined by the bony anatomy. Approximately 60% of the total load was transmitted from the metacarpals through the trapezoid-trapezium-scaphoid junctions (figure 2). This result is coherent with clinical evidence as the junction between the first metacarpal and the trapezium is a common site for wear.

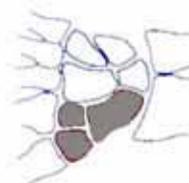

Figure 2: Trapezoid-Trapezium-Scaphoid force transmission.

### CONCLUSIONS

This study is an attempt to provide three dimensional finite element modelling of a complete wrist joint using real biomechanical boundary conditions. The results are consistent with previous work but reveal the importance of considering variations in wrist joint anatomy. Future work using this technique will investigate the effects of anatomical variation on wrist joint kinetics.

## AN INVESTIGATION OF WRIST JOINT FUNCTION UNDER LOAD

A.K. Kanellopoulos, M.K. Gíslason, N.K. Fowler  
 Bioengineering Unit, University of Strathclyde; email: [asimakis.kanellopoulos@strath.ac.uk](mailto:asimakis.kanellopoulos@strath.ac.uk)

### INTRODUCTION

Previous studies of the wrist joint have considered both individual carpal bone motion and the gross kinematics of the entire wrist complex. A variety of different grip tools have also previously been used to measure loading of the wrist joint during whole hand gripping tasks. Few of these studies however, captured kinematic data in conjunction with kinetic measurements and there is a lack of fully three-dimensional loading data. As a result there is disagreement in the literature, both about the definition of the ‘functional neutral’ position of the wrist and about the kinematic ‘envelope’ inside which the hand can provide its maximal gripping force [1].

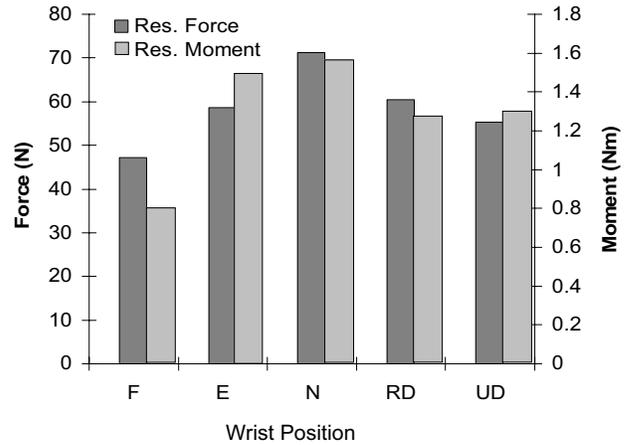

The aim of the current study was to investigate if the ‘functional neutral’ position of the wrist joint coincided with the ‘anatomical neutral’ position in relation to generating the maximal gripping force. The active operating ranges of the wrist during maximal gripping force were also examined.

### METHODS

Fifty right-hand dominant adults (25 males, 25 females), with no history of hand trauma participated in the study. The subjects were required to generate maximal gripping force in five different wrist positions: neutral, flexion, extension, radial and ulnar deviation. An eight camera, 120Hz VICON (Oxford Metrics) motion analysis system and a custom-built grip strength tool containing five six-component force transducers were used to obtain concurrent three-dimensional kinetic and kinematic data for each digital segment, the metacarpals, wrist and forearm. Subjects were asked to provide their maximal gripping force in maximal functional positions of wrist flexion, extension, radial and ulnar deviation. For the functional neutral wrist position, subjects adopted a self-defined position of optimal function around the anatomical neutral position.

### RESULTS AND DISCUSSION

The functional neutral position of the wrist was experimentally defined as slight extension of the joint, with a mean of 33 degrees extension (SD 17.6) in 94% of the subjects (Table 1). This wrist extension was coupled with a mean of 8 degrees of ulnar deviation (SD 10.1) and it was the position in which the subjects provided their maximal resultant gripping force (Fig.1). In extension, radial deviation and ulnar deviation of the wrist the subjects generated similar

**Figure 1:** The resultant forces and moments applied to the thumb in flexion (F), extension (E), radial (RD) and ulnar deviation (UD) of the wrist.

maximal resultant forces, whilst in flexion the applied forces were significantly lower. The largest values of the resultant moments were in the neutral and extended positions and the lowest values were obtained for the flexed wrist (Fig.1). For each intended wrist joint position there was a coupling of motion in other planes. Joint flexion was combined with radial deviation, extension with ulnar deviation, radial deviation with extension and ulnar deviation with flexion (Table 1). Previous studies have observed similar coupling patterns during unloaded radial and ulnar deviation but show free wrist flexion coupled with ulnar deviation [2]. This discrepancy may reveal altered kinematic patterns as the wrist is loaded.

### CONCLUSIONS

The optimum joint position for production of maximal grip force was a slightly extended and ulnar deviated wrist. This kinematic coupling of flexion-extension with radio-ulnar deviation, together with the definition of the functional neutral wrist position are important characteristics of wrist function under load.

## CAN A RUNNER'S ECONOMY AND ARM MOTION BE AFFECTED BY FEEDBACK TRAINING?

<sup>1</sup>Laura Hild, <sup>1</sup>Scott White, <sup>1</sup>Harold Burton, and <sup>2</sup>Louise Gilchrist

<sup>1</sup>State University of New York at Buffalo, Dept. of Exercise and Nutrition Science,

<sup>2</sup>State University of New York at Buffalo, Dept. of Physical Therapy; email: [laurah@amtmail.com](mailto:laurah@amtmail.com)

### INTRODUCTION

It has been shown that among runners with similar  $VO_{2max}$  a runner with higher running economy will perform better than one with lower running economy [1]. Several biomechanical variables have been related to running economy [2, 3, 4]. The coaching literature suggests that arm swing is important for "efficient" running. It has been suggested that training with a harness to modify arm swing can improve running economy [5]. The purpose of this research was to determine: 1) if initial reaction (first day of use) to an arm harness affects running economy and arm mechanics; and 2) if a training period with an arm harness improves running economy and arm mechanics.

### METHODS

**Initial Reaction Study:** Eighteen runners (male and female) volunteered to participate. Each subject ran less than 20 miles per week. Running economy, wrist excursion, superior-inferior (S-I) distance from the wrist to the jugular notch, and medio-lateral (M-L) distance from the wrist to the jugular notch were measured while running with and without a harness to modify arm swing [5].

**Harness Training Study:** Thirteen subjects who exhibited excessive crossover (M-L distance from the wrist to jugular notch  $\leq 9.6$  cm) or excessively low arm carriage (S-I distance from the wrist to jugular notch  $\geq 39.8$  cm) trained with the harness. A within subject design was used in which running economy, wrist excursion, S-I distance, and M-L distance were measured prior to training (Test), after 3 weeks of no harness training (Mid Test) and after 3 weeks of harness training (Post Test).

**Dependant Variables:** Running economy was defined as speed divided by  $VO_{2submax}$  ( $mi \cdot kg/ml$ ).  $VO_{2submax}$  was averaged over the last 5 minutes of a 10-minute run. Two video cameras recorded the spatial position of reflective markers at the ulnar styloid and jugular notch. Wrist excursion was defined as the total three-dimensional distance traveled by the wrist in one arm swing. All kinematic variables were averaged over 6 consecutive strides.

**Statistical Analysis:** One-way repeated measures ANOVA's with a significance level of  $p \leq .05$  was used to determine if there was an improvement in running economy, wrist excursion, S-I distance and M-L distance.

### RESULTS AND DISCUSSION

Wrist excursion and S-I distance were the only dependant variables that improved for both the initial reaction study (Table 1) and after training with the harness (Table 2). M-L distance did not improve in either study. Also, running economy did not improve despite a change in mechanics. One might suspect that the training period was not long enough; however, Messier et al. reported similar results; 5 weeks of technique training also saw an improvement in running mechanics and not in running economy [6].

Hinrichs reported that arm crossover was necessary to counteract the angular momentum of the legs about the vertical axis while running [7]. Egbuonu et al. reported that restricted arm movement decreased running economy [8]. Since arm crossover was not reduced in our study, angular momentum about the vertical axis was not likely affected and therefore, running economy was unchanged. The arm harness was ineffective for reducing arm crossover and had minimal effect on running economy.

### INTRODUCTION

Working on a moving platform, such as a seagoing vessel, imposes an increased risk for low back injury [1]. Such a dynamic environment will force a person to make continuous postural adjustments in order to maintain stability while performing a manual materials handling task. In some circumstances, these adjustments may require foot repositioning to maintain the centre of mass location within the confines of the base of support. A motion induced interruption (MII) occurs when the external perturbations are large enough to cause a person to stumble or abandon a task [2]. The purpose of this study was to evaluate the differences in thoracolumbar kinematics between lifts successfully executed and those during which a MII occurred.

### METHODS

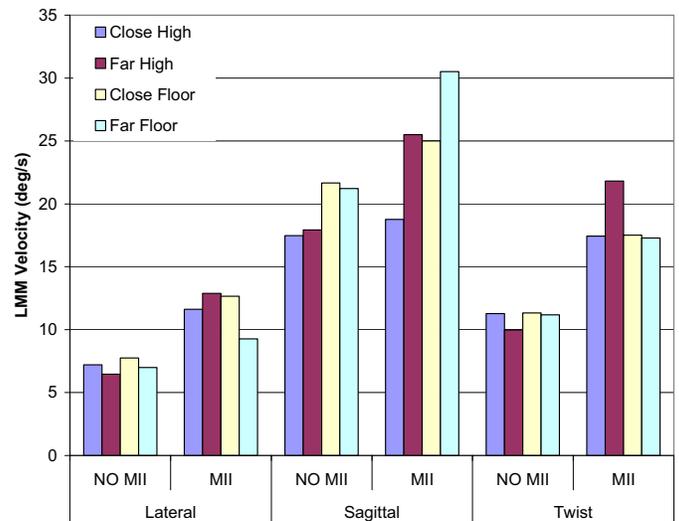

A ship motion simulator was employed to produce a pitch motion while 19 volunteer participants performed lifting activities. The activities consisted of lifting a 15kg mass under four conditions: a) load starting from floor with a final horizontal displacement of 300mm (Close Floor); b) load starting from floor with a final horizontal displacement of 400mm (Far Floor); c) load starting 250mm above the floor with a final horizontal displacement of 300mm (Close High) and d) load starting 250mm above the floor with a final horizontal displacement of 400mm (Far High). In all conditions the net vertical displacement was 750mm. Lifts were repeated at 10s intervals for a period of approximately two minutes. The 15kg load was connected to a handle which could be easily gripped symmetrically with two hands. The origin and destination of the lift were clearly identified and controlled between subjects. The load was returned to the ground by an investigator in preparation for the next lift. Thoracolumbar motions were collected with a Lumbar Motion Monitor (LMM) and stored on a personal computer for analysis.

A handheld signal was used by one of the investigators to identify the start and finish of each lift as well as the MII incidence. This temporal marker was sampled by an A/D converter and stored on a computer for subsequent analysis. These events were validated during analysis by referring to data collected from a load cell built into the load-handle apparatus. During the analysis procedure each lift was classified into two categories, a successful lift during which no foot adjustments were required or a lift completed but the participant was required to adjust the position of the feet in order to maintain balance (i.e. a stumble).

### RESULTS AND DISCUSSION

The maximum LMM velocities in the lateral, sagittal and twisting planes were compared across the four lifting tasks. A

repeated measures ANOVA indicated that there were significant increases ( $p < 0.001$ ) in thoracolumbar velocities in all three planes of motion for the lifts during which stumbles occurred compared to those lifts executed without MII's (Figure 1). This directional change was consistent across all lifting activities. What was most interesting is that the largest relative increases occurred in the lateral bending and twisting planes. Increases in thoracolumbar velocities in these planes of motion have been related to increased risk for occupationally-related low back disorders [3].

**Figure 1:** Three-dimensional LMM velocities across lift condition.

### CONCLUSIONS

While humans can be quite adept in making dynamic compensatory adjustments to maintain balance, these strategies may not compliment a person's goal of reducing the risk of personal injury.

## EFFECTS OF REACH DISTANCE UPON ELECTROMYOGRAPHICAL ACTIVITIES OF SELECTED UPPER BODY MUSCULATURE

<sup>1</sup>Scott N. MacKinnon and <sup>2</sup>Christopher L. Vaughan

<sup>1</sup>School of Human Kinetics and Recreation, Memorial University of Newfoundland, St. John's, Canada,

<sup>2</sup>Department of Human Biology, University of Cape Town, Cape Town, South Africa; [smackinn@mun.ca](mailto:smackinn@mun.ca)

### INTRODUCTION

In one-handed, submaximal pulling activities the forces required to move the load are not likely produced from trunk efforts alone, but with contributions from other parts of the body. The upper extremity plays an important role in exerting horizontal pulling forces [1] but more insight into the kinesiological strategies employed by an operator under varying pulling situations is still required.

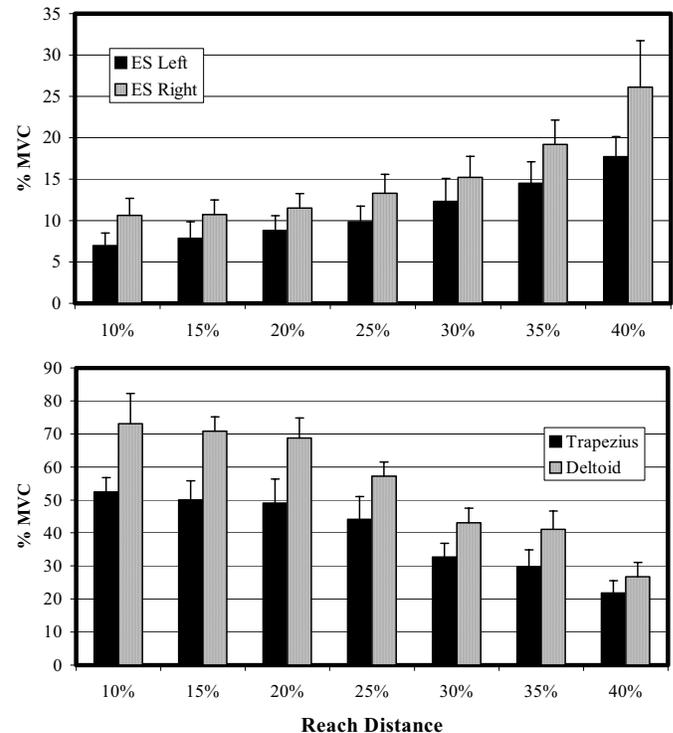

The purpose of this study was to examine the effects of reach distance on the electromyographical activities (EMG) of eight selected muscles of the trunk and shoulder regions during submaximal horizontal pulling exertions located at elbow height.

### METHODS

Eleven healthy male volunteer subjects were asked to execute a right-handed pull on an isoinertial load (12% of lean body mass) located at varying distances (10, 15, 20, 25, 30, 35 and 40% of subject stature) from the frontal plane containing the load handle. Controls were put in place to standardize foot placement, pull direction and tempo. A ME3000P (Mega Electronics Ltd, Kuopio, Finland) unit was employed to collect the EMG activity of the following muscles: left and right erector spinae (at the level of the fourth and fifth lumbar vertebrae), left and right external obliques and the trapezius, latissimus dorsi, deltoid and biceps brachii from the right side of the body. Each channel was sampled at 1000 Hz, band-pass filtered between 20 Hz and 500 Hz, amplified and stored on a personal computer for further analysis. The raw EMG signals were full-wave rectified and low-pass filtered at 4 Hz. The raw signal was then normalized to a maximal voluntary contraction (MVC).

### RESULTS AND DISCUSSION

EMG data revealed increasing erector spinae activity as reach distance increased (Figure 1) and this muscle group was found to be co-active with external oblique muscles during the exertion. Shoulder complex muscles were found to be highly active in all conditions, but only the trapezius and deltoid muscles demonstrated significantly decreasing activities as pull reach increased (Figure 1). If any strategy could be identified based on the experimental data, it might be that for closer pull locations (*i.e.* 10-20% stature from frontal plane containing the load) a shoulder strategy is employed, not necessarily because of mechanical efficiency but because the muscles controlling the spine are not in a desirable posture to create an extensor moment and contribute to a pull force. At further pull locations (*i.e.* 30-40% stature from frontal plane containing the load) the subject seems to employ trunk extensor strategies to assist in the pull exertion.

**Figure 1:** Mean (and standard error of the mean) EMG data. When performing *post hoc* comparisons with  $\alpha = 0.05$ , the following differences were found for the four muscles: (1) Left ES – 10%/15% different to 40%; (2) Right ES – 10%/15%/20% different to 40%; (3) Trapezius – 10%/15%/20% different to 40%; (4) Deltoid – 10%/15%/20% different to 30%/35%/40%; 25% different to 40%.

### CONCLUSIONS

Much work must be done to understand better the strategies an operator will attempt to adopt a pull force under various postural conditions. It seems that executing a pull under conditions such as those simulated in this study could be optimized if the subject stood with the front toe at a distance of approximately 25% of stature from the frontal plane containing the load handle. These data provide some direction in positioning the operator within a workstation demanding pull force exertions.

## MOTION INDUCED INTERRUPTIONS DURING SIMULATED SHIP MOTIONS

<sup>1</sup>Michael Holmes, <sup>1</sup>Scott MacKinnon, <sup>2</sup>Julie Matthews, <sup>2</sup>Wayne Albert, <sup>1</sup>Steven Mills and <sup>3</sup>Don Bass

<sup>1</sup>School of Human Kinetics and Recreation, Memorial University of Newfoundland,

<sup>2</sup>Faculty of Kinesiology, University of New Brunswick,

<sup>3</sup>Faculty of Engineering and Applied Science, Memorial University of Newfoundland; email: [smackinn@mun.ca](mailto:smackinn@mun.ca)

### INTRODUCTION

Seagoing vessels are designed to minimize the effects of environmental forces in order to reduce the stresses acting on both the structure and those working aboard. However, the external perturbations created by the environment can be considerable in magnitude and unpredictable in occurrence, even in reasonably benign weather conditions. The purpose of this study was to measure the number of motion induced interruptions (MII) a participant will experience while performing manual materials handling tasks typically executed on a seagoing vessel. A MII is defined when a person has to temporarily abandon the task or else execute alterations in the base of support in order to maintain balance [1].

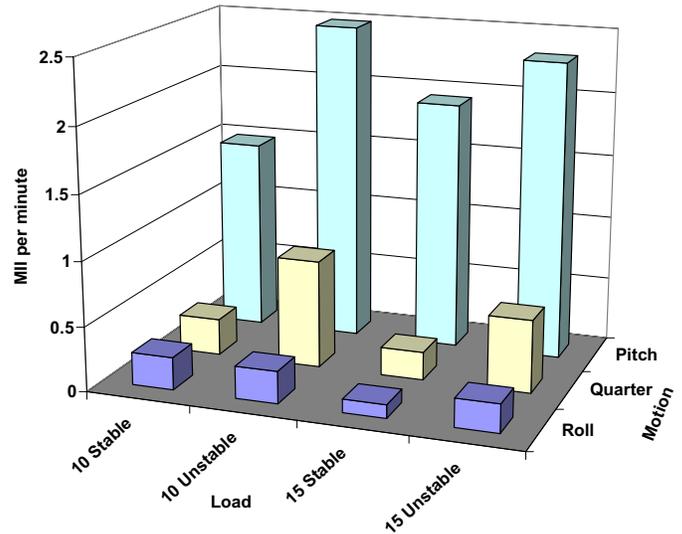

### METHODS

A ship motion simulator was employed to produce three different platform motions during which volunteer participants lifted loads. The platform motions were described as pitch, roll and quartering seas. The loads (10 and 15kg) were connected to a handle which could be easily gripped symmetrically with two hands. The connection between the mass and the handle was made by either a solid metal column (i.e. stable load) or a series of chain links (i.e. unstable load). The participants were instructed to ready themselves in a stable position in order to execute a two-handed sagittal plane lift. An audible signal was employed to direct the participants to execute a lift every 10 seconds. The origin and destination of the lift were clearly identified and controlled between subjects. The load began on the floor and was lifted a distance of 750mm in the vertical direction and translated a horizontal distance of 300mm away from the subject at the conclusion of the lift. The load was returned to the ground by an investigator in preparation for the next lift. A handheld signal was used by one of the investigators to identify any MII incidents that may have occurred. This temporal marker was sampled by an A/D converter and stored on a computer for subsequent analysis. Each trial lasted approximately 2 minutes.

### RESULTS AND DISCUSSION

A repeated measures ANOVA indicated that there were significant differences in the number of MII per minute for both the motion ( $p < 0.001$ ) and load ( $p < 0.001$ ) effects (Figure 1). A LSD post hoc analysis revealed that the pitch motion produced significantly more  $\text{MII} \cdot \text{min}^{-1}$  compared to the other motion conditions. There were no significant differences between the three remaining motions. Maintaining balance requires that the vector projection from the system's centre of mass remains within the boundaries of the base of support. In the para-transverse plane located at the foot-floor interface the shortest distance this projection has to travel to leave the boundaries of the base of support is the antero-posterior direction, thus a pitch motion is likely to produce the most MII. Given the significant increases in the  $\text{MII} \cdot \text{min}^{-1}$  for the pitch direction compared to the other motions it would not be

unreasonable to recommend that lifting activities be restricted when a vessel is faced with oncoming waves.

**Figure 1:** Number of MII per minute as a function of simulated ship motion and load characteristics.

Unstable loads produced significant increases in the rate of MII compared to the stable loads. Interestingly, there were no significant differences in the  $\text{MII} \cdot \text{min}^{-1}$  between the 10 and 15kg loads and in some cases the rate of MII was greatest for the lighter load. It is likely that as a person attempts adjustments to regain balance with an unstable load an asynchronicity between the load, segment and floor accelerations occur, making the dynamic corrections to regain stability much more complex and prone to MII.

### CONCLUSIONS

Balance control in a complex moving environment is related to the direction of platform motions and the type of load handled. Workers in such environments should be made aware that some situations have a greater risk of accident or injury.

## THORACOLUMBAR KINEMATICS DURING LIFTING EXERTIONS IN MOVING ENVIRONMENTS

<sup>1</sup>Julie Matthews, <sup>2</sup>Scott MacKinnon, <sup>2</sup>Michael Holmes and <sup>1</sup>Wayne Albert

<sup>1</sup>Faculty of Kinesiology, University of New Brunswick,

<sup>2</sup>School of Human Kinetics and Recreation, Memorial University of Newfoundland; email: [smackinn@mun.ca](mailto:smackinn@mun.ca)

### INTRODUCTION

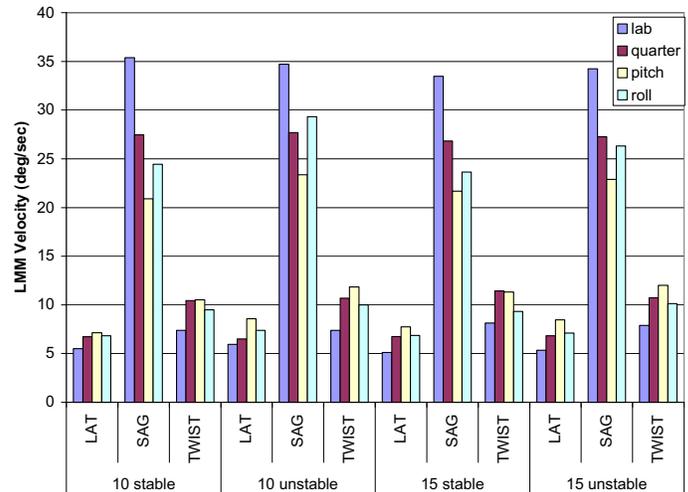

Seafaring occupations have been long recognized as a high risk occupation for injury and accidents and it is hypothesized that the external perturbations associated with vessel motions are responsible for the high incidence of low back exertions common to professional mariners [1]. Studies have shown that large thoracolumbar velocities during lifting activities, as measured by a Lumbar Motion Monitor (LMM), are related to an increased risk of low back overexertion injuries in several industrial occupations [2]. The purpose of this study was to examine the changes in thoracolumbar kinematics of persons performing a lifting activity while exposed to simulated ships motion compared to those collected under stable, laboratory conditions.

### METHODS

Nineteen healthy male subjects volunteered to participate in this study. These participants were asked to perform repeated bi-manual symmetrical lifts ( $6 \text{ lifts} \cdot \text{min}^{-1}$ ) while thoracolumbar kinematics were collected employing a lumbar motion monitor (LMM). 10kg and 15kg loads were considered in this study and lifted through a vertical displacement of 750mm. The articulation between the mass and the handle was made by either a solid metal column (i.e. stable load) or a series of chain links (i.e. unstable load). A ship motion simulator was employed to produce three different platform motions during which the participants lifted loads. The platform motions were described as pitch, roll and quartering seas. Thus a 3 floor motions by 4 loads design was considered in this experiment. The maximum angular velocity in the lateral bending (LB), sagittal (SG) and twisting (TW) planes were calculated from the collected displacement data and were compared across load and motion conditions using a repeated measures ANOVA.

### RESULTS AND DISCUSSION

It can be generally stated that the motions of the simulator platform influenced the maximum LB, SG and TW thoracolumbar velocities relative to the baseline laboratory condition. What was most interesting was the direction of these changes. There was a significant increase in the maximum LB ( $p < 0.001$ ) and TW ( $p < 0.001$ ) velocities for the platform motion conditions relative to the laboratory condition. In both thoracolumbar directions it was the pitch motion that induced the greatest increases in velocity compared to the laboratory values. What was most surprising is that the maximum SG velocities decreased significantly ( $p < 0.001$ ) relative to the stable, laboratory condition for all motion conditions, with pitch demonstrating the greatest reduction. SG reduction is characteristic of trunk stabilizing strategies exhibited by low back pain sufferers performing trunk extension activities [3].

**Figure 1:** Maximum thoracolumbar velocities across load and motion conditions.

The type of load handled significantly affected the magnitude of the maximum TW velocities ( $p=0.026$ ). In general, there were greater TW velocities when handling the unstable loads compared to the stable loads under the motion conditions.

### CONCLUSIONS

Performing lifting tasks in motion environments, particularly with unstable loads will likely increase the risk of overexertion injury to the lower back due to the increases in maximum angular velocities in the lateral bending and twisting planes. Further studies examining if there are changes in lifting strategies while working in a motion environment are warranted given the unexpected decreases in sagittal plane motions occurring at the lower back during the motion conditions.

<sup>4</sup>Division of Kinesiology, Laval University, Quebec, Canada

### INTRODUCTION

Postural control is known to result from the integration of visual, somesthetic and vestibular information. In the therapeutic settings, proprioception rehabilitation programs often prescribe exercises involving single-leg stance or single-leg hop in order to restore proprioceptive deficits and functional stability of the ankle [1]. We wish to test the hypotheses that, when proprioception is perturbed, the role of vision in postural control increases with the difficulty of the standing task. Additionally, we wish to investigate the effect of vision during postural adaptation after withdrawn of the somesthetic perturbation during double (DLS) and single limb stance (SLS).

### METHODS

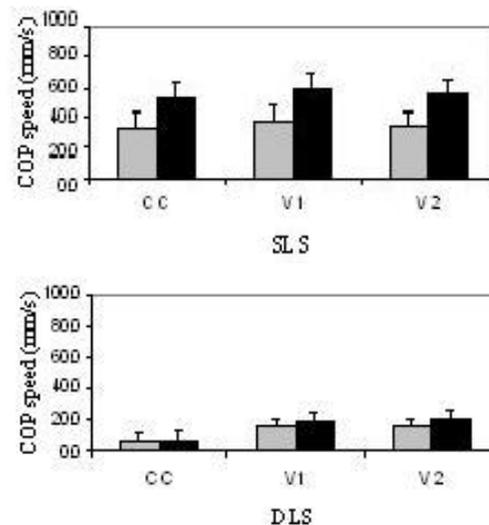

Eleven healthy and active young male adults ( $29.6 \pm 5.8$  years;  $181.2 \pm 4.6$  cm;  $81.9 \pm 11.5$  kg) participated in this study.

To perturb the visual input, the laboratory room was darkened in such a way that participants could not see the environment [2]. Ankle proprioception was perturbed with four vibrators placed transversely to the tendons of triceps surae and tibialis anterior muscles. Four test conditions were collected: normal vision + normal proprioception (20s); reduced vision + normal proprioception (20s); normal vision + perturbed proprioception (10s) to normal vision to proprioception reintegration (10s) and reduced vision + perturbed proprioception (10s) to reduced vision to proprioception reintegration (10s). Five trials of each condition were collected in DLS and SLS using an AMTI force platform. The COP speed of two intervals of proprioception perturbation (V1, V2) and proprioception reintegration (R1, R2) were compared to control conditions using Analysis of Variance (ANOVA) followed by Tukey HSD test ( $p < 0.01$ ).

### RESULTS AND DISCUSSION

A significant condition by task interaction was revealed. Post hoc comparisons showed that vision has a main effect in SLS ( $F(1, 20) = 47.70$ ,  $p < 0.001$ ) while proprioception perturbation showed effect only during DLS ( $F(2, 40) = 29.11$ ,  $p < 0.001$ ) (Fig. 1). Postural control in DLS was achieved independently of visual input after 5s of proprioception reintegration (R2). In the present study the difficulty of the task condition seems to be highly related to the visual dependency.

Our results suggest that to perform challenging tasks vision and possibly vestibular system dominates the postural control.

**Fig. 1:** Mean COP speed during control condition (CC) and two intervals (V1, V2) of proprioception perturbation. Normal vision (■); reduced vision (■); double limb stance (DLS); single limb stance (SLS).

Therefore, exercises involving single-leg stance can improve functional stability probably due to some neuromuscular requirement other than enhance of proprioception system.

### CONCLUSIONS

Vision plays a more important role according to the task to be accomplished. The more challenging is the task, more the balance control mechanisms rely on vision. These results can help clinicians and researchers to make decisions about tasks and sensorial availability during assessment and training.

## INFLUENCE OF MUSCLE PRE-ACTIVATION AND KNEE JOINT ANGLE ON AXIAL TIBIO-FEMORAL SHOCK TRANSMISSION

### INTRODUCTION

A number of cadaver studies has shown a shock attenuating capacity of intra- and periarticular tissues in axial impact loading [1,2]. This shock reduction was mainly explained by deformation. In vivo reductions in shock transmission in walking or running were primarily explained by variations in leg stiffness due to modified joint angles or muscle activity [3,4]. The interdependence of joint angles and muscle activation in locomotor activities makes it difficult to analyze determining factors of shock transmission during locomotion. The purpose of this study was to analyze the role of muscle pre-activation and knee angle on shock transmission in controlled situations.

### METHODS

Four male (35-47 years, 70-88kg) healthy subjects volunteered for this study. They were positioned supine with three different goniometric controlled knee angles (0°, 20°, 40°). The forefoot was strapped on the metal plate of an impact device. The hip angle (40°) and ankle angle (90°) were constant. Three muscle activation levels were defined in respect to prior maximal voluntary contractions (0%, 30%, 60% MVC) at each angle condition. Using EMG (Biovision®) the activation was measured at both gastrocnemii (GM, GL), both vasti (VM, VL) and the semitendinosus (ST). In each of the nine different angle-activation conditions ten impacts were initiated under the subjects' heel by means of the pneumatic impactor. The force was measured using a one dimensional transducer (Kistler®). Tibial and femoral shocks were measured using three dimensional accelerometers (Kistler®,  $m < 0.0025\text{kg}$ ). This abstract focuses on the longitudinal components only. The sensors were attached to Apex® pins (diameter 3.0mm, length 60mm) inserted under local anesthetic approx. 1.5cm into the right tibia and femur. The insertion locations were medial and approximately 5-7cm below (tibia) and 2-3cm above (femur) the knee joint space. After attaching the sensors their axes were aligned with the anatomical segment axes using a correction algorithm based upon reflective markers recorded by a movement analysis system (ProReflex®). The shock transmission through the knee joint was calculated by the ratio RAT of the acceleration maxima at the tibia (ACCtib) and femur (ACCfem) ( $\text{RAT} = \text{ACCtib}/\text{ACCfem} \cdot 100$ ). The linear displacement of tibia and femur was estimated by double integrating the acceleration time history and the knee compression (KOM) by the difference of tibial and femoral displacement. The sampling rate of all analog data was 1000Hz. An ANOVA ( $p < 0.05$ ) was carried out to identify significant differences of the mentioned parameters between knee angle or activation conditions.

**Figure 1:** Time normalized time history of mean ( $\pm$ sd) knee compression and femoral and tibial displacement of one subject achieved at 0° knee angle and 0% MVC level ( $n=10$ ).

### RESULTS AND DISCUSSION

In the described study conditions the average peak acceleration at the tibia varied between 2 and 4g and at the femur between 1.5 and 2.5g. With increasing muscle activation levels the tibia acceleration decreased significantly under all knee angles which was also true for the femur at 0° and 20°. ACCtib increased significantly with increasing angles at all MVC levels while ACCfem showed no systematic trend in all subjects. The average shock transmission over all trials was 59.7%. In the 0° and 20° knee angle condition three of the four subjects showed a significant increase in RAT of about 10% with increasing muscle activation levels while one subject showed no substantial change. In the 40° condition increasing muscle activation had a smaller effect on RAT compared to 0° and 20°.

Figure 1 shows the average segmental displacement for one subject at 0° knee angle and 0% MVC. In all knee angle conditions the relative axial movement of tibia and femur (KOM) was significantly decreasing with increasing muscle activation. Apparently the muscle forces pre-load the joint's peri- and intraarticular structures. Considering the facts that RAT was increasing while KOM was decreasing with higher muscle activity and that cadaver studies [1,2] have shown a shock attenuating effect of passive structures it could be assumed that the deformation of peri- and intraarticular tissue also has an effect on shock transmission in vivo. This effect could be substantially influenced by muscle activation.

### INTRODUCTION

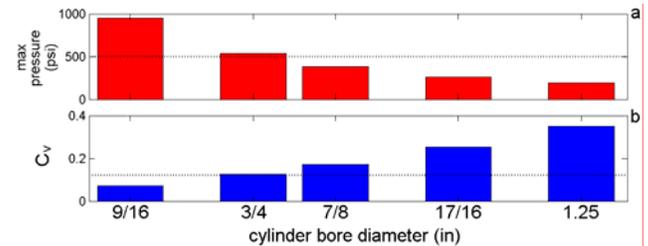

The hybrid orthosis system (HOS) is an assistive gait device for individuals with paraplegia that combines the stability provided by an exoskeletal brace with limb mobility controlled via functional neuromuscular stimulation [1]. A type of brace used in the HOS is the reciprocating gait orthosis (RGO) [2]. The RGO facilitates reciprocal gait by mechanically coupling hip extension with contralateral hip flexion. Hip reciprocation is however fixed at a 1:1 flexion/extension coupling ratio (FECR), limiting hip flexion to the extent of contralateral hip extension [3]. The aim of this research is to develop a hip reciprocating mechanism for the RGO that can couple the hips at variable FECRs. This study focuses on examining the feasibility of utilizing a hydraulic system for variable hip reciprocation.

### METHODS

The proposed design of the hydraulic system for variable hip reciprocation consists of a double acting hydraulic cylinder linked to the lever arm of each thigh upright. Corresponding outlets of the opposing cylinders are connected by tubing to produce a closed hydraulic circuit. Thus, hip extension forces the adjoining piston upward, which then pressurizes the contralateral piston to move downward, resulting in contralateral hip flexion. Solenoid valves are employed to control fluid flow through the hydraulic system resulting in the locking/unlocking of a hip joint and/or the disengagement/reengagement of hip coupling to establish variable FECRs. Pressure relief will be provided by an accumulator.

An initial prototype was developed using off the shelf components to test the efficacy of the design. Pneumatic cylinders with a 5/16 inch bore diameter were used to minimize flow rate and manual shutoff ball valves were used in place of solenoid valves to simplify operation.

An analysis of determining the operating pressures and flow rates of the hydraulic system during gait was undertaken to resolve optimal cylinder and valve specifications and verify if these components could be supplied off the shelf or necessitated the costs of customization. The goal is to minimize flow rate through the valves while selecting a cylinder with a large enough bore diameter to sustain the pressure ranges experienced during gait. Instantaneous cylinder pressures and flow rates during gait for a series of stock cylinder bore sizes were determined by using dynamic data from a three-dimensional computer model of the HOS that incorporated a RGO with 1:1 hip FECR [4]. A valve coefficient ( $C_v$ ) was then determined for each cylinder bore diameter.

**Figure 1:** The dotted lines in (a) and (b) indicate the pressure rating for small bore cylinders and maximum  $C_v$  for low powered solenoid valves respectively.

### RESULTS AND DISCUSSION

The prototype demonstrated the soundness of the proposed hydraulic design by verifying that (1) hip coupling could be readily engaged and disengaged and (2) each hip could be locked and unlocked independently without affecting the kinematics of the opposite hip.

Maximum pressures (Figure 1a) and  $C_v$  factors (Figure 1b) during gait indicate that a stock cylinder with a 3/4 inch bore diameter and pressure rating of 500 psi and valves with a  $C_v$  of 0.12 could be used for the hydraulic variable reciprocating hip mechanism.

Current and future work includes the bench testing of the hydraulic reciprocating hip mechanism with the established optimal components and subsequent able-body testing of the new orthosis.

**CONVERGENT VALIDITY OF GONIOMETRIC AND MOTION CAPTURE TECHNIQUES USED TO MEASURE TIBIAL TORSION**

<sup>1</sup>Kevin M. Cooney, <sup>2</sup>Tara Keister, <sup>2</sup>Eugenie Poignard, <sup>2</sup>Elizabeth Rupert, <sup>2</sup>Sarah Zerbe  
<sup>2</sup>Thomas Hudson, <sup>1</sup>Michael J. Rainbow, <sup>1,2</sup>Frank L. Buczek

<sup>1</sup>Shriners Hospitals for Children, Erie, PA, <sup>2</sup>Gannon University, Erie, PA; email: [kcooney@shrinenet.org](mailto:kcooney@shrinenet.org)

**INTRODUCTION**

Rotational and torsional abnormalities in the pediatric lower extremity can result in static and dynamic toeing-in or toeing-out, and are two of the most common reasons for parents to seek orthopaedic advice.<sup>1</sup> One common lower extremity torsional abnormality is atypical tibial torsion. Computed tomography (CT) is the gold standard for measurement of tibial torsion,<sup>2</sup> but its practicality is limited due to expense. Several goniometric measurement techniques have been described, but debate remains over which is most valid.<sup>3</sup> One goniometric method as described by King and Staheli was found to be within the accepted variability of CT, and therefore an accurate assessment tool.<sup>4</sup> The purpose of this prospective study was to determine the convergent validity of two other common goniometric methods used to measure tibial torsion, as well as a novel method using motion capture, by comparing them to the validated method described by King and Staheli.

**METHOD**

Twenty normal subjects (12 female, 8 male) between the ages of 10 and 25 years underwent four different measures of tibial torsion on the right lower extremity, including the CT validated method as described by King and Staheli (MKS), the thigh-foot angle (TFA)<sup>4</sup>, a supine trans-malleolar axis measure (TMA)<sup>5</sup>, and a novel method using motion capture (MC). One examiner, who was masked from the measurements via modification to a standard goniometer, assessed tibial torsion using the first three methods, while a second examiner recorded the results. After three measurements were obtained for each technique, a third examiner placed 6-mm markers on each subject's right medial and lateral tibial plateau, as well as medial and lateral malleoli.<sup>6</sup> Tibial torsion was then calculated as the rotation between two planes, one containing the tibial plateau markers and mid-point of malleolus markers and the other containing the malleoli and midpoint of the tibial plateau markers, about an axis between the proximal and distal midpoints. Three static motion capture trials were performed on each subject using a 10-camera Vicon 612 system (Oxford Metrics Group, Oxford, England). Biomechanical modeling was performed using Visual3D (C-Motion, Inc., Rockville, MD). Tibial torsion data were compared using a repeated measures analysis of variance with Tukey HSD *post hoc* tests performed in Statistica (Statsoft, Inc., Tulsa OK, USA).

**RESULTS AND DISCUSSION**

Statistically significant differences ( $p < 0.05$ ) were demonstrated between our goniometric gold standard MKS and the goniometric methods of TFA and TMA (Table 1, Table 2). No significant differences were found between MKS and the novel MC technique, or between TFA and TMA. The results demonstrate discrepancies in the validity of TFA and TMA when compared to MKS, which was found to be a valid measure when compared to CT in previous literature. These findings may be considered when performing goniometric measurement of tibial torsion in the clinical setting. Because motion capture demonstrated convergent validity when compared to MKS, it is concluded that it is also a valid method for measuring tibial torsion. It is recommended that care be taken to ensure accurate placement of the centroid of the markers over the bony landmarks when using the motion capture technique. The absence of comparison to CT, which is the gold standard for measurement of tibial torsion, was a minor limitation of this study. Because the distal reference line for measuring tibial torsion via CT involves the fibular notch of the tibia, but not the medial malleolus,<sup>2</sup> use of the trans-malleolar axis in all four of the techniques described in this study is another area of weakness for determination of true tibial torsion.

Table 1: Descriptive Statistics

Assessment Technique	Range (°)	Mean (°)	Standard Dev. (°)
MKS	20.0	23.3	4.7
TMA	14.0	17.8	3.6
TFA	17.0	17.6	3.8
MC	26.0	19.3	6.7

## ROTATIONAL SPRING AND DAMPER MODEL PREDICTION DURING LANDING

<sup>1</sup> Robert Ragan, <sup>2</sup>Thomas Kernocek, <sup>1</sup>David Buschke and <sup>1</sup>John Hart

<sup>1</sup>Physics Department, <sup>2</sup>Department of Health Profession, University of Wisconsin-La Crosse, La Crosse WI 54601

### INTRODUCTION

Lower extremity stiffness is thought to be an important factor related to performance and injury. There have been three basic approaches to quantifying stiffness during impact related movement activities: vertical stiffness, total leg stiffness and torsional stiffness<sup>1</sup>. The assessment of torsional stiffness allows researchers to quantify changes in stiffness in each joint. This opens the opportunity to assess the relative change in stiffness with experimental perturbations. Some models have also incorporated the use of damping as seen in Derrick et al's study of running<sup>2</sup>. The purpose of this study was to use a spring and damping model to describe landing and describe the relative strength of the fit to drop landing for the joints in the lower extremity.

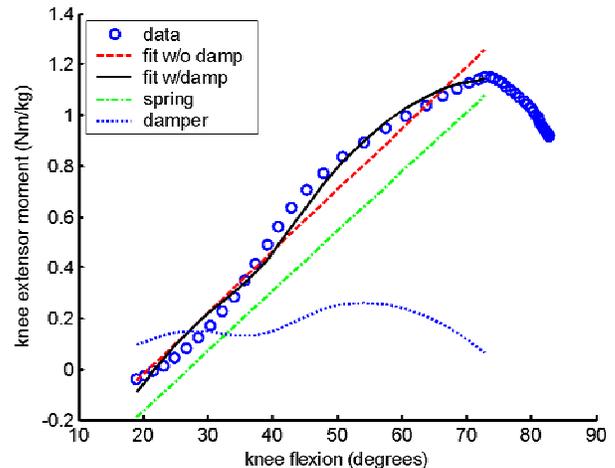

### METHODS

Twelve male recreational athletes performed six single legged drop-landing trials from a 40-centimeter height. Kinematic data were recorded at 240 Hz using a six-camera three-dimensional motion analysis system. Sixteen retro-reflective markers were used with a modified Helen-Hayes marker set. Kinetic data were recorded at 1200 Hz simultaneously with kinematic data using a Bertec force platform. Raw data were smoothed at a 10 Hz cutoff. Inverse dynamics calculations were performed in the Kintrak software package and exported to a custom program in Matlab. Sagittal plane joint angles and moments at the hip, knee and ankle were used to calculate rotational stiffness coefficients<sup>3</sup>. Sagittal plane joint velocities and joint moments were used to calculate damping coefficients for the hip, knee and ankle. Averages of the six trials were used. Descriptive data of the spring and damping coefficients of the hip, knee and ankle were calculated as well as the relative fit using a regression model.

### RESULTS AND DISCUSSION

The damped torsion spring model was found to fit the moment data during the impact part of the landing from initial contact until the peak joint moment (approximately 0.1 sec). Spring and damping constants for the knee and ankle maintained high R<sup>2</sup> values with and without the presence of damping (Table 1). Incorporating the effects of damping, however, consistently increased R<sup>2</sup> values in comparison to those without damping. Table 1 also shows that the ankle and knee joint of the lower extremity behave rather spring-like with minimal damping effects. Poor fits of this spring damping model were found for

the hip joint where damping coefficients were negative. Also, the model failed to predict joint moments beyond their respective peak moments, where other factors such as central nervous system control need to be considered<sup>4</sup>.

**Figure 1** Knee fitting results for a single landing trial from initial foot contact to maximum knee flexion. The spring and damper curves show the contribution from each separately in the fit with and without damping.

### CONCLUSIONS

Spring and damping model produces good results for the knee and ankle for the impact portion of landing. The damping effect for drop landing appears to be minimal for the knee and ankle. Much poorer fits were seen at the hip joint. Use of this model should be likely limited to more distal joints like the knee and ankle.

e-mail: [mehrdad.anbarian@umontreal.ca](mailto:mehrdad.anbarian@umontreal.ca)

### INTRODUCTION

Foot type classification methods are still controversial in the literature [1]. The difficulty lies in part in the different means of assessing foot disorders such as visual inspection, foot print, radiography, etc. and with the number of parameters to characterize foot morphology. Consequently, foot classification is often based on parameters related to a specifically pathology rather using a single set of angles for all pathologies [2]. The aim of this study was to determine if fuzzy logic (FL) can be applied to classify five foot types using only two geometric parameters and determine its performance.

### METHODS

An experienced podiatrist clinically categorized 321 feet into 4 pathological groups, namely, pes planus (n=52), pronation (n=80), pes cavus (n=115) and supination (n=48) and an able-bodied group (n=26).

A digital camera was used to capture two black and white images taken from the postero-anterior and medial views of feet while weight-bearing. Camera-subject distance was fixed at approximately 1.7 meter. The pictures were then processed by a numerical filter where the grey levels were transformed into a color-coded image highlighting muscle and bone prominences. This process facilitated the measurement of two foot parameters. These are the rearfoot and Djian-Annonier angles (Figure 1). In the literature, rearfoot angle is used to describe subtalar joint position while Djian-Annonier is described medial height arch.

The fuzzy logic toolbox in MATLAB was used to develop the classification model. The above two parameters were introduced in the FL model. For estimating the relative accuracy of the classification method, Kappa statistics were applied by comparing the result of the FL classification with that of the clinical sorting.

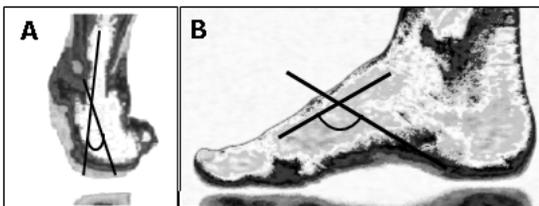

Figure 1: A) Rearfoot and B) Djian-Annonier angles.

### RESULTS AND DISCUSSION

The FL technique was successful in classifying 88.8% of all able-bodied and pathological feet. The lowest success rate was found for the able-bodied group (69.2%) as compared to a mean success rate of 93.7% for all pathologies groups (Figure 2). Misclassification of 5 of the 26 feet as pes cavus in the able-bodied group reduced the performance of the FL technique. The misclassification could be related to lower difference value of the rearfoot angle. In the able-bodied group it was 1° greater than in the pes cavus group while it ranged from 7.4° to 10.3° for other pathologies.

A Kappa value of 0.89 was obtained with the FL classification method when compared to the podiatrist's classification. To our knowledge no one has yet reported a classification in which both able-bodied and pathological feet were presented. Furthermore, previous studies were limited to parameters related to a single pathology.

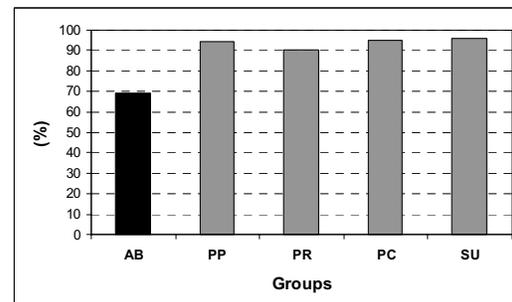

Figure 2: Classification results for able-bodied (AB), pes planus (PP), pronation (PR), pes cavus (PC) and supination (SU) groups.

### CONCLUSIONS

The fuzzy logic method was able to classify the five foot types using only two geometrical parameters with high accuracy.

## CYTOSKELETAL TENSION ENHANCES OSTEOGENIC DIFFERENTIATION OF ADIPOSE-DERIVED MESENCHYMAL CELLS

<sup>1,2</sup>Diane R Wagner, <sup>2</sup>Yue Xu, <sup>1</sup>Dennis R Carter and <sup>2</sup>Michael T Longaker

### INTRODUCTION

Cells isolated from adipose tissue possess multilineage potential, but strategies for driving the AMCs to a particular lineage have yet to be elucidated. A recent study has shown that cell density and shape regulate the differentiation of human mesenchymal stem cells (hMSCs) [1]. In hMSCs, RhoA and Rho Kinase (ROCK), which mediate tension in the actin cytoskeleton, are directly involved in density- and shape-dependent differentiation [1]. The RhoA/ROCK pathway is particularly interesting to us because it has also been implicated in the mechanotransduction of signals from the extracellular matrix to a cellular response [2,3].

To explore density-dependent differentiation of AMCs, we varied cell density and examined its effect on adipogenesis and osteogenesis. We inhibited ROCK to determine whether cytoskeletal tension is involved in the differentiation of our cells. Finally, we used microarray analysis to elucidate the mechanisms of density-dependent differentiation in AMCs and to determine whether genes that are regulated by density are also mechanosensitive.

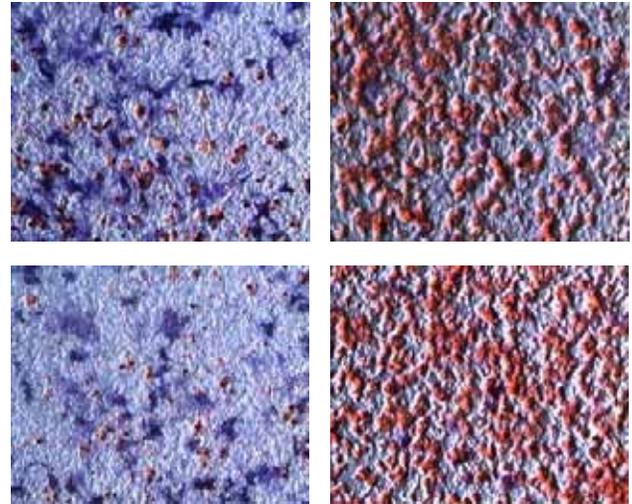

### METHODS

AMCs were harvested from inguinal fat pads of three-week-old FVB mice. After expansion, early passage (P1) cells were plated at low (2,500 cells/cm<sup>2</sup>) and high (25,000 cells/cm<sup>2</sup>) density. Cells were cultured in a bipotent differentiation media containing both osteogenic and adipogenic factors. At 1 week, adipogenic differentiation was determined by staining the cells with Oil Red O. Early osteogenic differentiation was assessed by staining cells for alkaline phosphatase (ALP) and by quantifying ALP activity normalized to total protein. These differentiation assays were performed both with and without the drug Y-27632, which inhibits ROCK.

RNA was harvested from cells at low and high density in bipotent differentiation media 24 hours after plating. Gene expression analysis was performed on cDNA microarrays containing nucleotide sequences for over 20,000 mouse genes.

### RESULTS AND DISCUSSION

We observed greater ALP staining in our low density cells. Conversely, Oil Red O staining was more pronounced in the cells plated at high density. Oil Red O staining appeared identical with and without the addition of the ROCK inhibitor Y-27632. However, we saw a decrease in ALP staining at low density with Y-27632 (Fig 1). The quantitative ALP activity assay confirmed the staining results (data not shown). Specifically, ALP activity in cells at low density without Y-27632 was significantly higher than in all other conditions.

**Figure 1:** Microscopic (10x) view of ALP staining in blue and Oil Red O staining in red. Left: cells at low density; Right: cells at high density; Top: cells in bipotent media; Bottom: cells in bipotent media with Y-27632.

Some of the genes that are significantly upregulated in low density cells are also mechanosensitive. For example, connective tissue growth factor and thrombospondin 1 were expressed more highly in our low density cells and were upregulated with tensile strain in primary rat calvarial cells [4]. Similarly, calponin was more highly expressed in our low density cells and was upregulated with uniaxial tensile strain in rat bone marrow progenitor cells [5]. A thorough review of our microarray data is ongoing.

### CONCLUSIONS

This study demonstrates that cell density influences osteogenesis and adipogenesis in AMCs and strongly suggests that increased cytoskeletal tension in the low density cells enhances osteogenesis. Our microarray data indicate that some similarities exist between genes that are sensitive to density-mediated changes in cytoskeletal tension and mechanosensitive genes. In the future, we plan to explore whether the mechanism of cytoskeletal tension is similar in density-dependent osteogenesis and in mechanotransduction of AMCs.

## GAIT KINEMATICS ON AN ELEVATED INCLINED SURFACE

<sup>1</sup> Lloyd (Chip) Wade and <sup>2</sup> Jerry Davis

<sup>1</sup>Human Movement and Balance Laboratory, Department of Bioengineering, University of Pittsburgh

<sup>2</sup>Department of Industrial and Systems Engineering; Auburn University <sup>1</sup>email: [cwade@engr.pitt.edu](mailto:cwade@engr.pitt.edu)

### INTRODUCTION

Fatal and non-fatal falls from elevation have been documented to be a significant issue in today's workforce. According to the Bureau of Labor Statistics (BLS) in 2003 falls from elevations were reported to be the second-leading cause of fatalities in industry, second only to workplace transportation fatalities, specifically falls from elevation accounted for 13% of all workplace fatalities, with a reported 691 fatalities for the year [1].

In industrial settings, elevated surfaces are typically associated with altered support surfaces (i.e. inclined). While previous research has suggested changes in elevation [2], and exposure to inclined surfaces [3], are risk factors for falls; research is sparse on gait kinematics while exposed to elevation and inclined surfaces simultaneously. Therefore, the purpose of this study was to investigate gait kinematics during exposure to an elevated inclined surface.

### METHODS

Twenty subjects, 10 male college students (inexperienced) and 10 male roofers (experienced) between the ages of 19 to 50 years old, participated in this study. The testing protocol was explained prior to providing informed consent consistent with the Auburn University Office of Human Subjects Institutional Review Board (IRB) standards. Exclusionary criteria included a history of neurological, orthopedic, cardiovascular and pulmonary abnormalities as well as any other difficulties hindering normal gait.

Subjects walked (ascending & descending) on an elevated inclined surface (10 to 16 feet from ground level), measuring 16x14 feet at a 6/12 (26°) pitch (Figure 1). A week later, subjects walked on the same inclined surface at ground level. While subjects walked, an 8-camera Peak Performance (Peak 5.0) Motion Analysis System acquired 3D motion data at 120 Hz from markers placed bilaterally on anatomical landmarks to configure the whole body model. Subjects were required to use fall protection that prevented rapid descents if a fall were to occur. Dependent measures included stride length (SL), stride width (SW), step period (SP), and walking velocity (V). A significance level of  $\alpha = .05$  was applied.

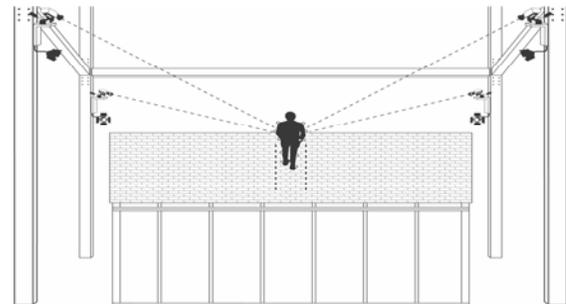

Figure 1. Artist rendering of the elevated inclined surface

### RESULTS AND DISCUSSION

Statistical analysis revealed a significant within subject's and between group difference(s) in step length, step width, step period, and walking velocity between the two height conditions and walking directions. Mean values ( $\pm$ SD) for each group, height, and direction are presented in Table 1.

### CONCLUSION

An analysis of the kinematics of gait while operating on an elevated inclined surface is important in understanding the effects of elevation on the potential for falls due to slips or loss of balance. While previous research has indicated that step length, width, period, and velocity are correlated to changes in postural stability; it is interesting to note the significant effect of experience at elevation between individuals. This difference may be an underlying factor in fall incidents. Inexperienced individuals demonstrated gait kinematics suggesting a perceived increase in the frictional demands, adjusting their behavior to reduce the risk of a slip or loss of balance. Experienced individuals demonstrated gait characteristics related to postural stability with insensitivity to height. These suggested underestimations of the frictional demands may be a contributing factor related to a loss of balance, resulting in a fall.

## RECRUITMENT OF SOLEUS AND GASTROCNEMIUS WITH RESTRICTED AND UNRESTRICTED ANKLE MOTION

<sup>1</sup> David Sanderson and <sup>2</sup> David Kenyon

<sup>1</sup> School of Human Kinetics, UBC, Canada, <sup>2</sup> Department of Physics, BCIT, Canada  
email: [david.sanderson@ubc.ca](mailto:david.sanderson@ubc.ca), web: [www.hkin.educ.ubc.ca](http://www.hkin.educ.ubc.ca)

### INTRODUCTION

Marsh and Martin [1] showed that the gastrocnemius and soleus muscles responded differently to cadence manipulations during cycling. Gastrocnemius excitation increased with increasing cadence whereas soleus did not. Subsequently, Sanderson et al. [2] repeated their experiment and presented data on muscle lengthening and EMG activity for gastrocnemius and soleus where cadence was manipulated (50 – 110 rpm in 15-rpm increments). They postulated that the difference in sensitivity to cadence manipulations between these two muscles was associated with their mechanical properties. To assess this postulate individual ankle-foot orthoses that kept the ankle joint at 90° of flexion, or the neutral position were worn as cyclists pedaled a series of cadence conditions at a fixed power output (200 W). In doing so the opportunity for soleus to contribute to pedal force was removed. We postulated that this would result in an increase in gastrocnemius excitation to compensate for the loss of the soleus contribution. Further, with the ankle joint fixed at 90° we would be able to separate the influence of ankle joint ankle changes on gastrocnemius length – i.e. it would solely be determined by knee-joint motion.

### METHODS

Participants (n=3) expert cyclists (2M, 1F), with a mean (SD) age of 29 (11) years, mass 68 (2) kg, and height 176 (5) cm.) rode for a minimum of 2.5 minutes at each of five randomly presented cadences (50, 65, 80, 95, and 110 rpm) at a constant nominal power output of 200 W while EMG from soleus and gastrocnemius muscles and lower-limb sagittal-plane video were recorded. Data collection occurred in the final minute of the test protocol and lasted for six revolutions of the crank per collection period. Marker kinematics were used first to compute the angle of the knee and ankle joints and then the muscle lengths of the soleus and gastrocnemius muscles using equations developed by Hawkins and Hull [3] over the complete pedaling cycle. EMG data were normalized to the 50-rpm condition. We used data from Martin et al [4] to provide a baseline condition.

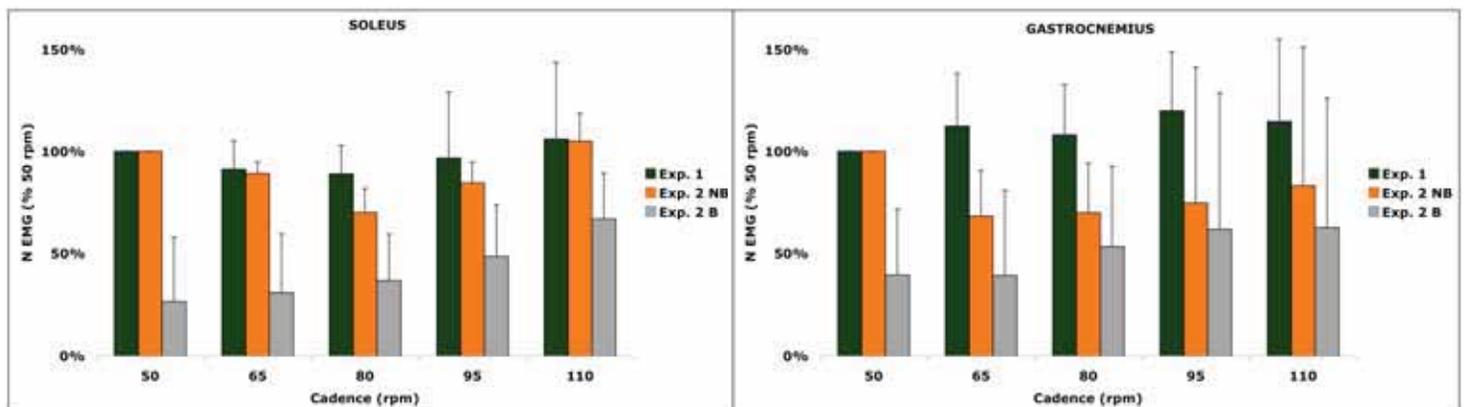

### RESULTS AND DISCUSSION

Wearing the ankle-foot orthosis reduced ankle angle motion from a range of 18° to a range of 3° which was consistent with the flexion of the brace. Knee motion range was reduced from 71° to 61°. This was a surprise because with the now limited ankle motion we had anticipated that knee extension would increase. Examination of the motion of the vertical component of hip marker revealed that there was increased hip vertical motion. The cyclists dropped their hip on the down stroke to make up for this shorter leg. Because there was no change in the overall knee-joint range of motion and the limited affect of the ankle joint, the length change of gastrocnemius did not change between conditions. It was concluded that perhaps the strategy was to keep gastrocnemius operating within a specific range. This is consistent with the earlier postulate that the mechanical properties of muscle to some extent dictate their recruitment. Another effect of wearing the ankle-foot orthosis was that both muscle EMG patterns were substantially reduced for all cadence conditions and the sensitivity to cadence shown in gastrocnemius disappeared. Soleus excitation was reduced on average by 48% whereas gastrocnemius excitation was NOT increased by rather decreased by 28%. As we anticipated, the effect of wearing the brace was more marked on soleus. The 28% reduction in gastrocnemius excitation indicated that its activity was primarily affected by knee motion and that this two-joint nature masked any increased loading on the gastrocnemius by soleus. This project suggests that further work is required to understand fully the interaction of the muscles within the triceps surae complex.

### INTRODUCTION

Tasks including drilling [1], gripping [2], automobile trim installation [3], and the mating of electrical connectors [4], have been studied recently using psychophysical approaches. However, no study to date has determined the forces that workers find acceptable during manual engine hose installations, even though hose failure in automobiles can in part be attributed to incorrect assembly practices [5].

### METHODS

Five women in each of 3 age groups (20 year olds (1.72 (0.07) m; 65.1 (7.9) kg), 30 year olds (1.66 (0.06) m; 72.9 (8.6) kg), and 40+ year olds (1.62 (0.08) m; 82.1 (12.7) kg)), had no previous upper limb injuries or experience with hose insertion tasks, and signed a consent form accepted by the University of Windsor Research Ethics Board.

A tri-axial load cell was mounted to a hose insertion jig supported by an angle iron frame. An ABS plastic hose (length 15.5 cm, diameter 3.8 cm) surrounded a hardwood dowel and base plate that was anchored to the load cell. The jig and load cell could swivel and be adjusted for height. The angle iron frame was mounted to the concrete floor of the lab.

Subjects in each age group were randomly assigned to 9 of 15 total conditions for posture (Lateral Push-Far (LPF), Lateral Push-Near (LPN), Midline Push (MPush), Midline Pull (MPull), and Push Down (PD)), and frequency (1, 3, and 5 insertions/minute. Each subject trained for a total of 24 hours (2.67 hours per posture/frequency condition), and was tested for 3 hours (0.33 hours per condition). Posture conditions were randomly presented. Subjects heard a signal at the set frequencies, via an earphone, after which they applied force to the hose using a power grip until the next signal was presented (750 ms). Subjects applied the maximum force that they found acceptable for 8 hours without feeling fatigued or discomfort. MVCs were executed in each posture.

Force data were A/D converted using a 12-bit card and sampled by computer at 1000 Hz using custom LabVIEW software. Signals were amplified and filtered with a dual pass Butterworth digital filter ( $f_c = 15$  Hz). A total of 1250 samples (1.25 s) of data were collected for each trial: 500 pre-trigger samples, and then 750 samples following the trigger. Data from the last 20 minutes (0.33 hours) of testing in each condition were analyzed.

ANOVAs were performed on mean acceptable peak force (APF), %MVC force, and impulse, with posture and frequency as between subject factors. Tukey/Kramer post hoc were performed for all significant effects ( $\alpha = 0.05$ ).

### RESULTS AND DISCUSSION

Significant main effects of posture and frequency were found ( $p < 0.0001$  and  $p < 0.03$ , respectively) for APF. A significant main effect of posture only was found ( $p < 0.0001$ ) for acceptable impulse. The MPull posture condition resulted in

the greatest mean APF and impulse, with the lowest seen in the LPF condition. An average decrease of approximately 17% and 13.4% was shown in mean APF and impulse, respectively, as frequency increased from 1 to 5 insertions/min. Average within-subject coefficients of variation (CV) for APF and impulse ranged from 7.2% to 11.2%, and from 5.6% to 9.9%, with means across all conditions being 9.0% and 8.1%, respectively. There were no significant main effects or interactions of posture or frequency for %MVC values. At a frequency of 1/min, subjects selected acceptable forces that were in the range of 63% MVC for each posture, despite the variable physical demands in the different conditions. Fairly comparable levels of APF (as a %MVC) have also been seen in other psychophysical studies in our laboratory involving the hand [4,6].

The results of well-trained novice subjects have been shown in the past not to differ from actual workers using a psychophysical approach [3]. In the current study, each subject executed 4860 trials in training and testing on average. Mean within-subject CVs were low in general and comparable to those reported elsewhere [3,4], suggesting that subjects were consistent and that training was adequate.

Posture conditions used in this study reflected the orientation of the upper limb and not just the wrist or the grip type, as reported in previous work [1]. The LPF posture put increased load on the operators' shoulders, compared to other orientations, as they supported the mass of their extended upper extremity and also applied force to the hose. This likely factored into subjects' decisions to accept less insertion force in this condition. The MVC data support this, with average maximal forces for the LPF condition being the lowest of the postures at 87.0 ( $\pm 19.2$ ) N.

The decreasing trend in APF and impulse, as frequency increased, is similar to previous work [3]. Declines in maximum APF (and torque) as frequency increases, have been shown in the literature for other tasks that have utilized power grips in a variety of posture conditions [1].

### CONCLUSIONS

This is the first study that has quantified APFs and impulses associated with engine hose insertions. Consistent %MVC forces seen across the variety of tested conditions compares favorably with other investigations of hand-intensive mating operations in automobile assembly, and will enable assessments of hose insertion tasks not explicitly tested in this study.

## FUNCTIONAL AND STRUCTURAL CERVICAL SPINE DYSFUNCTIONS WITH TEMPOROMANDIBULAR DISORDERS

Ângela Viegas Andrade and Luci Fuscaldi Teixeira-Salmela

Department of Physical Therapy, Federal University of Minas Gerais, Brazil; email: [aviegas.bhe@terra.com.br](mailto:aviegas.bhe@terra.com.br)

### INTRODUCTION

The incidence of temporomandibular disorder (TMD) has increased and has become a concern for various health professionals [1,2]. The relationship between TMD and cervical spine structural disorders has only been modestly demonstrated [2,3]. The objective of this study was to investigate functional and structural alterations of the head and neck with 17 TMD and 17 age and gender-matched asymptomatic individuals, using a cross-sectional design

### METHODS

Functional measures included scores on the temporomandibular index (TMI)<sup>1</sup> and of pain palpation of the superior trapezius, sternocleidomastoideus, and suboccipital muscles assessed by scores on the visual analog scale. Structural assessment of the cervical spine included radiographic measures of lordosis [2], determined by the methods of Cobb and Harrison, as well as the position of the hyoid bone [3]. All radiographic images were digitized using the Autocad software.

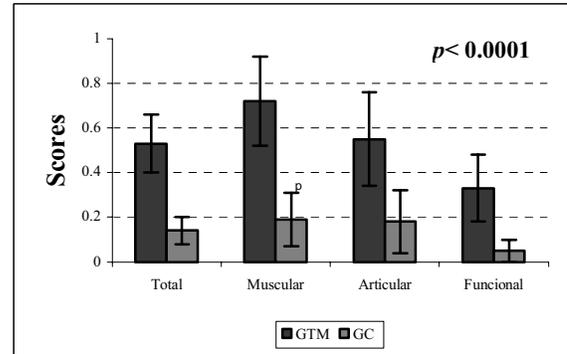

Descriptive statistics and tests for normality were carried out for all variables. Student *t*-tests for independent samples with Bonferroni correction were used to investigate differences between groups for all variables, with a significance level of  $\alpha < 0.02$ . Pearson correlation coefficients were calculated to investigate the relations between cervical alignment measures.

### RESULTS AND DISCUSSION

Seventeen subjects (16 female and one male) with a mean age of  $23.5 \pm 3.6$  years comprised the TMD group.

As illustrated in Figure 1, individuals with TMD, when compared with asymptomatic subjects, presented higher scores in total TMI and its indexes ( $t=11.09$ ;  $p<0.0001$ ), with the muscular index showing the greatest differences. They also demonstrated higher levels of perception of pain for all cervical muscles ( $p<0.0001$ ).

Even though no significant differences between groups were found, as shown in Table 1, the TMD subjects presented less cervical lordosis when compared with the reference values of  $17^\circ$  and  $26^\circ$  for the Cobb and Harrison methods [3]. These findings suggest an association between TMD and alterations of alignment of the cervical column, indicating

**Figure 1:** Means ( $\pm$  SD) of the ITM and its indexes

that the cervical column should be evaluated in the presence of TMD.

The position of the hyoid in relation to the cervical column was stable, indicating that its position was not influenced by TMD. In that the Cobb and Harrison measures revealed a strong correlation ( $r=0.82$ ;  $p<0.0001$ ), it is suggested that either measure can be used to evaluate cervical spine alignment

### CONCLUSIONS

The present findings demonstrated that subjects with TMJ demonstrated functional cervical dysfunctions and decreased cervical lordosis, suggesting that cervical assessment should always be performed in the presence of TMJ. Either method, Cobb or Harrison's, may be used to assess cervical spinal alignment.

## RELATIONSHIPS BETWEEN ILIOTIBIAL BAND LENGTH AND FRONTAL PLANE PELVIC TILT

Christina Danielli Coelho de Moraes Faria, Luci Fuscaldi Teixeira-Salmela, Fabiana Fernandes Pereira Lima  
 Department of Physical Therapy, Federal University of Minas Gerais, Brazil; email: [jhsalmela@hotmail.com](mailto:jhsalmela@hotmail.com)

### INTRODUCTION

The position of the pelvic bone is the key for the postural alignment [1]. Both structural and functional factors may be associated with lateral pelvic tilt [2], one of them being the length of the iliotibial band [1,3]. A lateral pelvic tilt could modify the position of several body structures, overload them, and, thus, causing compensations, dysfunctions and pain [1,3].

Therefore, the aim of this study was to investigate the degree of association between the length of iliotibial band and the frontal plane pelvic tilt.

### METHODS

Healthy individuals with no leg-length differences and without pelvic torsion were included in the study. The modified Ober test, performed with a pelvic level and an inclinometer, was used to assess the iliotibial band length. Before data collection, a test-retest pilot study was conducted to determine the reliability of the measurements.

Measures of pelvic alignment were obtained with an anthropometer with the individual positioned on standard support equipment.

Intra-class correlation coefficients were used to investigate intra-rater reliability. The Pearson correlation coefficient was calculated to determine the degree of association between the measure of pelvic alignment in the frontal plane and that of the iliotibial band length. Pelvic alignment was determined by differences in height between the anterior superior iliac spines, whereas the length of the iliotibial band was established by differences between the higher and lower anterior superior iliac spines. The level of significance was set at  $\alpha < 0.05$ .

### RESULTS AND DISCUSSION

Thirty-two subjects, 19 women and 13 men (mean age:  $22.5 \pm 2.6$  years) were included in the study. The means, standard deviations, and the intraclass correlation of the measures obtained during the test-retest are presented in Table 1 and demonstrated adequate intra-rater reliability ( $ICC > 0.99$ ).

Descriptive values of the variables obtained to investigate the degree of association between the iliotibial band length and pelvic alignment are presented in the Table 2. No significant correlation was found ( $r = 0.12$ ;  $p = 0.53$ ).

The assumption that pelvic biomechanical disorders lead to pelvic positioning asymmetries is still not completely understood. A possible explanation relies on soft tissue dysfunctions [4], mainly of iliotibial band [1,3]. However, the present findings did not provide evidence of significant correlations between pelvic alignment and length of iliotibial band.

These results suggest that alterations in length of the iliotibial band, measured by the modified Ober test, alone does not appear to directly influence pelvic alignment and, thus, might not be a relevant outcome measure for assessment and treatment of pelvic dysfunctions. However, these results should be interpreted cautiously, since only healthy subjects were included.

### CONCLUSIONS

Although measures of iliotibial band length showed to be highly reliable, they showed no functional relationship. The present findings indicated that iliotibial band length alone does not appear to influence frontal plane pelvic alignment and that other factors may be involved that still need to be identified.

## Mechanical Properties of Relaxed and Contracted Thigh Muscles using Magnetic Resonance Elastography

<sup>1</sup> Sabine Bensamoun, <sup>1</sup> Stacie Ringleb, <sup>1</sup> Qingshan Chen, <sup>2</sup> Richard Ehman, <sup>1</sup> Kai-Nan An

<sup>1</sup> Biomechanics Laboratory, Division of Orthopedic Research, Mayo Clinic, Rochester, MN 55905

<sup>2</sup> Department of Radiology, Mayo Clinic College of Medicine, Rochester, MN 55905

### INTRODUCTION

The determination of the mechanical properties of muscle in passive and active conditions may characterize the physiological changes within the muscle [1]. Thus, the measurement of the *in vivo* mechanical properties of muscles is clinically necessary in order to understand the transformations that occur in muscle with pathologies and treatments. A few techniques (palpation, sonoelastography, elastography) allow measurement of the *in vivo* stiffness of soft tissues but, they are restricted in depth and field of view. Magnetic Resonance Elastography (MRE) is a non-invasive phase contrast MR technique capable of quantifying the *in vivo* mechanical properties and imaging the entire spatial distribution of muscle elasticity [2]. The purpose of this study was to measure the mechanical properties of the vastus lateralis (VL), vastus medialis (VM) and sartorius (Sr) muscles in a relaxed and contracted position.

### METHODS

Fourteen volunteers (4 males and 10 females, mean age  $25.2 \pm 1.78$ ) participated in this MRE study. The volunteers lay supine in a 1.5T General Electric Signa MRI with the right leg resting in a custom MR compatible leg press, capable of measuring the applied load. Shear waves were applied to the thigh muscles with a mechanical (n=7 VL, n=10 VM, n=9 Sr) or pneumatic driver (n=5 VL, n=4 VM, n=4 Sr). Each driver was positioned on the thigh 1/3 of the distance from the patellar tendon to the greater trochanter. The mechanical driver was composed of a coil of copper wire with a hollow aluminum core driven with an alternative current of variable potential, induced shear waves into the thigh muscles at 120Hz. The pneumatic driver was composed of a thin silicone tube connected to a remote pressure driver (i.e., a large active loudspeaker). This system created a time varying pressure wave, which caused the tube around the thigh to expand and contract with the remote driver at 90 Hz. A custom-made Helmholtz surface coil was placed around the thigh. Axial images were obtained and oblique scan planes passing through the VL, VM and Sr were selected from these images. MRE data were collected with a gradient echo technique. The wavelength ( $\lambda$ ) was measured in each of the four offsets and the stiffness was calculated ( $\mu = \rho * \lambda^2 * f^2$ , where  $\rho = 1000 \text{ kg/m}^3$ ).

### RESULTS AND DISCUSSION

Figure 1 showed shear waves propagating in the vastus medialis (VM) and sartorius (Sr) muscles.

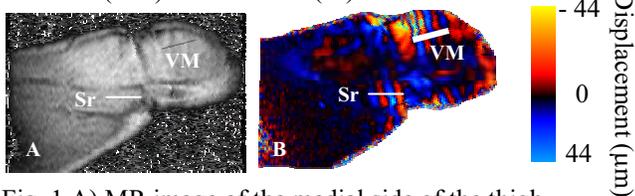

Fig. 1 A) MR image of the medial side of the thigh.  
B) Shear waves in the medial side of the thigh

The shear modulus measured at rest (Fig. 2) in the vastus lateralis, vastus medialis and sartorius were  $3.73 \pm 0.85 \text{ kPa}$  (VL),  $3.91 \pm 1.15 \text{ kPa}$  (VM) and  $7.53 \pm 1.66 \text{ kPa}$  (Sr). The stiffness of the sartorius is significantly higher than the vastus stiffness. This may indicate that the propagation of the waves was influenced by the muscle fiber orientation. The fiber orientation is unipennate in the vasti, while it is longitudinal in the sartorius.

During a thigh contraction of 10% MVC, the stiffnesses of the VL and the VM were  $6.11 \pm 1.15 \text{ kPa}$  ( $P < 0.1$ ) and  $4.83 \pm 1.68 \text{ kPa}$ , respectively. A faster increase of stiffness was measured for the VL than for the VM. This may be due to a larger percentage of fast fibers in the VL enabling a faster contraction.

With a level of 20% MVC, the stiffnesses of the VL and the VM were  $8.49 \pm 4.02 \text{ kPa}$  and  $6.40 \pm 1.79 \text{ kPa}$  ( $P < 0.1$ ), respectively. For both levels of contraction, the stiffness of the sartorius muscle did not exhibit any changes. This may be due to the leg press, which solicits the knee extensors while the sartorius flexes the knee.

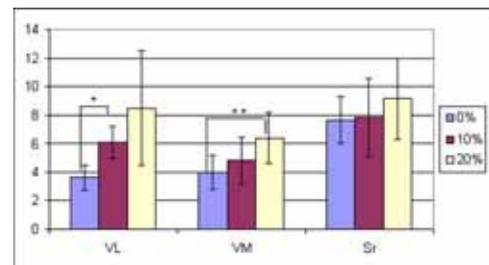

Fig 2. Representation of the muscle stiffness in a relaxed and contracted positions

### CONCLUSIONS

We concluded that the MRE technique is able to quantify the stiffness of thigh muscles. Furthermore, the wave length was sensitive to the morphology and fiber composition in each muscle. The MRE technique could be a helpful means to non-invasively improve diagnoses and to understand the effects of pathologies such as Graves Disease which effects proximal muscle strength by changing the composition of the muscle fibers [3].

## INFLUENCE OF THIGH MARKER CLUSTER DESIGN ON THE ESTIMATION OF HIP AXIAL ROTATION

<sup>1</sup> Anthony Schache, <sup>1</sup> Richard Baker and <sup>2</sup> Larry Lamoreux

<sup>1</sup>Murdoch Childrens Research Institute & Hugh Williamson Gait Laboratory, Royal Children's Hospital, Australia

<sup>2</sup>Gait Dimension, Benicia, California; email: [anthony.schache@mcri.edu.au](mailto:anthony.schache@mcri.edu.au)

### INTRODUCTION

Measurements of hip axial rotation are prone to considerable error [1]. Given the degree of soft tissue mass surrounding the femur, it is likely that most of this error is a consequence of soft tissue artifacts associated with markers mounted on the thigh. Therefore, the purpose of this study was to evaluate various thigh marker cluster configurations with a view to optimising the estimation of hip axial rotation.

### METHODS

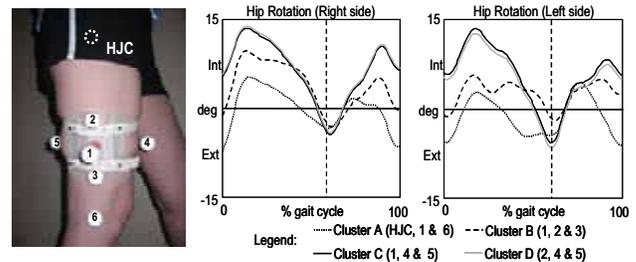

Five able-bodied adults (4F; 1M) participated in this study. Mean age, height and body mass were 23.7 years (SD 6.9), 164.9 cm (SD 2.9) and 58.1 kg (SD 7.4) respectively. Ethical approval was obtained prior to commencement. Reflective markers were placed over the pelvis, thigh and shank. A thigh wand fixed to a thermoplastic base plate was firmly mounted on the thigh using circumferential straps. Four different thigh clusters were then configured as defined in Figure 1 (see legend). Three were non-rigid (clusters A, C & D) and one was rigid (cluster B). Cluster A corresponded to the Helen Hayes marker set up. The HJC was estimated from the pelvic markers [2]. Clusters B, C and D were mounted distally on the thigh to optimise rigidity with the underlying femur [1].

A VICON motion analysis system (Oxford Metrics Ltd.) was used to capture 3D kinematic data (120 Hz). A static calibration trial was first captured to define the relationship between all clusters (technical frames) and the relevant anatomical frames. Subjects then performed two tasks: normal gait at a self-selected speed and isolated longitudinal rotation of the lower limb. For the latter task, the test subject stood with the test limb on a ball-bearing turntable and the knee extended. Subjects rotated the test limb about its long axis by internally and externally rotating the hip. As the knee does not permit axial rotation when extended and soft tissue movement in the shank is not expected during this task, markers on the tibia were used to represent true axial rotation of the femur.

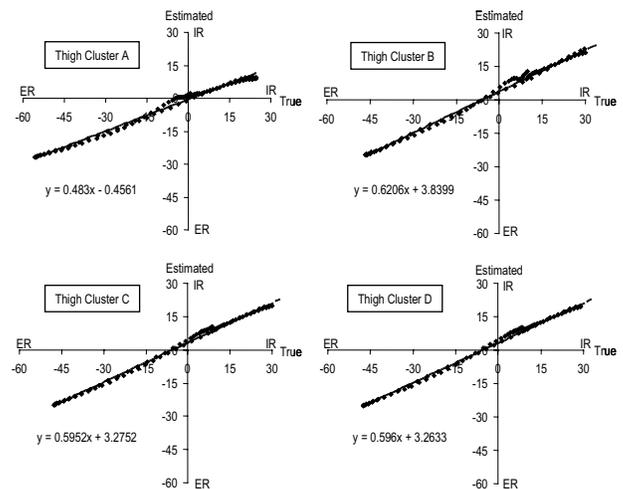

Hip axial rotation patterns during gait, as measured from the different thigh clusters, were compared for similarity using the coefficient of multiple determination (CMD or  $r^2$ ) statistic. Regression analysis was used to describe the relationship between estimated (thigh cluster) and true (tibial markers) hip axial rotation for the isolated longitudinal rotation task. Analyses were performed for the left and right side independently and results were averaged.

### RESULTS AND DISCUSSION

Hip axial rotation during gait was highly sensitive to thigh marker cluster design (Figure 1). The mean CMD value was 0.34 (SD 0.29) indicating quite poor similarity between clusters. All clusters underestimated true bone movement during the isolated longitudinal rotation task (Figure 2). Mean regression coefficients were 0.46 (SD 0.06), 0.60 (SD 0.05), 0.56 (SD 0.07) and 0.56 (SD 0.07) for thigh clusters A, B, C and D respectively. This indicates that marker clusters on the

**Figure 1** Hip axial rotation during gait as measured using the different thigh marker clusters for a typical subject.

**Figure 2** Estimated (thigh cluster) versus true (tibial markers) hip axial rotation during right-sided longitudinal rotation for a typical subject.

distal thigh were only capable of estimating, at best, up to 60% of the true magnitude of movement. When comparing the different clusters, the Helen Hayes convention (cluster A) was associated with the greatest degree of error. Clusters C and D produced near identical results. Thus, the addition of the thigh wand in cluster C had no measurable influence. Clusters C and D tended to produce hip axial rotation patterns during gait that were more systematic across subjects when compared to clusters A and B.

### CONCLUSIONS

The estimation of hip axial rotation was highly sensitive to thigh marker cluster design. Whilst none of the clusters were capable of satisfactorily estimating true bone movement, clusters C and D appear to be better alternatives than clusters A and B. Until further work provides a definitive solution, one must remain cautious when using estimates of hip axial rotation for purposes of research or clinical interpretation.

## COORDINATION CHANGE BETWEEN GAZE, HEAD AND HIP DUE TO EARLY EYE ROTATION DURING OPEN CUT MANEUVER

### INTRODUCTION

The integration of visuo-vestibular information achieved by eye-head synergy (vestibulo-ocular reflex), is presumed to play an important role in postural control, as it provides a frame of reference for a postural control system [1]. The frame of reference refers to the set of values to which each motor variable refers for planning their own movement. This hypothesis has been supported by previous data demonstrating that the eye-head rotation led to a change in the direction of gravito-inertial acceleration in curvilinear walking [2], or a trunk lateral rotation in a sudden direction change of locomotion (i.e., cutting maneuvers) [3]. However, previous studies have never confirmed that eye-head synergy solely integrates visuo-vestibular information and governs whole body movements.

Subsequently, we tested whether eye-head synergy occurs even when the gaze was experimentally constrained to rotate earlier than in a natural setting. If eye-head synergy exclusively acts to integrate visuo-vestibular information, an early rotation of the head would be emphasized, as it minimizes angular deviation between the eye and the head.

### METHODS

Five healthy graduate students were asked to walk a distance of 1.95 m with 2 steps, and cut into one of two directions (60 degrees to the left and right) or step straight ahead. The direction of cut is indicated by a semicircular array with a radius of 0.93 m consisting of 16 LEDs, which was placed at the subjects' eye level.

In the control condition (CNT), the subjects were instructed to start walking straight toward the center of the circular LED array and then step onto the right mat with a cross-over step when the right 8 LEDs placed at 0 to 90 degrees lateral to the approaching direction were turned on. The left 8 LEDs indicated that the subject should step onto the left mat with an open step, and the 8 center LEDs indicated that they should step straight ahead. The timing of the LEDs' onset was controlled by the (left) heel strike of the first approaching step. Eight trials were made for each direction in a randomized order.

To investigate the effects of compulsorily induced lateral gaze rotation, we conducted 24 additional trials for the EHR (eye-head rotation) condition, in which 2 of 8 LEDs located in the cutting direction (i.e., at 54 and 66 degrees) were turned on or off at 0 or 0.5 s after the LEDs' onset. The subjects were required to report when these 2 LEDs turned on or off (e.g., "At first, LEDs turned on (off) and then off (on)"; "remained on (off)"). The lateral rotation of the head, shoulder, and hip as well as that of the left eye during the left open cut maneuver was measured using 4 infrared cameras (ProReflex motion capture unit, Qualysis Medical, Sweden) and a video-based eye-mark recorder (EMR-8, Nac Image Tech., Japan) at a sampling rate of 60 Hz. The lateral angular displacement of

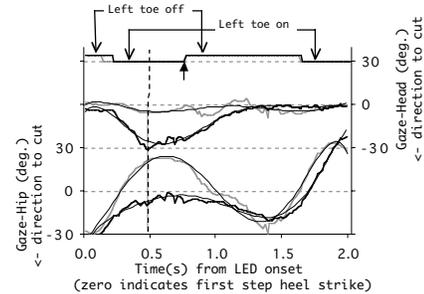

Figure 1: Deviation of angular displacement between Gaze-Head (middle) and Gaze-Hip (bottom) in CNT (gray) and EHR (black). Thin line on each plot represents a curve fit by a polynomial. Rectangular plot shown on top indicates the timing of left toe contact on the ground. Small upward arrow indicates the timing of the open step onset. Vertical broken line at 0.5 s indicates the timing on which 2 LEDs turned on or off. Mean of 8 trials performed by a typical subject.

the gaze was calculated by summing the lateral rotation of the eye in the orbit and that of the head in space.

### RESULTS AND DISCUSSION

In the EHR trials, the timing of the saccade onset was concentrated at 0.5 s after the LED onset in order to fixate on the 2 lighting LEDs placed in the cutting direction. The head rotation was not observed in this phase. The saccades in the CNT trials were immediately followed by head rotation, and the timing of those onsets ranged widely from 0.5 to 1.0 s after the LED onset. Thus, the manipulation undertaken in the EHR trials succeeded in guiding the earlier onset of saccade and disturbed eye-head synergy.

An angular deviation of the head relative to the gaze was kept approximately at 0 degree, that is, the eye-head synergy was maintained in every phase in the CNT trials, as reported in a previous study [2]. On the other hand, in the EHR trials, not the head, but the hip was aligned in the gaze direction when the eye fixated on the cutting direction at 0.5 s after the LED onset, following which the head rotated to align in the gaze direction (Figure 1). The results observed in the EHR trials indicate that not only eye-head but also gaze-hip coordination could be employed to integrate visuo-vestibular information.

These results suggest that it is also necessary to achieve the frame of reference for the open cut maneuver. Further, as suggested in a previous study about postural control [1], the strategy for this function is altered or compensated by body segments below the head due to the gaze constraint. We speculated that the earlier rotation of the head relative to the trunk presented in the previous analysis of cutting maneuvers [3] is a part of this dynamic nature of the mechanism to maintain a stable frame of reference.

### INTRODUCTION

The approach run and the takeoff in the long jump are important factors to determine the distance of the jump. Many studies on the approach or the takeoff in the long jump had been done. Recently, Omura et al. [2, 3] have focused on the characteristics of the step frequency, step length, support time, non-support time and visual control [1] during the approach run to investigate the effective approach run. They reported that Japanese junior long jumpers showed the unsteady step frequency during the approach run, and the longer non-support time during the last three or four steps compared to the Japanese top long jumpers. However, more studies are needed to discuss proper approach run for the junior long jumpers.

The purpose of this study was to investigate the approach run of Japanese junior long jumpers to obtain the fundamental findings on effective approach run and the takeoff.

### METHODS

Sixteen boy's long jumpers, with personal best records ranging from 7.17m to 7.87m, were filmed at the final of 2003 and 2004 Japan High School Track & Field Championships by the Biomechanical Project team of the Japan Amateur Athletic Federation. Two digital video cameras were used in this study. One camera was placed at the stands sideway to the runway, and filmed the whole of the steps of the approach (60f/s). All the trials of each jumper were analyzed using FRAME DIAS system (DKH Co., Japan), and calculated step length, step frequency, support time, non-support time. The visual control was calculated from standard deviation of the horizontal distance from the toe of the support foot to the front edge of the takeoff board (i.e. the toe-board distance) [1]. Another camera was placed at a distance of 20m perpendicular to the takeoff board, and filmed the jumpers from the 3<sup>rd</sup> last steps to takeoff (60f/s). The best performance of each jumper was analyzed, and the several joint angle & angular velocities were calculated. Approach velocities were measured with Laveg Sport (Henley Japan co., Japan)

### RESULTS AND DISCUSSION

The approach velocities of the top three jumpers (ranging from 10.3m/s to 10.4m/s) were higher than those of the other junior long jumpers. However, the values were lower than those of the Japanese top jumper (10.8m/s; 8m18) and the World's class jumper (Phillips; 11.0m/s, 8m31). Furthermore, most of the jumpers (including two of top three jumpers) decreased their approach velocities prior to the takeoff. From these results, Japanese junior long jumpers should improve their approach

velocity and the preparatory motion for the takeoff.

Hay[1] investigated how the elite long jumper use a visual control strategy, based on the data for the horizontal distance from the toe of the support foot to the front edge of the takeoff board (i.e. the toe-board distance).

As for the visual control in present study, the maximum value of the standard deviation was recorded from the 3<sup>rd</sup> last stride to the 12<sup>th</sup> last stride, and the maximum frequency was recorded at the 3<sup>rd</sup> last stride (five jumpers). Hay [1] revealed that the maximum value of the standard deviation was recorded from the 1<sup>st</sup> last stride to the 8<sup>th</sup> last stride, and the maximum frequency was recorded at the 5<sup>th</sup> last stride for the elite long jumpers. Such a difference between the Japanese junior jumpers and the elite long jumpers reported by Hay might be due to the difference of the physical ability, approach velocity, and the performance level. Hay [1] also established the standard value for assessment of the approach run. According to his study on the elite long jumper, the maximum standard deviation of 0.20m or less was classified as "very good", and that of 0.25m or more was classified as "poor". In this study, more than the half of the jumpers (nine of sixteen jumpers) showed the maximum standard deviation of 0.25m or more (poor), and the maximum value of the junior jumpers was 0.47 m. These results suggested that the approach run of the junior long jumpers were unstable; therefore they have to spend more time to improve and stabilize their approach run.

The peak angular velocities of the free leg during the takeoff for the top three junior jumpers were greater than those of other junior jumpers. And also, the peak angular velocity was observed at the similar phase for the elite long jumpers. These free leg movements for the top three junior jumpers might be effective to obtain the distance of jump. Therefore, it is conceivable that they had mastered the proper technique for the takeoff.

## DIFFERENCES IN CENTER OF PRESSURE MOVEMENT BETWEEN BOYS AND GIRLS DURING ONE-FOOTED LANDINGS

<sup>1,2</sup>Michelle Sabick, <sup>1</sup>Kristi Unholz, <sup>3</sup>Jeanie Sutter and <sup>1,3</sup>Ron Pfeiffer

<sup>1</sup>Center for Orthopaedic & Biomechanics Research, <sup>2</sup>Department of Mechanical Engineering,

 web: [coen.boisestate.edu/cobr](http://coen.boisestate.edu/cobr)

### INTRODUCTION

The effects of gender on lower extremity mechanics during landing have been studied extensively in adults, but little is known about landing mechanics in preadolescent populations. By studying landing strategies in preadolescent children, body morphology differences between the genders are essentially eliminated. Hass et al. [1] found that prepubescent females landed with their hips and knees more flexed than post-pubescent females. These results hint that age related morphology changes play a role in landing strategies, at least within female subjects.

Movement of the body's center of pressure (COP) is often used as a measurement of postural stability [2]. The purpose of this study was to determine whether gender in preadolescent soccer players affects postural stability during one-footed landings. To our knowledge, this is the first study to examine the effects of gender in any age group on postural stability during landing.

### METHODS

Twelve girls and 11 boys (10 - 12 years of age) were recruited from a local youth soccer league. Subjects dropped from a horizontal bar (net drop 30.5cm) landing barefoot on one leg. The test leg was randomized. The landing surface was a force platform sampling at 1250 Hz. Each subject performed 5 to 10 trials and the first five successful trials were analyzed.

The location of the center of pressure (COP) on the force platform was calculated using the equations provided by the manufacturer (Kistler) for a duration of 100 ms from the time of first contact with the force platform. Displacements and velocities of the COP in the anterior-posterior ( $D_{A-P}$ ,  $V_{A-P}$ ) and medial-lateral ( $D_{M-L}$ ,  $V_{M-L}$ ) directions, and the mean velocity of COP displacement ( $V_m$ ) were calculated [3]. Comparisons of kinetic variables between the two groups were made using two tailed Student's t-tests with an  $\alpha$  level of 0.05.

### RESULTS AND DISCUSSION

While age, height, and weight were not significantly different between groups, the COP displacement and velocity measures tended to be higher in the boys than in the girls (Table 1).

**Figure 1:** Comparison of COP paths in subjects with low  $V_m$  (left) and high  $V_m$  (right).

Displacement and velocity in the medial-lateral direction were significantly greater in the boys than in the girls.  $V_m$  was also significantly greater in the boys.

Higher values for displacement or velocity of the COP are considered evidence of postural instability [2]. Therefore, it appears that our group of boys were less stable during landing than the girls. Many subjects in both groups appeared to have a difficult time landing and balancing on one foot. Subjects that exhibited low  $V_m$  values tended to stabilize within the first 100 ms after contacting the force platform (Figure 1), while many subjects didn't stabilize within that time frame.

### CONCLUSIONS

It is not clear whether the boys exhibited greater postural instability during the first 100 ms after landing, or whether they were merely more comfortable using a larger proportion of their base of support. Qualitative evaluation of the COP curves suggested that fewer of the boys reached a stable position within 100 ms than did their female counterparts.

### INTRODUCTION

In order to understand and predict the onset of human head injury due to traumatic impact loads, there is a need to develop realistic constitutive relations so that the biomechanical response of the brain may be modeled more accurately. Although brain tissue is rather complex, possessing both fluid- and solid-like properties, it is common to find simple linear elastic or viscoelastic models in applications such as the simulation of neurosurgery. These models are, however, inadequate in many dynamic impact situations such as automobile accidents, where large strains are often encountered. For example, Bain and Meaney<sup>1</sup> have proposed a threshold strain criterion of nearly 0.21 for axonal injury by comparing morphological injury and electrophysiological impairment to estimated tissue strains. Trosseille *et al.*<sup>2</sup> found that a strain above 0.15 would result in irreversible brain injury and a strain above 0.2 could be fatal. These injury criteria are clearly beyond the linear elastic limit, usually taken to be about 1% strain (Brands *et al.*<sup>3</sup>). Therefore nonlinear viscoelastic models must be used for brain injury modeling and prediction.

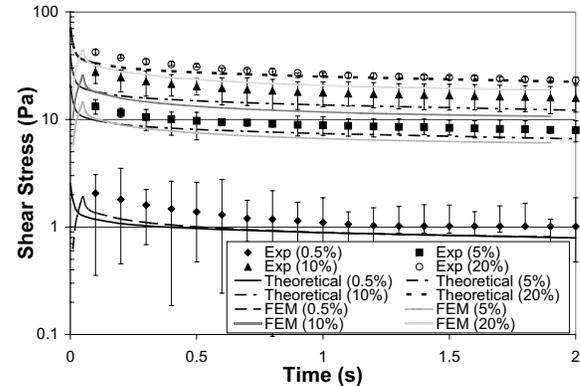

In this paper, a non-linear model first proposed by Bilston *et al.*<sup>4</sup> is modified and implemented into a commercial finite element (FE) code. To obtain the required model parameters, rheological tests on mechanical properties of brain tissue are performed.

### MODELING, TESTING AND IMPLEMENTATION

The proposed 3-dimensional constitutive model consists of three parts: the volumetric, deviatoric and viscoelastic stress components. The long-term elastic stress is modeled by the Mooney-Rivlin rubber model, which is commonly used for hyperelastic materials under large deformation. The upper convected multi-mode Maxwell model is used for the computation of the viscoelastic stresses. The deviatoric stress terms are further modified by a damping function, which is a function of strain invariants.

The parameters in the constitutive model are determined by performing various rheological experiments such as small strain oscillation tests, shear relaxation tests, and compression tests. Porcine brain tissue samples are tested by means of a conventional stress-controlled MCR 300 Paar-Physica rheometer. Furthermore, oscillatory shear tests (both strain and frequency sweeps) and relaxation tests are performed for material property characterization.

We further implemented the 3-dimensional nonlinear constitutive model into the multi-purpose commercial explicit FE code PamCrash. The user-defined material model MAT80

**Figure 1:** Shear relaxation: comparison between theoretical prediction, FE simulation and experiment

was used in the program. Simulation of the shear relaxation test is performed.

### RESULTS AND DISCUSSION

Based on small strain oscillation test, a 12-mode Maxwell model is obtained by curve-fitting procedure. By applying Time-Temperature Superposition principle, the frequency regime is extended to 6 decades ( $\omega=10^{-2}\sim 10^4$ rad/s). Shear relaxation tests with different amplitudes of shear strain are performed. A comparison between theoretical and numerical predictions and shear stress relaxation experiment is shown in Figure 1. Good agreement can be observed. Theoretical predictions are within the error bars up to a strain of 20%. Numerical predictions are slightly lower, about 20% lower than the averaged values for large strain case (20%).

### CONCLUSION

A 3-dimensional nonlinear viscoelastic constitutive model for brain tissue is proposed and implemented into commercial FE code successfully. The predicted mechanical response of the brain tissue by the FE method show good agreement with shear stress relaxation test data. Combined with a proper head FE model, it is expected that the proposed brain tissue model can be used for head injury analysis.

### INTRODUCTION

Many bioactive bone cements were developed for total hip replacement, and found to bond with bone directly [1,2]. However, the mechanical properties at the bone/bone cement interface are not fully understood. The aim of the present study was to investigate the interfacial mechanical and morphological properties of newly formed tissue by nanoindentation and microscopic analysis.

### METHODS

Unilateral hip replacement was performed with Sr-HA cement in rabbits. Six months later, the femurs were removed and cut into parallel sections. Observations were taken at the interface of Sr-HA cement and cancellous bone for metaphyseal sections and interface of Sr-HA cement and cortical bone at diaphyseal sections.

### RESULTS AND DISCUSSION

For the interface between Sr-HA cement and cancellous bone, osseointegration was widespread. Many multinucleus cells covered the surface of the cement, and resorbed the superficial layer of the cement. New bone infiltrated into Sr-HA cement. An interface with a thickness of about 10  $\mu\text{m}$  was found covered on the Sr-HA cement by scanning electron microscopy (SEM). By nanoindentation testing, sharp increase was found at the interface in terms of Young's modulus and hardness (Figure 1).

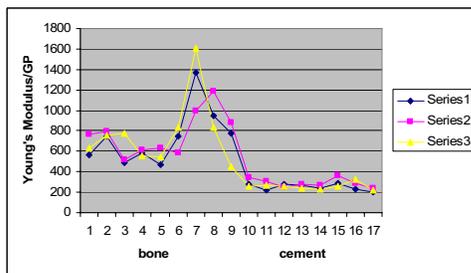

Figure 1: Young's modulus of cancellous bone, interface and Sr-HA cement. The peak was at the interface.

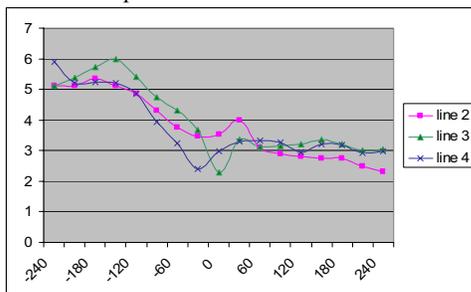

Figure 2: Young's modulus of cortical bone, interface and Sr-HA cement. A smooth transition was found.

As for the interface between Sr-HA cement and cortical bone, intimate contact was observed without fibrous layer intervening by histological and SEM observations. Nanoindentation test showed that, in terms of Young's modulus and hardness, a smooth transition was observed from bone, interface, to Sr-HA cement (Figure 2).

The cement/bone interface is crucial to the stability of the cemented femoral component. However, its mechanical property is far from full understanding because traditional mechanical tests, such as bend testing and compression testing, are not suitable due to specimen size requirements. Fortunately, nanoindentation may offer valuable information about intrinsic mechanical properties, and has been used to evaluate mechanical properties near the implant/bone interface [3].

In the present study, nanoindentation test showed that the Young's modulus and hardness at the interface were higher than those at the Sr-HA cement and cancellous bone. This was further supported by the histological observation. Osseointegration of Sr-HA cement with cancellous was widespread, which is similar to calcium phosphate cement [4]. Fujita et al found that the bone/cement interface was the weakest point mechanically for the cemented femoral component when a bioactive bone cement consisting of glass powder and Bis-GMA based resin was used in canine total hip arthroplasty [2]. The impregnated ceramic particles which are incompatible with the acrylic cement matrices might be blamed.

Different mechanical properties between cement/cancellous bone interface and cement/cortical bone interface may be explained by the different response of Sr-HA cement to cancellous bone and cortical bone. Further study is needed to explore the way in which the Sr-HA cement bonds with cortical bone.

### CONCLUSIONS

Under weight-bearing conditions, intimate contact was found between Sr-HA cement with both cancellous and cortical bone. The stable interface was further proven by nanoindentation. Sr-HA cement has potential to be an alternative to the conventional bone cement in total hip replacement.

### INTRODUCTION

Posture describes body position in space, and the proper control keeps the center of pressure (COP) within the base of support. Most studies investigated the posture control in normal subjects [1]. There is lack of studies concerning the postural control in spinal cord injured subjects (SCI) who may lose balance without support [2]. The purpose of this study was to compare the postural sway, joint angles and postural muscle activities in complete and nearly complete SCI who had to wear knee-ankle-foot orthosis (KAFO) during stance with and without support.

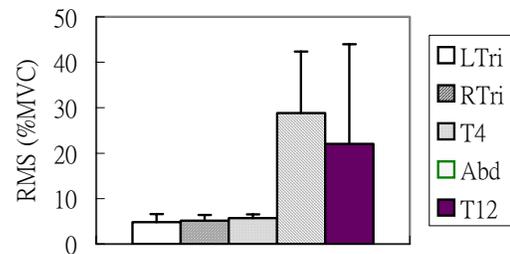

### METHODS

The inclusive criteria of this study were SCI who had to wear the KAFO for standing, and would lose balance less than 5 seconds without support. Seven complete and nearly complete mid-low thoracic cord (T6-T12) injured SCI with mean age of 38.6 years old participated in this study. The duration of injury was  $94.4 \pm 79.2$  months. Participants performed standing with each leg on separate force plate (AMTI, USA) for 5 seconds while holding the bars, then released holding until lost balance. Surface electrodes recorded the electromyographic activities (EMG) of trunk muscles and triceps. The joint angles were recorded by 3-D Motion Analysis System (Vicon 250, Oxford, UK). The Wilcoxon signed ranks test was performed to compare the differences in subjects with and without holding.  $p < 0.05$  was considered statistically significant.

### RESULTS AND DISCUSSION

All the subjects lost the balance within 3 seconds after releasing the hands from the bars. As shown in Table 1, the sway path and sway area are significantly increased in subjects without holding ( $p < 0.05$ ). Compared with holding, the hip angle is less hyperextended at the time starting to lose balance, but the pelvis remains to be posterior tilt. The ankle angle between the neutral line and the line from ankle to greater trochanter is reduced at the time starting to lose balance, although it is not statistically significant (Table 1). During standing with holding, the EMG activities of right and

left triceps recruit  $4.8 \pm 1.8\%$ , and  $5.1 \pm 1.3\%$  of maximal voluntary contractions (Figure 1). The EMG of abdominal and T12 paraspinal muscles seem to recruit more during standing with and without holding. However, the voluntary contractions of abdominal and T12 paraspinal muscles are low, so that the supporting effect of those muscles would be small.

**Figure 1.** The root mean square (RMS, % maximal voluntary contraction) of triceps and trunk muscle electromyographic activities.

### CONCLUSIONS

The postural control in complete SCI depends not only the mechanical alignment of pelvis and other joints, but also on the postural muscle activities [3]. The training of proper alignment of joints and the strength of residual muscles would be important for fall prevention. The anticipatory effect of muscle recruitment needs further study.

The relation of the trunk-pelvic movement and lower extremity joint moment on elderly people during the sit-to-stand motion

<sup>1</sup> Masaya Anan, <sup>1,2</sup> Nobuhiro Kito and <sup>2</sup> Koichi Shinkoda

<sup>1</sup> Kawashima Orthopedic Hospital, <sup>2</sup> Division of Physical Therapy and Occupational Therapy Sciences, Graduate School of Health Sciences, Hiroshima University; e-mail: an\_an0219@ybb.ne.jp

**INTRODUCTION**

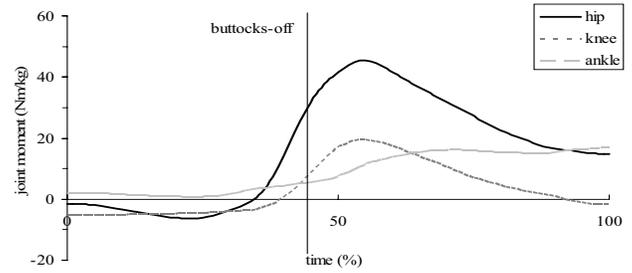

The sit-to-stand motion (STS) is one of the most frequently executed activities although it poses a high risk of falling in elderly. It can be said that an important factor essential to improving movement ability is related to the acquisition of STS during practical activities such as transferring and walking. The purpose of this study was to create a physical therapy strategy related to properly supporting oneself during STS by making a clear relationship between trunk-pelvis movement and lower extremity joint moment.

**METHODS**

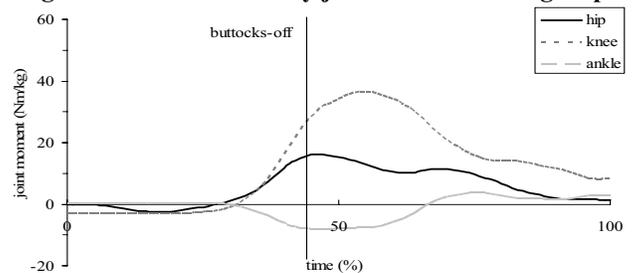

Fourteen elderly subjects (mean age 82.1) with no prior history of CNS-related diseases were recruited for this study. All subjects were able to perform STS without using their arms when the height of the chair equaled the length of their lower leg. Markers were placed on various parts of the body (top of head, tragus, acromion, lowest rib, ASIS, PSIS, great trochanter, lateral knee joint line, lateral malleolus, calcaneal tuberosity, and tip of toe). The movements of the markers on the sagittal plane were taken by a digital video camera (Sanyo, KDR2004) at 30 frames/s, and processed using a picture analysis software (NIH Image). By looking at the data points, the center of gravity (COG) and joint angles were calculated. The center of pressure of the buttocks and foot, and the vertical floor reaction force were measured at a frequency of 30Hz, using 2 force plates. This data was synchronized using an optical stimulus, and the time series behavior of the hip, knee, and ankle joint moments were measured.

**RESULTS AND DISCUSSION**

Eleven elderly subjects used the predominant hip extension moment during STS, while the other 3 subjects used the predominant knee extension moment from buttocks-off to motion termination. Here, we designated the former subject group as H, and the latter subject group as K. Comparison of the H and K-groups during STS was performed using Mann-Whitney's U Test. In comparison to the H-group, the total STS time of the K-group had a tendency to be longer (p=0.06), while the maximum horizontal velocity and anterior pelvic

**Figure 1: Lower extremity joint moment in H-group.**

**Figure 2: Lower extremity joint moment in K-group.**

tilting angle at buttocks-off had a tendency to become smaller (p=0.06, p=0.07). Hip flexion angle and knee extension moment at buttocks-off were significantly larger (p<0.05). Hip extension moment and ankle flexion moment at buttocks-off were also significantly smaller (p<0.05). The data results show that the K-group is unable to use the kinetic energy of the trunk at the hip during STS, but rather uses the motion of the predominant knee extension moment. Specifically, the pelvic movement had an effect on the lower extremity joint moment. It is suggested that during smaller pelvic anteversion STS, the kinetic chain between the pelvic and lower extremity movement is easily broken, and therefore knee extension moment predominates after buttocks-off.

**CONCLUSION**

In order to make a practical physical therapy strategy for STS, it is necessary to facilitate not only lower extremity extensor muscle strength, but also the kinetics chain which links the pelvic and lower extremity movement.

**Table 1: Comparison of H and K-groups**

		H-group (n=11)	K-group (n=3)	
Total STS time(s)		2.38 ± 0.53	3.16 ± 0.68	
Maximum velocity (cm/s)	Horizontal	47.9 ± 10.0	33.8 ± 10.7	
Joint angles at the buttocks off (deg)	Pelvis	26.9 ± 8.7	14.9 ± 11.0

## OPTIMAL STRATEGY OF CANE USE DURING STAIR ASCENT

Bih-Jen Hsue, Fong-Chin Su

Institute of Biomechanical Engineering, National Cheng Kung University, Tainan, Taiwan  
 email: [fcsu@mail.ncku.edu.tw](mailto:fcsu@mail.ncku.edu.tw)

### INTRODUCTION

Going up and down stairs require strength, range of motion, balance, and coordination, therefore, presents a challenge for the elderly and individuals with disability, and assistive devices may be needed. Therapists and clinicians usually have several approaches for teaching stair locomotion while using an assistive device, i.e. a cane would be for the patient with pain at the lower extremity to start with the stronger leg first followed by the weaker leg and the cane [1]. Some therapist may alter this traditional approach by having the patient progress the cane first, then the stronger leg and weaker leg. However, there is no document in the literature supporting these techniques. The purpose of this study was to compare the effect of placement of a quadricane (four-point cane) during stair ascent on body posture, center of mass (COM), and joint position. The change in the COM and relative orientation of the trunk were examined during five methods: (1) ascending stairs without a cane with right foot stepped up first, then left foot; (2) forward placement of the quadricane at the initiation of stair ascent followed by the ipsilateral foot (ipsilateral to the cane), then contralateral foot (SA1); (3) forward placement of the cane followed by the contralateral, then ipsilateral foot (SA2); (4) lateral placement of the cane with ipsilateral foot stepping up, followed by the contra-lateral foot and the cane (SA3); (5) lateral placement of the cane with contra-lateral foot stepped up, followed by the ipsilateral foot and cane (SA4). All conditions were associated with step-to (non-reciprocal) walking pattern.

### METHODS

A five-step wood staircase with a slope of 32.7°, a step height of 18 cm, a tread depth of 28 cm and a width of 90cm was used. Fifteen able-bodied participants in good general health aged from 24 to 30 years old were enrolled. Twenty-five reflective markers were secured to the participant's anatomical landmarks locating on the both sides of the body. An eight-camera Eagle Motion Analysis System (Motion Analysis Corporation, Santa, CA, USA) was used to capture the three-dimensional trajectory data of the markers.

The quadricane was adjusted to ensure that the handgrip was at the height level between the participant's wrist crease and greater trochanter. The participants were asked to ascend stairs with each of the five methods for three times in random orders. One gait cycle was completed as the three weight-bearing points (both legs and cane) were progressed from a tread to another tread one step above. The data were smoothed and normalized to stride period of 100% in one gait cycle. The data was analyzed utilizing repeated measures analysis of variance (ANOVA) at the 0.05 level of significance.

### RESULTS AND DISCUSSION

The maximal range of motion of the trunk, hip, knee and ankle from neutral position were list in Table 1. Trunk movements,

including flexion, rotation and side-bending are significantly larger in lateral placement of cane, especially in SA4. It agrees with the clinical adaptation to prevent fall from lack of shoulder and trunk extension and the desire to keep the COM anteriorly. The leading leg always demonstrates more hip and knee flexion, and less ankle plantarflexion, no matter what the placement of cane is. As observing the excursions of the joint movement in a stride, some double peaks of the movement at the hip and knee joints of the leading leg in SA3 and SA4.

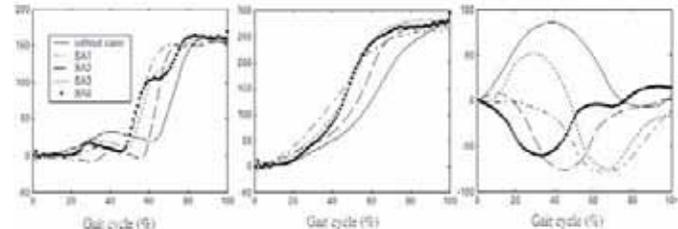

**Table 1:** Mean and standard deviation of maximal flexion in degrees of the trunk, hip, knee and ankle in sagittal plane

	No cane	SA1	SA2	SA3	SA4
Trunk	8.0 (2.4)	8.3 (2.3)	7.7 (2.2)	9.1(2.5)	10.9(3.2)
I.Hip*	57.9(4.3)	58.8(5.1)	27.8(7.0)	52.1(13.8)	36.8(7.4)
C.Hip *	27.7(4.7)	27.5(5.2)	58.7(4.6)	30.6(9.2)	56.8(5.1)
I.Knee	79.2(4.2)	80.2(4.1)	56.5(10.4)	73.8(19.5)	69.9(8.4)
C.Knee	55.6(5.6)	54.8(5.4)	77.1(5.3)	62.2(16.7)	79.5(5.0)
I.Ankle**	25.5(5.7)	23.8(4.5)	37.8(6.6)	21.8(6.0)	32.6(5.8)
C.Ankle**	38.6(6.6)	39.2(5.1)	22.54(3.6)	35.3(9.8)	23.4(3.8)

\* I: the ipsilateral side; C: the contralateral side

\*\* Degrees of maximal plantarflexion

The excursions of COM displacement in three directions are shown in Figure 1. Significant differences are found in the excursion and maximal medial-lateral COM displacement among five methods.

**Figure 1:** The plot at the left is the COM displacement (in mini-meter) in vertical direction, the plot at the middle is COM displacement in forward-backward direction, and the plot at the right is the COM displacement in medial-lateral direction.

### CONCLUSIONS

In order to find an optimal strategy for stair walking while using a cane, not only causes of the disability, i.e. instability or pain at the leg, should be considered, but also the proximal control, such as how to progress with COM within a small base of support and maintain an unavoidable asymmetry posture etc.

## RELATIONSHIP BETWEEN MOMENT-JOINT ANGLE CHARACTERISTICS OF KNEE FLEXION AND ARCHITECTURE OF HAMSTRINGS MUSCLES IN HUMAN

<sup>1,2</sup> Hiroshi Arakawa, <sup>2</sup> Akinori Nagano and <sup>1</sup> Senshi Fukashiro

<sup>1</sup> Department of Life Sciences (Sports Sciences), The University of Tokyo, Japan

<sup>2</sup> Computational Biomechanics Unit, Riken, Japan

### INTRODUCTION

There have been few biomechanical studies that tried to investigate individual variations of human musculoskeletal parameters, e.g., moment of inertia or ratio of fascicle-tendon structure length. Additionally, many synergist muscles that have different moment arm one by one have often been analyzed as a single muscle. However, we need to pay more attention to musculoskeletal differences among individuals, which have a possibility to result in different characteristics of force generation and moment-joint angle relationship. The purpose of this study was to investigate how individual variations of architecture of hamstrings muscle tendon complex, which are agonists of knee flexion, influence moment-joint angle relationship.

### METHODS

Ten healthy males (age,  $26.4 \pm 2.9$  yrs; height,  $174.5 \pm 5.0$  cm; mass,  $72.0 \pm 6.0$  kg) participated in this study. A dynamometer (MYORET RZ-450: Kawasaki, Japan) was used to measure isokinetic knee flexion moment. All measurements were performed from the left leg. We measured three maximal-effort voluntary contractions at 30 degree/sec, with different hip joint angles. Subjects were tested at 0 and 90 degrees of hip flexion (Figure 1). We firmly fixed subject's thigh and trunk on the apparatus with straps so that their body did not move while testing. Each testing was performed with sufficient rest. We measured subject's muscle architectural property using ultrasonography. Muscle thickness was measured by B-mode ultrasonography (SSD-2200, Aloka, Japan) at two sites, i.e., posterior thigh at 40% (upper thigh) and 70% (lower thigh) of the thigh length (Figure 2).

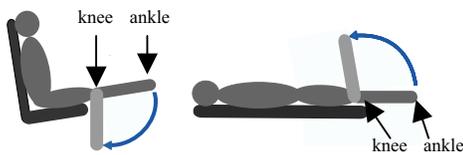

Figure 1: Experimental positions.

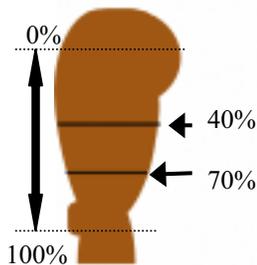

Figure 2: This picture shows the point we measured in muscle thickness measurement. One is 40% of the thigh length (upper thigh), and the other is 70% (lower thigh).

### RESULT AND DISCUSSION

Figure 3 shows the relationships between the ratio of the upper and lower thigh thickness and the ratio of the knee flexion moment at 0 and 90 degrees of hip flexion. In both cases, the knee flexion angles are at 30 degrees. It was found that subjects whose relative muscle thickness of upper thigh is larger tended to be able to generate larger relative strength when the hip flexion angle is 90 degrees. And there was a significant correlation between the ratio of the upper and lower thigh thickness and the ratio of the knee flexion moment at 0 and 90 degrees of hip flexion ( $R=0.828$   $p<0.01$ ). Several studies have focused on relationship between sprint performance and thigh muscle thickness of upper and lower parts [1,2]. There remains some uncertainty whether the ultrasonography data obtained from skin surface have enough accuracy to address individual differences. Currently we are proceeding with examination using MRI to obtain more reliable architectural data of hamstrings.

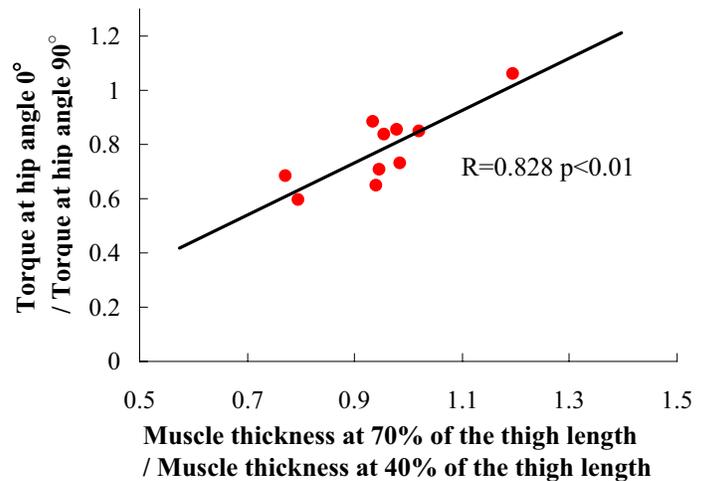

Figure 3: The relationships between the ratio of the upper and lower thigh thickness and the ratio of the knee flexion moment at 0 and 90 degrees of hip flexion. Both of knee flexion angles were at 45 degrees.

### CONCLUSIONS

It is likely that differences among individuals in the architecture of hamstrings muscles result in differences of moment-hip angle relationship of their knee flexion.

**INTRODUCTION**

Numerous surgical techniques have been proposed to manage the femoral neck shortening and the greater trochanter overgrowth secondary to retarded growth of the femoral capital epiphysis but with little success [1]. For the reconstruction of residual deformities of the hip, Papavasiliou et al. performed a new type of proximal femur L-osteotomy with hip spica casts, and achieved good results [2]. Although the results were good with this osteotomy, a thorough understanding and study of the biomechanical characteristics will be helpful to improve the technique and aid in preoperative planning. A three dimensional finite element analysis was thus designed to understand the mechanical characteristics of postoperative femur after L-osteotomy.

**METHODS**

A patient with left hip dysplasia was recruited as the study model of L-osteotomy. The normal right hip was used as a guide to perform the corrective surgery. The length and the angle of the intersected line between the femoral head center and the most superior point of the greater trochanter in the normal right femur were considered as the final resultant configuration postoperatively (Figure 1). C-T images were used to create the 3-D finite element models. Four FEA models with the same longitudinal length of osteotomy (126mm) but different fixation screw configurations (P2/D2, P2/D3, P3/D2, P3/D3, P: Proximal fixation; D: Distal fixation) together with four FEA models with the same fixation screw number (P3/D2) but different longitudinal length of osteotomy (116, 126, 136 and 146mm) were created. Analysis was performed on a loading condition simulating single legged stance. The von Mises stress distributions of postoperative femora and displacements of the femoral head were analyzed and compared.

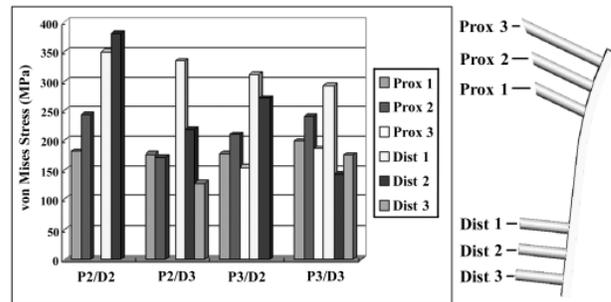

**Figure 1:** (a) normal right femur, (b) left femur with residual deformity, and (c) resultant configuration after L-osteotomy.

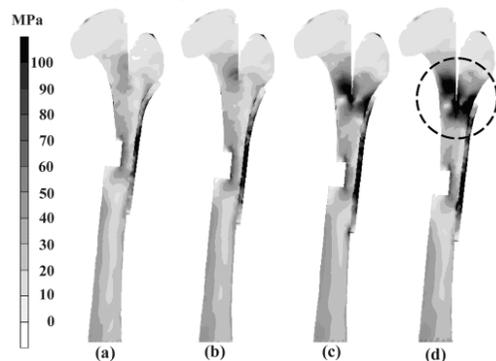

**RESULTS AND DISCUSSION**

This study achieved the following findings: A). The fixation devices (plate and screws) sustained most of the external loading, the peak value of von Mises stress on the fixation screws decreased with increasing screw number (Figure 2). B). More screws placement on the proximal segment would be more beneficial to improve the postoperative stability as compared to

that on the distal segment. C). The extent of osteotomy should be limited because a high local stress concentration might occur around the femoral neck regions with increasing longitudinal length of L-osteotomy (Figure 3).

**Figure 2:** Peak value of Von Mises stress on fixation screws for femora instrumented with four different configurations of screw placement but at the same longitudinal length of osteotomy (126mm). The peak stress of screws increased with decreasing screw number, and the highest value was found on the most distal screw (D2) on condition that the femur was instrumented with four screws (P2/D2).

**Figure 3:** Von Mises stress for femora instrumented with four different longitudinal lengths of osteotomy but the same screw number (P3/D2). (a) 116mm, (b) 126mm, (c) 136mm and (d) 146mm. The von Mises stress around the femoral neck regions progressively increased as the longitudinal length of osteotomy increase from 116 mm to 146 mm.

**CONCLUSIONS**

The results indicate that the more screws placement on the proximal segment the more the stability improvement in the postoperative femur. Therefore, the cobra type plate with more screw holes on the proximal part might be a good alternative for the L-osteotomy.

### INTRODUCTION

The development of personalized numerical models of the human being requires a deep knowledge of the human body geometry. Several studies have been performed on the external [1] or on the internal geometry of body parts [2]. As far as the statistical relationships between external and internal geometries are concerned, most studies focused only on the relationships between stature and specific bone dimensions as the length of long bones [3]. The aim of this study is to obtain linear statistical models for estimating internal (trunk bones) and external (full body) human body geometry from a small number of body measurements.

### METHODS

The geometrical data used in this work were obtained by combining internal and external measurements performed on 64 healthy adults (20-55 yrs old, 30 yrs on avg.) representative of three morphotypes (16 5<sup>th</sup> percentile female subjects, 33 50<sup>th</sup> and 15 95<sup>th</sup> percentile male subjects) collected by *Bertrand et al.* [4]. The data were analysed using the R statistical environment. The different steps of the statistical analysis are listed hereafter :

- 1- Agglomerative Hierarchical Clustering of the measured parameters based on the linear correlation coefficient ;
- 2- Identification of clusters of linearly dependent parameters ;
- 3- Identification of Isolated Parameters (IP) corresponding to clusters of size 1 ;
- 4- Selection of a subset of explanatory parameter(s) (Main Parameters, MP) in each cluster ;
- 5- Estimation of simple linear regression models in order to explain every non-MP parameters in a cluster (Secondary Parameters, SP) by the MP of the cluster.

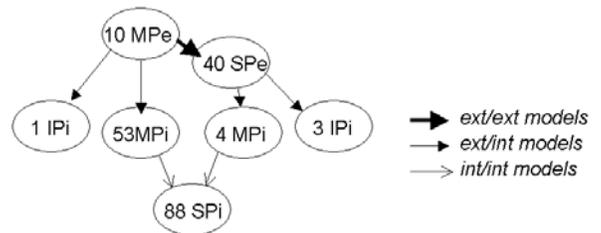

This procedure was separately applied on external and on subgroups of internal data obtained by regrouping measured parameters belonging to the same anatomical group (i.e. : rib cage, cervical spine, thoracic spine, lumbar spine, pelvis). Thus, external/external and internal/internal anthropometrical models were obtained. Then, the procedure was applied on the whole external parameters associated with internal MP (MP<sub>i</sub>) and internal IP (IP<sub>i</sub>) in order to determine external/internal models, thereby enabling the prediction of MP<sub>i</sub> and IP<sub>i</sub> from external parameters (Figure 1).

**Table 1:** Examples of ext/ext, int/int and ext/int models. The table contains for each the intercept, the regression coefficient, and its standard error in mm and in % (explained parameter (mm) = coef x explanatory parameter (mm or kg) + intercept ± 2·SEE(mm) ).

Explained parameters	Explanatory parameters	R <sup>2</sup>	constant	coef.	2·S.E.E. (mm)	2·S.E.E. (%)
eves-ground height (standing position) (SP <sub>e</sub> )	height (MP <sub>e</sub> )	0.99	-42.4	0.96	16	1.0
Arm upper circumference (SP <sub>e</sub> )	weight (MP <sub>e</sub> )	0.91	141.2	2.28	26	8.4
height of the right half of the pelvis (MP <sub>i</sub> )	acromion -ground height (standing position) (MP <sub>e</sub> )	0.83	-3.5	0.15	14	6.4
height of the left half of the pelvis (SP <sub>i</sub> )	height of the right half of the pelvis (MP <sub>i</sub> )	0.94	-7.8	1.05	9	4.2
inferior width of the vertebral body of L2 (MP <sub>i</sub> )	height (MP <sub>e</sub> )	0.66	-15.9	0.04	6	12.3
superior width of the vertebral body of L2 (SP <sub>i</sub> )	inferior width of the vertebral body of L2 (MP <sub>i</sub> )	0.87	0.4	0.94	3	8.0

### RESULTS AND DISCUSSION

The present statistical analysis proposes 189 anthropometrical models (Figure 1, Table 1) enabling to estimate personalized external and internal geometry from 10 external measurements that can be easily measured on any subject : height, acromion-ground height, iliac crest-ground height, sitting height, chest axillary circumference, head (glabella-occiput) circumference, low pelvic circumference, thigh bottom circumference, greatest forearm circumference, weight. The quality of the regressions was evaluated by the Standard Error of Estimate (SEE), with 2·SEE giving the 95% of errors. Among the 189 models estimated 117 had a 2·SEE≤10% (34 ext/ext, 72 int/int, and 11 ext/int models).

**Figure 1:** Organigram of MP<sub>i</sub>, SP<sub>e</sub>, SP<sub>i</sub>, IP<sub>i</sub> estimation from the MP<sub>e</sub> (e: external ; i: internal).

### CONCLUSIONS

Numerous anthropometrical ext/ext (n=40), int/int (n=88), and ext/int (n=61) models were estimated and studied in this work. In particular, 11 external/internal models with 2·SEE≤10% were found, enabling the estimation of internal trunk dimensions from external body measurements. It brings a deeper knowledge on human morphology and opens the way for wide applications (human model personalisation for crash-test simulation, planning of clinical interventions...).

<sup>3</sup>Department of Computer Engineering and Information Technology, City University of Hong Kong

### INTRODUCTION

It is widely recognized that computer modeling and simulation provide valuable contributions to the research of biomechanics. Using forward dynamic computer simulation, it is possible to predict influences of such biomechanical interventions as injury, surgical operations, strength training and so on in quantitative terms.

However, it is also true that the methodology of computer modeling and simulation has not been utilized handily by all researchers / research groups who are interested in using it. One of the reasons is that the procedure of modeling requires very complex technical treatments. Although there are several commercial software packages to help this procedure, even with the aid of these tools, this methodology is not being conveniently utilized by many researchers. This is disadvantageous for the whole society as high-impact contributions can be made by many researchers if this methodology is utilized by more researchers in biomechanics.

We thought that it would be meaningful to present a code (computer program) of a human whole body model to the society of biomechanics for further development of this field. By simply copying the code, interested researchers can easily run a computer simulation. The purpose of this study was to present a three-dimensional linked segment model of the human skeletal system that has large degrees of freedom.

### METHODS

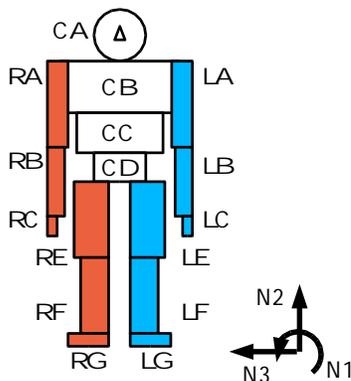

Figure 1: The skeletal model developed in this study.

The model was coded to be processed with a modeling and simulation tool AUTOLEV [1]. The code will be posted on the internet for public access by the time of conference. The model has sixteen rigid body segments in total: head, chest, mid-trunk, lower-trunk, right and left upper arms, right and left lower arms, right and left hands, right and left upper legs,

right and left lower legs, right and left feet (Figure 1). The degrees of freedom of the model was thirty-five. Anthropological parameter values were derived from [2-4].

For an example, a hanging motion was simulated using this model. The body was tilted in the forward direction by 45 deg. The upper endpoint of the head segment was fixed in the global coordinate system. Thereafter, a hanging motion was simulated in which the whole body swayed back and forth with an effect of the pull of gravity.

### RESULTS AND DISCUSSION

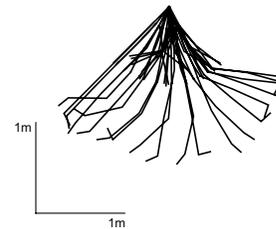

Figure 2: The hanging motion simulated in this study.

It was shown that the code developed in this project can be utilized for simulation of human whole body motions (Figure 2, hanging motion). The following four factors need to be taken into account to simulate a wider range of phenomena that researchers in biomechanics are interested in. Those four major factors are: (1) muscles, (2) ground reaction forces, (3) detailed joint motions and (4) addition or removal of segments. Currently we are trying to address these points utilizing built-in functions of AUTOLEV, and making a steady progress.

## DO OVERWEIGHT AND OBESITY AFFECT DYNAMIC PLANTAR PRESSURE DISTRIBUTIONS IN PRE-SCHOOL CHILDREN?

Karen J Mickle, Julie R Steele and Bridget J Munro  
Biomechanics Research Laboratory, University of Wollongong, Australia;  
Email: kjm06@uow.edu.au

### INTRODUCTION

It has been speculated that foot pain caused by high plantar pressures generated during walking may decrease a child's desire to participate in physical activity and, in turn, perpetuate the cycle of obesity. Although obese primary school children have been found to generate higher plantar pressures when walking compared to their leaner counterparts [1], it is not known whether younger overweight and obese children also generate these potentially negative higher pressures. Therefore, the purpose of this study was to determine the effects of overweight and obesity on plantar pressures generated by pre-school children during gait.

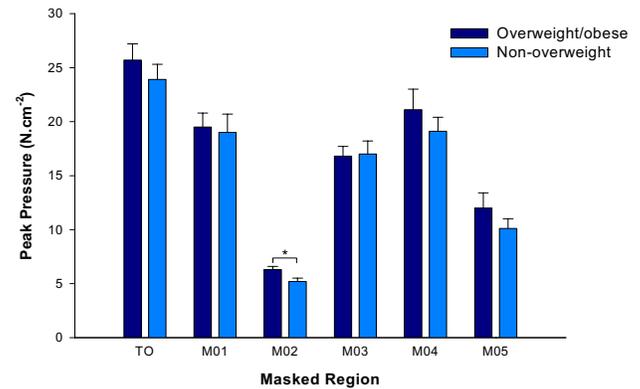

### METHODS

The height and mass of 86 consenting children (mean age =  $4.2 \pm 0.6$  years) from 10 randomly selected pre-schools in the Illawarra region of New South Wales, Australia, were measured following standard procedures. Each child walked across an emed AT-4 pressure platform (25 Hz; Novel<sub>gmbh</sub>, Munich) using the first-step method, with up to 6 successful trials being collected on each child's left and right foot. A subset of 17 overweight/obese children (BMI =  $18.5 \pm 1.2$  kg.m<sup>-2</sup>) were then identified from the sample and matched for height, age and gender with 17 non-overweight children (BMI =  $15.7 \pm 0.6$  kg.m<sup>-2</sup>).

Peak plantar pressures (N.cm<sup>-2</sup>), maximum force (N), contact area (cm<sup>2</sup>), force-time integrals (N.s) and pressure-time integrals (N.s.cm<sup>-2</sup>) were then derived for five regions of each child's feet, averaged across all trials. Independent *t*-tests were then applied to the data to determine whether there were any significant differences ( $p < 0.05$ ) in the plantar pressure variables between the two subject groups.

### RESULTS AND DISCUSSION

The overweight/obese children had significantly larger contact areas between the total foot (TO), heel (M01), midfoot (M02) and forefoot (M03) and the ground when walking, compared to the non-overweight children. The overweight/obese children also generated significantly larger forces in the total foot, heel, midfoot and forefoot regions of the foot when walking. This was to be expected, as heavier children should generate greater forces than their leaner counterparts. Despite generating the higher forces over larger contact areas, the overweight/obese children displayed significantly higher peak pressures (Figure 1), force-time integrals and pressure-time

**Figure 1:** Means (+ SEM) of the peak pressures generated in each masked region of the foot, displayed by the overweight/obese and non-overweight children. \* indicates a significant difference between the two subject groups.

integrals in the midfoot region of the foot (M02), compared to the non-overweight children.

### CONCLUSIONS

These results imply that the additional contact area displayed by these overweight/obese pre-school children in the midfoot area of the foot was not able to compensate for the high forces generated in that area of the foot during walking, resulting in higher pressures under the midfoot. As force-time and pressure-time integrals provide an indication of the load imparted on particular bony and soft tissue structures in the foot, these results suggest that the midfoot area of these overweight/obese young pre-school children may be exposed to increased stress and, in turn, vulnerable to bony fatigue and soft tissue damage. It is postulated that these changes may be exacerbated if excess weight bearing continues throughout childhood and into adulthood. Therefore, urgent interventions, appropriate to the structural and functional needs of very young overweight and obese children, are required to prevent further weight gain and structural and functional complications to the feet.

**THE INFLUENCE OF THE FIREMEN BOOTS ON THE HEEL STRIKE TRANSIENT DURING WALKING**

<sup>1</sup>Cámara Tobalina Jesús, <sup>2</sup>Begoña Gavilanes  
<sup>1</sup>e-mail: [txus@libreriacamara.com](mailto:txus@libreriacamara.com)  
<sup>2</sup>Instituto Vasco de Educación Física, web: [www.shee-ivef.com](http://www.shee-ivef.com)

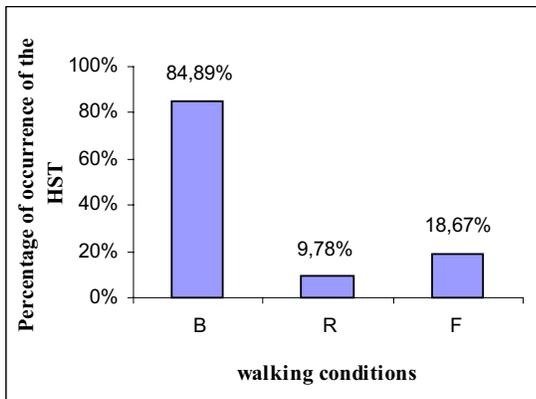

**INTRODUCTION**

The shape of the first part of the vertical ground reaction force depends on many factors such as the footwear characteristics [1-4, 6], the walking velocity [1, 4], the gait pattern [1], the foot morphology [4, 5] and the sampling rate of the force platforms [1]. These factors have an influence on the presence and magnitude of the heel strike transient (HST). The term “heel strike transient” refers to the impact between the foot and the ground, when a spike of force is superimposed on the upslope of the vertical ground reaction force [5]. We considered the presence of the HST when the spike of force descended 20N. before its final ascending up to the first trust maximum. This force transient is thought to be deleterious [5, 6] The objective of this study was to analyze the influence of different walking conditions on the HST.

**METHODS**

Fourty five firemen took part in the study. It took place at the Human Motion Analysis Research Laboratory in the Basurto’s Hospital. One force platform was installed flush with the ground in the centre of a 10 meters walkway. The subjects undertook several practice to ensure that they were familiar with the laboratory dimensions and the placement of the force platform. Five trials were conducted under each condition; barefoot (B), with their own runners (R) and with their firemen boots (F). Subjects were asked to walk at self selected speed over the force platform. Trials would be accepted if the speed showed a consistency between conditions, there were no visible alteration of the stride as the subjects walked across the platform and the entire right foot landed on the platform. The vertical ground reaction force was collected at a sampling frequency of 500Hz. Forces were normalized to the subjects’ bodyweight.

**RESULTS AND DISCUSSION**

**Figure 1:** Descriptive statistics of the occurrence of the HST in the three different condicions.

**Table 1:** Heel strike transient mean magnitudes in each condition.

Numbers in parenthesis are standard deviations.

\* indicates a significant difference between groups (P<0.01).

Conditions	Mean		
	B	R	F
HST (Bw)	1.00* (0.16)	0.41 (0.32)	0.59 (0.12)

In barefoot walking (B) the HST showed a higher presence (Figure 1) and magnitude (Table 1) than when subjects walked in runners (R) and in firemen boots (F). No significant differences were found between walking in runners and in firemen boots. These results indicate that barefoot walking implies the highest impact of the foot with the ground , whereas walking with runners and with firemen boots reduces significantly the impact of the foot with the ground. This corroborates the statement of Whittle who mentioned that when footwear is used, it provides a line of defense [5] against transient forces. As the walking velocity, the foot morfology and the sampling rate of the force platform did not change among the three walking conditions, the highest presence and magnitude of the heel strike transient during barefoot walking are explained by the differences in the gait pattern and/or by the absence of shoes.

**CONCLUSION**

Barefoot walking showed a higher presence and magnitude of the heel strike transient than when subjects walked with runners and with firemen boots.

## AN ALGORITHM FOR ESTIMATION OF SHOULDER MUSCLE FORCES FOR CLINICAL USE

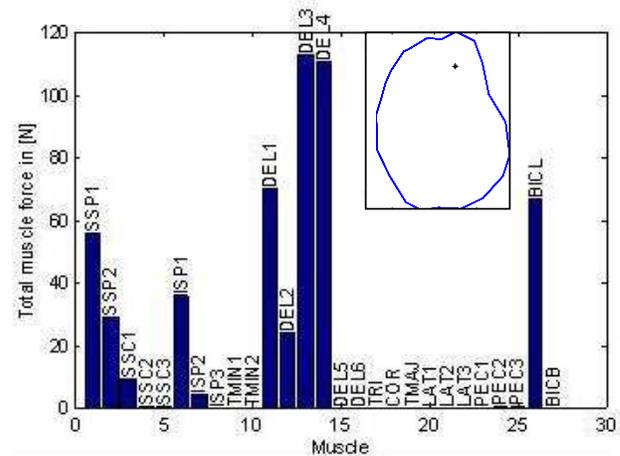

Philippe Favre, Ralph Sheikh, Sandro F. Fucentese, Hilaire A.C. Jacob  
Department of Orthopaedic Surgery, Balgrist, University of Zurich, 340 Forchstrasse, Zurich 8008, Switzerland.  
Email: pfavre@research.balgrist.ch

### INTRODUCTION

The complexity of the shoulder joint, with its extensive range of motion and large number of muscles, calls for close examination of possible muscular strategies involved, to understand some of the disorders of this intricate articulation and to treat these more effectively. Because each muscle can possibly give rise to rotation components about three orthogonal axes simultaneously (for instance, it could abduct, flex, and medially rotate the humerus at the same time), it becomes necessary to describe the muscular effect on the shoulder joint for each of these three actions, separately. Most of the previously developed computational methods have unfortunately been tailored to meet special cases of loading (usually to balance an external moment acting in one principal direction) and therefore do not readily lend themselves for application in a clinical environment where one wishes to test, for instance, the effect of a neurological or muscular deficiency on a model in which an arbitrary combination of external loading conditions would apply. We therefore developed an algorithm to predict muscle forces and test joint stability, for any external load and in 12 discrete positions of the humerus with respect of the scapula.

### METHODS

Moment arm length and line of action of each muscle segment was measured off a realistic three-dimensional full-size epoxy model of the thorax, scapula and proximal humerus, based on a fresh cadaver adult specimen, using the tendon travel method [1], in the 12 arm positions of interest. The muscles of the shoulder were segmented to allow for differentiated actions. The algorithm for shoulder force estimation (ASFE) involves decision-making iteration loops. In the main loop, muscle segments that can exert a significant moment to oppose the greatest of the three external moment components, while totally disregarding the two lesser ones, and muscle segments that can exert moments which oppose all three external components simultaneously, are first chosen. A small arbitrary force is initially attributed to this set of muscles in proportion to their cross-sectional area and introduced in the system of equilibrium equations. In further, similar, iteration steps, new values of muscular forces are attributed that again equilibrate only a small proportion of the remaining unbalanced external force. Only small increments of muscle force are attributed in each loop to ensure that at no stage, the muscular moment overshoots the external one. The issuing imbalance, also referred to as 'error', converges to an acceptable level. Each thus determined muscle force is stored after every loop and finally summed up to give the final estimate. The resulting joint force is calculated by adding all muscle forces to the external force and is controlled to fall within the glenoid boundaries. If joint stability is not reached at the end of the process, a superimposed force exerted by all

**Figure 1:** Forces exerted by the 27 muscle segments for abduction with a 9Nm external moment and with the humerus in 30° elevation in the scapula plane and in neutral rotation. The inserted field shows the intersection of the resultant with the glenoid.

the rotator cuff muscles (enforced cavity-compression through co-contraction) is simultaneously raised, and the algorithm restarted until stability is achieved.

### RESULTS AND DISCUSSION

The worked-out examples show interesting features of probable muscular activity and give results in good agreement with the literature (simulations, electromyographic studies). Figure 1 is an example. Although stability can be achieved by increasing the overall rotator cuff activity (co-contraction), this is rarely necessary. This also ensures that the magnitude of the resultant is kept as low as possible. Muscle segmentation is of paramount importance for spatial control. The ASFE offers the advantage of very short calculation time, in generally less than 5 minutes, with a commonly available PC when run with the well-known and widespread Matlab© software.

This algorithm represents a novel force estimation method and a new alternative to the available shoulder simulations.

The strategy of force sharing among muscles opens up the possibility to examine the outcome of muscle deficiencies and to investigate causes of joint instability as encountered in clinical practice.

## COMPARISON BETWEEN TRIPOD AND SKIN FIXED RECORDING OF SCAPULAR MOTION

Carel G.M. Meskers, Michiel A.J. van der Sande and Jurriaan H. de Groot

Laboratory for Motion Analysis, Departments of Rehabilitation Medicine and Orthopaedic Surgery, Leiden University Medical Center, P.O. box 9600, 2300 RC Leiden, The Netherlands. Email: c.g.m.meskers@lumc.nl

### INTRODUCTION

To record 3D scapular rotation, we currently use a scapula-locator: a tripod with an electromagnetic receiver mounted on it, which has to be placed manually and repetitively over the scapula during static humeral elevations. Measurements of scapular motion by means of an electromagnetic receiver fixed onto the flat part of the acromion (=skin fixed method) potentially enables dynamic and fast motion recording, making it very suitable for clinical measurements. This study was undertaken to: 1) compare tripod to skin fixed recording (concurrent validity); 2) determine the inter-observer variability of skin fixed recording; 3) determine the intra-trial variability; 4) compare static versus dynamical measurements of scapular rotation at moderate speed.

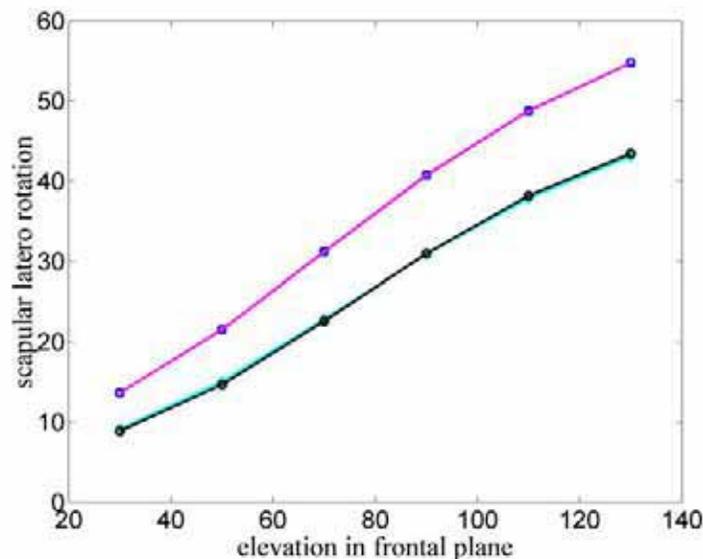

### METHODS

3D shoulder kinematical recordings were performed at eight healthy subjects using both an electromagnetic receiver fixed to an adjustable tripod [1,2] and a receiver fixed to the flat part of the acromion. Measurements were performed according to the standard of the International Shoulder Group [3]. Scapular rotation of the right shoulder was measured during symmetrical elevation in frontal and sagittal plane respectively. Measurements were performed by three observers. Measurements of scapular rotation were performed repetitively to full maximal elevation. Interpolation of data of each of the three scapular rotations (pro-retraction, latero-rotation and spinal tilt) was performed using p-splines [4]. Sampled data at 30, 50, 70, 90, 110 and 130° of humeral elevation were used for statistical testing using a GLM-ANOVA with repeated measurements (SPSS 11.0) to establish the difference between tripod- and skin fixed recordings, intra-trial variability and inter-observer variability of skin fixed measurements and to assess the difference between static and dynamical (cyclic elevation at about 0.5 Hz) measurements of scapular orientation using the skin fixed method.

### RESULTS AND DISCUSSION

The skin fixed method underestimated scapular rotations compared to tripod-based measurements. We found a maximal difference of 6° for orientation (=offset) and 7° for rotation regarding scapula latero rotation during elevation in the frontal plane. These errors exceed the expected error of about 2° evolving from palpation inaccuracies [5] and are attributed to: 1) differences in definitions of local co-ordinate systems (offset error); 2) palpation variability (offset error); 3) skin motion relative to bone (rotational error); 4) influence on acromion receiver position by a stiff receiver cable (rotational error) and 5) interposition of *m. deltoideus* between acromion receiver and scapular bone (rotational error). Inter-observer

variability was low compared to tripod measurements (1.91°-4.95° vs. 4.35°-5.15°) and inter trial reliability was high (intra class correlation coefficient > 0.84). The RMSE of static versus dynamical measurements was below 1°.

**Figure 1:** scapular latero rotation as measured by means of a tripod (□) and a skin-fixed method, both statically (Δ) and dynamically (o)

### CONCLUSION

A skin fixed method to record scapular rotations is precise but less accurate compared to tripod measurements. Advantages over the latter method are a lower inter-observer variability and the possibility to record scapular motion during low speed continuous arm elevations. Based on the current data, considering a maximal rotational error of 7°, we conclude that shoulder kinematical measurements in a clinical setting can be performed using an electromagnetic receiver attached to the flat part of the acromion.

## TELESCOPING ACTION IMPROVES THE FIDELITY OF AN INVERTED PENDULUM MODEL IN NORMAL HUMAN GAIT

Frank L. Buczek, Michael J. Rainbow, Matthew R. Walker, Kevin M. Cooney, James O. Sanders  
 Shriners Hospitals for Children, Erie, PA, USA  
 email: [fbuczek@shrinenet.org](mailto:fbuczek@shrinenet.org), web: <http://www.shrinershq.org/research/erie/>

### INTRODUCTION

Inverted pendulum models, operationalized in ballistic walking studies [1] and passive dynamic robots [2], have been used to describe normal gait in the absence of active mechanisms, leading some clinicians to minimize the importance of joint powers [3]. We hypothesized that a telescoping action, associated with joint powers, would improve the fidelity of a simple inverted pendulum model applied to normal gait, as measured by its ability to predict horizontal and vertical ground reaction forces ( $F_h$ ,  $F_v$ , respectively). Unlike previous studies, we made direct comparisons between model predictions and actual gait data for a sample of normal subjects.

### METHODS

Kinematic data were collected for 24 normal children at 120 Hz using a ten camera Vicon 612 system, and low-pass filtered (6 Hz cutoff). A thirteen-segment, full-body model was implemented in Visual3D (C-Motion Inc.), and the instantaneous location of the full-body center-of-mass (COM) was calculated.  $F_h$  and  $F_v$  were collected at 1560 Hz using three AMTI force plates, and center-of-pressure (COP) coordinates were averaged, consistent with Eqs. (1) and (2) derived for a stationary pendulum pivot. (Here,  $m$  is body mass,  $g$  is gravitational acceleration,  $r$  is pendulum length, and  $\theta$ ,  $\omega$ ,  $\alpha$  are the pendulum angular position, velocity, and acceleration, respectively.) Subtracting coordinates of the average COP from those of the instantaneous COM provided a telescoping inverted pendulum. Radial and angular kinematics of this pendulum were calculated using central difference techniques, and input to Eqs. (1) and (2), valid only for single support. Setting radial kinematics ( $\dot{r}$ ,  $\ddot{r}$ ) to zero removed the telescoping action. Inverse dynamics in Visual3D provided associated lower extremity joint powers. Five separate repeated measures ANOVAs detected differences ( $p \leq 0.05$ ) among measured and predicted kinetic parameters (minima and maxima in  $F_h$  and  $F_v$ ), with and without telescoping. Root mean square (RMS) errors were also calculated across ensemble averages to quantify differences between actual and predicted  $F_h$  and  $F_v$ .

$$F_h = m \left[ (\ddot{r} - r\omega^2) \cos \theta - (r\alpha + 2\dot{r}\omega) \sin \theta \right] \quad (1)$$

$$F_v = m \left[ (\ddot{r} - r\omega^2) \sin \theta + (r\alpha + 2\dot{r}\omega) \cos \theta \right] + mg \quad (2)$$

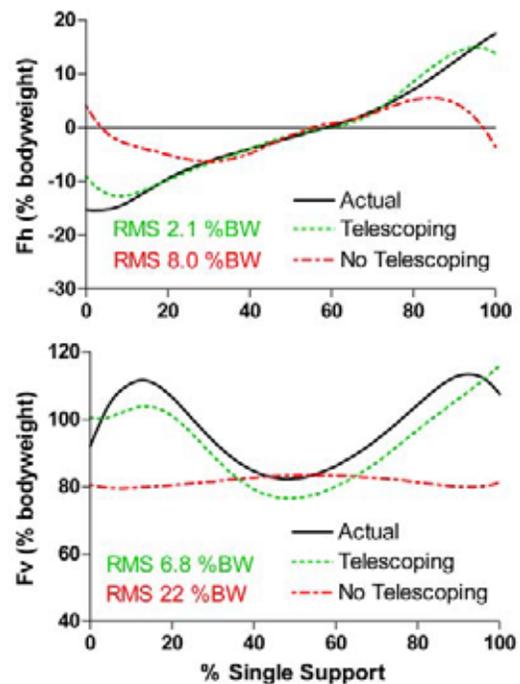

### RESULTS AND DISCUSSION

Pendulum compression averaged 1.7 cm over the first 20% of single support, length changes were variable at mid single support, and extension occurred over the last 20% of single support. Ground reaction forces were predicted best when this telescoping action was included (Figure). RMS errors for  $F_h$  increased from 2.1%BW to 8.0%BW when telescoping was

removed, as the predicted force diverged from actual values in early and late single support. RMS errors for  $F_v$  increased from 6.8%BW to 22%BW, and the double peak pattern was lost, when telescoping was removed. Peaks in  $F_h$  and  $F_v$  were significantly different for all comparisons (actual vs. telescoping, actual vs. no telescoping, telescoping vs. no telescoping), but this was not true for a local minimum in  $F_v$  near 50% single support. In every case, deviations from actual data were worse when telescoping was removed, and these deviations were greatest during lower extremity power bursts calculated for these subjects. We conclude that telescoping contributes to  $F_h$  and  $F_v$  during single support, and reflects changes in hip, knee, and ankle angles modulated by joint powers. We expect these findings to be amplified in a companion study of pathological gait, now underway. We also plan to explore correlations between radial powers ( $F \cdot \dot{r}$ ) and joint power bursts.

## COMPARING NORMAL GAIT ANALYSES USING CONVENTIONAL AND LEAST-SQUARES OPTIMIZED TRACKING METHODS

Frank L. Buczek, Michael J. Rainbow, Kevin M. Cooney, Matthew R. Walker, James O. Sanders  
Shriners Hospitals for Children, Erie, PA, USA  
email: [fbuczek@shrinenet.org](mailto:fbuczek@shrinenet.org), web: <http://www.shrinershq.org/research/erie/>

### INTRODUCTION

The conventional gait model (CN) was pioneered in the late 1960s [1] and has seen widespread clinical use since that time. A desire to minimize the number of motion capture markers in this model was motivated by equipment limitations, including the use of only two or three cameras, and manual digitization of each camera's cine film. This led to the use of markers on one segment to define virtual markers that tracked adjacent segments with no correction for measurement error, and the use of a simple vector to represent the foot. The advent of multi-camera, automated motion capture systems provided opportunities to improve upon these techniques. In particular, an optimized (least-squares), six degree-of-freedom approach (OP) can use an over-determined set of physical markers to track individual segments while adjusting for measurement error [2]. The purpose for this human subjects approved study was to compare gait analysis variables across CN and OP models in normal children. We hypothesized that OP would provide data similar to CN in the sagittal plane, and different from CN in both coronal and transverse planes.

### METHODS

Both biomechanical models were created in Visual3D (C-Motion, Inc.). CN was implemented using the Helen Hayes option for the lower extremities and pelvis. OP began with CN joint centers and local reference frames, but tracked all body segments using a minimum of four physical markers. A hybrid marker set allowed a single stride to be analyzed using CN and OP models in 25 normal children. Marker trajectories were collected at 120 Hz using a ten-camera Vicon 612 system, with interpolation and low-pass filtering (6 Hz cutoff) performed in Visual3D. Ground reaction forces were collected at 1560 Hz using three AMTI force plates. Twenty key, functionally-grouped gait analysis variables were calculated in Visual3D (e.g., maxima and minima in hip, knee, and ankle angles, moments, and powers). Dependent t-tests detected differences in these variables across models, using a Bonferroni-adjusted alpha of 0.0025 (i.e., 0.05/20).

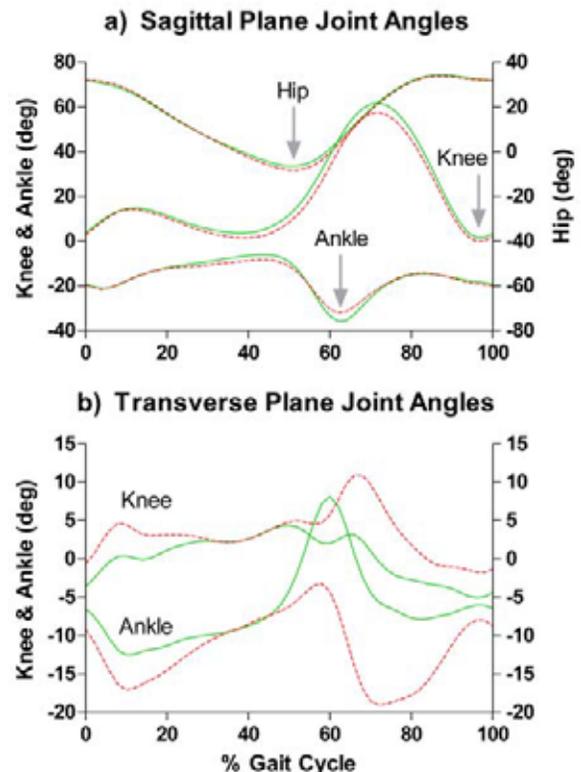

### RESULTS AND DISCUSSION

Six of nine variables were significantly different in the sagittal plane, yet associated graphical data were unlikely to change clinical interpretations (see sample data, Figure 1a). These differences were attributed to the higher fidelity foot model in OP, and to a more anterior position of the knee center when correctly tracked by four thigh markers in OP, rather than a virtual hip center, a thigh wand, and a lateral knee marker in CN. This latter marker moves posterior to the femoral epicondyle when the knee is flexed, causing decreased hip and knee flexion angles calculated in CN. No differences were found in five coronal plane variables. Four of six variables were significantly different in the transverse plane, and these

were appreciated graphically (see sample data, Figure 1b). In all planes, important, yet untested, features of curves were identified for additional analysis (e.g., maximum knee valgus, etc.). Results for all three anatomical planes require more rigorous accuracy tests. In the meantime, our study shows that for normal children, sagittal and coronal plane biomechanical interpretations, based upon these tested variables, are unlikely to change due to optimized segment tracking alone. The value in these methods seems instead to involve higher fidelity input for forward dynamics [3], and we intend to explore this as one measure of accuracy. These relationships may change when pathological movements exacerbate model differences in a companion study of patients not yet completed.

### INTRODUCTION

For the execution of a maximal vertical jump from stance, humans show a unique movement pattern. Over the past decades, researchers have tried to identify the criterion that generates the control signals for this. Through simulation studies it has been shown that a unique movement pattern most likely generates the maximal height achieved by the musculo-skeletal system [1]. In a recent study we found that for jumps towards a sub-maximal target height, humans also have stereotyped movement patterns across individuals [2]. These mainly consisted of decreasing countermovement amplitude for decreasing target heights. According to [2], this indicated that humans could minimize energy-consumption for a sub-maximal jump. Another possibility is that humans simply minimize the total duration of the jump. The purpose of this study was to test the hypothesis that one of these criteria causes the stereotype adaptations for sub-maximal jumping in humans. For this purpose, sub-maximal vertical jumps of a simulation model were generated and the movement patterns were compared with movement patterns observed in humans.

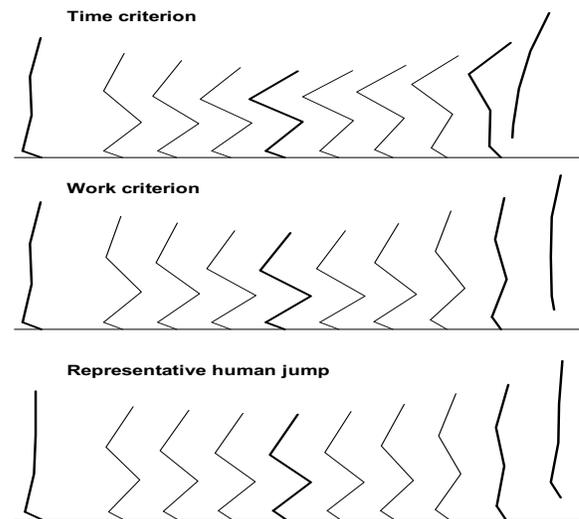

### METHODS

An existing 4-segment model with 6 muscle actuators [3] served to simulate countermovement vertical jumps from stance. The initial state of the model was an upright standing position. Switching the muscle actuators “off” and “on” controlled the movement of the model. Two different objective functions were used, one of which generated a given sub-maximal jump height in a minimum amount of time (= minimal time criterion) and the second achieving it with minimal work (= minimal work criterion). The latter criterion involved a rough estimate of energy consumption, counting both eccentric work and concentric muscle work in a ratio of 1:3. Jumps towards heights of 50-60-72-86-93-98-100% of maximal jump height were simulated.

Joint kinematics and kinetics were compared with those of human sub-maximal jumps. The experimental setup was described previously [2], and contained jumps towards heights of 25-50-75-100% of maximal jump height.

### RESULTS AND DISCUSSION

Optimizations with both the minimal time and minimal work criterion resulted in unique movement patterns for jumps to heights of 50%-100% of maximal jump height (75% example in figure 1). Both criteria led to similar movement patterns for jumps that were close to maximal jump height (90-100%). For lower jumps (50-90%), solutions of the minimal time criterion were different from those of the minimal work criterion in that

**Figure 1:** Stick figures showing simulations of minimal time and minimal work optimizations and a human jump for a vertical jump of approximately 75% of maximal jump height.

they led to incomplete joint extensions and excessive rotational and horizontal energies at toe off. Throughout all jump heights ranging from 50 to 100%, optimizations with the work criterion generated movement patterns that showed a greater resemblance with those of human jumps (representative example in figure 1). Typical adaptations were decreasing hip extension, slightly decreasing knee extension and constant ankle plantar flexion as jump height decreased.

### CONCLUSIONS

Solutions obtained with the minimal time criterion had poor correspondence with humans because of flexed joints, backward velocity and body rotation at take off. Solutions with the minimal work criterion, on the other hand, showed less countermovement in a sub-maximal jump than in a maximal jump and more extended joints and more vertical velocities at take off. This has good correspondence with human jumps and demonstrates that minimized energy-consumption is a viable criterion for sub-maximal jumping.

## DYNAMIC SIMULATION AND EXPERIMENTAL VALIDATION OF THE PLANTAR FOOT PRESSURE DURING HEEL STRIKE

<sup>1</sup>Weng-Pin Chen, <sup>1,2</sup>Shih-Cherng Lin and <sup>2</sup>Fuk-Tan Tang

<sup>1</sup>Department of Biomedical Engineering, Chung Yuan Christian University, Chungli, Taiwan,

<sup>2</sup>Department of Rehabilitation, Chang Gung Memorial Hospital, Kweishan, Taiwan; email: wpchen@cycu.edu.tw

### INTRODUCTION

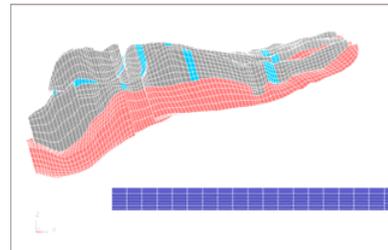

Computational analysis of the foot biomechanics has its advantage in providing an overall stress distribution of the foot. It is also more economical than in vitro cadaver experiments. In the current study, a general mesh generation software, Gridgen V14, was used to establish a three-dimensional hexahedral foot finite element model with detailed joint characteristics and partial plantar soft tissues. In addition, a dynamic finite element analysis software, LS-DYNA 970, was incorporated with the kinematic data from gait analysis for the dynamic simulation of foot motion during heel strike. The pressure distributions at the heel region during heel strike were investigated. Furthermore, in order to validate the analysis results, the plantar pressures of the same subject who provide the foot geometry was measured during heel strike. Both the analysis and measured results showed similar trends and within the same range.

### METHODS

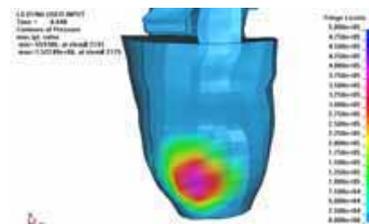

A detailed 3-D finite element foot model was created based on the computed tomography images of the left foot of a 24 yr male subject. A finite element mesh generation program (Gridgen V14, Pointwise, Inc., Fort Worth, Texas, USA) was used to generate 10-node hexahedral elements for the bones (12985 elements), cartilages (536 elements) and portion of the plantar soft tissues (6686 elements). (Fig. 1). The material properties for the bone was assumed to be linear elastic while the cartilage and soft tissue were assumed to be visco-elastic. The Young's modulus, Poisson's ratio, density, bulk modulus (short term and long term) were adopted from literature [1,2]. The kinematic data of the foot of the male subject during heel-strike at normal walking speed (1.2 m/s) was obtained using a Vicon-370 motion analysis system. Also, the plantar pressure of the foot was recorded for ten times using a RS-SCAN foot plate system. The vertical and horizontal velocities of the foot (0.6 m/s; 3.12 m/s) were used as loading condition in the simulation. Initial contact angle of the foot with respect to the ground was assumed to be 23° (Fig. 1). A force varying linearly from 0-420 N was applied on the trochlea of talus to simulate the effect of body weight during heel strike. The analysis was performed using LS-DYNA 970 (Livermor, USA) on an HP-SPP2200 supercomputer. The stresses in the bone and plantar soft tissues were computed at each of the 100 increments during the simulation time span of 0.048 s.

### RESULTS AND DISCUSSION

Analysis results showed that the plantar pressure increased with respect to the time as the foot starting to be in contact with the ground. The plantar pressures at the heel region obtained from the analysis were compared with the measured results using RS-SCAN plate system. Similar trends were found and the peak value for the analysis results at t=0.48 was

**Figure 1:** Hexahedral finite element model of the foot bone with plantar soft tissues

**Figure 2:** The normal stress of the plantar soft tissue at the heel region at t=0.048s obtained from simulation

found to be 302 KPa. On the other hand, the measured peak plantar pressure was found to be ranging from 248 to 316 KPa (10 measurements). As for the bone stresses, calcaneal stress distribution was transferred gradually from calcaneocuboid joint nearby to posterior calcaneus. Thus, the mean von Mises stress was around 30 ~ 180 KPa. However, anterior and posterior joint surfaces of the subtalar joint sustained compressive stress, and medium joint surface of subtalar joint received tensile stress.

### CONCLUSIONS

A 3-D hexahedral finite element model was established and analyzed in this study. The simulation results were validated from plantar pressure measurements. With the application of this model, dynamic finite element analysis for a full gait cycle can be completed in future studies. This model can also provide useful information for footwear and orthosis designs.

## SCALING AND JUMPING: GRAVITY LOSES GRIP ON SMALL JUMPERS

Melanie N. Scholz, Maarten F. Bobbert and A.J. “Knoek” van Soest

Institute for Fundamental and Clinical Human Movement Sciences, Vrije Universiteit, Amsterdam, The Netherlands; email: [m.scholz@fbw.vu.nl](mailto:m.scholz@fbw.vu.nl), web: [www.ifkb.nl](http://www.ifkb.nl)

### INTRODUCTION

The current view on the scale effects on jumping is that (1) jumping performance is independent of size in the absence of air friction: all animals would achieve the same jump height (rise of the body center of mass while airborne) if they were geometrically similar and delivered the same amount of work per kg body mass during the push-off (Borelli’s Law), and (2) in the presence of air friction smaller jumpers are at a disadvantage, because they waste relatively more energy on air friction than larger animals due to their larger surface to volume ratio.

It can not be explained from an evolutionary view why jumping locomotion is primarily adopted by small animals, such as insects. Besides, jumping is a battle against gravity and for static situations, i.e. standing with flexed legs, defying gravity becomes easier with decreasing size because the moment of gravity that needs to be counteracted decreases at a higher rate than the muscle moment ( $L^4$  and  $L^3$  respectively, where  $L$  is the scaling factor for length). It is evaluated analytically and numerically how this mechanical advantage translates to dynamic situations and affects jumping performance as a function of size.

### METHODS

On the basis of energy balances for geometrically similar jumpers consisting of a point mass and massless legs, it is shown analytically that Borelli’s Law is wrong. With the same mass specific work (work per kg body mass), smaller jumpers achieve higher take-off velocities and hence greater jump heights.

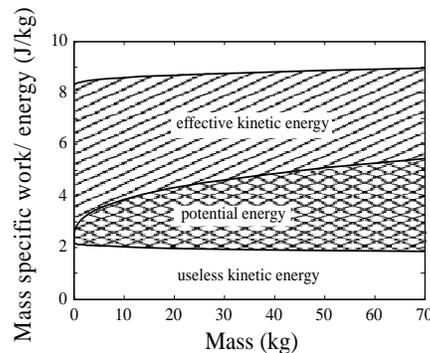

$$v_{take-off} = \sqrt{2(W_m - Lg\Delta h)}$$

where  $v_{take-off}$  is take-off velocity,  $W_m$  is mass specific work,  $g$  is the acceleration due to gravity,  $\Delta h$  is the height gained prior to take-off and  $L$  is the scaling factor for length.

To assess how the relationship between size and jumping performance contributes to our understanding of real jumping animals, numerical simulations were conducted using a more realistic generic jumper model [1]. One hundred geometrically similar bipedal jumpers ranging from  $7 \cdot 10^{-6}$  kg to 70 kg were modeled. Jumpers were actuated by constant knee extensor torques that scaled with mass, so that all jumpers produced the same amount of mass specific work over the same angular knee-extension.

### RESULTS AND DISCUSSION

Smaller jumpers achieved greater jump heights than larger jumpers. Absolute jump height increased by 70% when scaling down a jumper from 70 kg to 0.7 g. Figure 1 shows the amount of mass specific work delivered by each jumper during push-off, as well as how it was expended. A division is made in (1) effective kinetic energy (energy due to vertical

**Figure 1:** Energy expenditure for different sized jumpers in the absence of air resistance. Total energy expenditure is divided into effective kinetic energy (hatched), potential energy (double hatched) and ‘useless’ kinetic energy (solid white).

velocity of the body centre of mass), (2) potential energy and (3) ‘useless’ kinetic energy, energy that does not contribute to jump height (e.g. rotational kinetic energy). Smaller jumpers actually delivered slightly less mass-specific work during the push-off. This is because they took off with more flexed legs, for reasons explained elsewhere [2]. Nevertheless, smaller jumpers jumped higher because they converted a larger fraction of the work into effective kinetic energy. In other words, smaller jumpers achieved higher take-off velocities because of a higher efficacy.

### CONCLUSIONS

To conclude, size does matter in jumping. If all animals were geometrically similar and delivered the same amount of work per kg body mass, small jumpers would jump higher than larger ones. In nature, small jumpers do not consistently jump higher than larger ones, hence they are not geometrically similar and it can be predicted that small jumpers require relatively less muscle mass. According to the literature, relative jumping muscle mass amounts to 25-40% of the body weight in the galago, 11-15% in various frogs and only 4-6% in locust. A small jumper needs relatively less muscle mass than a large jumper to achieve a certain take-off velocity. Muscle tissue is energetically expensive for an animal because of its high (resting) metabolism. If the benefits of high take-off velocity (i.e. fast escape from predators) are combined with the challenge to sustain as little muscle tissue as possible, being small seems to present the best compromise.

### INTRODUCTION

The US Navy is currently developing a finite element model of the human spine to investigate the response of the spine to high-rate loading similar to the input pulse during an aircraft ejection [1]. The University of Virginia Center for Applied Biomechanics is performing experimentation to develop material properties [2] and failure properties of soft-tissues (ligaments and intervertebral discs), which will be implemented into the spine finite element model. This paper presents the failure properties of the anterior longitudinal ligament (ALL), posterior longitudinal ligament (PLL), and ligamentum flavum (LF) in the human cervical spine.

### METHODS

Six male and five female human cervical spines were used in this study. The average age of the male and female subjects was 60 yr ± 9 yr and 58 yr ± 6 yr. The average stature and mass were 1749 mm ± 40 mm and 77 kg ± 17 kg for the male subjects and 1626 mm ± 51 mm and 62 kg ± 19 kg for the female subjects. The ALL, PLL, and LF were isolated from each cervical spine at C3-C4, C5-C6, and C7-T1, resulting in a total of 54 male ligaments and 45 female ligaments. Of those, 47 male ligaments and 42 female ligaments were suitable for testing. Ligaments were excluded from testing if they were damaged during specimen preparation. The ligaments were mounted in a universal test machine (Instron, Inc. # 8874 Canton, MA) for uniaxial tests in an orientation that represents physiological conditions. The fixture was enclosed in an environmental chamber to maintain physiological temperature (99 ± 1 °F) and humidity (>90%). After the appropriate preconditioning, each ligament was subjected to a battery of material property tests [2], followed by failure tests. The failure tests included step inputs of 75% strain, 100% strain, and 300% strain. A typical strain rate in the failure step tests was 70-150 s<sup>-1</sup>. Injury risk functions were then generated using a survival analysis on the peak stresses resulting from a 100% step strain input.

### RESULTS AND DISCUSSION

The failure analysis was performed using the 100% strain step input tests; therefore, the strain rate (~80 sec<sup>-1</sup>) did not vary substantially between tests. Otherwise, the viscoelastic nature of the ligaments would result in varying peak stresses depending on the strain rate. A consistent strain rate allows for a direct comparison of peak stress among the ligaments. The engineering stress was calculated using published cross-sectional areas for the ALL, PLL, and LF [3]. The following equations were then used to compute true strain,  $\epsilon_T$ , and true stress,  $\sigma_T$ , assuming that the ligaments are incompressible, thus maintaining a constant volume during the tensile loading:

$$\epsilon_T = \int d\epsilon = \int_{l_0}^{l_f} \frac{dl}{l} = \ln \left( \frac{l_o + \Delta l}{l_o} \right) = \ln(1 + \epsilon_E) \quad (1a)$$

$$\sigma_T = \frac{F}{A} = \frac{F}{A_0} \cdot \frac{l}{l_0} = \sigma_E(1 + \epsilon_E) \quad (1b)$$

where  $F$  is force,  $A$  is cross-sectional area,  $A_0$  is initial cross-sectional area,  $l$  is length,  $l_0$  is initial length,  $\sigma_E$  is engineering stress, and  $\epsilon_E$  is engineering strain. Figure 1 and Figure 2 is a representation of the failure strain and corresponding failure stress for each ligament. The similarities of the failure characteristics between genders are consistent with the findings from a statistical analysis of cervical spinal ligament material properties in a previous study by Lucas et al. [2]. From the injury risk functions, the true stress corresponding to a 50% risk of an AIS 3 injury for the ALL, PLL, and LF is 11.6 N/mm<sup>2</sup>, 12.6 N/mm<sup>2</sup>, and 13.2 N/mm<sup>2</sup>.

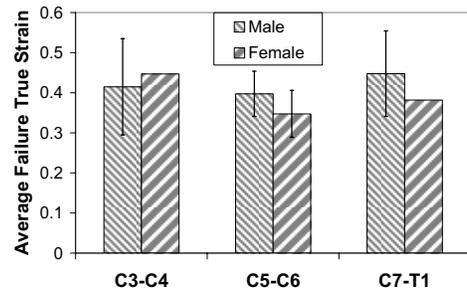

Figure 1: Failure true strain for posterior longitudinal ligament

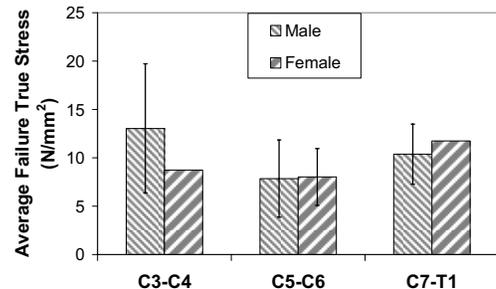

Figure 2: Failure true stress for posterior longitudinal ligament

### CONCLUSIONS

The primary objective of this study was to develop failure characteristics of the ALL, PLL, and LF in the human cervical spine under high-rate loading. The injury tolerances are implemented into a finite element model of the cervical spine to assess injury due to aircraft ejection.

## Elderly adults perform less limb work during walking

Justus Ortega and Claire Farley  
Locomotion Laboratory, Department of Integrative Physiology  
University of Colorado, Boulder, CO, USA  
E-mail: Justus.Ortega@colorado.edu

### INTRODUCTION

Elderly adults consume more metabolic energy for walking than young adults across a range of speeds (3). It has been hypothesized that the mechanical work performed by the limbs, including the simultaneous positive and negative work by the two limbs during double support, is an important determinant of the metabolic cost of walking (2). This study tests the hypothesis that walking is more metabolically expensive for elderly adults because they perform more mechanical work with their limbs than young adults.

### METHODS

Ten young ( $25 \pm 5$  yrs, mean  $\pm$  SD) and ten elderly ( $75 \pm 5$  yrs) adults walked at five speeds on a treadmill and on a 40 m walkway with imbedded force platforms. Subjects performed one seven-minute trial at each speed on the treadmill and three trials at each speed on the walkway.

Metabolic cost was determined using indirect calorimetry (1) during the last two minutes of each treadmill trial. We calculated net metabolic cost of transport by subtracting standing metabolic power from gross metabolic power and dividing by body mass and speed.

We measured ground reaction force (GRF) under each limb on the walkway and subsequently calculated individual limb mechanical work (ILW) from the dot product of the GRF and the center of mass (COM) velocity (2). ILW exceeds the traditionally calculated external work because it includes the simultaneous opposing work performed by the two limbs during double support (2).

### RESULTS AND DISCUSSION

Despite consuming 20% more metabolic energy ( $p=0.010$ ; Figure 1), elderly adults perform about 7% less limb work to travel a meter than young adults ( $p=0.028$ ; Figure 2). This difference is mainly due to the elderly subjects performing about 14% less positive limb work during double support than young adults.

The reason why elderly adults perform less individual limb work may be that they take shorter steps at a faster stride frequency. By taking shorter steps, elderly adults exert lower peak propulsive GRF and reduce the vertical excursion of the COM. Both of these factors reduce the mechanical work needed to redirect the COM when it transitions from arcing over one stance limb to arcing over the next stance limb (2).

Elderly adults have a faster stride frequency than young adults primarily because they spend less time in the single limb

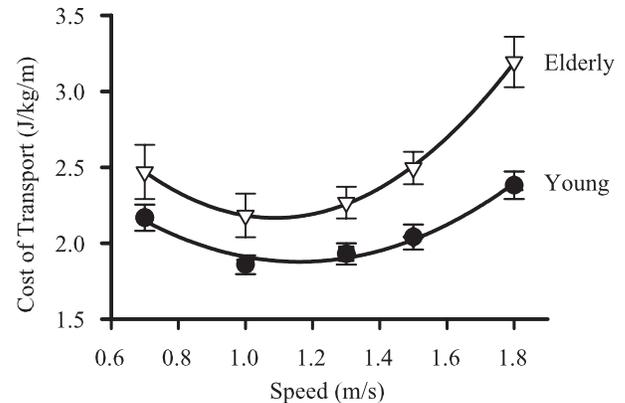

Figure 1: Net metabolic cost of transport (mean  $\pm$  SEM) versus speed.

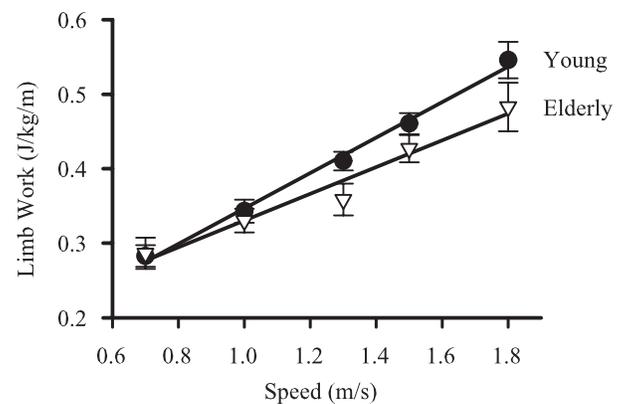

Figure 2: Positive limb work (mean  $\pm$  SEM) versus speed.

support phase. It seems likely that the single support phase is the least stable part of a stride, and therefore, shortening this phase may be a response to reduced stability with aging.

### CONCLUSIONS

Although elderly adults consume more metabolic energy to travel a meter than young adults, they perform less limb work than young adults. Although the shorter stride length of elderly adults may partly explain the difference in step-to-step transition work, the high metabolic cost of walking in elderly adults is likely due to other factors, such as greater muscle force generation for stabilization.

**EFFECT OF GENDER ON KNEE ABDUCTION AND FLEXION DURING MEDIAL AND LATERAL LANDINGS**

<sup>1</sup>Kevin R. Ford, <sup>1</sup>Gregory D. Myer and <sup>1,2</sup>Timothy E. Hewett

<sup>1</sup>Cincinnati Children's Hospital Medical Center, Sports Medicine Biodynamics Center,

<sup>2</sup>University of Cincinnati, College of Medicine; email: kevin.ford@cchmc.org, web: [www.cincinnatichildrens.org/sportsmed](http://www.cincinnatichildrens.org/sportsmed)

**INTRODUCTION**

Females who participate in pivoting and jumping sports suffer anterior cruciate ligament (ACL) injuries at a 4 to 6-fold greater rate than males participating in the same sports. ACL injuries often occur during single leg landings or quick changes of direction from either the medial or lateral direction[1]. The purpose of this study was to compare the knee joint kinematics during two types of single leg landings in male and female collegiate athletes. The hypothesis was that females would demonstrate greater knee abduction, but similar levels of knee flexion compared to male athletes.

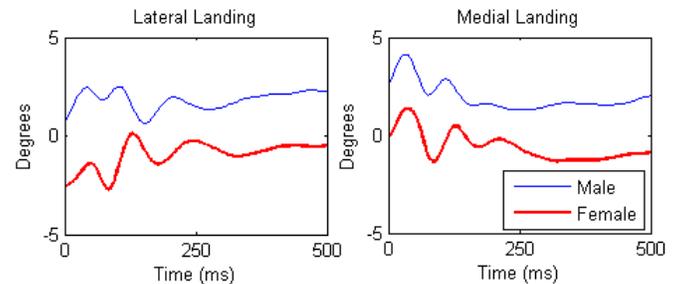

**METHODS**

Eleven female and 11 male collegiate athletes were height (female 176±8cm, male 176±8cm) and weight (female 73±7kg, male 74±6kg) matched. Informed written consent was obtained from each subject. Each subject was instructed to balance on one leg on a 13.5 cm block positioned adjacent to the force plate. They were then randomly instructed to drop off the block medially or laterally and land on the same leg and balance for approximately 2 seconds.

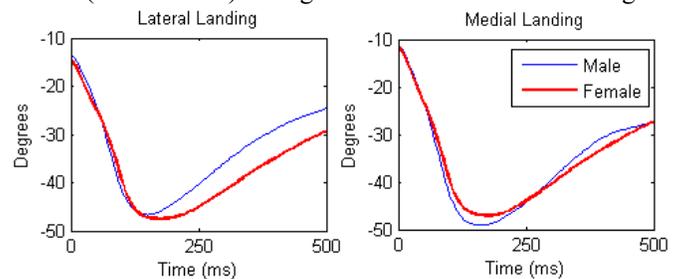

An 8 camera motion analysis system (Eagle, Motion Analysis Corp.) with two force platforms (AMTI) were used for data collection. Video and force data were time synchronized and collected at 240 Hz and 1200 Hz, respectively. 37 retroreflective markers were secured to each subject in predetermined anatomical locations. A kinematic model was defined from a standing static trial using Mocap Solver (Motion Analysis Corp.)[2]. Joint rotations in the hip, knee, and ankle were expressed relative to a neutral position where all segment axes are aligned. The data were low-pass filtered with a cubic smoothing spline at a 15 Hz cut-off frequency. A mixed ANOVA was utilized to test for the main effects of gender, task and side with alpha level of 0.05.

**RESULTS AND DISCUSSION**

Mean and standard deviations for each variable are presented in Table 1. The data are presented as averaged between the two sides as there were no side main effects or interactions. Female subjects had significantly greater knee abduction angles at IC (P<0.001) and maximum (P<0.001) compared to males (Figure 1). In contrast males displayed greater knee adduction maximum during the landings (P=0.005). There were no gender effects on knee flexion angle at either IC or maximum (Figure 2). During the lateral landings both male

**Figure 1.** Knee abduction (-) angle in male (thin blue line) and female (bold red line) during the lateral and medial landings.

**Figure 2.** Knee flexion (-) angle in male (thin blue line) and female (bold red line) during the lateral and medial landings.

and female subjects had greater knee flexion and abduction angles at IC (P<0.001)(Table 1). There were no task\*gender interactions.

**CONCLUSIONS**

Increased knee abduction angles has been previously shown to be predictive of ACL injury risk in female athletes [3]. In the current study females landed with increased knee abduction angles compared to males. Although further research is needed, a higher occurrence of ACL injuries may result from lateral landings as compared to medial landings.

## THE EFFECT OF MILD LIMB LENGTH INEQUALITY ON ABLE-BODIED GAIT ASYMMETRY: A PRELIMINARY ANALYSIS

<sup>1</sup>Matthew Kirk Seeley, <sup>1</sup>Jody Clasey, <sup>1</sup>Brian R. Umberger, & <sup>1</sup>Robert Shapiro

<sup>1</sup>University of Kentucky, Lexington, KY, USA

email: [mksee2@uky.edu](mailto:mksee2@uky.edu), web: [www.coe.uky.edu/biodynamics/](http://www.coe.uky.edu/biodynamics/)

### INTRODUCTION

Gait is one of the most basic of all human movements, but many aspects of gait, such as the causes of bilateral, lower-limb asymmetries, are still not fully understood [1]. Subtle morphological differences have been suggested as one cause of asymmetries [2], but have not been thoroughly investigated. Therefore, the purpose of this study was to investigate the relationship between morphological differences, specifically mild (< 3 cm) limb length inequalities (LLI), and bilateral, lower-limb, mechanical asymmetries during able-bodied gait.

### METHODS

Fourteen females and thirteen males participated in this study (Age = 30 ± 6 yrs; Mass = 73.9 ± 16.9 kg; Height = 1.73 ± 0.10 m). Participation included two data collection sessions: 1) limb-length assessment, and 2) gait analysis. All participants signed an informed consent form before participating.

Limb-length was assessed using dual energy x-ray absorptiometry. Total body scans were performed using a Lunar DPX-IQ bone densitometer. Limb length was calculated by summing femoral and tibial lengths [3]. LLI were quantified by subtracting the left limb length from the right limb length. The absolute value of this calculation served as the measure of LLI.

Gait analysis was performed using a six-camera motion analysis system (60 Hz) and the Cleveland Clinic marker set. Sagittal plane hip, knee, and ankle joint powers, normalized to body mass, were the gait variables of primary interest. Participants walked at a self-selected pace over two embedded force platforms (960 Hz) so that the right and left feet struck separate force platforms during simultaneous gait cycles. Bilateral, lower-limb asymmetry throughout the gait cycle was quantified using the Euclidean distance ( $\epsilon$ ) formula:

$$\epsilon = \sqrt{[(X_{R1} - X_{L1})^2 + (X_{R2} - X_{L2})^2 + \dots + (X_{R100} - X_{L100})^2]} \quad (1)$$

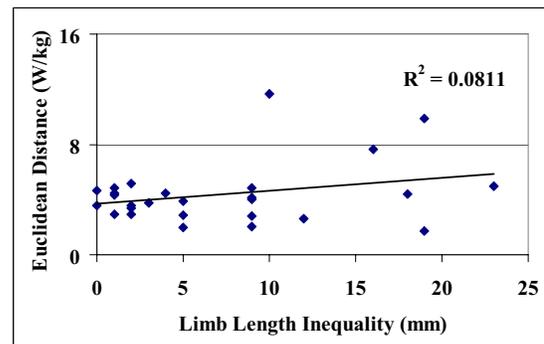

where X represents the gait variable under consideration; R and L subscripts represent the considered side (left or right); and the numerical subscripts represent the normalized time interval during the gait cycle.

A Pearson's correlation coefficient was used to describe the linearity of the relationships between LLI and gait asymmetries.

### RESULTS AND DISCUSSION

Mild LLI were observed (7 ± 7 mm). Using  $\epsilon$  as a single measure of joint power asymmetry throughout the entire gait cycle, bilateral asymmetries were observed at the hip (4.84 ± 2.86 W/kg), knee (4.35 ± 2.23 W/kg), and ankle (2.83 ± 1.50

W/kg). However, no significant, linear relationships between LLI and hip power ( $R^2 = .012$ ), knee power ( $R^2 = .081$ ), or ankle power ( $R^2 = .006$ ) were observed (Figure 1). Three other gait variable asymmetries that did result in statistically significant, but weak, linear relationships with LLI were: 1) knee flexion moment ( $R^2 = .196$ ), 2) ankle abduction moment ( $R^2 = .158$ ), and 3) ankle flexion angle ( $R^2 = .183$ ).

**Figure 1:** A scatter plot, typical of the plots observed during this study, showing a non-significant, linear relationship between limb length inequality and bilateral, knee joint power asymmetry during able-bodied gait.

Based on the current analysis, there are only weak relationships between mild LLI and bilateral asymmetry during human gait. It is unknown whether a mean LLI closer to our 3 cm threshold might have led to larger gait asymmetries. It is also not clear whether our  $\epsilon$  measure is the single best indicator of asymmetry over the gait cycle (as opposed to at a specific point in the cycle). We are currently considering other indicators of asymmetry that might better take into account the whole movement cycle.

### CONCLUSIONS

During the present study, only a few weak, linear relationships between LLI and able-bodied gait asymmetry were revealed; no statistically significant, linear relationships were observed between LLI and able-bodied gait asymmetry for the gait variables of primary interest. Further research considering: a) other methods effective in quantifying gait asymmetry; b) variables that resulted in significant correlations during this study; and c) other issues that may contribute to able-bodied gait asymmetry such as footedness, the environment, skill, or neuromuscular factors may also help illuminate this topic.

## DEVELOPMENT OF A BIOMECHANICAL SHOULDER MODEL FOR ERGONOMIC ANALYSES

<sup>1</sup>Clark R. Dickerson, <sup>2</sup>Don B. Chaffin and <sup>3</sup>Richard E. Hughes

<sup>1</sup>Department of Kinesiology, University of Waterloo, [cdickers@uwaterloo.ca](mailto:cdickers@uwaterloo.ca)

### INTRODUCTION

The study of work-related shoulder disorders has recently elicited an increased amount of attention by scientists [1]. Indeed, load levels in shoulder tissues have been identified as a risk factor for the development of these musculoskeletal disorders [2]. Despite this, few tools are available for the assessment of loading of shoulder structures for dynamic work tasks, especially in prospective job design. Thus, a computerized biomechanical model of the shoulder was developed. There are three major modules in the model: 1) a shoulder geometry module; 2) a dynamic torque module; and 3) a muscle force prediction module. The modules were evaluated empirically with a set of load transfer tasks.

### METHODS

The most critical design criterion for the modules was future implementation in prospective job analysis tools, including digital human modeling (DHM) software. Hence, the modules are driven by data types producible in virtual environments: body landmark motion, task and anthropometric properties.

Several aspects of the geometric model were based on prior findings [3,4], including segment and muscle unit definitions, placements of muscle attachment sites, and a mathematical shoulder rhythm. A graphical representation of the internal musculature was developed (Figure 1), allowing visualization of the movements of the shoulder components during motion.

**Figure 1:** Internal Shoulder geometry. Muscles are shown as having linear and wrapped lines of action.

The external torque module requires 3-D dynamic equilibrium about each of the three joints in the upper arm (wrist, elbow, and glenohumeral), and generates 3-D shoulder joint torques. These torques are inputs to the internal force prediction module. This module distributes these torques amongst 38 muscle units through use of an optimization paradigm. The model includes a novel glenohumeral constraint based on empirical data [5].

Additionally, load transfer tasks were performed by 8 subjects. The tasks were one-handed transfers of loads to locations in

the right-handed reach envelope. Hand Loads were varied between 0 and 50% of extended arm flexion/abduction strength. Surface Electromyography (sEMG) data was collected for 11 shoulder muscles to enable model evaluation.

### RESULTS AND DISCUSSION

The model showed differential ability across muscles to predict the levels of activation demonstrated by the sEMG recordings as shown by the correlation coefficients in Table 1. Concordance analysis also showed higher concordance ratios for muscles that were primary agonists.

Table 1. Correlation coefficients of predicted and recorded muscle forces levels in the shoulder.

Muscle	<i>r</i> value
Infraspinatus	0.63
Biceps	0.61
Deltoid, Total	0.53
Lower Trapezius	0.52
Middle Deltoid	0.42
Latissimus Dorsi	0.32
Posterior Deltoid	0.31
Trapezius, Total	0.27
Anterior Deltoid	0.26
Upper Trapezius	0.01
Pectoralis Major	0
Triceps	-0.20

### CONCLUSIONS

The model showed the highest predictive performance for those muscles that were demonstratively most active by sEMG recordings. Muscles that were not mechanical contributors to resisting the calculated external shoulder torques were predicted less accurately. These results are likely due to the combination of the use of a monotonically increasing cost function in the optimization (muscle stress cubed), and the exclusion of potential confounding factors (i.e. segment stiffness, detailed muscle properties). Nonetheless, from an ergonomic analysis point of view, the model is useful for identifying those tissues that are most stressed for a given task.

#### INTRODUCTION

The human ankle joint presents a complicated mix of geometry and anatomy that together create an intricate, multi-axis joint capable of complex motions. Past cadaveric and radiographic examinations of the ankle joint have attempted to assess the radii of curvature of the talus by assuming the talar dome to be cylindrical, at least in the 2D sagittal view.<sup>1,4,5,6</sup> Recent studies focused on total ankle arthroplasty applications suggest that the talar dome has a more complicated polyradial and polycentric shape.<sup>2,3</sup> There is little, if any, literature regarding assessments of the surface of the talus with respect to 3D geometry using a numerical optimization approach. The goal of this study was to accurately describe the 3D geometry of the talar dome by combining 3D digitization of cadaveric specimens with numerical optimization.

#### METHODS

Eight fresh, frozen, non-paired cadaver lower extremities with a mean age of 61.3 years (range 25-80) were used for this experiment. The group was composed of four male and four female specimens equally divided between right and left. Prior to testing, the specimens were thawed, radiographed, and subjected to a number of anthropometric measurements. Each specimen was then dissected and the talus was removed, potted in bone cement (PMMA), and secured in a rigid fixture. A 1mm x 1mm grid was drawn onto the entire articular surface of each talus and a Microscribe 3D digitizing tool (Immersion Corp., CA, USA) was used to collect points along the gridlines.

Following digitization, the data were analyzed in Matlab (V.7.0, Mathworks, MA, USA) using a least-squares optimization approach with the Levenberg-Marquardt algorithm to assess the accuracy of fitting a cylinder to the native shape of the articular surface. First, the superior articular surface of the talar dome was isolated from the medial and lateral walls. Next, a best-guess axis was established by finding the direction vector that connected the most superior point on both the medial and lateral edges of the surface data. This line was then inferiorly offset to provide an initial guess for the cylinder axis. The unit direction vector of this guess axis, a point on the axis, and a radius was provided as an initial estimate to the optimization routine, which then determined the best fit cylinder to all the data points on the superior articular surface of the talus. The resulting output of the optimization was a new axis point, axis direction vector, and a radius that described the best-fit cylinder (Figure 1). The accuracy of the cylinder fit was described by the mean-square error (MSE) of the optimization.

**Figure 1.** Talar dome surface points for one specimen and the cylinder fit to the points by numerical optimization.

#### RESULTS AND DISCUSSION

According to the results, a cylinder accurately describes the geometry of the superior talar dome (Table 1). MSE for the optimizations ranged from less than 0.1 mm to 0.43 mm. These data confirm that the overall shape of the superior talar dome can be accurately represented by a cylinder in 3D. The optimized cylinder radii were found to be similar for all males (~22mm) and all females (~18mm) respectively, and the difference between the two groups was significant. The calculated radii of curvature are in the range of previous 2D estimates of talar dome radii of curvature.<sup>2,4,6</sup> Examinations of the anthropometric data showed low variance in foot size, however, limiting statistical power. Further examinations are necessary to draw any conclusions regarding predictors of talar dome radii, such as foot size and gender. These data have direct applications to numerical models of the ankle as well as to the design of components for ankle arthroplasty.

## COMPARISON OF GOLFERS AND NON-GOLFERS WEIGHT-BEARING HIP ROTATION JOINT RANGE OF MOTION

### INTRODUCTION

Participation in sports places specific demands on the musculoskeletal system that, over time, may cause adaptations in soft-tissue. Athletes who participate in sports requiring repetitive rotational movement on one side and not the other (such as overhead sports) have experienced differences in their side-to-side joint range of motion<sup>1</sup>. Range of motion (ROM) asymmetry such as this has been linked to injury. Although this phenomenon has been documented for the upper extremities, little is known about similar adaptation in the lower extremity structures such as the hip. Athletes who participate in sports experience rotational movement in a functional capacity (weight-bearing status). Although there are established norms for passive and active hip rotation ROM, these measures have typically been made in a non-weight-bearing status. The purpose of the study was to examine anatomical limits of hip rotation ROM (weight-bearing conditions) in elite female golfers and age-matched non-golfing controls to determine if asymmetry between the hips exists.

### METHODS

Following a five minute bike warm-up, fifteen healthy, female collegiate golfers (mean age  $19.6 \pm 1.4$  yrs; ht.  $163.3 \pm 6.5$  cm; wt.  $59.5 \pm 6.6$  kg) and twenty age-matched females (mean age  $20.5 \pm 1.7$  yrs.; ht.  $166.8 \pm 7.7$  cm; wt.  $61.5 \pm 10.2$  kg) were evaluated for hip rotation ROM during weight-bearing. All subjects were right-hand dominant, and free from hip or back pain in the past six months. Data were acquired through 3-D videography (Motion Analysis Inc.) and a multi-segment bilateral marker set. Medial and lateral rotation for all subjects was measured on both the right and left side at a stance width equivalent to the distance between each subject's greater trochanters (Cond. A), as well as in a golf stance width (Cond B). For each condition, the mean of each subject's three trials was used for statistical analysis. A two-way ANOVA (group x measure) was run to test for the presence of a significant difference between the two groups (alpha level

set at 0.05), as well as separate paired t-tests (golfers and non-golfers) for examining side-to-side differences within groups.

### RESULTS AND DISCUSSION

Non-golfers's right lateral ROM was significantly greater than the golfers ( $48.7^\circ \pm 10.3$ ,  $40.7 \pm 6.5$ ;  $p = 0.02$ ) in Cond A, whereas the remaining hip rotation ROM measurements did not significantly differ between the groups. In condition B, there were no significant differences between the golfer group and non-golfer group hip rotation ROM measurements. In addition, both groups (non-golfers and golfers) demonstrated symmetrical hip rotation ROM, as none of the measured directions were significantly different. Thus, a golfer's right medial rotation did not significantly differ from left medial rotation, and a non-golfers right medial rotation did not significantly differ from left medial rotation.

### CONCLUSIONS

Except for a difference in right side lateral rotation during Cond A, the hip ROM of the golfer group was not significantly different from that of the age-matched, non-golfer group. Although the golfer group experiences repetitive unilateral rotations on the left (lead) hip, there does not appear to be an accommodation of joint range of motion, as evidence by the symmetrical range of motion among these subjects. However, previous unpublished data<sup>2</sup> has shown that there is a significant difference when measuring side-to-side hip joint range of motion in a non-weight-bearing status. Thus, there may be a true anatomical adaptation in the soft-tissue, but this does not appear in a dynamic (weight-bearing) measurement.

## ASSESSMENT OF FUNCTIONAL JOINT SPACE REPEATABILITY DURING IN VIVO DYNAMIC LOADING

William Anderst and Scott Tashman

Motion Analysis Lab, Bone and Joint Center, Henry Ford Health System, Detroit, MI 48202; email: anderst@bjc.hfh.edu

### INTRODUCTION

More than 20 million Americans have osteoarthritis [1]. The recommended measure for anatomical progression of osteoarthritis is joint space narrowing [2,3], typically measured by radiography or MRI. However, these techniques are not a comprehensive measure of articular cartilage thickness because the joint is imaged in only one orientation and under static loading. Thus, conventional measures do not account for differences in articular cartilage thickness over the entire contact region during active motion or how cartilage responds to dynamic loads common in daily activities.

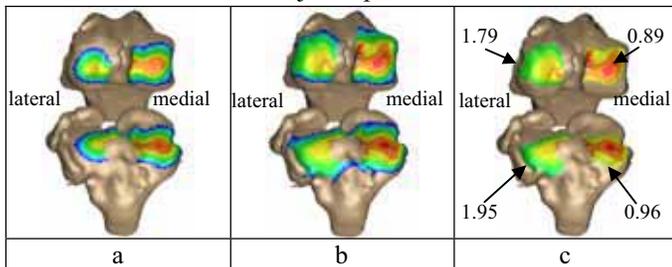

These shortcomings are addressed by the functional joint space (FJS) score, a measure of subchondral joint space over the entire articular surface during a dynamic loading activity. The purpose of this study was to assess the within-day and between-day repeatability of FJS scores.

### METHODS

Subjects were five adult foxhounds that served as controls for a larger study. 3D knee kinematics were determined from pawstrike to .20 s after pawstrike by tracking implanted beads (accuracy  $\pm 0.10$  mm [4]) in x-ray images collected at 250 fps as the dogs ran on a treadmill [5]. Ten tests were performed over two years. Three trials were collected each test session.

Using previously published methods [6], the minimum distances between tibia and femur subchondral bone surfaces were determined for each frame of data. A single parameter, the functional joint space (FJS) score, was created to quantify the minimum joint space over the entire .20 s post-pawstrike.

FJS score was calculated over a 200 mm<sup>2</sup> surface area. This area was big enough to account for large regions of cartilage loss and to reduce the effect of minor irregularities in the calculated close-contact region (e.g. near the spine of the tibia, an unlikely weight bearing region). The FJS score was the average distance between the closest 200 mm<sup>2</sup> subchondral surface areas during the .20 s after pawstrike (Figure 1). A smaller score indicated less joint space.

**Figure 1:** Femur (above) and tibia (below) articulating surfaces colored according to minimum joint space (red=closest, blue=farthest). a) One instant of the analyzed motion. b) The closest distance between surfaces over the entire 0.2 s of motion. c) The closest 200 mm<sup>2</sup> area in each compartment and accompanying FJS score.

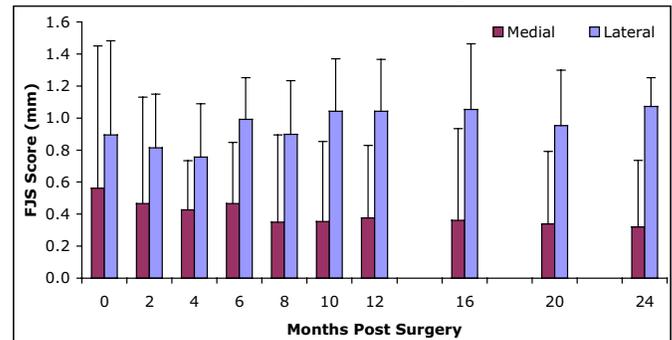

The three trials collected each day determined FJS score within-day precision. The average FJS score for the three trials each day was used to calculate the between-day repeatability. The effect of compartment (medial, lateral) and test session (1-10) on FJS score was evaluated with a 2-way repeated measures ANOVA with significance set at  $p < 0.05$ .

### RESULTS AND DISCUSSION

FJS scores were highly correlated between bones within each compartment (medial  $r=0.95$ ; lateral  $r=0.95$ ). Thus, for statistical tests, medial femur and tibia scores were averaged to make one medial compartment score, and likewise for lateral scores.

The within-day FJS score precision was 0.09 mm for both the lateral and medial compartments. This result is similar to the most precise static joint space measurements in humans [7,8]. The average between-day FJS score precision was 0.20 mm for both the medial and lateral compartments.

Average FJS scores were greater in the lateral compartment than in the medial compartment ( $p=.004$ ) (Figure 2). FJS score did not change significantly in either compartment over the 10 test sessions (lateral  $p=.403$ ; medial  $p=.637$ ).

**Figure 2:** Medial and lateral FJS score for the 10 test sessions.

### CONCLUSIONS

The FJS method to quantify joint space in vivo produced highly repeatable measurements both within-day and between days, making it a useful tool for serial studies. Unlike conventional joint space measurements, FJS measurements can be performed as the joint is dynamically loaded and moved through a range of motion while variable forces act on the joint. In the future, this tool may be used to serially track in vivo joint space during common activities such as walking in subjects at risk for the development of osteoarthritis.

## The Effects of Temperature, Pressure, and Humidity Variations on 100 Meter Sprint Performances

J. R. Mureika

Department of Physics, Loyola Marymount University, Los Angeles, CA 90045

Email: jmureika@lmu.edu Web: <http://myweb.lmu.edu/jmureika/>

### INTRODUCTION

It is well known that “equivalent” sprint race times run with different accompanying wind speeds or at different altitudes are anything but equivalent races. Adjusting these times for atmospheric drag effects has been the focus of many past studies, including but not limited to [1,2,3,4,5] and references therein. The drag force acting on a sprinter running at speed  $v$  in a wind  $w$  is a function of air density and the relative wind speed,  $F_{\text{drag}} \propto \rho_{\text{air}}(v - w)^2$ , where density has traditionally been calculated using the race venue’s elevation above sea level.

However, air density variation is dependent on more than just altitude. This work will quantify how changes in air temperature, barometric pressure, and humidity levels influence 100 m sprint performances. These variables collectively determine an effective altitude known as *density altitude*, which depending on atmospheric conditions can be significantly different than a venue’s physical elevation above sea level. The density of hot air is low, yielding a higher density altitude and thus simulating an increase in physical altitude. Increased humidity levels have a similar effect. Conversely, colder temperatures and lower humidity can potentially simulate a decrease in physical altitude.

### METHODS

The numerical model of sprinting performances used in Reference [4] is modified using standard hydrodynamic principles to include the effects of air temperature, pressure, and humidity levels on aerodynamic drag. Race times are obtained by numerically-integrating the associated equations for various temperatures in the range 15-35°, relative humidity levels (RH) between 0 and 100%, and atmospheric pressures between 85-105 kPa. These calculations are performed for wind speeds between -3 m/s and +3 m/s. The resulting data are then compared to a defined standard race with no wind, sea level atmospheric pressure and temperature of 25°.

### RESULTS AND DISCUSSION

Temperature alone does not have a profound impact on the simulations, giving a performance differential of 0.02 s over the 20° range. Wind and physical altitude corrections under these conditions are thus essentially identical to those discussed in the literature, confirming the earlier result of [3]. The combined effect of relative humidity and temperature plays a slightly more crucial role in adjusting performances, since the air density of hot, saturated air is significantly lower than that of colder dry air.

When the effects of pressure, temperature, and relative humidity changes are considered in combination, the

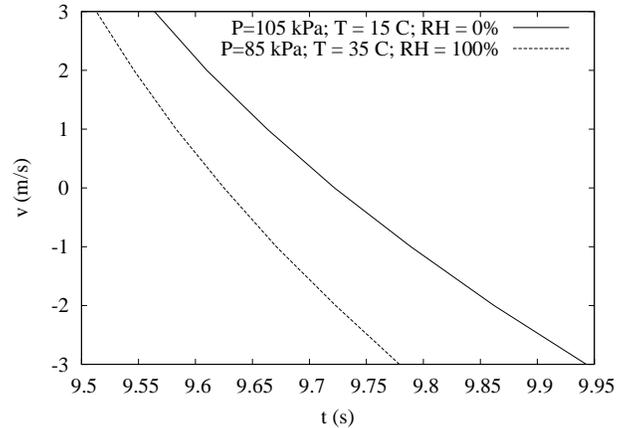

Figure 1: Range of wind-aided and hindered (+3 to -3 m/s) performances equivalent to a “standard” 9.70 second 100 m sprint at sea-level with no wind for extreme high-pressure (top curve) and low pressure (bottom curve) conditions.

corrections to performances can be very large. Figure 1 shows the range of possible simulation times, bounded by times run in extreme conditions: 85 kPa, 100% RH, and 35° (yielding the least dense atmosphere) and 105 kPa, 0% RH, 15° (most dense). The race times vary by up to or over 0.1 seconds between these extremes even after wind correction is taken into account. The results suggest that a non-negligible difference in race times can be expected for “equivalent” performances run with the same wind speed at the same venue or physical altitude, but under different atmospheric conditions.

## QUANTIFYING FLUID INGRESS TO THE JOINT SPACE DURING TOTAL HIP IMPLANT SUBLUXATION

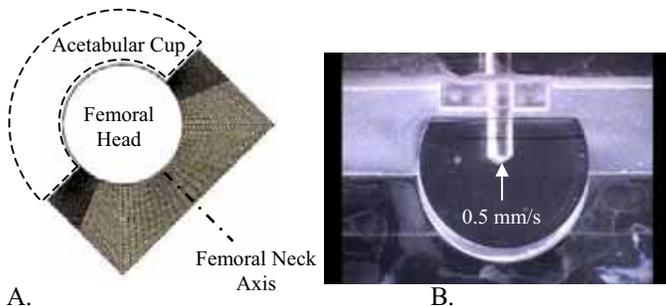

<sup>2</sup>Hannah J. Lundberg, <sup>1</sup>Douglas R. Pedersen, <sup>3</sup>Marian V. Muste, <sup>1</sup>Thomas E. Baer, <sup>1,2</sup>Thomas D. Brown  
University of Iowa <sup>1</sup>Department of Orthopaedics and Rehabilitation, <sup>2</sup>Department of Biomedical Engineering, <sup>3</sup>IHR-  
Hydroscience and Engineering; email: hannah-lundberg@uiowa.edu, web: mnypt.obrl.uiowa.edu

### INTRODUCTION

Ingress of 3<sup>rd</sup> body debris responsible for femoral head scratching and wear acceleration of total hip implants may be facilitated by convective fluid transport during hip subluxation. To study subluxation-induced particle ingress, a computational fluid dynamics (CFD) model has been developed to quantify the associated fluid motions. Validation of the model was performed using particle image velocimetry (PIV), a method of measuring fluid velocity by tracking marker particles in the flow. Two different femoral head displacement events were evaluated using a fully 3D model.

### METHODS

A proof-of-concept 2D CFD model (Figure 1A) was first created for comparison with experimental PIV results. The synovial fluid was assumed to be Newtonian and incompressible (viscosity of 1.0 Pa·s [1]). All external surfaces were designated as “no slip” boundaries. The femoral head was moved (subluxed/separated) out of the cup at a speed of 0.5 mm/s. For PIV validation (Figure 1B) marker particles introduced into the fluid were illuminated and their movement recorded with a digital video camera (Sony DCR-VX2000). EdPIV software was used to track particle movement and calculate fluid velocity.

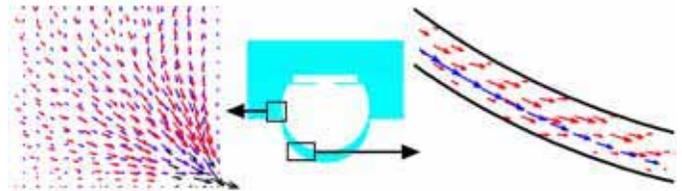

**Figure 1:** A. 2D CFD model mesh and B. physical PIV setup.

Two distinct head separation events were then studied using a definitive 3D CFD model (Figure 3A). One implemented the medial separation and femoral head superolateral cup edge pivot reported by Komistek et al. during the swing phase of gait [2]. The other implemented lever-out subluxation due to impingement/lever-out about the inferomedial cup edge [3]. Both regimes resulted in a 0.8 mm separation between the femoral head and acetabular cup after 0.6 s.

### RESULTS AND DISCUSSION

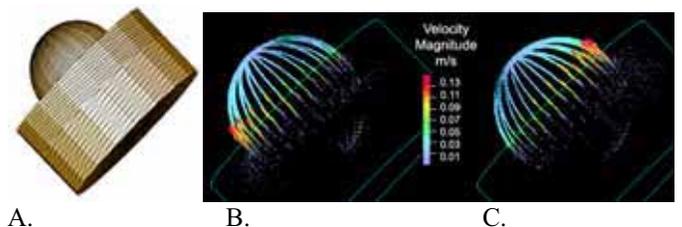

The results of the PIV validation are shown in Figure 2. The agreement of PIV versus 2D CFD was 85% or better for velocity vector magnitudes in the clearly visualized areas just away from the entrance to the gap between the femoral head and acetabulum. (The fluid velocity at the gap entrance could not be measured accurately with the physical setup because of

high fluid velocity at that point.) Additionally, any incidental fluid motion that might have occurred out of the plane of the image would result in lost/inaccurate vectors.

**Figure 2:** Velocity vectors of the 2D CFD model (red and black) compared to PIV results (blue). CFD velocity vectors shown in red are plotted so that vectors of equal length in the PIV results are equal velocity magnitudes. Black velocity vectors in the left panel, lower right corner, are scaled so that vectors of equal length are 50% greater in the CFD model than PIV.

The 3D CFD results showed markedly different fluid ingress kinematics for swing phase separation versus lever-out subluxation (Figure 3). It was noted that the lever-out femoral head displacement resulted in high velocities at the beginning of the subluxation event at the inferomedial cup edge like that of the gait cycle separation, although at 0.6 s high fluid velocities were located at the superolateral cup edge. The results also suggest that lever-out subluxations may attract debris from multiple locations into the joint space. Dramatic differences in flow patterns suggest that the two subluxation modalities evaluated subject very different regions of the bearing surface to preferential debris embedment, with very different consequences for subsequent head scratching and polyethylene wear acceleration.

**Figure 3:** A. 3D CFD mesh and flow patterns during B. swing phase separation and C. lever-out, both at 0.6 s.

**DIRECTION-DEPENDENCE OF UHMWPE WEAR FOR METAL COUNTERFACE SCRATCH TRAVERSE**

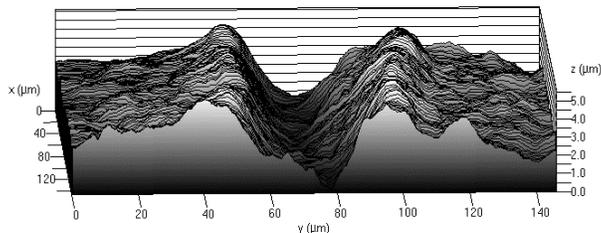

<sup>1</sup>Liam P Glennon; <sup>1</sup>Matthew C Paul; <sup>2</sup>William D Lack <sup>1</sup>Thomas E Baer; <sup>1</sup>James A Martin; <sup>1</sup>Thomas D Brown  
<sup>1</sup>University of Iowa, Iowa City, IA, <sup>2</sup>Harvard University, Cambridge, MA  
 email: GlennonL@mail.healthcare.uiowa.edu, web: mnypt.obrl.uiowa.edu

**INTRODUCTION**

Scratches on bearing surfaces of joint prostheses are known to appreciably accelerate wear. The dependence of polyethylene wear rates on counterface motion relative to scratch direction has heretofore not been explored.

**METHODS**

Arrays of parallel scratches (Fig. 1) were machined at 150 μm intervals on polished stainless steel plates. 25.4mm plugs were machined from conventional and highly-crosslinked UHMWPE.

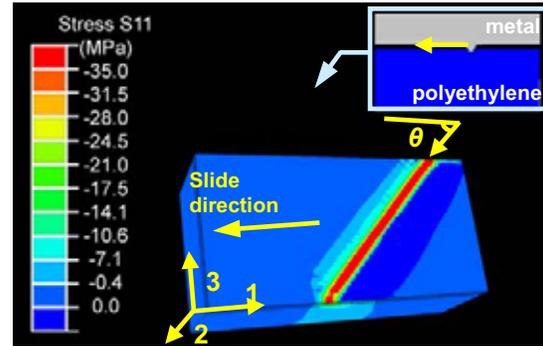

**Figure 1.** Laser scanning microscopy image of custom profile created on steel. Note axes scales

The scratched counterface plate was immersed in bovine serum and driven reciprocally against the polyethylene plug. The plug was made to traverse the plate at angles ranging from 0° to 90° relative to the scratch orientation, with wear being measured gravimetrically. Based on the scratch geometry of the experiment, a 3-D geometrically and materially nonlinear local finite element (FE) model (Fig. 2) of scratch sliding/overpassage was developed, to explore continuum-level stress/strain parameters related to orientation-dependent scratch wear. A total of 1,027 candidate surrogate parameters were ranked according to goodness-of-fit to the experimental wear relationship.

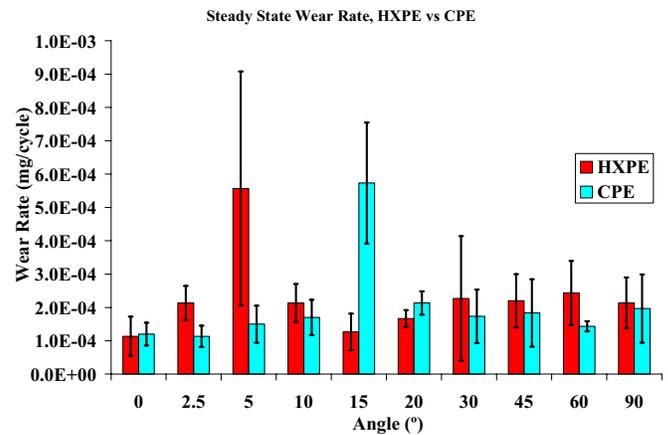

**RESULTS AND DISCUSSION**

Experimentally, steady state wear for all angles was reached by approximately 60,000 cycles. Under this extremely abusive test regimen, in which scratches greatly dominate the surface engagement tribology, the absolute wear rates for both polyethylenes were nominally similar, Fig. 3. Maximum wear rates occurred at 15° for conventional and at 5° for highly-crosslinked UHMWPE. This suggests that at certain low angles, a slicing modality removed large amounts of material as the pin traveled across the scratch lips. The recovered debris was volumetrically dominated by strip/ribbon-like particles often hundreds of μm in length (Fig 4a) unlike the much smaller more bioactive particles worn by a polished counterface (Fig 4b). In the FEA, computed maximum stress values exceeded polyethylene yield for all scratch orientations. The many FE metrics showed a spectrum of statistical fit with experimental direction-dependence, with (1) cumulative compressive total normal strain in the direction of loading and

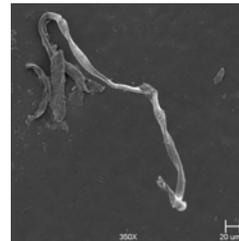

(2) maximum instantaneous compressive total normal strain transverse to the sliding direction having best overall performance.

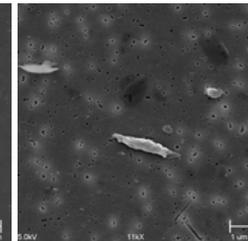

**Figure 2.** FE model depicting stress contours at  $\theta=45^\circ$ .

**Figure 3.** Experimental wear rates vs. scratch orientation.

**Figure 4a.**

**Figure 4b.** Polyethylene debris.

**CONCLUSIONS**

Conventional and highly-crosslinked UHMWPE both showed similar dependence on scratch vs. motion direction, and had comparable volumetric wear rates, in this very abusive regimen. However, the typical particle size was well above the most bioactive range.

## A PEDICLE SCREW BASED DESIGN FOR AN ARTIFICIAL FACET JOINT

<sup>1</sup>Miranda N. Shaw, <sup>1</sup>Vijay K. Goel, <sup>1</sup>Koichi Sairyo, <sup>1</sup>Srilakshmi Vishnubholta, <sup>1</sup>Ashok Biyani

<sup>1</sup>Spine Research Center, University of Toledo and Medical College of Ohio, Toledo, OH; email: vijay.goel@utoledo.edu

### INTRODUCTION

Spinal disorders such as disc degeneration can cause debilitating pain. Currently, several surgical interventions are used to restore spinal stability and normal function in LBP patients. Such surgical techniques include spinal fusion which impairs normal function and the success rate varies. Recently, normal biomechanical motion is restored utilizing artificial discs. Although controversial, if normal function of the spine is to be restored the facet joints may be replaced. Facet replacements may be indicated in cases of facet hypertrophy, spinal stenosis, etc. The following study presents a biomechanical analysis of a pedicle screw based artificial facet design using the finite element technique.

### METHODS

A 3-dimensional, non-linear, ligamentous, experimentally validated, finite element model of the L3-S1 segment was used to determine the effectiveness of an artificial facet. The L4 inferior and L5 superior facets were removed and replaced with artificial L4/5 facets constructed of titanium. The artificial facets were attached to L4/5 titanium pedicle screws (Figure 1A). The capsular ligaments and L4/5 facets were removed for simulation of the surgical technique used to replace the facet joint. For comparison purposes, a rigid pedicle screw and rod system was also simulated with a facetectomy at the L4/5 segment. A 400N compression load and 10.6 Nm extension and rotational moment were applied, being the most relevant loading modes for facet function.

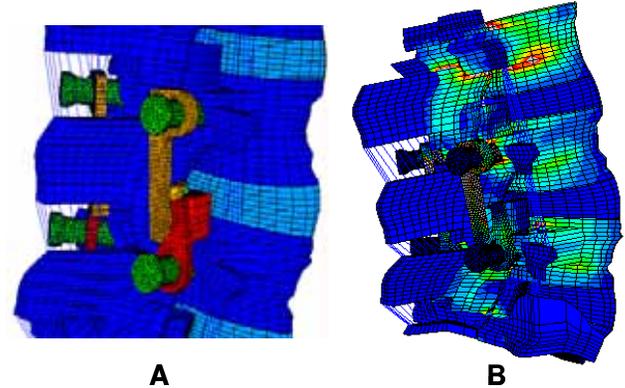

### RESULTS AND DISCUSSION

**Table 1:** Angular motion (deg) across L4/5 for 400N compression and a 10.6Nm bending moment.

Relative angular motion across L4/5	Intact Spine	Spine with artificial facet
Extension	3.6	5.1
Rotation	2.9	4.2

**Table 2:** Facet loads (N) transmitted across the L4/5 facet joint at 400N compression and a 10.6Nm bending moment.

Facet load (N)	Normal facet	Artificial facet
Extension	324	245
Rotation	157	159

**Figure 1:** L3-S1 Finite element model. (A) Model of facet joint replacement across L4/5. (B) Stresses acting on the spine and artificial facet joint in extension.

The relative angular motion across the L4/5 segment increased as compared to intact, in both extension and rotation. Loads through the artificial joint increased in rotation by 1% but decreased in extension by 25% as compared to the intact case. In extension, a peak von Mises stress of 109MPa was located in the L4 artificial facet pedicle screw while in the rigid screw system the peak stress in the pedicle screw was 122MPa. Stresses on the joint and spine are shown in Figure 1B. For the pedicle screw system, a peak stress in the L4 pedicle screw of 107MPa occurred in rotation as compared to 161MPa for the rigid screw system.

### CONCLUSIONS

The pedicle screw artificial facet design resulted in increased motion at L4/5 due to capsular ligament removal. Loads transferred through the artificial joint also differed from intact loads. The L4 pedicle screw stresses were less with artificial facets than a rigid screw system suggesting that the artificial facet design will perform similarly to the rigid screw system in the pedicles. Additional investigations are needed for other loading modes and designs to understand the complex biomechanical issues involved with the design of artificial facets.

## POSTURAL CONTROL RELATED TO FLEXIBILITY OF THE HINDFOOT WHEN BEARING HEAVY LOADS

<sup>1</sup>H.J. Sommer, <sup>1</sup>Michelle Heller, <sup>2</sup>John Challis and <sup>2</sup>Neil Sharkey

<sup>1</sup>Mechanical and Nuclear Engineering, and <sup>2</sup>Kinesiology, The Pennsylvania State University, University Park, PA, USA  
 email: [hjs1@psu.edu](mailto:hjs1@psu.edu), web: [www.biomechanics.psu.edu](http://www.biomechanics.psu.edu)

### INTRODUCTION

Flexibility of the hindfoot is often used to help prescribe in-shoe orthotics for intervention or treatment of overuse injuries to the lower extremity. The high incidence of stress fractures in military recruits during basic training is of particular concern because high frequency of loading is exacerbated by carrying a heavy backpack. Properly designed in-shoe orthotics could potentially reduce the incidence of stress fractures and shorten recovery time, but clinical assessment of hindfoot flexibility is generally qualitative, and prescription of orthoses is often subjective and occasionally contentious. Concomitantly, this study investigated a quantitative measure of hindfoot flexibility versus postural control with a heavy load, as a prelude for future gait studies.

Karlsson et al. [1] suggest a load-unload strategy for medial-lateral (ML) postural control by shifting weight from one foot to the other, and a more active strategy for anterior-posterior (AP) stability using the muscles crossing the ankle joint. ML load-unload is typically actuated by lateral sway of the torso with feet and ankles in a more passive role.

Random walk analysis has been applied to center of pressure (COP) measurements under the feet during quiet standing to investigate control characteristics of postural stability [2]. It employs the mean-square-difference (MSD) in digitized signal  $x_i$  over different latency intervals  $\tau$  as shown in Equation 1. Correlating MSD with  $\tau$  as shown in Equation 2 permits estimation of scaling exponent H.

$$MSD(\tau) = \Sigma [(x_{i+k} - x_i)^2] / (n-k) \quad \text{for } \tau = k \Delta t \quad (1)$$

$$MSD \sim \tau^{2H} \quad (2)$$

Scaling exponent H equals 0.5 for classical Brownian motion, is above 0.5 for more active control, is below 0.5 for less active control, and equals 0 for a purely random signal. Typical plots of  $\log(MSD)$  versus  $\log(\tau)$  for COP during quiet standing with shoes exhibit characteristic  $H_1$  between 0.4 to 0.7 for  $\tau$  below a critical time interval (CTI) of approximately 1 second, and  $H_2$  between 0.1 to 0.2 for  $\tau$  above the CTI.

### METHODS

A vernier caliper was used to measure navicular drop [3] for each foot of 22 female volunteers. At least two measurements per foot by different investigators were averaged. The sum of right and left navicular drop was used to quantify hindfoot flexibility. The subjects then donned cross-training shoes and stood on a force platform under two conditions: two feet quiet standing, and wearing a military backpack (18.1 kg). COP data were collected at 1000 Hz over 30 seconds per trial. One trial per condition was used. Correlation coefficients for scaling exponent  $H_1$  in ML and AP directions for each trial were computed as linear functions of navicular drop.

### RESULTS AND DISCUSSION

AP scaling exponent  $H_1$  for two feet was effectively constant across all values of navicular drop with mean 0.60 ( $r^2 = 0.01$ ). AP scaling exponent  $H_1$  while wearing the backpack was effectively constant with mean 0.68 ( $r^2 = 0.03$ ). These values indicate moderately active control in the AP direction with slightly more active control effort when wearing a backpack.

ML scaling exponent  $H_1$  for two feet was effectively constant across all values of navicular drop with mean 0.38 ( $r^2 = 0.04$ ) indicating less active control than AP. However ML scaling exponent  $H_1$  while wearing the backpack was moderately correlated to navicular drop ( $r^2 = 0.32$ ) as shown in Figure 1. More flexible feet exhibited less ML active control while stiffer feet exhibited more active control.

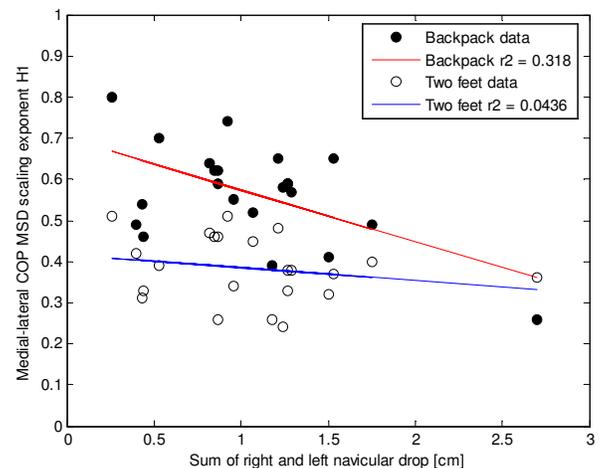

Figure 1: ML postural control versus hindfoot flexibility

### CONCLUSIONS

These data support active AP ankle strategy with higher  $H_1$  in the AP direction compared to ML for two feet, and even higher  $H_1$  when a heavy load is carried on the back. In regard to the ML load-unload model, a flexible foot would provide a better damping mechanism and require less ML control than a more rigid foot.

A correlation with  $r^2 = 0.32$  is not definitive. However the relationship between ML postural control when wearing a backpack and hindfoot flexibility quantified by navicular drop warrants further investigation, particularly in regard to prescribing in-shoe orthotics to reduce lateral ankle forces.

### INTRODUCTION

Quantifying the changes in skeletal muscle stiffness that occur with pathologies will improve our understanding of disease and injury and should lead to advances in treatment. Magnetic Resonance Elastography (MRE), a non-invasive phase contrast MRI technique, can visualize small displacements from applied shear waves and quantify the stiffness of soft tissues *in vivo* [1]. This technique has shown significant differences in the medial gastrocnemius muscle stiffness between the healthy volunteers and patients with spastic paraplegia, flaccid paraplegia and poliomyelitis, however, variations in the muscle stiffness in the left and right legs were observed in both populations [2]. Currently, we would like to use MRE to evaluate the effects of hemiplegic stroke and unilateral disuse atrophy on muscle stiffness by comparing the muscle stiffness in the affected limb to the unaffected limb. However, before this study can be conducted, it is necessary to determine a confidence interval to indicate if the differences are due to anatomic variations or if they are caused by pathology.

### METHODS

Five healthy volunteers (4 female, 1 male, mean age: 26.4±3.3 years, BMI 21.3±2.0) were placed in a test jig with integrated MR compatible torque cells (Interface, Scottsdale, AZ). This jig fixed the ankle position in a range from 20° dorsiflexion (DF) to 40° plantarflexion (PF) in 10° increments. The loading was monitored with a custom LabView program (National Instruments, Austin, TX) including visual feedback to ensure that a constant load was applied by the subject. The volunteers' ankles were fixed at 10° of PF and they were asked to resisted isometric loads of 5-20 Nm in 5 Nm increments. MRE data were also collected with no contraction at 10° of DF, 10° of PF and 30° of PF in healthy volunteers and in one patient with hemiplegic stroke.

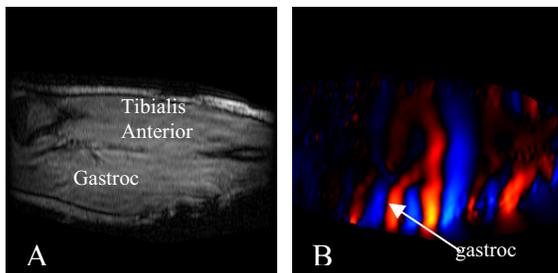

Fig 1. A) 2D MR image B) MRE image of gastroc

To collect MRE data, an electromechanical driver was strapped around the lower leg to induce shear waves into the gastroc at 100 Hz ( $f_e$ ). A 2D 5 mm thick slice including the lateral gastroc was imaged with a gradient-echo, cyclic motion sensitizing sequence (TR/TE of 100ms/min full, 256x64 acquisition matrix, 24cm FOV) (Fig. 1). Each scan took 64 seconds to complete. The stiffness was calculated using a

phase gradient technique after the data were smoothed with a directional filter. A 1D profile was drawn along the direction of the wave propagation in the complex first harmonic. The spatial frequency ( $f_s$ ) was measured from the 1D profile and stiffness was defined as:  $\mu = f_e^2 / f_s^2$ .

Left to right symmetry was assessed using the Bland-Altman technique [3]. For each volunteer, the side-to-side difference in gastrocnemius stiffness was plotted against the mean stiffness. The confidence interval of anatomic variations was defined as the mean value of the difference in stiffness  $\pm$  two standard deviations of the difference.

### RESULTS AND DISCUSSION

The left to right difference and confidence interval ranged from -9.27 to 7.88 kPa, and -7.89 to 8.11 kPa, respectively in the Bland-Altman plot (Fig. 2). In the stroke patient, the difference between the gastroc stiffness in the affected and unaffected limbs was -3.45, 32.28 and 32.41 kPa when the ankles were fixed at 30° of PF, 10° of PF and 10° of DF, respectively. These differences exceeded the confidence interval in two of the three conditions tested, indicating a change in the muscle properties after a stroke.

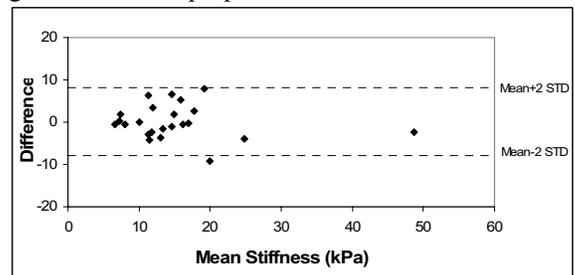

Fig. 2 Bland-Altman Plot of the left to right difference of gastrocnemius stiffness in five healthy volunteers.

### CONCLUSIONS

A symmetry threshold was determined for the gastroc in PF loading and with no load at various ankle positions. While more data must be collected to include a more representative population, the preliminary results suggest that comparing the affected to unaffected limb when unilateral pathology is present will enable us to detect changes caused by injury or disease.

## THREE-DIMENSIONAL SHOULDER JOINT POSITION SENSE

David N. Suprak and Andrew R. Karduna  
Department of Human Physiology, University of Oregon, Eugene, OR, USA  
email: dsuprak@darkwing.uoregon.edu

### INTRODUCTION

Joint position sense (JPS) is an important ability contributing to coordinated joint function, and is especially important for the stability and function at the shoulder [1]. The vast majority of studies in this area focus on movement about one axis of rotation, whereas there exists a scarcity of information concerning how shoulder joint position sense behaves in three dimensions. Therefore, the purpose of this study was to examine the effects of elevation angle on three-dimensional (3D) active repositioning error of a presented joint position. We hypothesized that error magnitude, defined as the angle between the presented and reproduced joint positions, would increase as the humeral elevation angle moved away from 90°, the position in which torque due to gravity about the shoulder joint is maximized.

### METHODS

A total of 20 subjects (12 males, 8 females), with a mean age of 23.3 yrs. ( $\pm 4.8$  yrs.) participated in the study. Following a standardized warm-up procedure, subjects were fitted with a head-mounted display and asked to remove shirts (females wore sports bras) to minimize visual and tactile cues (Figure 1). Kinematic data were collected via the Polhemus Fastrak magnetic tracking system, with one receiver on the thorax and one on the humerus. Testing involved the presentation of five target positions, consisting of various elevation angles in the scapular plane (35° plane). These positions were presented via custom-made Labview software through the head-mounted display. Once the target position was achieved, the display turned black and remained so for the remainder of the trial. Subjects held the position for five seconds, and returned to the side. Subjects then attempted to replicate the target position in three dimensions, in the absence of visual cues. Target positions were presented in a randomized order.

Figure 1: Experimental Set-up.

### RESULTS AND DISCUSSION

A one-way repeated measures ANOVA revealed a significant main effect for elevation angle. Pairwise comparisons across elevation angle showed significantly smaller repositioning error at 90° compared to that at 30°, 50°, and 70° of elevation (Figure 2). The trend indicating improved JPS as the presented position is moved toward 90° elevation may be related to the torque generated at the shoulder joint due to gravity. Greater muscle activation is required in order to counteract this increase in torque and maintain the presented shoulder position. This finding may implicate muscle spindles as a primary source of afferent input related to JPS, due to the increased stimulation of these receptors with increasing muscle activation. This role of the muscle spindles has been hypothesized by various authors in the past [2, 3].

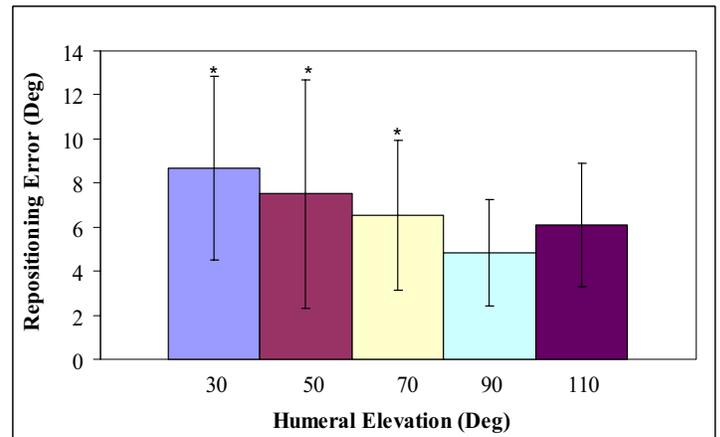

Figure 2: Error Magnitude Across Elevation Angle (Mean  $\pm$  SD).

### CONCLUSIONS

The results of this study indicate that 3D JPS in the shoulder is affected by the humeral elevation angle. More investigation is necessary to elucidate the role of muscle contraction intensity in 3D JPS.

## Influence of Pericellular Matrix on Cell Strains in the Intervertebral Disc

Prabhu, R.D., Iatridis, J.C and Keller, T.S.

Department of Mechanical Engineering, University of Vermont,  
 Burlington, Vermont 05405, [email:rdprabhu@cem.uvm.edu](mailto:email:rdprabhu@cem.uvm.edu)

### INTRODUCTION

Mechanical signals on intervertebral disc cells are important determinants of biosynthetic activity and can result in cell death if excessively large. Computational modeling demonstrated that a narrow pericellular matrix (PCM) surrounding the chondrocytes substantially alters the cell's micromechanical environment [1]. In cartilage, alterations to the cell and PCM are implicated in the initiation and progression of arthritis [2,3]. The PCM has been observed around the cells of the annulus and nucleus of the intervertebral disc with the suggestion of increasing PCM thickness with degeneration [4,5]. However, the role of the PCM in determining the micromechanical environment of cells in the disc has not been investigated. The purpose of this study is to investigate the influence of PCM thickness on cell strains in the three different regions of the intervertebral disc.

### METHODS

Cells in the outer annulus fibrosus (AF) region of the disc are elongated and embedded in a highly anisotropic extracellular matrix whereas cells in the nucleus pulposus (NP) are spherical and surrounded by isotropic tissue. The cells of the transition zone (TZ), or inner annulus, are ellipsoids and surrounded by matrix with a moderate degree of anisotropy. To model the micromechanical environment in and around the cells a 2-D transversely isotropic axisymmetric model of the cell, PCM and tissue was developed using FEMLAB (Comsol, Natick, MA). The model computed the volume averaged cell strains normalized by the far-field matrix strains as a function of varying PCM thickness. For all disc regions, the PCM thickness was varied from 0 to 3 microns. Uniaxial loading conditions were applied, and effective strain fields were calculated. Material properties and geometries for the cell, PCM and the extracellular matrix in the three disc regions were taken from literature [6] and assumed linearly elastic. To further elucidate the effects of cell aspect ratio and extracellular matrix anisotropy on cell strains, four baseline cases were investigated (spherical-isotropic, spherical-anisotropic, non-spherical-isotropic and non-spherical-anisotropic) and cell averaged radial, azimuthal and axial strains were calculated. Anisotropy was simulated by varying the matrix modulus along the axial ( $E_z$ ) and radial ( $E_r$ ) directions and cell aspect ratio ( $a/b$ ) was varied from 1 to 5.

### RESULTS AND DISCUSSION

For uniaxial loading, relative variations in effective strain both within and across the cells in the TZ were larger than that for the cells in the AF region (Figure 1). The presence of the PCM 'amplified' the cell strains in a nearly linear increase in strain with PCM thickness (Figure 2). Anisotropy in the extracellular matrix enhanced the dependence of cell-strains on PCM thickness while cell-elongation reduced the dependence.

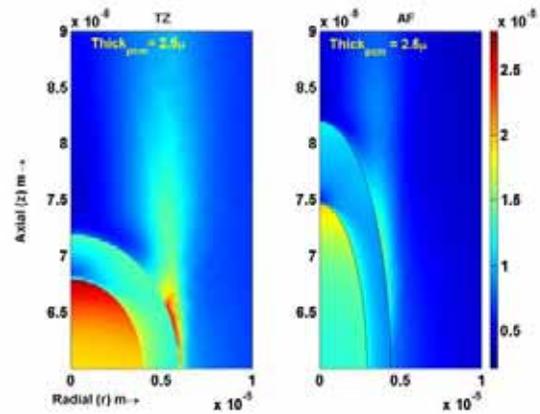

Figure 1: Effective Strain fields for TZ and AF regions

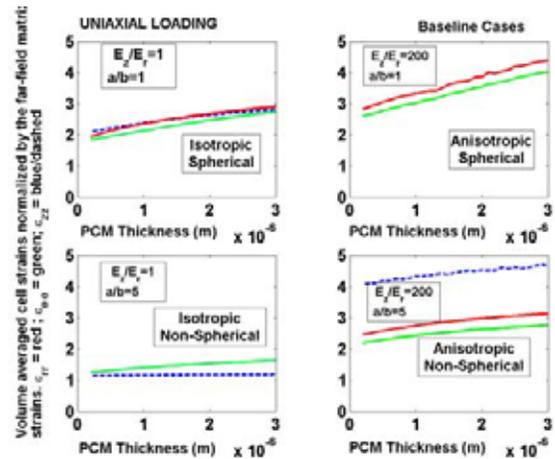

Figure 2. Average cell strains for the baseline cases

Thus cell strains are a function of the competing effects of anisotropy and cell elongation. Large strain amplification in the TZ region is consistent with increased apoptosis in this region found in a mouse tail model of degeneration [7]. This model coupled with detailed information on microstructural geometry, properties and other loading conditions will help in understanding the mechanobiology of health and disease.

**DEVELOPMENT AND VALIDATION OF THE FINITE ELEMENT HUMAN BODY MODEL FOR LESS – LETHAL BALLISTIC IMPACTS**

Sriram Rajagopal, Cynthia Bir, Jong Lee and King Yang  
 Wayne State University  
 Email : rs.sriram@wayne.edu

**INTRODUCTION**

The need to test less lethal kinetic energy rounds before their deployment in the field is becoming increasingly necessary with the increase in their usage and potential associated injuries. A cost effective and efficient way to test these rounds is by observing their effects on previously validated finite element human body models. This paper deals with development and validation of the Wayne State Human body model and comparison of the model response with the physical tests performed on cadavers for the assessment of blunt ballistic impacts [1].

**METHODS**

The Wayne State Human Body Model includes a detailed representation of the lung, heart, liver, spleen, spine, ribcage, sternum and major blood vessels [2,3]. Material properties for various tissues of the model were derived from those reported in the literature and the material tests performed at Wayne State University. The model was developed using Hypermesh (Altair Engineering) as the pre/post processor and LS-DYNA (Livermore Software Technology Corporation) as the solver.

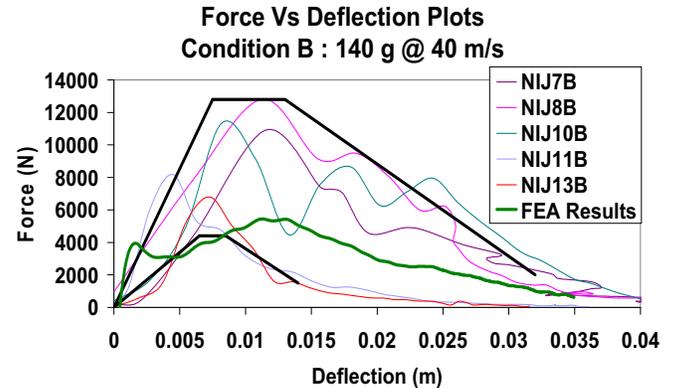

The model was tested for three impact conditions listed in Table 1. Displacement of the projectile was calculated using the nodal displacements and the force was calculated based on the contact interaction forces. Displacement-time, force-time and force-displacement graphs were plotted so as to compare the results with the corridors developed from the experimental test results [1].

**RESULTS AND DISCUSSION**

Results obtained from the FE analysis show good correlations between numerical simulations and experiments. It was observed that the properties and thickness of the skin covering the thorax plays a major role in the response characteristics. Based on the stresses observed in the FE model, sternum and rib fractures can be predicted. Figure 1 shows the force-displacement plot for Condition B. Similar co-relation was observed for the remaining two conditions. The displacements and the forces were computed until 4 ms after which the impactor is not in contact with the body in all the three conditions.

**Table 1:** Impact conditions from experimental testing.

Impact Conditions	Diameter (mm)	Length (mm)	Mass (grams)	Velocity (m/s)
Condition A	37	100	140	20
Condition B	37	100	140	40
Condition C	37	28.5	30	60

**Figure 1:** Force-Deflection Plot for Condition B

The energy balance was maintained by reducing the hourglass energies and the skin was given a fully integrated element formulation. In the force-time curves an initial steady rise in force is observed due to the energy absorbed by the skin.

**CONCLUSIONS**

Results from this study demonstrate that finite element thorax model is powerful tool for assessment of the injury mechanisms to the human thorax against blunt ballistic impacts.

## INVESTIGATION OF APPROPRIATE WEIGHTED BAT BY MUSCLE ACTIVITY

<sup>1</sup>Tsung-Ying Hung, <sup>2</sup>Ya-Chen Liu, <sup>1</sup>Chiang Liu, and <sup>1</sup>Tzyy-Yuang Shiang  
<sup>1</sup>Taipei Physical Education College, Taiwan. <sup>2</sup>Chung-Hua University, Taiwan

### INTRODUCTION

Swing velocity is a critical factor for batting performance. There is a certain relationship between swing velocity and bat weight (Fleisig *et al.*, 2002). Some studies have demonstrated that baseball player could significantly improve swing velocity through using regular bat, weighted bat, and combine weighted and lighter bat for several weeks training period (Sergo & Boatweight, 1993, DeRenne *et al.*, 1995). During warm-up in the on-deck circle, using lighter bat could produce significantly higher velocity compared to using regular or weighted bat (DeRenne & Branco, 1986). On the other hand, Tu *et al.* (2002) found that swing weighted bat could significantly improve velocity. But only in the first swing after warm-up with weighted bat (Otsuji *et al.*, 2002). Each player has specific ideal weight bat (Bahill & Karnavas, 1991). However, there are big gap between ideal weight bat and general use bat for practice or game. Therefore, the purpose of this study was to determine appropriate weighted bat by analyzing muscle activity.

### METHODS

Eleven collegiate baseball players were voluntary participated in this study. Each subject randomly swung nine different weighted bat: 1200g (weighted bat), 900g (general using bat), 850g, 800g, 750g, 700g, 650g, 600g, and 490g (fungo bat). After finished warm-up session, participant swung each kind of bat three trials. Each swing has a break period for 30 seconds. In order to discriminate swing phases, the desk bell and sound recorder were use to be a trigger and record sound signal. Surface active electrodes (Biovision system) were used to detect muscle activity of triceps and biceps brachii muscles. Integral EMG and Mean EMG during swing phase were calculated after normalizing by MVC. We also calculated the ratio of biceps and triceps muscle activities for intermuscular coordination between agonist and antagonist muscle. The sound signal was collected including sound of bell (I), bat-ball impact (II), and ball flight into protective net (III) (shown in Figure 1, channel 1 is sound signal, channel 2 and 3 are EMG of triceps and biceps brachii muscles). Swing phase was defined as I to II.

### RESULTS AND DISCUSSION

In table 1, muscle activities in triceps and biceps of right arm appeared slightly change with increasing bat weight. Triceps is agonist muscle result from extending elbow during swing. Triceps is the major contributing muscle during swing phase because of higher muscle activity. As Figure 2 shown, 850g-bat and 650g-bat also have better intermuscular coordination between triceps and biceps brachii muscles. According to muscle force-velocity relationship, swing velocity and muscle activity could be used as index to find suitable weight bat (Liu *et al.*, 2003). Our other study found that 850g-bat and 650g-bat could induce higher swing velocity. Combining description above, 850g-bat and 650g-bat have some advantage

characteristics, such as higher IEMG and MEMG in triceps, lower IEMG and MEMG in biceps, as well as better intermuscular coordination. Therefore, 850g-bat and 650g-bat are appropriate weighted bats for game and practice.

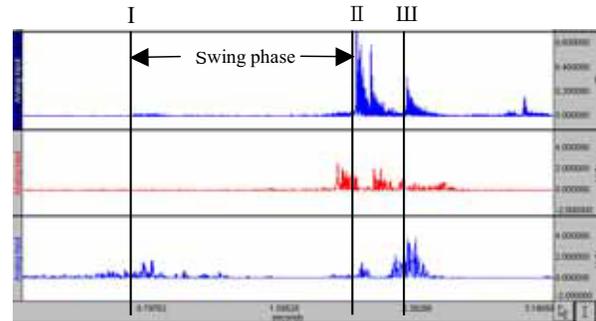

Figure 1: Signals of sound and muscle activity.

Table 1: Muscle activity with different weighted bats

Bat	Triceps		Biceps	
	IEMG	MEMG	IEMG	MEMG
1200g	13.29±1.89	25.04±5.75	3.17±1.23	5.92±2.38
900g	11.18±2.28	21.22±2.99	3.24±1.37	6.20±2.53
850g	11.73±2.68	21.14±4.64	3.06±0.76	5.66±2.11
800g	10.31±1.78	21.13±3.10	3.06±1.28	5.94±2.26
750g	11.00±2.60	19.82±4.38	3.00±0.66	5.67±1.58
700g	11.72±2.59	22.24±4.52	2.74±0.80	5.28±1.66
650g	13.05±5.75	20.16±2.52	2.37±0.52	4.98±1.56
600g	9.81±1.87	19.77±3.49	2.63±0.92	5.20±2.29
490g	11.01±2.36	21.72±4.55	2.72±0.57	5.48±1.84

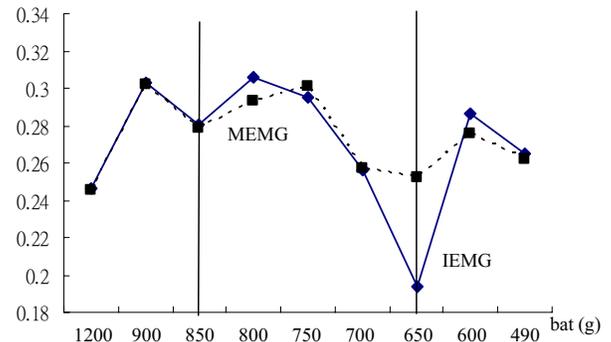

Figure 2: Intermuscular coordination of swing weighted bats

### CONCLUSIONS

The results reveal that triceps brachii muscle was a major muscle group during swing. IEMG and MEMG decreased with decreasing bat weight. Consequently, 850g-bat is appropriate bat weight for hitting in competition. 650g-bat is suitable bat weight for improve swing velocity and intermuscular coordination in swing practice.

## AN EMG DRIVEN OPTIMIZATION MODEL FOR ESTIMATING DYNAMIC KNEE MUSCLE FORCES WITHOUT MAXIMUM VOLUNTARY CONTRACTION TESTS

Bing Yu and Evan J.X. Tong

Center for Human Movement Science, Division of Physical Therapy, The University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; email: [byu@med.unc.edu](mailto:byu@med.unc.edu)

### INTRODUCTION

Anterior cruciate ligament (ACL) injuries are common in sports. Women are at a greater risk for ACL injuries than men. Previous studies show significant gender differences in lower extremity kinematics and kinetics when performing athletic tasks, but have not established the relationship between the observed gender differences in motion patterns and the risk for ACL injuries. To investigate the biomechanical risk factors for ACL injuries, a musculoskeletal model is needed to estimate dynamic knee muscle forces in athletic tasks. The purpose of this study was to develop an EMG driven optimization model to estimate dynamic knee model forces in athletic tasks without maximum voluntary contraction tests.

### METHODS

The muscle fiber force was expressed as the sum of forces generated by the contractile and parallel elastic elements. The force generated by the contractile element was expressed as a function of dynamic EMG, EMG-to-force gain, muscle specific stress, muscle physiological cross section area, muscle length-tension adjustment, and velocity-tension adjustment. The force generated by the parallel elastic element was expressed as a function of muscle specific stress, muscle physiological cross section area, and parallel elastic length-tension adjustment. The muscle origin and insertion coordinate, physiological cross section area, optimum fiber length, muscle tendon length, muscle maximum contraction velocity, and muscle pennation angle data, and length-tension and velocity-tension relationships in the relevant literature were used in the model to determine muscle length, PCSA, length-tension adjustments and velocity adjustments. Force fiber force was converted to the muscle tendon force using the muscle pennation angle. Vastus medialis, lateralis, and intermedius, rectus femoris, semimembranosus, semitendinosus, biceps femoris long and short heads, medial and lateral gastrocnemius were considered as the knee flexion-extension moment generators. EMG-to-force gains and muscle specific stresses were optimized to minimize the sum of squares of the differences between the muscle generated knee flexion-extension moment and knee resultant flexion-extension moment, subject to the constraints to the muscle EMG-to-force gains and muscle specific stresses.

Five male and five female recreational athletes were recruited as the subjects. Three-dimensional (3D) kinematics and kinetics, and EMG were collected for a stop-jump and a running task. The kinematics data were collected at 120 frames/second while the kinetic and EMG data were collected at 1200 sample/channel/second. The raw coordinate data of critical body landmarks were filtered at the estimated optimal cutoff frequencies. Knee joint resultants were estimated using an inverse dynamic procedure. EMG signals were band-pass filtered (10 – 300 Hz) and then low-pass filtered (6 Hz) for linear enveloped EMG. The stop-jump and running tasks

were rotated as calibration and validation tasks to validate the estimated EMG-to-force gains and muscle specific stresses. Regression determinant ( $R^2$ ) and mean error ( $e$ ) between muscle generated knee flexion-extension moment and knee resultant flexion-extension moments were used to evaluate the quality of predicted knee flexion-extension moment. Paired t-tests were performed to compare the regression determinants and mean errors between calibration and validation tasks.

### RESULTS AND DISCUSSION

The proposed EMG driven optimization model predicted knee flexion-extension moment for calibration and validation tasks with a good accuracy (Table 1). Although the accuracy of the predicted knee flexion-extension moment was slightly decreased for validation tasks, there was not statistically significant difference in the regression determinant of the predicted knee flexion-extension moment between calibration and validation tasks (Table 1).

The ability of the proposed EMG driven optimization model to predict knee flexion-extension moment for the calibration task was comparable to the similar models in literature. The decreased ability to predict knee flexion-extension moment for the validation task is likely due to assumed linear EMG-to-force relationship. The lack of consideration of the relationship between muscle activation level and muscle length-tension relationship did not seem to have critical effects on the ability to predict knee flexion-extension moment for the validation task. Further studies may be needed to further validate estimated muscle forces and joint structure loadings.

**POSTURAL SWAY ON A SLIDING PLATFORM: ASSESSING SPATIAL AND TEMPORAL STABILITY**

<sup>1</sup> Haruhiko Sato, <sup>1</sup>Yoshitaka Shiba, <sup>1</sup>Toyokazu Saito and <sup>1</sup>Toshiro Futami  
<sup>1</sup>Allied Health Sciences, Kitasato University  
 email: haru@kitasato-u.ac.jp

**INTRODUCTION**

If a fall is regarded as a situation in which a person fails to recover the body center of mass from the edge of the base of support, balance assessment is required to measure the excursion distances of the center of pressure (COP) as well as reaction time [1]. A quick response is preferable to achieve efficient recovery from stability limits. In order to assess spatial and temporal stability [2], we designed a sliding platform anchored at one end of a sliding rail. The platform helps the subject to transfer his or her weight from heel to toe or from toe to heel when performing voluntary anterior-posterior (AP) sway of the COP on the platform. The aim of the present study was to describe the various characteristics of AP sway among young, and elderly subjects, as well as in subjects with Parkinson's Disease (PD).

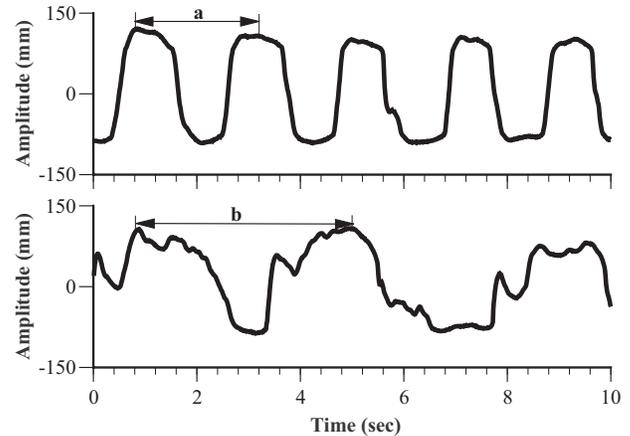

**METHODS**

Our subjects consisted of 37 healthy university students (17 female and 20 male; age range = 18-27 years, mean = 20.1 ± 2.3 years), 29 healthy elderly subjects (13 female and 16 male; age range = 65-89 years, mean = 69.9 ± 4.7 years), and 7 subjects with PD (4 female and 3 male; age range = 55-72 years; mean = 63.7 ± 6.6 years). PD subjects were recruited from Kitasato University East Hospital and elderly subjects were recruited from the local community.

Wearing a safety harness, subjects performed voluntary cyclic AP sway standing on the sliding platform or a fixed platform, each of which contained three load cells to measure vertical ground force. Data were recorded at 100 Hz and the associated COP was then computed. An auditory metronome guided subjects to sway the COP at 0.5 Hz. Once the subject swayed rhythmically, force data were recorded for 10 seconds. Time series were analyzed for each trial corresponding to COP sway (Fig. 1). COP amplitude was calculated using the distances between the peaks and the valleys, and duration was defined as the times between the peaks. The calculated values were averaged across three trials per subject.

**RESULTS AND DISCUSSION**

The mean duration achieved by elderly and PD subjects was found to be longer than that of young subjects under both fixed and sliding conditions (Fig. 1, Table 1). Most young subjects were able to pace their AP sway with the auditory cue, while elderly and PD subjects did not maintain the pace. The ranges of duration on the sliding platform were 1.8 to 3.0 sec for the

**Figure 1:** Representative AP displacements of the COP on the sliding platform in a young subject (top) and an elderly subject (bottom). The intervals designated by “a” and “b” indicate duration.

young, 1.0 to 6.4 sec for the elderly, and 1.8 to 6.1 sec for PD subjects. Both elderly and young subjects showed shorter duration under sliding conditions than under fixed conditions ( $p < 0.001$  and  $p < 0.05$ , respectively), and the mean amplitude of elderly and PD subjects was significantly smaller than that of the young under both conditions ( $p < 0.01$ ). Sliding conditions produced smaller amplitude than fixed in the young and the elderly ( $p < 0.01$ ). The sliding mechanism was found to be an effective method of testing the speed of sway, especially in elderly subjects, however, this method was less effective in the case of PD subjects. The duration of voluntary AP sway was found to decrease with decreasing amplitude.

**CONCLUSIONS**

The sliding platform was found to help subjects perform fast AP sway provided that they were able to easily move their body weight. In subjects with a balance problem, fast AP sway is more difficult to achieve.

### INTRODUCTION

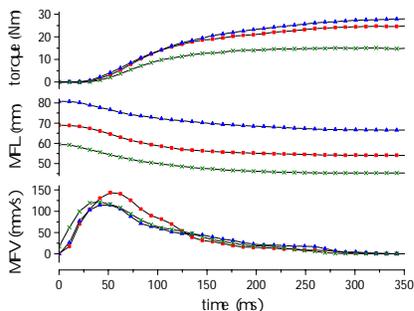

The muscle fiber force is a function of muscle fiber length (MFL), muscle fiber shortening velocity (MFV) and active state (AS) [1, 2]. However, little is known how these factors determine the time-course of muscle fiber force in human muscles *in vivo*. The present study aimed to investigate the time-course of muscle fiber kinetics during isometric tetanic contractions. For this aim, we measured MFL and MFV, and estimated the time-course of the force generating capacity (FGC) determined from each of MFL, MFV and AS.

### METHODS

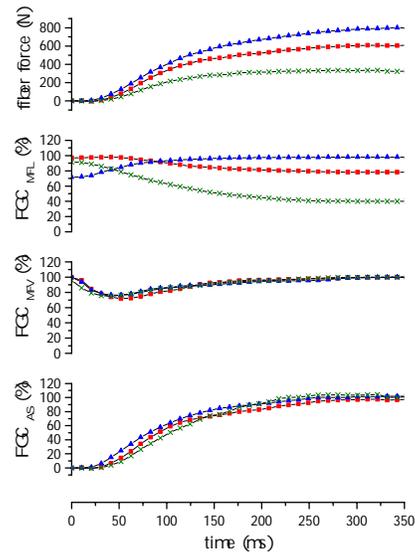

Six healthy male volunteers participated in this study as subjects. The subject was seated with the knee joint fully extended. To change the initial length of MFL, three ankle joint angles (30, 10 and -10 deg; 0 deg is an anatomical position) were chosen. Isometric tetanic contractions (2s at 50Hz) were evoked by percutaneous supramaximal electrical stimulations to the common peroneal nerve. The ultrasound apparatus (SSD-6500SV, Aloka, Japan) having a 10 MHz linear-array probe was used to measure the sequence of longitudinal ultrasonic images (96.4Hz) of the tibialis anterior muscle at the level of 40 % of the lower leg length. From the serial images, MFL, MFV and pennation angles were measured using an image analysis software. Muscle fiber force was estimated using measured dorsi-flexion torque, moment arm length and pennation angle. FGC related to MFL and MFV were estimated from force-length and force-velocity relationships. FGC related to AS was calculated using the following equation:

$$F_{exp} = P_0 \cdot FGC_{F-L}(MFL) \cdot FGC_{F-V}(MFV) \cdot FGC_{F-AS}(AS)$$

where  $F_{exp}$ =estimated muscle fiber force,  $P_0$ =maximal force at optimum length,  $FGC_{a(b)}$ =force generating capacity related to  $a$  as function of  $b$ . F-L, F-V and F-AS mean force-length, force-velocity and force-active state relationships, respectively.

**Figure 1:** Time-courses of dorsi-flexion torque, muscle fiber length (MFL) and muscle fiber shortening velocity (MFV). (average of six subjects) [ 30deg, ■10deg, ×-10deg]

**Figure 2:** Time-courses of fiber force and force generating capacity of each muscle fiber length (MFL), muscle fiber shortening velocity (MFV) and active state (AS). (average of six subjects) [ 30deg, ■10deg, ×-10deg]

### RESULTS AND DISCUSSION

The time courses of the measured dorsi-flexion torque, MFL and MFV are shown in Figure 1, and the estimated time-courses of FGC for each of MFL, MFV and AS in Figure 2. For MFL, the magnitude of FGC changed by as much as 27% at the initial phase of contraction (~100 ms). The shapes of the time-course curves were considerably different between joint angle conditions (maximal difference; 31%). For MFV, the magnitude of FGC decreased rapidly at the initial phase (maximal change; 28%) and then increased gradually in all joint angle conditions. For AS, although the magnitude of FGC increased gradually from 0 to 100% in all joint angle conditions, the shape of the time-course curve differed among joint angle conditions (~17%). These findings suggest that the time-course of muscle fiber force developed during tetanic contraction of the tibialis anterior muscle is determined by summation of various changes of the time-course of FGC as a function of MFL, MFV and AS, and that, when the joint angle is changed, it is influenced mostly by the force-MFL and force-AS relationships rather than the force-MFV relationship.

### INTRODUCTION

Resistance training results in improved strength by increasing muscle size and by altering the pattern of nervous drive (Sale, 1988). Resistance training changes the functional properties of spinal cord circuitry in humans, but does not substantially affect the motor cortex (Carroll et al, 2002). Hoffman reflex (H-reflex) was evoked by an electrical stimulus applied on peripheral nerve. It reflects the excitability of motoneuron pool in spinal cord (Schieppati, 1987). Almeida-Silveira et al (1996) monitored the H-reflex and found a decrease in reflex excitability after repeat Stretch-Shortening-Cycle training in rats. Passive Repeated Plyometric training (PRP training), a new training method for strength and power, was developed based on the concepts of Stretch-Shortening-Cycle training (Chen & Shiang, 1996). Several researches have found that PRP training significantly improved strength and power in elite athletes (e.g. Liu *et al*, 2001). However, how neuromuscular system contributes to the gain of strength and power after PRP training is still not well understand. Therefore, the purpose of this study was to investigate the excitability of the reflex arc and the presynaptic inhibition (PSI) could be modulated by the PRP training.

### METHODS

Ten male collegiate (aged 20.30±0.82 yr; weight 68.87±10.26 kg; height 171.70±3.53 cm) voluntary participated in the study. The subjects participated in a 10-wk PRP training program with three sessions per week (see Figure 1). In each of the training sessions, five sets of PRP training were carried out with a 2min break between sets. Each set lasted for 20 sec and the movement frequency was at 2.5Hz.

Figure1: PRP training

The assessment of H-reflex and M-wave amplitudes were conducted before 1<sup>st</sup>, 15<sup>th</sup>, and 30<sup>th</sup> training session. The subjects were positioned on a leg extension machine with ankle and knee joints fixed. The surface EMG was recorded from the soleus muscle of non-dominant leg by using bipolar surface electrode with 2k Hz sampling frequency. The maximum H-reflex was elicited by stimulating the posterior tibial nerve with a constant-current stimulator (DS7H, Digitimer, UK) at 0.2 Hz to detect motoneuron excitability and at 2 Hz to detect PSI. The intensity of the stimulation was gradually intensified to elicit the maximal M-wave. Ten peak-to-peak amplitude of the H-reflexes at each frequency and ten M-waves were recorded. The  $H_{max}$ -to- $M_{max}$  ratio (H/M) at 0.2 Hz was calculated for indicating the excitability of alpha neuron pool. The averaged amplitude of 2<sup>nd</sup> to 10<sup>th</sup> H-reflex at 2 Hz was divided by first H-reflex (PSI ratio=  $\Sigma H_2-H_{10}/H_1$ ) for indicating PSI changed.

### RESULTS AND DISCUSSION

A Repeated Measures of ANOVA revealed that the H/M ratio significantly depressed at 30<sup>th</sup> training session ( $p=0.015$ ) (Figure 2), indicating about 23.5% decrease of motoneuron pool excitability after 10-wk PRP training. This result was consistent with the findings of previous studies (Almeida-Silveira et al, 1996; Scaglioni et al, 2002). Almeida-Silveira et al (1996) found that H-reflex decreases were accompanied by relative increases in the number of type II fibres after SSC training, suggesting the decrease of motoneuron pool excitability after long term PRP training might relate to the change of fiber type composition. In Figure 2, there was significantly increased in PSI ratio after 10-wk PRP training ( $p=0.037$ ). The PSI mechanisms are considered mainly responsible for depression of the H-reflex (Zehr, 2002), which might relate to the function of Ia inhibitory interneurons. The long term PRP training induced PSI ratio increase about 9.7% indicating the PRP training might be able to inhibit effect of Ia inhibitory interneuron and decrease presynaptic inhibition in spinal circuitry.

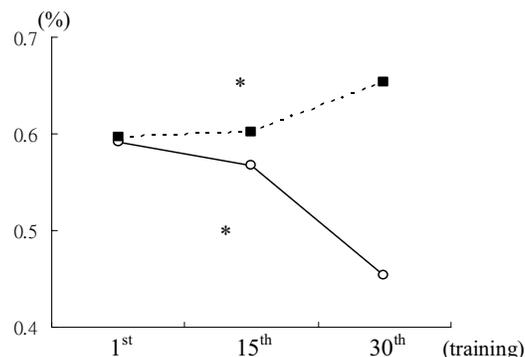

Figure 2: Variety of H/M ratio (○) and PSI ratio (■) via the PRP training for ten weeks. (\*means significant difference between 1<sup>st</sup> and 30<sup>th</sup>,  $p<.05$ ).

### CONCLUSIONS

The findings revealed that excitability of motoneuron pool significant decreased and PSI significant increased by the long term PRP training. The PRP training affected reflex modulation of spinal cord and induced plasticity change of spinal circuitry.

## BALANCE AND GAIT OF ELDERLY WOMEN DURING STAIRS LOCOMOTION IN HIGH-HEELED SHOES

Bih-Jen Hsue, Fong-Chin Su

Institute of Biomechanical Engineering, National Cheng Kung University, Tainan, Taiwan  
 email: [fcu@mail.ncku.edu.tw](mailto:fcu@mail.ncku.edu.tw)

### INTRODUCTION

It is well known that a large number of falls occur on stairs, and females appear to be at higher risk of stair injury based on the high incidence of stair accidents in the elderly women. But, only few studies have been conducted to evaluate the specific factors that contribute to falls on stairs [1,2], or what the strategies are as one's balance is challenging during stair locomotion (SL). The high falling rate and the threatening consequences indicate important needs for the understanding of biomechanics, the identification of the risk factors and the development of preventive strategies. The purposes of this study are (1) to determine the differences in gait pattern between young and elderly females by examining the changes in temporal and kinematics parameters, and (2) to determine the balance strategies in terms of the changes in body posture, center of mass (COM), and joint position while the balance is challenging by wearing high-heeled shoes (HHS).

### METHODS

A five-step wood staircase of 18x28x90 cm in dimension was used. The fifth step was created by a 60cm x 90cm platform. Twenty-five reflective markers were secured to the participant's anatomical landmarks locating on the both sides of the body. An eight-camera Eagle Motion Analysis System (Motion Analysis Corporation, Santa, CA, USA) was used to capture the three-dimensional trajectory data of the markers.

Participants were limited to the individuals who were able to ambulate without using any assistive device and ascend and descend stair without handrail. Five medium body-sized elder females (> 65 y/o) and five young women were enrolled. The participants walked from a start point about 3-5 steps away from the stair to the top platform reciprocally and descended stairs to the start point at their preferred walking speeds under two conditions: wearing low-heeled shoes (LHS) with heel height less than 2 cm and HHS with stiletto more than 5.5 cm. One stride for stair ascent (SA) began with heel contact on the second step and ended with subsequent heel contact of same foot on the step four. For stair descent (SD), one stride began with toe contact on step three and terminated with toe contact of same foot on step one. The data was analyzed utilizing repeated measures analysis of variance (ANOVA) with one within, and one between factor at the 0.05 level of significance.

### RESULTS AND DISCUSSION

The temporal phases for SA and SD under two shoe conditions are listed in Table 1. The walking speed of elder females is slower to either in SA or SD. The elder females seem to gain stability by increasing the stance phase, and this tendency is more obvious while wearing HHS. In young female, the major changes of joint and segment motion while wearing HHS are the decreases in hip and knee flexion. For elder females, the most significant changes caused by wearing HHS are increases of hip

internal rotation both in SA and SD, and foot varus in SD.

**Table 1:** Stance and swing phases in percentage and the period of one cycle in second (Y: 5 young females; E: 5 elder females)

		SA			SD		
		Cycle*	ST (%)**	SW (%)	Cycle*	ST (%)**	SW (%)
LHS	Y	1.19	58.17	41.83	1.16	55.01	44.99
	E	1.58	62.12	37.88	1.59	56.46	43.54
HHS	Y	1.24	60.07	39.93	1.19	55.25	44.75
	E	1.65	64.16	35.84	1.68	58.47	41.53

\* The unit is in seconds; \*\*ST: stance phase, SW: swing phase

The maximal peak-to-peak COM displacement in medial-lateral (ML), anterior-posterior (AP) and vertical (V) directions are shown in Table 2. The findings in COM displacement agree with the trunk motions in Figure 1. The changes in the trunk movement are also more apparent in transverse plane and frontal plane than in sagittal plane.

**Table 2:** The peak-to-peak COM displacement in centimeter (Y: 5 young females; E: 5 elder females)

		SA			SD		
		ML	AP	V	ML	AP	V
LHS	Y	4.56	67.62	34.14	4.04	66.71	33.03
	E	7.41	64.73	34.22	8.36	65.62	34.13
