INTRODUCTION

Running is modeled as a spring-mass system, which gives rise to the concept of leg stiffness (i.e. "quasi-stiffness). Modulating leg and joint stiffness allows a runner to adapt to different surfaces, speeds, and cadences. Individuals self-select a wide range of stiffnesses for a given speed—two to four-fold differences in stiffness are not unusual (even when mass-normalized). Given the fundamental role of stiffness in gait, stiffness may be related to injury susceptibility among runners. Previous work has hypothesized that an "optimal" window of stiffness exists, and runners outside of this window may be predisposed to injury [1]. The purpose of this study was to examine the influence of leg and joint stiffness on running injury development. It was hypothesized that runners in the middle tertile of leg and knee joint stiffness would have the lowest incidence of injuries per 100 hours of running.

METHODS

Fifty-seven recreational runners free from injury in the previous three months volunteered for a cohort study with a maximum follow-up of 52 weeks. Upon enrollment, subjects completed a 3D kinematic and kinetic evaluation that involved five running trials at 4.0 m/s ± 5% on an 18 m runway. Motion data (Qualisys, Gothenburg, Sweden) and force data (AMTI, Watertown, MA) were captured at 240 Hz and 1200 Hz, respectively. Motion capture and force data were lowpass filtered in Visual 3D (C-motion, Germantown, MD) at 12 Hz and 50 Hz, respectively.

Subjects continued their typical training while filling out weekly surveys detailing their training habits and any injuries that occurred. Injuries were defined as "any physical pain located at the lower limbs or lower back region, sustained during or as a result of running practice and impeding planned running activity for at least one day" [2].

If cumulative survey compliance over the subject's follow-up period dropped below 75%, subsequent surveys were ignored and not included in the analysis. Subjects were excluded if they failed to report weekly training volume, completed zero surveys, dropped out prior to gait analysis, or had a pre-existing injury. Forty-one subjects remained after exclusion (16 males, 24 females, 31.7 ±9.9 yrs, 1.73 ± 0.09 m, 67.6 ± 10.8 kg).

Leg stiffness was calculated as the change in leg length from initial contact to the instant of maximum ground reaction force divided by peak vertical ground reaction force [3]. Knee stiffness was calculated as the slope of the least-squares linear regression line for the angle-moment plot from foot-ground contact to the time that peak joint flexion occurred [4]. Participants were stratified into tertiles according to leg stiffness and knee stiffness, both normalized and not normalized to body mass. Injury rate was calculated as injuries per 100 hours of running. Differences in injury rates were assessed using a Pearson χ^2 test ($\alpha = 0.05$). Rate ratios were used to determine the effect size of low and high leg stiffness on injury rates using the middle tertile as the reference group. Survey and gait data were processed using MATLAB (Mathworks, Natick, MA). Statistical analysis was conducted using R 3.4.3 (R Foundation, Vienna, Austria).

RESULTS AND DISCUSSION

Twenty-seven runners reported injury during the follow-up period (mean 14.5 weeks, range 1 - 52). The overall incidence rate of injuries was 2.22 per 100 hours of running (95% CI: 1.46 - 3.23) with a median survival time of 24.62 hours of running as derived from the Kaplan-Meier estimator.

The χ^2 test revealed no statistically significant difference in injury rates among the three leg stiffness tertiles and the three knee stiffness tertiles, regardless of whether stiffness was normalized to body mass (leg stiffness p = 0.15, normalized leg stiffness p = 0.16, knee stiffness p = 0.43, normalized knee stiffness p = 0.39).

Compared to the middle tertile, low and high leg stiffness were associated with an injury rate ratio (RR) of 2.50 (CI 0.94 - 7.40) and 2.18 (CI 0.80 - 6.53), respectively. Knee stiffness followed a similar trend (low RR 1.79, CI 0.70 - 4.50; high RR 1.22, CI 0.46 - 3.13). That is, the high and low leg stiffness tertiles had over twice as many injuries than the middle tertile per 100 running hours. Similarly, the low knee stiffness tertile experienced ~1.8 times more injuries than the middle tertile per 100 running hours. These trends provide merit to the hypothesis. However, after normalization to body mass, this trend did not hold for leg stiffness (low RR 0.49, CI 0.19 - 1.20; high RR 0.49, CI 0.18 - 1.24) or knee stiffness (low RR 1.39, CI 0.55 - 3.50; high RR 0.73, CI 0.27 - 1.87). These shifts can be seen graphically in **Figure 1**. In the case of both knee and leg stiffness, evidence supporting an increased rate of injury among the high and low stiffness groups diminished after normalizing stiffness to body mass.

Normalization was performed to avoid confounding by body mass [5]. However, mass-normalized stiffness may simply be a proxy measure for stride frequency, given the relationship between body mass, stiffness, and ground contact time implied by the mass-spring model. Future research should investigate whether the apparent decrease in injury risk at moderate stiffness levels is an artifact of body mass.

CONCLUSIONS

We are currently planning follow-up cohorts to evaluate the association between stiffness and injury with higher statistical power. This study did not find evidence supporting a relationship between leg stiffness and the rate of running-related overuse injury, regardless of whether leg stiffness was normalized to body mass. However, the higher rate ratios in the lowest and highest tertiles of leg and knee stiffness suggest more research is warranted into the relationship between stiffness and the development of running injuries.

INTRODUCTION

Knee osteoarthritis (KOA) is one of the most common joint diseases in the US, and is characterized by a progressive degeneration of the articular cartilage [1]. While the direct cause of KOA progression is unclear, obesity and female sex are significant risk factors for KOA development [2, 3]. Higher body mass index (BMI) and body fat mass are associated with abnormal cartilage composition and higher compressive forces at the knee joint [1, 4, 5]. Additionally, sex specific anthropometrics, may contribute to altered gait mechanics and knee joint loading in females. Furthermore, alterations in gait mechanics are implicated in KOA incidence and progression [1]. Specifically, individuals with KOA exhibit larger peak external knee adduction moments (KAM) and smaller external knee flexion moments (KFM), which contribute to disease progression [5, 6]. As such, abnormal sagittal and frontal knee joint loading in conjunction with obesity and female sex may predispose individuals to early onset of KOA. However, few data are available on the interaction of sex and obesity in the younger population despite their independent contributions to KOA risk. Therefore, the purpose of this study was to examine the influence of sex and BMI on knee joint sagittal and frontal plane gait mechanics. Dependent variables included knee flexion moment (KFM) and the first knee adduction moment peak (KAM1).

METHODS

Table 1. Subject Demographics (mean ± SD)

Group	Normal	Obese
Age (years)	22 ± 2.89	22.25 ± 3.7
Height (cm)	168 ± 9.42	168 ± 9.78
Mass (kg)	61.48 ± 8.96	92.53 ± 15
BMI (kg/m^2)	21.48 ± 1.74	32.46 ± 3.67
% Female	56	55
Body Fat (%)	20.09±6.99	37.98±7.29

Gait biomechanics were assessed in 42 obese (BMI≥30.0) and 39 normal weight (BMI 18.0-25.0) participants that were cohort matched on age and sex. Marker position and force plate data were sampled using a 9-camera motion capture system (Qualysis, Göteborg, Sweden) and 2 force plates (AMTI, Germantown MD). Participants completed 5 over-ground walking trials in laboratory standard neutral cushion footwear (Nike Pegasus, Beaverton, OR) at a self-selected speed. Speed was maintained within ±5% and monitored using infrared timing gates (Tractronix, Belton, MO) placed 2m apart surrounding the force plates.

Marker position and force plate data were exported to Visual 3D, and low pass filtered using a 4th order zero-phase lag Butterworth at 6Hz and 50Hz, respectively. Stance phase was identified as the time-point between when the vertical GRF exceeded 20N and fell below 20N. A custom LabVIEW (National Instruments, Austin, TX) program was used to extract the peak external KFM during the first 50% of stance phase, and the first peak KAM. Joint moments were normalized to a product of bodyweight (N) and height (m) for analysis.

A 2 (BMI: normal, obese) by 2 (Sex: male, female) analysis of co-variance (α=0.05) was used to examine dependent variables (KFM, KAM,). Preliminary analyses indicated that self-selected gait speed was slower in the obese compared to normal weight group, and therefore, was used as a co-variate.

RESULTS AND DISCUSSION

The BMI by sex interaction was not significant for KAM1 ($F_{1,76}$=.146, p= .703) or KFM (df=1, F=.329, p=.073). A main effect was observed for sex in KAM1 (F=3.879, p=.05) and KFM (F=8.776, p=.004). After co-varying for gait speed, females exhibited larger KAM1 (.025 %BW•HT (95%CI: .022, .028) vs. .021 %BW•HT, (95%CI: .017, .024)

and lower KFM (0.052 %BW•HT, (95%CI: .047, .057) vs. .063 %BW•HT, (95%CI: .058, .069) compared to males.

There was no effect of BMI on KFM or KAM1 after co-varying for gait speed. This is contrary to previous findings in which obese individuals exhibited reduced peak knee extensor torque and larger KAM compared to normal weight participants at self-selected speed [4, 7]. Additionally, the discrepancy in findings may be explained by the difference in samples. Our obese sample is younger and with no previous clinical diagnosis of KOA. However, our results agree with a previous study in which no differences were found between younger obese individuals and normal controls [8].

Additionally, there was a significant main effect of sex on KFM and KAM1. Female sex is a significant risk factor for KOA incidence and aberrant biomechanics may be a key contributor. Females exhibited larger peak KAM1 compared to males, which contributes to preferential loading across the medial knee compartment. Previous studies have attributed lesser KAM in females to a more valgus knee alignment [9]. Additionally, greater KAM is attributed to greater varus alignment. However, we did not control or measure knee joint alignment, which may explain the discrepancies in our findings. Furthermore, females exhibited lower external KFM compared to males, which may indicate a quadriceps avoidance gait strategy [10] that is common among individuals with KOA. A quadriceps avoidance gait strategy may be explained by decreased quadriceps strength and muscle activity [10], which leads to decreased knee joint loading in the sagittal plane. A moderate amount of mechanical loading applied to the articular cartilage is necessary to maintain joint health, particularly in a normal joint environment absent of injury. [1]. Conversely, overloading or under-loading the cartilage may lead to degeneration of cartilage and development of OA [1]. As such, females may be at higher risk of OA due to lower sagittal and higher frontal plane knee joint loading regardless of the presence of obesity [3].

CONCLUSIONS

We observed no interaction between sex and BMI on KFM or KAM1. Furthermore, no differences were found in KFM or KAM1 between obese and normal weight participants. However regardless of BMI, females exhibited aberrant gait mechanics that are indicative of OA progression. Future studies should investigate the relationship between altered gait in females and knee cartilage morphology

SEX DIFFERENCES IN RUNNING, CUTTING AND DROP-LANDING BIOMECHANICS POST-ACL RECONSTRUCTION

[1] JJ Hannigan, [1] Brian Newcomb, [1] Justin Ter Har, and [1] Christine Pollard

[1] Oregon State University – Cascades, OR, USA
email: jj.hannigan@osucascades.edu, web: https://osucascades.edu/force-lab

INTRODUCTION

The anterior cruciate ligament (ACL) is the most commonly injured knee ligament, with approximately 250,000 anterior cruciate ligament ruptures occurring each year. Approximately two-thirds of ACL injuries occur without direct contact to the leg during either a cutting or drop-landing task [1]. Several biomechanical factors have been identified that may predispose an athlete to tearing their ACL, particularly greater hip adduction and knee valgus during either cutting or drop-landing compared to uninjured participants [1].

Patients hoping to return to their sport or activity typically choose to undergo surgical reconstruction of the ACL (ACLR) using a patellar, hamstring, or cadaver graft to replace the torn ligament. Approximately 80,000 to 100,000 patients undergo an ACL repair each year, which generally involves a 9-12 month rehabilitation process before being cleared for full activity [2]. However, recent evidence suggests that even after full rehabilitation, ACLR patients still display the biomechanical patterns during these tasks that would place them at risk of re-injury, which may explain why re-injury rates are as high as 50% after surgery [2].

Males and females display markedly different running, cutting, and jumping biomechanics compared to healthy [3-4]. It is currently unclear whether there are sex differences in these biomechanics upon return-to-sport following ACLR. Any sex differences in biomechanics in ACLR patients could mean that sex is an important factor to consider during ACLR rehabilitation. Thus, the primary purpose of this study was to compare running, cutting, and jumping biomechanics between males and females following ACLR.

METHODS

Nine females (age = 29.5 ± 7.5 yrs) and eight males (age = 30.4 ± 4.8 yrs) who had previously torn their ACL, underwent reconstructive surgery, and returned to sport have participated in this study. All subjects signed an informed consent form approved by IRB at Oregon State University prior to participating. Twenty-one reflective markers and six marker clusters were placed on subjects who performed 3 tasks in the lab: 1) overground running, 2) cutting at a 45° angle on their reconstructed limb, and 3) drop landing from an elevated platform. Five successful trials for each task were collected at 250 Hz with an 8-camera 3-D motion capture system (Vicon Motion Systems, Oxford UK). Two embedded force plates collected ground reaction forces and were used to determine heel strike and toe-off (AMTI, Watertown MA).

Joint kinematics were calculated using Visual3D software (C-Motion, Germantown MD). Variables of interest included peak angles for hip flexion, hip adduction, hip internal rotation, knee flexion, knee valgus, and ankle eversion for each task. Differences between sexes were calculated using independent sample *t*-tests with the alpha-level set to 0.5.

RESULTS AND DISCUSSION

During running, females displayed greater peak hip adduction (females: 14.6 ± 4.1°; males: 8.8 ± 4.9°, p = .024) and a trend towards greater peak knee valgus (females: 5.4 ± 4.3°; males: 1.9 ± 3.8°, p = .094)

During cutting, females displayed greater peak hip adduction (females: 2.1 ± 7.3°; males: -4.4 ± 4.1°, p = .043) and peak knee valgus (females: 9.8 ± 4.5°; males: 5.1 ± 3.0°, p = .025).

No differences were seen for other variables during running or cutting or for any variables during drop-landing.

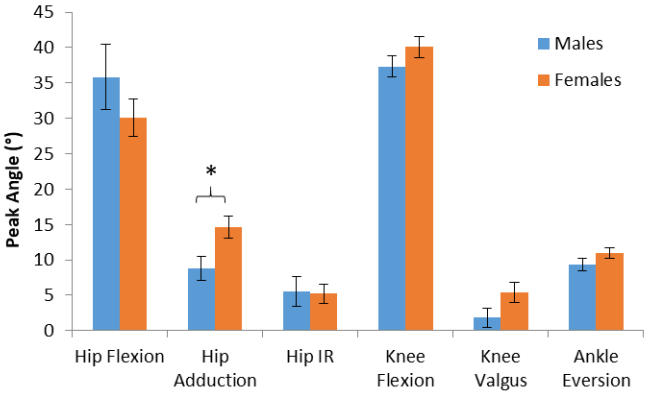

Figure 1: ACLR females displayed significantly greater peak hip adduction compared to ACLR males during running.

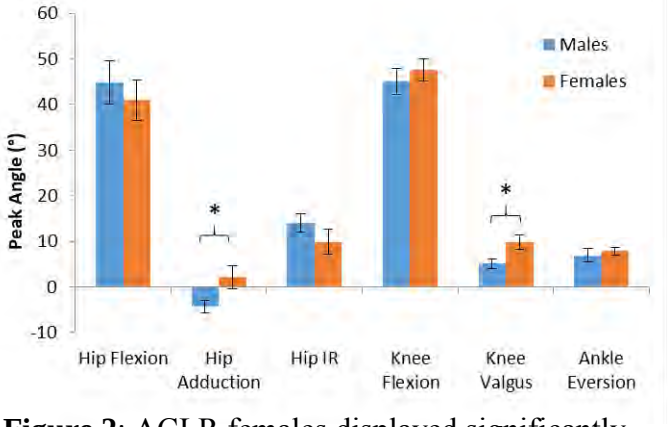

Figure 2: ACLR females displayed significantly greater peak hip adduction and peak knee valgus compared to ACLR males during cutting.

Greater peak hip adduction and peak knee valgus during cutting in females is concerning, as these are known risk factors for ACL tears [1]. The fact that females still display these poor frontal plane hip and knee mechanics after rehabilitation illustrates that females particularly may be at increased risk for re-injuring their ACL after return to sport. Based on these findings, current rehabilitation protocols may be insufficient, particularly for females.

Elevated peak hip adduction during running is a risk factor for developing patellofemoral pain [5], which appears to be a precursor to developing patellofemoral osteoarthritis later in life [3]. This finding may help explain why chronic anterior knee pain and the eventual development of knee osteoarthritis is particularly common among female ACLR patients [2].

CONCLUSIONS

Females displayed running and cutting mechanics that place them at an increased risk for an ACL re-injury and anterior knee pain.. Current ACL rehabilitation programs may not be sufficient in correcting poor biomechanics that likely contributed to the initial ACL injury, particularly in females.

SEX DIFFERENCES IN MOTOR UNIT BEHAVIOUR DURING FORCE DEVELOPMENT

[1] J. Greig Inglis, Justin Parro and David A. Gabriel

[1] Brock University, St. Catharines, ON, Canada
email: ginglis@brocku.ca

INTRODUCTION

Inglis et al. [1] previously reported that differences between males and females in the peak rate of force development (RFD) could be accounted for by using maximal strength as a covariate. However, there were significant differences in the rate of muscle activation and electromechanical delay, suggesting underlying differences in motor unit (MU) activity patterns. Therefore, the purpose of the current research was to quantify MU activity patterns during the force development phase of submaximal and maximal effort contractions, to identify potential sex-related differences in MU behavior associated with the peak RFD.

METHODS

Forty-eight (Females=24; Males=24) college-aged individuals free from any orthopedic abnormalities and neurological disorders were seated in a testing chair with their hip and knee fixed at 90^{o} and the ankle fixed at 20^{o} plantarflexion. A foot plate and padded bar across the distal metatarsal was used to perform isometric dorsiflexion. Force was recorded from a load cell (JR3 Inc., Woodland, CA) beneath the distal metatarsals. An oscilloscope (Tetronix, TDS 460A, Beaverton, OR) was used to provide real-time feedback about the quality of the EMG signal from the needle electrode. A second oscilloscope (Hitachi, VC-6525, Woodbury, NY) provided real-time force feedback with ± 2.5% error bars around the desired force. Surface EMG (sEMG) was recorded from the tibialis anterior (TA) electrically identified motor point with monopolar Ag/AgCl electrodes (Grass F-E9, Astro-Med Inc., West Warwick, RI). An intramuscular quadrifilar needle electrode (Viasys Healthcare UK; Surrey, England) was inserted 2 cm distal to the surface electrode. Myoelectric activity was amplified (Grass P511; Astro-Med Inc., West Warwick, RI) and band-pass filtered (sEMG: 3 & 1000 Hz; intramuscular EMG (iEMG): 1 & 10 kHz). Force and EMG were sampled at 25.6 kHz and stored for offline analysis (DASYLab; DASYTEC National Instruments, Amherst, NH, USA).

Anthropometric measurements and force target practice occurred on day 1. Day 2 all participants completed 3 isometric dorsiflexion contractions at 20, 40, 60, 80 and 100% of a maximal voluntary contraction (MVC). The submaximal contractions were arranged for both males and females in a balanced design with 100% MVC contractions taking place both pre and post submaximal trials. Each contraction was eight seconds in duration with three minutes rest in-between. Surface and intramuscular EMG signals were reduced in Matlab (The Mathworks Inc.; Natick, MA, USA). Measures were calculated during force development. Motor unit action potentials were identified using EMGlab (www.emglab.net) (Figure 1.).

RESULTS AND DISCUSSION

Sex differences in the peak RFD were observed from 20 to 100% MVC. On average males were 197.22 ± 118.11 N/sec greater than females (Δ=33.6% difference, $P<0.01$). There was a significant sex by force level interaction term ($p<0.01$). The incidence of doublet discharges during the RFD was 44.54% greater in females, during submaximal contractions ($P<0.01$). At maximum, males had a 9.42% greater incidence of doublets ($P<0.01$). Interestingly, there were no sex differences in time to peak RFD ($P>0.05$). However, there was an increase in the time to peak RFD as the percent of MVC increased (11.66 ms, Δ=89.1%, $p<0.01$). Likewise, there was a progressive increase in doublets for both groups from 20 to 100 percent MVC (Δ=20.2%, $P<0.01$).

Manal and colleagues [2] showed that the pennation angle-muscle length relationship is different between males and females. We believe that the specific ankle joint angle used for testing in this study produced a less optimal pennation angle for females compared to males.

Therefore, sex differences in motor unit behavior during the RFD may be a result of a sex-related compensation mechanism to overcome a sub-optimal muscle length and pennation angle during submaximal levels of force production in females. Placing the ankle joint at an optimal angle to create the appropriate muscle length and pennation angle to maximize motor unit activation efficiency could assist in the development of specific training modalities for both athletic and older populations.

Sex and mechanism of injury (MOI) influence knee mechanics after anterior cruciate ligament reconstruction (ACLR)

Naoaki Ito, Jacob J. Capin, Ashutosh Khandha, Kurt Manal, Thomas S. Buchanan, Lynn Snyder-Mackler

University of Delaware, Newark, DE, USA
email: nito@udel.edu, web: http://sites.udel.edu/pt/

INTRODUCTION

Anterior cruciate ligament (ACL) injuries and ACLR are linked to altered knee gait mechanics and asymmetry in athletes [1]. Gait asymmetries, such as medial compartment tibiofemoral underloading, are associated with early joint degeneration and radiographic OA five years after ACLR [2,3,4].

Sex influences ACL injury risk and it can also influence outcomes. Women are more susceptible to ACL injuries than men [5]. Women are especially at risk for non-contact ACL injury, as around 70% of all ACL injuries in women are non-contact, compared to 52% in men [5]. The relationship between sex, mechanism of injury (MOI), and gait mechanics in athletes after ACLR has not been examined. The purpose of this study was to quantify gait mechanics after ACLR in male and female athletes who sustained contact versus non-contact ACL injury.

METHODS

This is a secondary analysis of prospectively collected data from an ongoing clinical trial. Testing was conducted 5.9 ± 1.9 months after ACLR. We included 28 contact (18 male [M]/10 female [F]) and 39 non-contact (19 M/20 F) participants between ages 13-54 who were recruited from the University of Delaware Physical Therapy clinic and the community. All participants sustained a primary ACL injury, were involved in level 1 or 2 sports (sports involving jumping, cutting, or pivoting) [6] ≥50 hours/year at the time of injury, planned on returning to activity at their pre-injury level and had ≥80% quadriceps strength index and effusion of trace or less [7]. Participants were excluded if they had an osteochondral defect >1cm^2 or a history of a previous ipsilateral/contralateral limb injury, combined grade III ligament injury or previous lower extremity surgery. MOI was self-reported by the participants.

We used an 8 camera motion capture system (Vicon, Oxford, UK; 120Hz) to track 39 retroreflective markers during overground walking at self-selected gait speeds maintained throughout testing. Ground reaction forces were collected at 1080Hz using a force plate (Bertec Corporation, Columbus, OH). Kinetic and kinematic variables were calculated using Visual 3D (C-Motion, Germantown, MD). Variables of interest included: peak knee flexion angle (pKFA), peak knee flexion moment (pKFM), and peak knee adduction moment (pKAM).

Surface electromyography (EMG) (MA-300 EMG System, Motion Lab systems, Baton Rouge, LA) data were collected bilaterally on 7 lower extremity muscles (rectus femoris, vastus medialis, vastus lateralis, medial and lateral hamstrings, medial and lateral gastrocnemius) at 1080Hz. The data were high-pass filtered using a 2nd order butterworth filter at 30Hz, rectified, and low-pass filtered at 6Hz to create a linear envelope, then normalized to maximum voluntary isometric contractions collected prior to gait.

The EMG data were then used to derive knee flexor (FlexpKFM) and extensor muscle force (ExtpKFM) at pKFM. Peak medial compartment contact force (pMCCF) and total contact forces (pTCF) were calculated using a validated musculoskeletal model [8]. Three trials per limb per participant were selected by minimizing the root mean square error and maximizing the R^2 value between the curves of the inverse dynamics knee flexion moment and the forward dynamics knee flexion moment, derived through simulated annealing to optimize muscle parameters. pMCCF was calculated using the Winby frontal plane moment algorithm that balances external pKAM with internal knee moments [9].

pMCCF and pTCF were then normalized to each participants' body weight [8].

Statistics were run using SPSS Version 24.0 (IBM Corp, Armonk, NY). We used a 2×2×2 (sex by MOI by limb) ANOVA (α=0.05) to analyze pKFA, pKFM, pKAM, FlexpKFM, ExtpKFM, pMCCF and pTCF. Demographic characteristics were evaluated using Pearson Chi-squared and Univariate ANOVA.

RESULTS AND DISCUSSION

Height, weight, and BMI were higher in male participants. Patellar tendon grafts (1contact:7non-contact) tended to be used more frequently in the non-contact group for men compared to hamstring grafts (11contact:7non-contact) or allografts (6contact:5non-contact). Other variables showed no significant difference among sex or MOI.

A 3-way interaction effect was observed among limb, sex, and MOI for pMCCF (Figure 1; p=0.001). In men, athletes who sustained non-contact injuries underloaded their involved knee approximately 6 months after ACLR, whereas female athletes who sustained non-contact injuries tended to overload their involved knee. In contrast, female athletes who sustained contact injuries underloaded their involved knee. No interlimb difference was observed in the male contact group. Previous studies have found links between knee underloading and early OA development [3,4]; our findings suggest sex and MOI may influence medial tibiofemoral joint loading, a risk factor for early OA development after ACLR, although long-term follow-up is needed.

Additionally, main effects of limb were observed in pKFA (p=0.000), pKFM (p=0.000), pTCF (p=0.027), and ExtpKFM (p=0.000), where all values were lower in the involved versus uninvolved limb. No other significant main or interaction effects were observed.

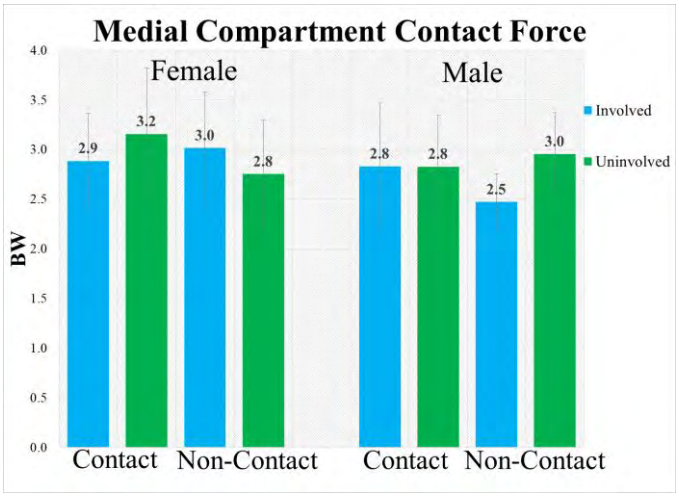

Figure 1: pMCCF grouped by limb, sex, and MOI.

CONCLUSIONS

The combination of sex and MOI may influence gait mechanics after ACLR. There is limited evidence on the effect of MOI on outcomes after ACLR, such as gait mechanics or early onset knee OA. It may be important to further investigate the influence of MOI on gait in athletes after ACLR, as targeted rehabilitation interventions may need to differ based on sex and MOI. Ultimately, these findings may lead to future studies emphasizing rehabilitation protocols aimed towards specific sex and MOI groups.

INTRODUCTION

Ankle stiffness has been known as one of the most important components contributing to the maintenance of lower body stability during postural balance and locomotion. It has been repeatedly shown that women have lower stability and increased risk of injury when compared to men participating in similar sports activities, yet sex difference in neuromuscular control of the ankle, including the modulation of ankle stiffness, and its contribution to lower body stability remains unknown [1].

As a first step to fill this knowledge gap, we investigated sex difference in ankle stiffness in a multi-dimensional space spanning the sagittal and frontal plane and over a range of muscle activation levels. Based on previous findings on higher incidence of musculoskeletal injury at the ankle joint in females as well as higher anatomical risk factors (higher joint laxity, lower Young's modulus, and greater range of motion) in females, we hypothesized that ankle stiffness in females is significantly lower than males in both the sagittal and frontal planes and across all muscle activation levels.

METHODS

To identify sex difference in human ankle stiffness, this study quantified multi-dimensional ankle stiffness in 20 young men and 20 young women (age: 20−32 with the mean age of 23) with no reported history of neuromuscular or biomechanical disorders. Subjects gave written informed consent prior to participation.

A wearable ankle robot (Anklebot, Bionik Laboratories, Canada) capable of actuating 2 degree-of-freedom (DOF) of the ankle, was used to reliably quantify ankle stiffness in a 2-dimensional space spanning the sagittal plane and the frontal plane. Ankle stiffness was quantified at 3 different muscle activation levels: relaxed (0%), 10%, and 20% of maximum voluntary co-contraction (MVC) of ankle muscles. To this end, electromyographic (EMG) signals of tibialis anterior (TA) and soleus (SOL) were measured using differential surface electrodes (Trigno, Delsys, MA). Amplitudes of EMG signals were estimated and normalized with respect to MVC measurements.

During experiments, subjects sat in a chair with their ankle held by the ankle robot in a neutral position, defined as zero dorsiflexion-plantarflexion (DP) and inversion-eversion (IE) angles from the horizontal plane. A visual feedback was used to inform the subjects of real-time muscle activation of TA and a target activation level in %MVC. To control the constant level of co-contraction, subjects were instructed to simultaneously maintain the target activation level of TA and the neutral ankle position. A total of 3 repeated trials were performed for each muscle activation level. The order of target muscle activation was randomized. In each trial, mild random torque perturbations were applied to the ankle for 20 seconds, and the corresponding ankle angles in 2 DOFs (DP and IE) were recorded at 1 kHz. A minimum rest period of 3 minutes was provided between trials. All experimental protocols were approved by the Arizona State University Institutional Review Board.

Multi-dimensional ankle stiffness was quantified by applying the multi-input multi-output stochastic system identification method to the measured torques and angles at the ankle [2]. Ankle stiffness in the sagittal plane (DP stiffness) and ankle stiffness in the frontal plane (IE stiffness) were quantified. In addition, a spatial structure of ankle

stiffness was investigated by quantifying three parameters defining the stiffness ellipse of the ankle: area, aspect ratio, and orientation.

Sex difference in ankle stiffness was evaluated by running a mixed ANOVA where muscle activation level is a within-subjects factor and sex is a between-subjects factor. Separate analyses were completed for DP stiffness, IE stiffness, ellipse area, ellipse aspect ratio, and ellipse orientation. Following the mixed ANOVA, unpaired, independent, two-tailed t-tests were performed to identify sex difference at each muscle activation level. All tests were made at a significance level of $p<0.05$.

RESULTS AND DISCUSSION

First, significant sex difference in ankle stiffness was observed (Fig. 1). In all muscle activation levels, DP stiffness and IE stiffness were significantly lower in females than males. In detail, for DP stiffness, $p=0.001$, $p=0.001$, and $p=0.004$ for 0, 10, 20 %MVC, respectively. For IE stiffness, $p=0.001$, $p=0.003$, and $p=0.008$ for 0, 10, 20 %MVC, respectively. Furthermore, the sex difference of ankle stiffness increased with the increase of ankle muscle co-contraction.

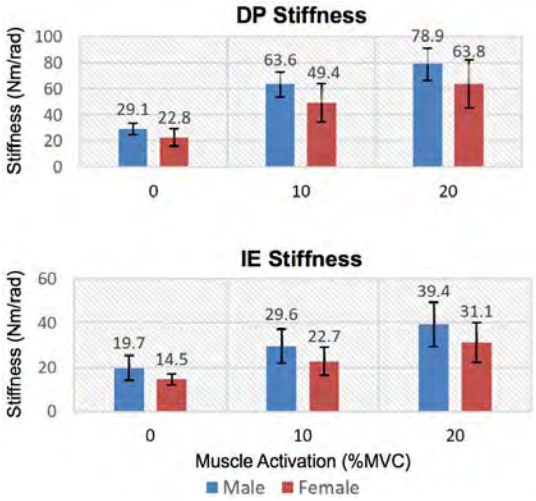

Figure 1. Group results of DP stiffness and IE stiffness. Error bars denote mean±1 standard deviation.

Next, while a significant sex difference was identified for the area of stiffness ellipse, no statistical sex difference was observed in the aspect ratio or orientation (Fig. 2). In detail, for the area, $p=0.000$, $p=0.003$, $p=0.008$ for 0, 10, 20 %MVC, respectively.

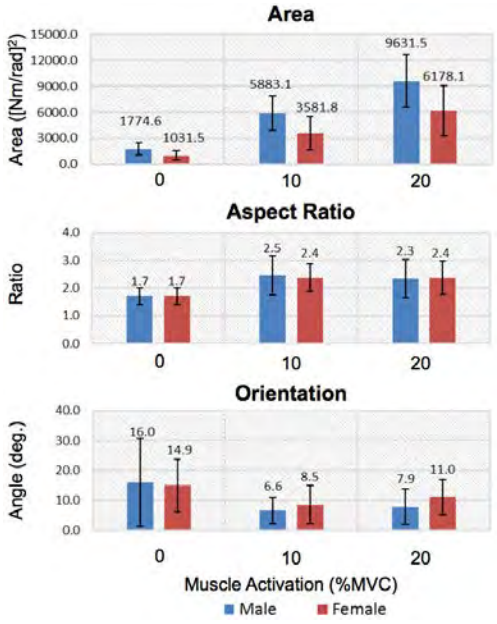

Figure 2. Group results of area, aspect ratio, and orientation of stiffness ellipse in a 2-dimensional space.

For the aspect ratio and angle, no significant main effect was found for the between-subjects factor: $p=0.91$ and $p=0.50$ for the aspect ratio and angle, respectively.

CONCLUSIONS

Clear sex difference in the magnitude of multi-dimensional ankle stiffness was observed, evidenced by significantly higher DP stiffness, IE stiffness, and the area of stiffness ellipse in males than females. These results are relevant to previous studies demonstrating that women have higher joint laxity, larger range of motion, and lower Young's modulus values. Contrary to the magnitude of ankle stiffness, no significant sex difference was observed for other structural information on the shape of stiffness ellipse, specifically aspect ratio and orientation. The sex difference in this study would shed lights on our understanding of sex difference in risk of ankle injury and contribute to the implementation of sex-specific exercise training programs to prevent ankle injuries.

INTRODUCTION

Seven million Americans have survived a stroke. Unfortunately, at six months post-stroke, 75% of these individuals report that their motor impairment significantly impedes their ability to perform activities of daily life. Muscle architecture is indicative of a muscle's force-generating capacity. Understanding changes in the overall capability for force generation in individual muscles following stroke may aid in the development of more effective, targeted rehabilitation protocols.

Comprehensive *in vivo* muscle architecture studies involving impaired populations do not exist. Despite many exciting and important advances in recent years, there is currently no *in vivo* muscle imaging study that measures all of the critical architectural parameters for any upper limb muscle, in any population. Here we combined multiple novel imaging techniques to directly measure each parameter needed to calculate optimal fascicle length and physiological cross sectional area in the biceps brachii, a parallel-fibered muscle. We compare inter-limb differences in a single subject with hemiparetic stroke to a nonimpaired, age-matched control subject.

METHODS

Sarcomere length (l^S), fascicle length (l^F), and muscle volume (V) of the biceps brachii were measured *in vivo* (Fig. 1) in both arms of two subjects under passive conditions; one subject with chronic hemiparetic stroke (male, 59 yrs old, Fugl-Meyer = 24, 8 yrs post-stroke) and one control subject with no history of musculoskeletal disease or injuries of the upper limb (male, 61 yrs old). Both subjects provided informed consent; Northwestern University's Institutional Review Board approved this study's procedures.

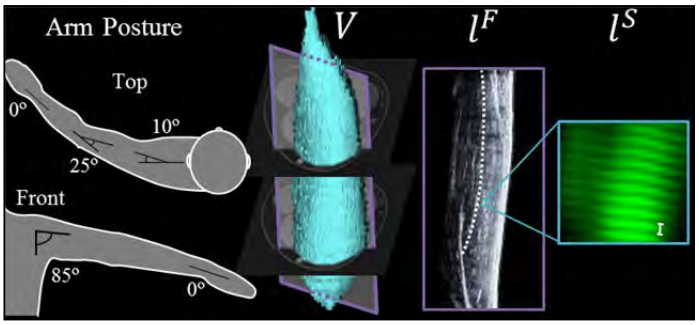

Figure 1: Multiscale muscle imaging.

To image sarcomeres *in vivo*, a microendoscopic needle was inserted into the long head of the biceps brachii with its optical lenses aligned parallel to the fascicle direction. A microscope (Zebrascope, Zebra Medical Technologies, Palo Alto, CA) which uses second-harmonic generation to capture the intrinsic striation pattern of sarcomeres was attached to the needle for imaging. Mean sarcomere length per image was calculated offline with an average of 15 images per arm [1]. In a separate session, extended field-of-view ultrasound (EFOV-US) images of the long head of the biceps were obtained [2]; 3 images were obtained per arm, 4 fascicles were measured per image. In both studies, subjects were seated, secured to a chair, with their arms supported in a controlled posture (Fig. 1). Surface EMG was obtained simultaneously; data collected while the biceps was active was excluded.

In a third imaging study, the Dixon method, a fat suppression MRI sequence, was used to acquire MR images of the biceps brachii (3D GRE, TR = 7ms, TE of 2.39ms and 4.7ms, flip angle = 12°, matrix size = 256x216, slice thickness = 3mm) [3]. Manual segmentation of the combined long and short heads of the biceps brachii was performed using Analyze 12.0 (AnalyzeDirect, Overland Park, KS). Volume of muscle contractile material was calculated as the volume of intramuscular fat subtracted from the total biceps volume, as described previously [3].

Optimal fascicle length (l_o^M) and (PCSA) were calculated for both arms of both subjects using the following equations:

$$l_o^M = l^F * \frac{2.7\mu m}{l^S} \qquad PCSA = \frac{V}{l_o^M}$$

where 2.7μm is optimal sarcomere length.

RESULTS AND DISCUSSION

Inter-limb differences in the volume of the biceps brachii and the average fascicle length of the long head were markedly more pronounced in the subject with chronic stroke (Table 1). For the nonimpaired subject, absolute differences between limbs were <5% for all parameters (Fig. 2). Biceps sarcomere lengths in the paretic limb of the stroke subject were ~6% longer than those in the nonparetic limb. Inter-limb differences in fascicle length and sarcomere length resulted in an optimal fascicle length that was 22.6% shorter in the paretic limb of the stroke subject (Fig. 2). A concomitant 23.1% decrease in muscle volume resulted in remarkably comparable muscle PCSAs across limbs, the only architectural parameter that was not more different between limbs in the subject with hemiparetic stroke than the corresponding measure in the control subject.

Our data for individual parameters are similar to previously reported values from studies that focused on measuring only a subset of muscle architectural parameters. For example, our measurement precision and mean sarcomere length are consistent with previously reported values for the biceps [1]. In addition, l_o^M values for both of the healthy individual's arms and the non-paretic arm of the stroke individual are within the range of values reported in cadaveric studies (e.g., [4]).

The inter-limb differences observed in this individual with stroke are greater than established accuracy and precision measures for each of the imaging modalities we implemented. EFOV-US applied to fascicle length measurement in the upper limb has been shown to result in absolute error <5% [5]. Measurement error of microendoscopic measures are reported to be about 1% of mean sarcomere length [6]. MRI volume measures have been shown to be accurate to within 4% [7].

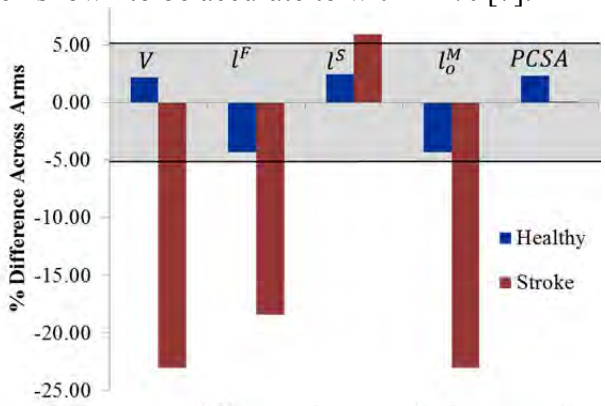

Figure 2: Percent difference between limbs, normalized to nonparetic (or dominant) arm. Negative indicates the value from the paretic (or non-dominant) arm is smaller.

CONCLUSIONS

This study demonstrates the feasibility of collecting comprehensive, *in vivo* muscle architecture data sets in individuals with severe motor impairments. Strikingly, our initial data suggests that in this subject with chronic hemiparetic stroke, the excursion capacity of the paretic long head of the biceps brachii is substantially decreased while the force generating capacity is similar to that of his non-paretic limb.

MOTOR MODULE GENERALIZATION ACROSS WALKING AND BALANCE IS ASSOCIATED WITH BETTER WALKING PERFORMANCE POST-STROKE

INTRODUCTION

Motor module (a.k.a muscle synergy) analysis related to mobility performance in clinical populations commonly focuses on walking behaviors. Although recruiting a larger number of modules has been associated with faster walking speeds post-stroke [1], differences in speed remain in individuals who recruit an identical number of modules. Maintaining balance is critical for mobility tasks such as walking, yet little is known about motor modules recruited for balance and how they compare to those recruited for walking. We recently demonstrated that recruiting common motor modules across walking and balance (i.e., motor module generalization) may be related to motor performance. For example, improved motor performance due to long-term training in healthy young adults is accompanied by increases in motor module generalization [2]. Similarly, gains in motor performance after rehabilitation in individuals with Parkinson's disease are accompanied by gains in motor module generalization [3]. Thus, our overall hypothesis is that motor module generalization across walking and balance is a neuromuscular strategy for producing well-coordinated walking. We posit that motor module recruitment for walking and balance are differently affected after stroke, and thus predict that 1) fewer common modules are recruited across behaviors post-stroke, which is 2) associated with reduced motor performance.

METHODS

Nine individuals post-stroke (3 male, 57.2±12.7 years, 6 right hemiparesis, 46.3±23.1 months post-stroke, Fugl-Meyer lower extremity score 23.7±3.7) and eight sex-, and age-similar neurotypical controls (3 male, 62.0±6.6 years) participated in the current study. Electromyography (EMG) was recorded from each subject while they (1) walked over-ground at self-selected speed for ~25ft, and (2) responded to ramp-and-hold translations of a support surface during standing that translated in 12 equally-spaced directions in the horizontal plane. For walking, at least 10 gait cycles were collected to ensure adequate capture of step-to-step variability. For balance, three trials in each direction were collected in random order, all subjects were exposed to the same level of perturbation, and subjects were instructed to maintain balance without stepping.

Motor modules were found using nonnegative matrix factorization [2] using EMG recorded from 12 muscles spanning the hip, knee, and ankle of each leg. For reactive balance, EMG data were analyzed during four different time bins: one before the perturbation and three during the automatic postural response. For walking, EMG data were analyzed as a function of time. To capture trial-by-trial / step-by-step variability, trials for each condition were concatenated together end to end. A total of four EMG data matrices were created for each subject [2 legs x 2 conditions]. Assembled EMG data matrices were normalized to the maximum activation observed during walking at self-selected speed.

The number of motor modules independently extracted in each leg (control, nonparetic, paretic) were compared using separate Kruskall-Wallis tests for walking and reactive balance (α =0.05). The number of motor modules recruited during each condition was chosen such that lower bound of the 95% confidence interval of variability accounted for was greater than 90% [2].

Motor module generalization was defined as the percentage of common motor modules across walking and reactive balance [3] and was compared across legs using a one-way ANOVA. The number

of common motor modules was identified using Pearson's correlations. A pair of motor modules were considered "common" if $r \geq 0.708$, which corresponds to the critical value of r^2 for 12 muscles at $p = 0.01$. The number of common motor modules was expressed as a percentage of total motor module number to account for the fact that each subject recruited a different number of modules (Fig. 1A).

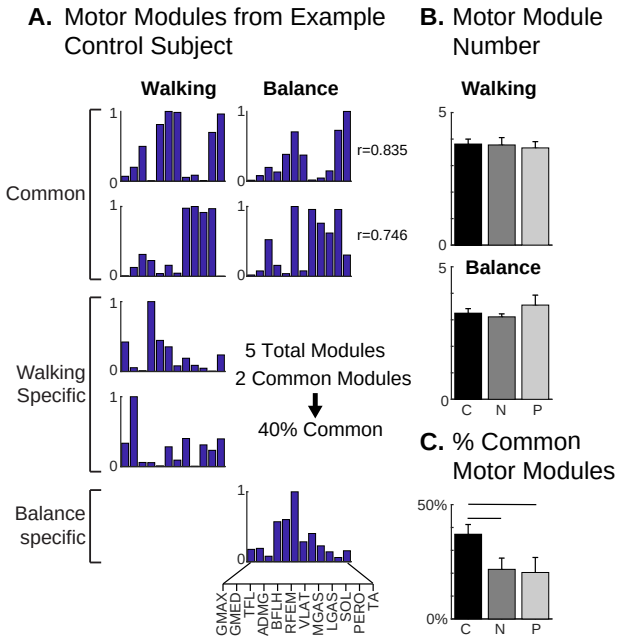

Figure 1: A) Motor modules from a representative subject illustrating motor modules recruited across walking and reactive balance. B) Motor module number was similar across control and stroke subjects. C) The percentage of common motor modules across walking and balance was reduced post-stroke in both the paretic and nonparetic legs. (legend: C = control legs, N = nonparetic legs, P = paretic legs)

RESULTS AND DISCUSSION

We found no difference in motor module number (Fig. 1B) recruited between control, non-paretic, or paretic legs for either walking ($p=0.801$) or reactive balance ($p=0.486$). The median number of motor modules recruited for walking was 4 [range 2- 5] in control legs, 4 [3-5] in nonparetic legs, and 4 [3-5] for paretic legs. The median number recruited for reactive balance was 3 [2-4] in control legs, 3 [3-4] in nonparetic legs, and 4 [2-5] in paretic legs.

Consistent with our prediction, motor module generalization was reduced post-stroke. The percentage of common modules across walking and reactive balance was 37.0±17.0% in control legs, 21.7±14.8% in nonparetic legs, and 20.3±1.7% in paretic legs (Fig. 1C). There was a trend for reduced generalization in both paretic ($p=0.066$) and nonparetic legs ($p=0.098$) compared to controls, but no difference between legs post-stroke ($p=0.984$).

In addition, higher levels of generalization post-stroke were associated with faster walking speeds. The percentage of common motor modules recruited in stroke subjects was positively correlated with walking speed ($r=0.45$). The most commonly recruited module across behaviors was composed of the ankle plantarflexors (e.g. Fig 1A, 2nd row). This module was recruited in both conditions in 13/16 control legs, 8/9 nonparetic legs, but only 4/9 paretic legs. Regression analysis identified presence of this common plantarflexor module in the paretic leg as a significant predictor of walking speed ($p=0.028$), pointing to this module as a potentially critical pattern of muscle coordination.

CONCLUSIONS

Here we show that motor module generalization (e.g. recruiting common motor modules) across walking and balance is related to motor performance post-stroke. Taken together with our prior results in young adults [2] and individuals with Parkinson's disease [3], this provides further evidence that motor module generalization is a neuromuscular strategy for producing well-coordinated walking. Therefore, examining how muscles are coordinated across walking and balance behaviors may have important implications for rehabilitation aimed at improving motor control in those with reduced mobility.

INTRODUCTION

Stroke is the leading cause of long-term disability in the United States with approximately 795,000 people experiencing a stroke each year [1]. The ankle plantarflexors (PFs) are often impaired post-stroke [e.g., 2], which can have significant consequences as the PFs are critical to walking performance by being primary contributors to body support, forward propulsion and leg swing initiation [3].

Prior studies have shown that well-coordinated walking in healthy subjects can be produced by five co-activation modules: 1) hip and knee extensors in early stance, 2) PFs in late stance, 3) tibialis anterior and rectus femoris in swing, 4) hamstrings in late swing and early stance, and 5) hip flexors in pre- and early swing [4, 5]. Research has found that in post-stroke hemiparetic walking, modules in the paretic leg can merge or become co-activated, which prevents the independent activation of specific muscles and causes suboptimal execution of biomechanical functions [5].

Considering the critical biomechanical roles the PFs have in unimpaired walking, we hypothesized that a merged PF module would result in 1) increased paretic leg braking and nonparetic leg propulsion, 2) reduced paretic leg body support, and 3) increased stance and stepping asymmetry.

METHODS

Kinematic, kinetic and electromyography (EMG) data were collected from 45 hemiparetic post-stroke individuals (16 left hemiparesis, 18 female; age: 56 ± 13 years) and 16 healthy controls (8 female, age 53 ± 7 years) during 30 second treadmill walking trials at a self-selected speed.

EMG data were processed and analyzed using nonnegative matrix factorization (NNMF) as in [5]. NNMF determined the minimum number of muscle modules required to account for >90% of the EMG variability. Subjects were classified as having an independent PF module if NNMF produced a module composition with a Pearson's correlation coefficient of 0.8 or greater compared to weighted muscle contributions in the average healthy control PF module. If that criterion was not met, the subject was classified as having a merged PF module with other muscle groups.

Body support, braking and propulsion were calculated from the time integral of the vertical and anterior/posterior GRF and normalized by body weight. Braking and propulsion were also normalized by walking speed. For these quantities, paretic leg ratios were defined as the paretic value divided by the sum of the paretic and nonparetic values, with 0.5 being perfectly symmetric. Stance symmetry was defined as the percentage of total stance on the paretic and nonparetic legs.

Independent samples t-tests were used to test for significant differences between each group with Bonferroni-Holm corrections for multiple comparisons (uncorrected $p<0.05$).

RESULTS AND DISCUSSION

Twenty-nine of the hemiparetic subjects had a merged PF module and sixteen hemiparetic subjects had an independent PF module. The merged group's self-selected walking speeds were significantly

slower than the independent and control groups' ($p < 0.001$), while the difference between the independent and control group was not significant (Table 1).

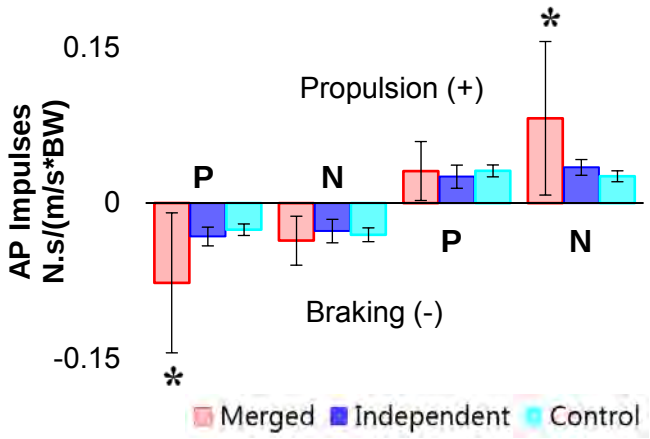

Figure 1: Paretic (P) and nonparetic (N) braking and propulsion for each group. (* denotes a significant difference between both other groups).

We hypothesized that the merged group would have increased paretic leg braking due to premature PF co-activation with the knee extensor and/or hamstring modules in early stance [e.g., 3]. As expected, merged paretic braking was higher than the independent ($p=0.002$) and control ($p<0.001$) groups. To maintain a constant walking speed (i.e., produce net zero anterior/posterior impulse), the merged group also produced higher nonparetic propulsion than the independent ($p=0.002$) and control ($p<0.001$) groups (Fig. 1).

The reduced paretic body support ratio in the merged group is consistent with a shorter stance time of the paretic leg compared to the nonparetic leg ($p<0.001$, Table 1). The merged group also had greater step length asymmetry than the independent ($p=0.002$) and control groups ($p<0.001$) (Table 1).

Paretic braking and propulsion ratios were the only significant differences between the independent and control groups ($p<0.001$). Notably, the independent group often performed more closely to the control group than to those in the merged group (Fig. 1, Table 1). Future work will use synergy-based control in musculoskeletal simulations to better understand the role of merged PF modules on walking performance measures.

CONCLUSIONS

These results indicate that gaining independent function of the plantarflexors is a crucial component of stroke rehabilitation in terms of walking speed and symmetry. Prior research has shown that stroke patients can gain additional modules [6]. Thus, patients who receive targeted rehabilitation of the PFs may be able to gain an independent PF module and improve walking performance.

INTRODUCTION

Forward propulsion, a primary mechanical sub-task of human walking, is often altered following a stroke. The magnitude of post-stroke propulsive deficits has commonly been quantified using *propulsive impulse*, calculated by integrating the anterior component of the ground reaction force (GRF) during late stance [1]. In comparison to controls walking at matched speeds, stroke survivors typically walk with reduced propulsive impulses from the paretic leg, but near-normal impulses from the non-paretic leg [2-3].

In addition to post-stroke changes in propulsion magnitude, propulsion timing also appears to shift. Most notably, anteriorly directed GRFs tend to begin later in the stance phase for the paretic leg, and earlier for the non-paretic leg [1-2].

Beyond the primary effects of propulsion on anterior progression, an altered propulsive pattern could also affect motion of the swing leg. Deficits in paretic propulsion have been suggested to contribute to reduced knee flexion during the swing phase [4], often termed "stiff-knee gait". In turn, this may require greater circumduction to safely clear the ground. While not as commonly investigated, changes in the timing of propulsion could also influence swing phase mechanics [5].

This study investigated whether post-stroke changes in paretic propulsion magnitude or timing influence paretic swing phase kinematics. We hypothesized that reduced propulsion magnitude and delayed propulsion timing would predict reduced swing phase knee flexion and increased circumduction.

METHODS

The present study involved 29 chronic stroke survivors (11 F / 18 M; age = 59±12 yrs). Inclusion criteria were: hemiparesis secondary to a unilateral stroke > 6 months prior; daily home walking; self-selected treadmill walking speed of ≥0.3 m/s. Exclusion criteria were: orthopedic or neurologic conditions beyond stroke that would be expected to influence gait; impairments contraindicative to walking. All participants provided informed consent using a form approved by the University Institutional Review Board.

Participants performed 30-second walking trials on an instrumented treadmill at their self-selected and fastest-comfortable speeds. For each stride, we calculated several metrics based on anteroposterior GRF (see Fig. 1). We calculated paretic propulsive impulse as the area under the positive portion of the GRF-time trajectory, surrounding the point of maximum anterior GRF. We calculated paretic late braking impulse as the area under the negative portions of this trajectory that followed the propulsive impulse, an unusual pattern observed in a subset of participants. We identified the paretic propulsion onset time, quantified relative to contralateral initial contact. In addition, we identified

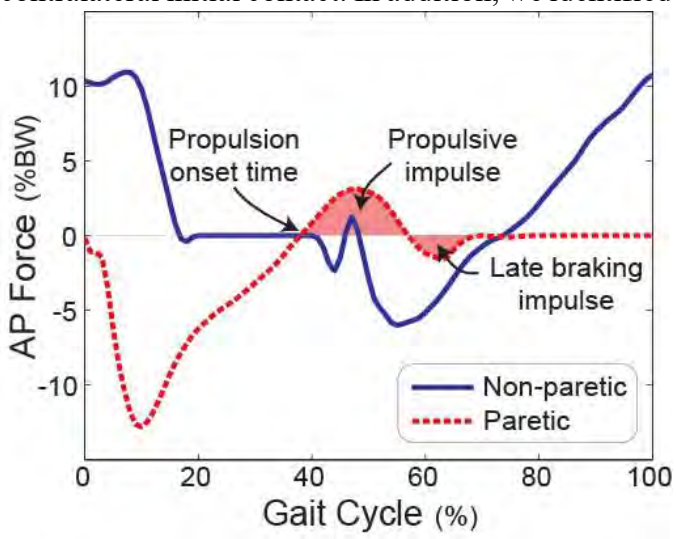

Figure 1: Metrics quantifying paretic propulsion, illustrated for a single participant. Forces are plotted for one stride, defined by paretic leg initial contact.

the peak paretic knee flexion angle from marker kinematic data, and quantified paretic circumduction as the maximum lateral displacement of the paretic heel relative to its location at the start of swing.

We used multiple regressions to determine whether paretic knee flexion and circumduction were predicted by various aspects of the paretic leg propulsive pattern. Specifically, independent variables in these regressions were: walking speed; propulsive impulse magnitude; late braking impulse magnitude; and propulsion onset time. We quantified the overall prediction ability of this combination of variables using R^2 magnitude, and the unique predictive contribution of each individual variable using partial η^2 value (a measure of effect size).

RESULTS AND DISCUSSION

Across participants, paretic knee flexion was predicted by a combination of walking speed and late braking forces (Table 1). Specifically, greater knee flexion was observed with faster walking speeds (η_p^2 = 0.11) and smaller late braking impulses (η_p^2 = 0.39). Neither propulsive impulse nor propulsion onset time made a significant unique contribution to the intersubject variance in knee flexion.

Paretic swing leg circumduction was similarly predicted by the preceding gait characteristics, although to a lesser extent than knee flexion (Table 1). Greater paretic circumduction was observed with larger late braking impulses (η_p^2 = 0.13). Neither gait speed nor the propulsion metrics made a significant unique contribution to variance in circumduction.

The single best predictor of both paretic knee flexion and paretic circumduction was the magnitude of the late braking impulse, contradicting our hypothesis. While the magnitude of propulsive forces has been extensively investigated in the chronic post-stroke population [1-3], little attention has been paid to the unusual braking forces observed here. Such forces may be linked to increased leg flexor activity in late stance [6], a potential outcome of disrupted post-stroke coordination.

The present results suggest that posteriorly directed GRFs just before the paretic foot leaves the ground may be particularly detrimental to achieving typical swing phase kinematics. Speculatively, this may be due to an inability to rapidly unload the paretic leg, causing this foot to "drag". Future research will more directly investigate whether interventions focused on reducing these late braking forces have beneficial effects on swing phase kinematics.

CONCLUSIONS

Many individuals who have experienced a stroke exhibit both propulsive deficits and altered swing phase kinematics. The present study revealed a link between unusual braking forces late in the paretic stance phase, and atypical paretic swing phase motion. The results suggest the importance of eliminating these late posterior forces in order to restore a typical gait pattern.

Methodology to Estimate Voluntary Activation of the Paretic Elbow and Wrist Muscles in Chronic Hemiparetic Stroke Using Twitch Interpolation

[1]Lindsay R. P. Garmirian, [1]Ana Maria Acosta and [1]Julius P. A. Dewald

[1]Northwestern University, Chicago, IL, USA
Email: Lindsay.Garmirian@u.northwestern.edu

INTRODUCTION

Approximately 50-70% of stroke survivors experience long-term upper-extremity functional impairments[1]. Paresis, a decrease in the voluntary activation of muscles, causes weakness, and makes it difficult for stroke survivors to complete activities of daily living (ADLs). The amount of paresis that occurs at specific joints in the upper extremity has not been quantified. This paper will describe the methodology and preliminary results for using twitch interpolation to quantify the ability to fully activate the elbow and wrist flexors and extensors in the paretic upper limb post chronic hemiparetic stroke.

METHODS

The ability to fully activate elbow and wrist flexors and extensors volitionally was assessed in the paretic and non-paretic limbs of two individuals with chronic hemiparetic stroke. The individuals were 56 and 62 years old, 4 and 29 years post-stroke and scored a 24/66 and 16/66 on the upper-extremity portion of the Fugl-Meyer, respectively.

Participants were seated in a Biodex chair (Biodex, Shirley, NY) and the tested arm was rigidly attached to an isometric setup to measure elbow and wrist joint torques. A 6 degree-of-freedom load cell (JR3, Woodland, CA) was used to measure elbow flexion and elbow extension torque while a single axis torque sensor (Futek, Irvine, CA) mounted at the wrist was used to measure wrist torque. The subject was positioned with 15° shoulder flexion, 20° shoulder abduction, 90° elbow flexion and in neutral with respect to pronation/supination and wrist and finger posture.

A standard twitch interpolation protocol[2] was used with the following specifications and modifications to optimize measurement of the paretic upper extremity. A monopolar stimulation setup with a motor point pen (Compex, Guildford, UK) and a reference electrode (anode) was used to find the location for each muscle where the lowest amplitude of stimulation triggered the largest visible muscle contraction. Two self-adhesive electrodes (Dura-Stick, Hanover, Germany) were placed on each muscle group, one over the muscle specific motor point (cathode) and the other distal to the motor point (anode).

For each of the four muscle groups, participants were asked to generate at least six voluntary maximum contractions (MVC), with additional MVC trials collected if needed, to ensure that the six greatest torque values were within 10% of each other and that the last trial was not the greatest value.

The electrical stimulus consisted of a single monophasic pulse with duration of 100μs to maximize motor recruitment while minimizing activation of pain (Aδ and C) fibers. The maximal stimulation amplitude was set at the 1mA increment where the measured joint torque plateaued or began to decrease. This is in contrast with standard twitch interpolation protocols in the lower limb that employ 110% of the maximal stimulation amplitude. Due to the reduced muscle and limb size in the arm and forearm, using those supramaximal amplitudes will result in current spread to antagonist muscles decreasing the net joint torque production. Participants were asked to relax followed by a maximum voluntary contraction held for 4 seconds. A stimulus of maximal amplitude was applied after 250 ms of sustained contraction level within 10% of the target effort. A second stimulus was applied after the first stimulus, with the limb at rest (see Figure 1). This was repeated for 6 trials. Between trials, participants were asked to activate the antagonist muscle group, to eliminate residual torque from the previous trial. This is an important consideration since individuals post stroke often

have hypertonicity and difficulty relaxing the flexor muscles, thus the use of reciprocal inhibition is needed to minimize any potential residual torques from the previous trial.

Elbow joint torque was calculated offline from the measured forces and moments at the forearm through a Jacobian-based transformation. The wrist torque was obtained directly from the torque sensor based on its calibration equation determined previously.

For each of the four muscle groups, voluntary activation was estimated for each trial using the following formula (1):

Voluntary Activation = $(1-\tau_A/\tau_R)*100\%$ (1)

Where τ_A, the twitch torque, represents the torque produced by electrical stimulation during MVC and τ_R, the resting twitch torque, represents the torque produced by electrical stimulation with the limb at rest (Figure 1).

RESULTS AND DISCUSSION

Fig. 1 shows example data from an elbow flexion twitch interpolation trial for the paretic limb of one of the subjects. Electrical stimulation, shown in grey, has been superimposed on the elbow extension torque data, shown in black. The percent activation calculated for this trial was 48%.

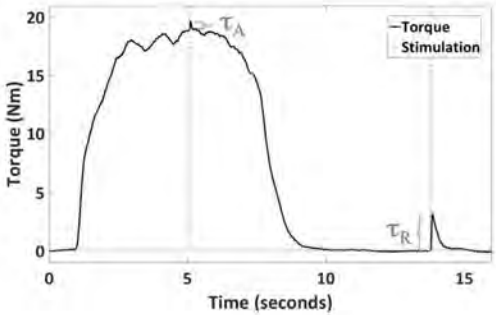

Figure 1. Example data from an elbow flexion twitch interpolation trial for the paretic limb.

Voluntary activation of the non-paretic limb in both participants was similar across muscle groups, ranging from 90.5% for the wrist extensors up to 96% for the elbow flexors (Fig. 2). Preliminary results show decreased ability to fully activate muscle groups in the paretic, compared to the non-paretic upper limb (Fig. 2). For the paretic limb, voluntary activation of the wrist muscles appears to be less than the elbow muscles, however, conclusions must be made cautiously due to small sample size (Fig. 2).

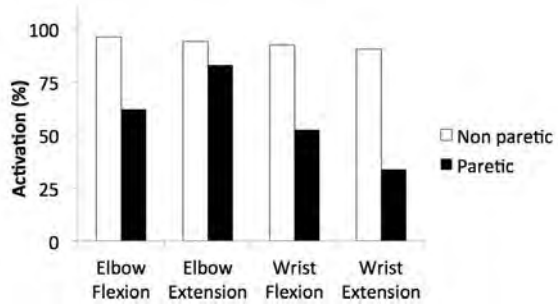

Figure 2. Voluntary activation of the paretic and non-paretic limb for elbow and wrist flexors and extensors (mean for two subjects).

CONCLUSIONS

This study shows that it is feasible to quantify voluntary activation of the elbow and wrist flexors and extensors in individuals with chronic hemiparetic stroke and describes methods to do so. The use of the twitch interpolation method to quantify deficits in voluntary activation in the paretic upper extremity of stroke subjects will help us determine differences between proximal and distal muscles and between flexors and extensors. It will also allow us to explore whether these activation impairments parallel losses in rate coding also observed in this cohort[3] and may impact development and assessment of rehabilitation approaches that seek to overcome upper extremity paresis in hemiparetic stroke.

THE EFFECTS OF FALL-RECOVERY TRAINING ON SINGLE- AND MULTIPLE-STEPPING THRESHOLDS IN INDIVIDUALS WITH CHRONIC STROKE

[1] Jamie Pigman, [1] Darcy S. Reisman, [1] Ryan T. Pohlig, and [1] Jeremy R. Crenshaw

email: crenshaw@udel.edu

INTRODUCTION

Individuals with chronic stroke have a fall risk that is twice that of age- and sex-matched controls [1]. A third of falls in this population are from a trip or a slip [2]. An impaired ability to recover from anterior and posterior falls [3] likely contributes to this high risk of trip- and slip-related falls. We previously demonstrated that fall recovery is modifiable in this population through task-specific training [4,5]. Within-training modifications included improvements in step and trunk kinematics, the proportion of successful recoveries, and the highest disturbance magnitude from which a successful recovery was achieved. It is not clear, however, how this within-training adaptation transfers to other evaluations of balance and mobility.

The Berg Balance Scale (BBS) [6] and the Functional Gait Assessment (FGA) [7] are both established clinical measures of balance and mobility that are sensitive to stroke impairment. These measures, however, do not specifically evaluate the response to an external postural disturbance. Single-stepping (SST) and multiple-stepping (MST) thresholds, defined as the anterior and posterior disturbance magnitudes that consistently elicit one or more steps, are a reliable and objective measure of fall-recovery ability [8]. These assessments differ from fall-recovery training in the size of the disturbances and by including instructions that constrain the number of steps.

The purpose of this study was to determine if, within a single group of individuals receiving fall-recovery training, measures of balance and mobility improve after training. We hypothesized that performance on all assessments would improve. However, we expected that compensatory stepping thresholds, an assessment specifically evaluating fall-recovery ability, would demonstrate the largest training effects. In order to understand the biomechanical mechanisms that underlie observed changes in stepping thresholds, we evaluated the minimum margin of stability (MoS) [9] of feet-in-place responses and the step kinematics [10,11] of single-stepping responses.

METHODS

We recruited six participants with chronic stroke (mean (SD) age: 60 (7) years, BMI: 29.5 (4.6) kg/m^2, Fugl-Meyer LE 23 (9)) for this IRB-approved study. First, balance and mobility were evaluated using the BBS and FGA. Then, fall-recovery ability was measured with anteroposterior SST and MST tests using a computer-controlled treadmill (ActiveStep®, Simbex, Lebanon, NH). Participants were instructed to "try not to step" or "try to recover in a single step". Within each test progression, the disturbance magnitude was increased by 0.5 m/s^2 until four consecutive failures were observed, indicating the anterior or posterior threshold. During the SST and MST tests, failure was defined as taking one step or taking more than one step, respectively. Failure was also considered if more than 20% of body weight was supported by an instrumented harness system (Dillon, Fairmont, MN) [12]. Using a simple inverted pendulum model of standing, thresholds were expressed as the destabilizing moment caused by the treadmill acceleration [8].

Participants then underwent six fall-recovery training sessions consisting of simulated trips and slips. Within each session, four progressively challenging, 10-minute series of disturbances were delivered for anterior and posterior falls. The disturbance magnitude was incremented depending on recovery success. After training, participants repeated all assessments on a separate visit.

Whole-body motion during stepping threshold tests was recorded using motion capture technology (Qualisys., Sweden; 120 Hz). In order to compare response kinematics before and after training, we

selected successful responses at the highest common disturbance magnitude across evaluations. For the feet-in-place response of the SST, we determined the minimum MoS in the anteroposterior direction. For the stepping response of the MST, we evaluated the anteroposterior and lateral distances between the stepping foot and whole body CoM at foot strike. All measures before and after training were compared using repeated measures t-tests and effect sizes (Cohen's *d* for repeated measures).

RESULTS AND DISCUSSION

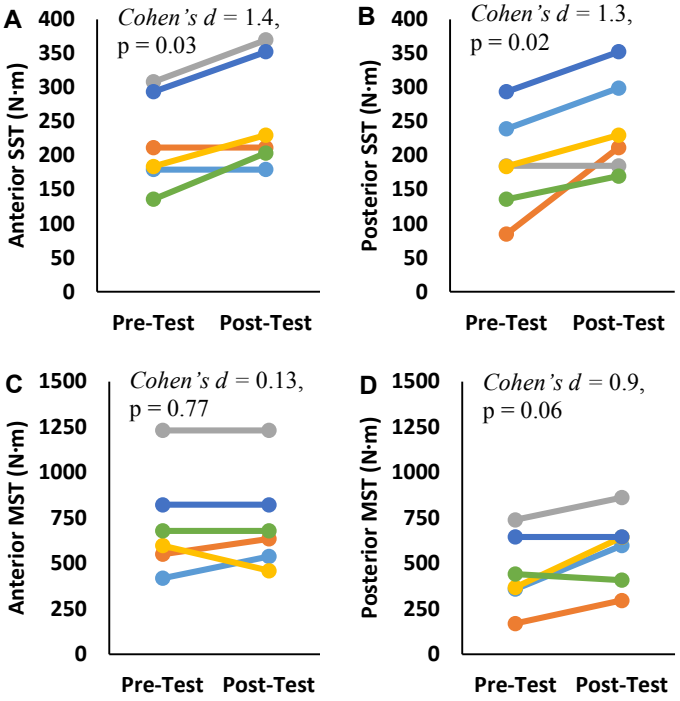

Figure 1: Stepping thresholds from pre- and post-training evaluations. With training, SST improved in anterior (**A**) and posterior (**B**) directions. The MST did not improve in the anterior direction (**C**), but there were effects of training in the posterior direction (**D**).

With training, both SST measures, as well as posterior MST measures, improved (Figure 1). Training was accompanied by moderate effects in the BBS (mean (SD) pre-test = 50/56 (6); change = +2 (3); d = 0.5, p = 0.3) and the FGA (pre-test = 18/30 (7); change = +2 (4); d = 0.6, p = 0.2).

We anticipated that, with training, participants would increase resistance to the destabilizing effects of the perturbation. In other words, we expected the minimum MoS to become *less negative*. However, when comparing the feet-in-place response at the same anterior disturbance magnitude, participants recovered from *more dynamic instability* after training (pre-test = -3.7 (4.4) cm; change = -1.6 (1.2) cm; d = 1.6, p = 0.3). This result suggests that, with training, participants altered their ability or willingness to recover from dynamic instability. There was no effect on the minimum MoS in the posterior direction (pre-test = 0.6 (1) cm; change = +0.3, d = 0.43, p = 0.36).

For the posterior stepping response of the MST assessment, medium effects of training were observed on foot placement. Steps became longer (pre-test = 15.8 (8.6) cm; change = +3.3 (8) cm) and narrower (pre-test = 7.6 (4.2) cm; change = -2.9 (7) cm; d = 0.41-0.43, p = 0.34-0.36). Although such moderate benefits in foot placement may have benefitted posterior thresholds, it could also be that participants learned to prevent second steps that weren't necessary for stability maintenance (i.e. steps due to low efficacy or fear).

CONCLUSIONS

Training had beneficial transfer to some, but not all stepping threshold measures. Kinematic analyses suggest that participants altered their ability or willingness to recover from dynamic instability. In response to a posterior slip-like disturbance, there was a trend of improved initial step placement.

To a lesser extent, training improved scores on the clinical measures of balance and mobility. This smaller effect may be due to limited transfer between a fall-recovery task and self-initiated balance and mobility.

RESTORING PROPULSIVE FORCES IN ELDERLY GAIT DOES NOT IMPAIR DYNAMIC STABILITY

Michael G. Browne and Jason R. Franz

University of North Carolina at Chapel Hill and North Carolina State University, Chapel Hill, NC, USA
email: mgbrowne@email.unc.edu, web: http://abl.bme.unc.edu

INTRODUCTION

Older adults are at an exceptionally high risk of falls, and most of these falls occur during locomotor activities such as walking. Older adults may thus opt to walk slower to improve their resilience to unexpected balance challenges and mitigate their risk of falls. However, prior to eliciting slower preferred speeds, advanced age is accompanied by a precipitous reduction in propulsive forces (F_P) exerted during the push-off phase of walking [1]. Winter et al. (1990) originally proposed that many of the hallmark biomechanical features of elderly gait, including reductions in F_P generation during push-off, reflect the adoption of a safer, more stable pattern of movement [2]. Contrary to that perspective, we recently found that a diminished push-off during walking severely compromises dynamic stability, at least in young adults [3]. Indeed, our findings alluded to unfavorable consequences of reduced F_P generation on dynamic stability that could themselves precipitate slower speeds.

Together, these results suggest that mitigating age-related reductions in F_P may increase dynamic stability during walking toward values seen in young adults. Indeed, although interventions often aim to restore push-off intensity (e.g., F_P) in older adults, it remains unclear how these changes would affect dynamic stability – a major gap in our understanding with important translational implications. Do older adults decrease propulsive force generation to attenuate their risk of falls or can we enhance push-off intensity without unfavorable effects on dynamic stability? In this exploratory study, we investigated the extent to which older adults prioritize dynamic stability in selecting their preferred push-off intensity (i.e. F_P generation). We hypothesized that increasing F_P generation in older adults would improve dynamic stability while decreasing F_P generation would worsen dynamic stability.

METHODS

16 older adult subjects (5 males/11 females, mean ± SD, age: 75.3 ± 3.6 years) participated this study. We first calculated subjects' preferred walking speed (PWS: 1.23 ± 0.19 m/s) using a photo cell timing system and a 10 m walkway (Bower Timing Systems, Draper, UT, USA). We then implemented a visual biofeedback paradigm based on real-time force measurements from a dual-belt force measuring treadmill (Bertec, Corp., Columbus, OH) (Fig. 1A). Specifically, for trials involving biofeedback, a custom Matlab (Mathworks, Natick, MA) script continuously computed the average bilateral peak F_P during push-off from each set of four consecutive steps and projected a visual representation of those values as dots in real-time to a screen positioned in front of the treadmill (Fig. 1A).

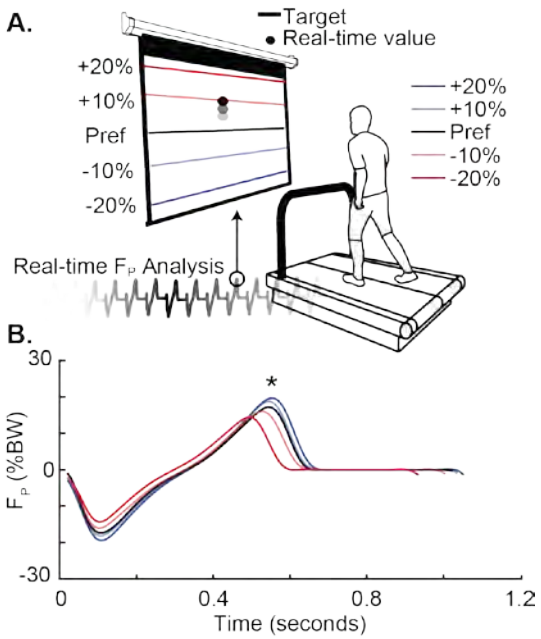

Figure 1: A.) Experimental design using real-time peak propulsive force measurements projected in front of participants with targets representing ±10 and 20% different from preferred. **B.)** Group average anterior-posterior ground reaction force by condition across time. Asterisks (*) denote a significant main effect of F_P biofeedback ($p<0.05$).

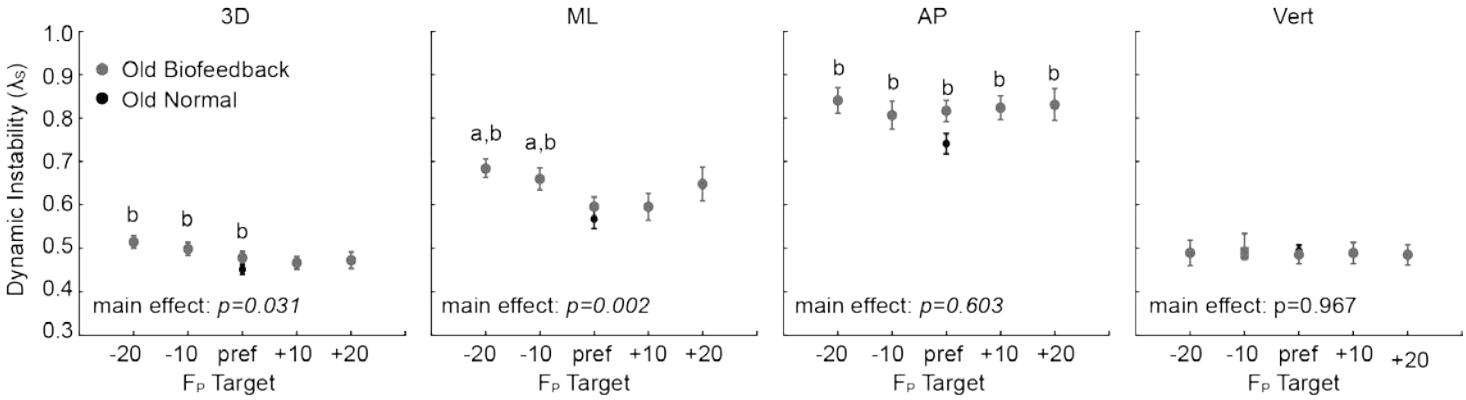

Figure 2: Group mean ± SE short-term maximum divergence exponents (λ_S) defined using three-dimensional (3D), mediolateral (ML), anterior-posterior (AP) and vertical (Vert) C7 velocities. 'a' and 'b' indicate significant ($p<0.05$) pairwise difference of biofeedback trial from preferred F_P biofeedback and normal walking, respectively.

Subjects walked at their PWS while matching their instantaneous F_P to target values representing ±10 and ±20% of preferred F_P (Fig. 1B). Using motion capture data, we constructed a state vector from the time series of C7 velocity in the anterior-posterior (AP), mediolateral (ML), and vertical directions to calculate short-term maximum divergence (i.e., Lyapunov, λ_s) exponents. Finally, we analyzed the variability of C7 kinematics given its complement to dynamic stability within the context of balance control (Data not shown).

RESULTS AND DISCUSSION

Older adults walked with a 10% F_P deficit compared to previously reported values in young adults walking at similar speeds ($p<0.05$) [4]. Older adults successfully modulated their F_P to target values, reaching +14% and -14% when targeting +20% and -20% different from preferred F_P. Older adults walked with progressively longer, wider steps across the range of presented F_P targets (i.e., from -20% to +20% F_P). Biofeedback alone (i.e. biofeedback of preferred F_P) increased AP dynamic instability, and thereby, 3D instability (Fig. 2). This effect of biofeedback on divergence in the AP direction is perhaps unsurprising considering that participants have to continually modulate F_P along the AP axis. Targeting decreases in F_P of as little as 10% worsened (i.e., increased) ML dynamic instability compared to preferred F_P biofeedback and normal walking. We posit that this is clinically meaningful; previous work suggests that older adults may be more prone to impairments in ML dynamic stability [5] and reducing F_P may further exacerbate those consequences. Compared to walking with smaller than preferred F_P, dynamic instability was much less susceptible to walking with larger than preferred F_P. Interestingly, increasing F_P generation in older adults, and thereby restoring push-off intensity to values seen in young adults, had no significant effect on dynamic stability. While we must reject our hypothesis that increasing F_P generation in older adults would improve their dynamic stability, the absence of a negative impact when restoring older adults F_P generation remains an exciting finding.

CONCLUSIONS

Our findings suggest that restoring propulsive force generation in older adults does not negatively impact their dynamic stability. These potentially favorable results may be combined with our previous work to paint an interesting story associated with restoring push-off intensity in old age. Increasing push-off intensity in old age appears to elicit beneficial changes in joint-level biomechanics without compensatory tradeoffs in whole-body measures of balance control (i.e. dynamic stability). As such, our study builds confidence toward continued efforts to restore push-off intensity during walking in old age.

Young adults are surprisingly bad at walking: Sex differences in the circumstances associated with falls

INTRODUCTION

Falls are not a trivial problem for young adults [1-3], and fall-related fractures have increased in young adults [3]. However, there are only a few studies of falls in young adults, and most of this information is from medical reports. For example, a higher proportion of fall injuries occur on stairs for young females as compared to males [2], and fall-related fractures in young females (aged 16-19 years) increased 59% from 2000 to 2010 [3]. However, it is still unclear whether young adult females are injured more because they fall more, or if they are more likely to sustain injuries from falls.

The purpose of this abstract is to determine if the frequency and circumstances of falls in young adults are associated with sex.

METHODS

Undergraduate students (N=230, 19.8 ±0.9 years, 74 males) participated in either the fall semester (106 students, 33 males) or the spring semester (124 students, 41 males).

Two surveys were distributed via email:

1. Initial survey (distributed once): Included participant demographics, number of falls in the past year, number of medications, and physical activity level with Leisure-Time Exercise Questionnaire (LTEQ) [4].
2. Daily survey (distributed daily for 16 weeks): Participants were asked if they had slipped, tripped or fallen in the past 24 hours. When participants reported a fall, follow-up questions regarding the circumstances and injuries were asked. If a participant had more than one fall a day, they were asked to report the most serious fall.

A generalized linear mixed model was used (GLIMMIX in SAS 9.3, Cary, NC, USA) to quantify differences between males and females. The odds of falls associated with fall frequency, primary cause, activity, injury, and medications were compared for men versus women. Significance level was set at $p = 0.05$. Insufficient observations were available to compare types of injuries and activity at time of injury, so these comparisons are described without statistics.

RESULTS AND DISCUSSION

1. Response Rate: The average response rate was 91%. The response rate demonstrated a linear decrease of 0.7% per week ($p<0.001$). Ten participants (4%) were excluded from the results because the response rate was less than 35%. The response rate ranged from 46-100% for the analyzed participants.

2. Fall frequency: A total of 260 falls were reported, circumstances were provided for 193 falls, so the following analysis focuses on those reports. One hundred ninety three falls were reported by one hundred six fallers (36 males). 52% of males and 46% of females fell at least once, and are henceforth termed fallers. 28% of males (n=19) and 23% of females (n=34) fell more than once, and are henceforth termed frequent fallers. (Fig. 1). There was not a significant difference in the frequency of falls between males and females (odds ratio (OR) 1.04; confidence interval (CI) 0.70-1.53; p=0.86; Fig. 1). The high fall frequency supports the observation that falls are not a minor issue, even for 20 year-old adults [1-3].

3. Causes of falls: The three main causes of falls for males were slip (40%), trip (32%), and hit/bump

(13%). Similarly, the three main causes of falls for female were slip (33%), trip (32%), and hit/bump (9%). No differences were observed between sexes on the causes of falls. The main causes of falls, slips and trips, are similar to observations for community dwelling older adults [5], highlighting the prevalence of these perturbations across all age groups.

4. Activity at time of fall: The three main activities for males were sports (58%), walking (35%), and transfer (3%). The three main activities for females were walking (48%), sports (40%), and transfer (5%). Males were more likely to fall during sports activities than females (OR 2.29; CI 1.04-5.02; p=0.04); no other differences were observed. For sports activities, it is expected that people will fall due to exposure to environmental and task-related hazards. However, a substantial number of falls occurred during walking, and walking was the main activity for females, which highlights the inherent instability of bipedal locomotion [1].

5. Physical activity (LTEQ score): No differences in physical activity level were observed between male and female fallers (p=0.68).

6. Injuries from falls: Injuries were reported as follows: males, 17% of falls (n=6); females, 37% (n=26). The number of injuries were not significantly different (p=0.12). The types of injury in males were 2 contusions (25% of injuries), 4 abrasions (50%), 2 sprain/strain (25%), and all of the injuries were due to sports-related falls. Females reported 14 contusions (45%), 10 abrasions (32%), 4 sprain/strain (13%), two concussions (6%), and one fracture (3%). The fall-related injuries were due to sports (n=15), walking (n=10), and transfer (n=1).

The number of injuries were not different between males and females, but all injuries sustained by males were sports-related, while 38% of injuries sustained by females were walking-related. Further, the most serious injuries, concussions and fractures, were only observed in females.

7. Prescribed medications: Female fallers took more medications than male fallers (p<0.001). Since this finding was unexpected, we also compared number of medications as a function of sex in the non-faller group; the number of prescribed medications was not significantly different across sex in the non-faller group (p=0.12). While it is well known that prescribed medications increase fall risk in older adults [6], this is the first observation of fall-risk related to medications in young female adults.

This study is limited by the relatively small and homogeneous subject sample.

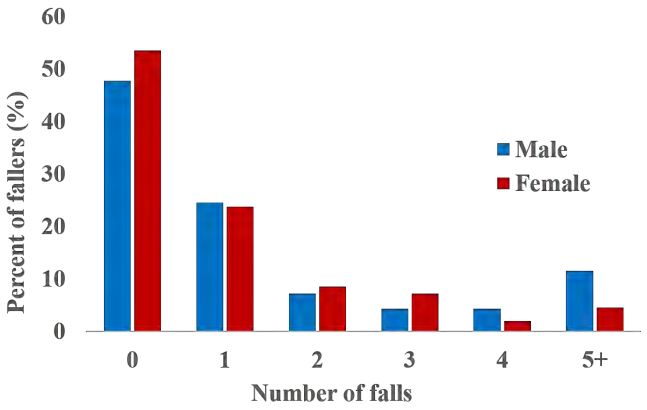

Figure 1: Percentage of participants described as a function of the number of falls; ten subjects with a response rate less than 35% were excluded.

CONCLUSIONS

The high fall rate and number of frequent fallers in 16 weeks reinforces the finding that falls are not a trivial problem for young adults [1-3]. Frequency of falls and fall-related injuries were not different for young adult males and females. While males sustained no injuries during walking, females did, and the types of injuries were more serious in females. Therefore, at 20 years of age, we provide preliminary support that females fall at the same rate as males, but they appear more likely to sustain injuries during less challenging activities and also appear to suffer more serious injuries.

DOES FOOT POSITION AFFECT MUSCLE FUNCTION DURING GAIT IN CEREBRAL PALSY?

INTRODUCTION

Altered gait patterns in children with cerebral palsy (CP) are often characterized in the sagittal plane; however, altered transverse plane kinematics are also common. For example, previous work found 61% of children with CP walk with internal foot progression angles (FPAs) and another 21% of children with external FPAs [1]. The source of altered FPAs is often a combination of excessive femoral anteversion, tibial torsion, and dynamic hip rotation, among others. Surgical interventions and physical therapy can be prescribed to address differences in FPAs; however, the effect of FPA on muscle function during gait is unclear. Only 25% of FPA variance can be attributed to femoral anteversion and tibial torsion [2], therefore a clear understanding of these musculoskeletal deficits on muscle function can augment current treatment planning decisions.

Previous work found excessive tibial torsion reduces the capacity for muscles to accelerate the knee and hip joints by 10% [3]. However, the effects of internally and externally rotated FPAs on muscle function remains unclear.

Therefore, the purpose of this study was to characterize the effect of both internally and externally rotated FPA gait strategies for children with CP on the capacity of muscles to accelerate the body center of mass (COM).

METHODS

Three dimensional gait analysis was completed for 18 children with spastic CP (Gross Motor Function Classification System: level II, age: 12.5 ± 2.9 yrs., height: 1.52 ± 0.15 m, weight: 45.5 ± 14.9 kg). Lower body kinematics (120 Hz) and ground reaction forces (1200 Hz) were collected for each child walking overground at their self-selected walking speed, and low-pass filtered with a cutoff frequency of 6 Hz. Joint kinematics were calculated using a least-squares optimization algorithm in Visual3D (C-Motion, Inc., Germantown, MD).

A generic musculoskeletal model with 14 segments, 23 degrees of freedom, and 92 Hill-type musculo-tendon actuators was scaled to match each child's body size and mass (simtk.org). Contributions from lower-limb muscles to whole body COM acceleration were analyzed using an induced acceleration analysis with a rolling without slipping kinematic constraint for foot-ground contact.

Three walking trials for each participant were normalized to the gait cycle, and the root-mean-square (RMS) values of the muscle's capacity to accelerate the body center of mass were calculated over the stance phase of gait. Each participant's FPA was identified as the average value during stance, and used to characterize the limb as *internally rotated* (FPA < 0° external rotation), *externally rotated* (FPA > 17° external rotation), or *standard* (FPA 0 - 17° external rotation). A linear mixed effect model was used to predict the effect of foot position on muscle function for several lower limb muscles for each acceleration direction with two fixed effects (Foot Position x Muscle). Statistically significant effects were assessed using an ANOVA F-test, and pairwise comparisons with Tukey multiple comparison adjustments were completed when significant main effects or interactions were indicated.

RESULTS AND DISCUSSION

Significant main and interaction effects in each anatomical direction ($F>3.05$, $p<0.044$ for all tests) indicate FPA affects the capacity of muscles to produce COM acceleration. Posthoc pairwise comparisons were completed for each muscle group and each acceleration direction.

We found significantly greater forward COM acceleration capacity from individuals walking with internal FPA compared to external FPA for the hamstrings (HAM, p=0.012), and between internal, standard, and external FPAs for the vasti (VAS, p<0.001, p=0.007, p=0.016, Fig. 1A).

We found significantly greater vertical COM acceleration capacity from individuals walking with internal FPA compared to external FPA for the gastrocnemius (GAS, p=0.001), soleus (SOL, p=0.006), and VAS (p=0.069), and from individuals walking with standard FPA compared to external FPA for the GAS (p=0.031, Fig. 1B).

We also found significantly greater medial/lateral COM acceleration capacity from individuals walking with internal FPA compared to external FPA for the gluteus maximus (GMAX, p=0.044), and SOL (p=0.021), and between internal and standard FPA, and internal and external FPA for the gluteus medius (GMED, p<0.001, p<0.001, Fig. 1C).

Our data suggest that increasingly externally rotated gait patterns result in reduced muscle capacity to accelerate the COM, similar to previous work that examined tibial torsion [3]. The capacity of muscles to produce COM accelerations provides insight into whole body metrics such as walking speed and balance. Muscle induced accelerations are influenced both by muscle mechanics such as muscle length and moment arm, and by the skeletal posture dictating the distribution of intersegmental forces throughout the lower-limbs. We suspect the observed trend seen within our results is primarily caused by altered posture for those walking with internally rotated FPA. Kinematic differences are seen in hip abduction and frontal plane pelvis rotation during stance. We speculate that an internally rotated foot position provides a mechanism for sagittal plane joints to accelerate the hip into abduction and to increase acceleration of frontal plane pelvis rotation.

CONCLUSIONS

Foot progression angle is likely an important factor to consider when treating gait deficits for children with CP because it affects the capacity of muscles to accelerate the body during gait. This highlights the substantial effect that transverse plane kinematics can have on sagittal plane mechanics (e.g., forward and vertical acceleration of the body COM), which are likely critical for improving clinical outcomes such as walking speed. Future work will investigate whether internally rotated gait patterns may be used as a compensation for low force producing muscles.

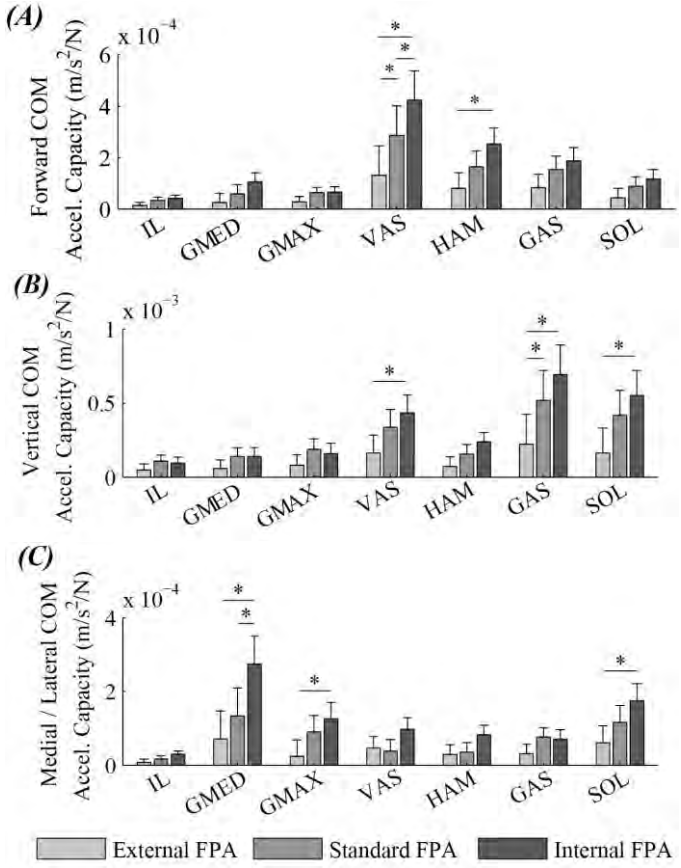

Figure 1: Capacity of major lower limb muscles to accelerate the body center of mass (COM), reported as RMS over the stance phase of gait (p<0.05*).

ISOLATING EFFECTS OF TOE AND FOOT LENGTH ON BIPEDAL WALKING

Eric C. Honert, Gerasimos Bastas and Karl E. Zelik

Vanderbilt University, Nashville, TN, USA
email: eric.c.honert@vanderbilt.edu, web: http://my.vanderbilt.edu/batlab/

INTRODUCTION

The purpose of this ongoing study is to quantify the effects of toe length and foot length on walking biomechanics. Computational simulations [1, 2] and experimental motion analysis studies [1] have shown how varying the length of a rigid foot can affect gait mechanics. However, less is known about the effects of varying sub-segments of the foot; for example, varying the distance from the heel to the toe joint (hereafter referred to as *sole length*), or varying the distance from the toe joint to the distal end of the toes (hereafter referred to as *toe length*). We seek to address this knowledge gap using a custom-designed, adjustable prosthesis to systematically and independently vary toe and sole lengths. We expect the results to provide insight into how biological foot proportions (sole vs. toe length) affect walking, which in turn will inform the design of prosthetic and robotic feet.

METHODS

We designed and fabricated a pair of adjustable ankle-toe prostheses (Fig. 1A) to systematically quantify the effects of toe and sole length on bipedal walking biomechanics. Three healthy, able-bodied subjects (2 males, 1 female, 23±4 yrs, 79±10 kg, 1.8±0.5 m) have thus far consented and participated in this two-session gait analysis study. Subjects wore the adjustable ankle-toe prostheses bilaterally below simulator boots (which immobilize the biological ankles). The first session (~1 hour) served to acclimate individuals to walking on the ankle-toe prostheses with seven different conditions that would subsequently be evaluated in the experimental data collection.

Subjects returned within one week of the training session to participate in an experimental data collection. Subjects walked at 1.0 m/s on a split-belt, instrumented treadmill while we recorded ground reaction forces (GRFs) and lower-limb kinematics. Each subject walked with 25 different toe length and sole length combinations. We tested five toe lengths from 50 to 90 mm in 10 mm increments and five sole lengths from 170 mm to 230 mm in 15 mm increments. The overall lengths of the feet (ranging from 220 mm to 320 mm) are typical for persons ranging from 1.6 to 1.9 m tall. The ankle stiffness and toe joint stiffness were held constant. GRFs were used to compute center-of-mass (COM) power through the individual limbs method [3]. COM Collision and Push-off work were computed as key outcome metrics, based on prior literature (e.g., [4]).

RESULTS AND DISCUSSION

Increasing sole length from 170 mm to 230 mm (with a fixed toe length of 70 mm, Fig. 1B, left) resulted in an increase of 29% (4 J) in COM Push-off work and decrease of 23% (2 J) in COM Collision work magnitude. These trends were fairly consistent across all three subjects (Fig. 1B), and also for different fixed toe lengths (not shown here).

Unlike increasing the sole length, increasing the toe length did not initially reveal clear trends in COM Push-off or Collision work (Fig. 1B, right). At a sole length of 200 mm (Fig. 1B), the maximum COM Push-off work was attained at the 80 mm toe length (17 J). However, there was little difference (~1 J) in COM Push-off work between this toe length and all other toe lengths. Similarly, toe length appeared to have only a small influence (~2 J) on COM Collision work. Thus far, trends have been fairly consistent across all subjects and across different nominal sole lengths.

We plan to extend this toe and sole length study to 10 subjects and examine lower limb kinematics and kinetics. We will perform ANCOVA statistical analyses to examine trends in outcome metrics with

increasing toe and sole length. We expect the results of this study, in conjunction with a prior study we performed on toe joint stiffness and toe shape (manuscript in review), to inform our scientific understanding of biological feet and applications such as foot prostheses and walking robots.

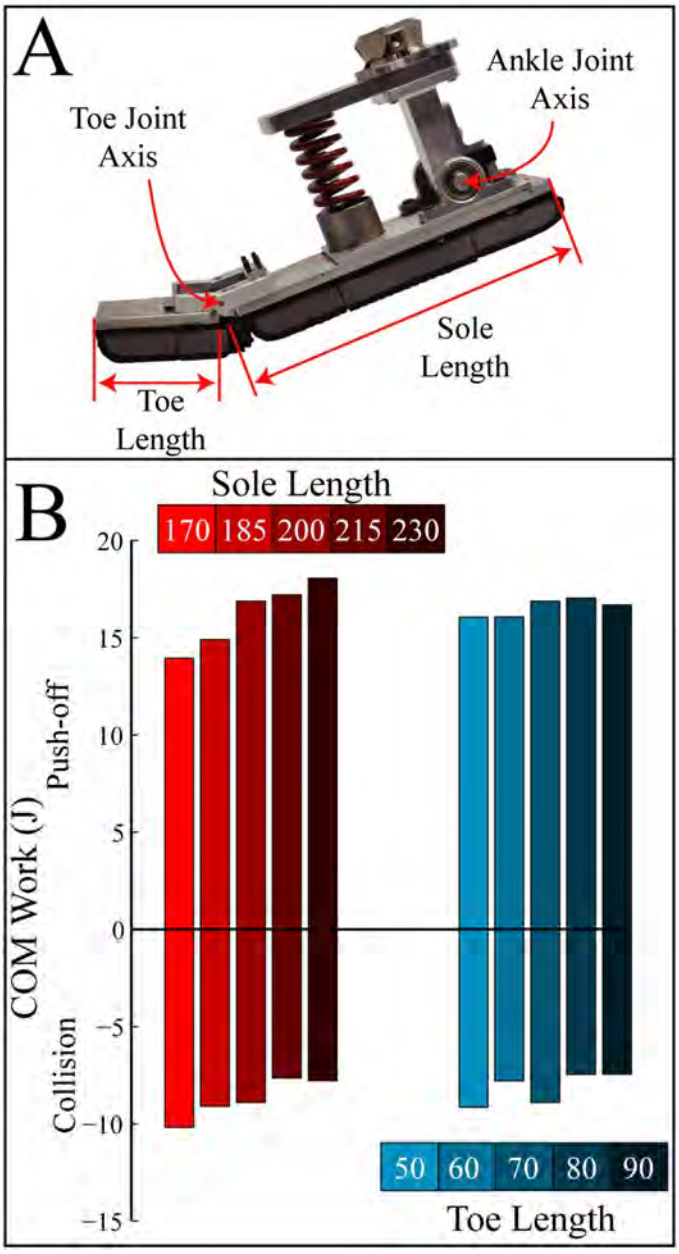

Figure 1: A) Adjustable ankle-toe prosthesis. B) Average COM Collision and Push-off work. Left: Vary sole length with a fixed toe length of 70 mm. Right: Varying toe length, with a fixed sole length of 200 mm. Dimensions are in mm, and work in Joules. Subjects walked at 1.0 m/s. Preliminary data (N=3), thus statistical analyses not yet performed.

CONCLUSIONS

This study is the first to systematically vary toe and sole lengths, and to isolate their effects on gait biomechanics. Thus far, sole length appears to have a greater effect than toe length on key metrics such as COM Push-off and Collision work. More comprehensive kinematic and kinetic analysis on a larger sample size is forthcoming.

INTRODUCTION

Gait asymmetry and motor variability have both been associated with pathologic gait changes and increased injury risk [1, 2]. While both gait variability and asymmetry have been evaluated concerning injury risk and pathology, the direct relationship between motor variability and gait asymmetry has not yet been studied. Understanding this relationship may enable a deeper understanding of their respective roles with respect to injury and pathology during gait.

This study examined the correlation between gait asymmetry and motor variability in a healthy control population. We hypothesized that gait asymmetry and motor variability would be positively correlated in treadmill walking.

METHODS

Fifty-one recreationally active adults ages 18 to 35 were recruited (Table 1). Exclusion criteria included history of major lower extremity surgery, currently seeking medical treatment for any musculoskeletal disease/injury, and any lower extremity injury in the past 3 months that limited physical activity for more than 1 day.

Table 1: Participant demographics. Mean (SD).

	Age	Height (m)	Weight (kg)
Men (n = 23)	24.17 (4.84)	1.80 (0.07)	78.81 (14.76)
Women (n = 24)	24.54 (2.50)	1.70 (0.05)	66.90 (9.44)
p-value	0.620	<0.001	<0.001

An 8-camera Miqus MI system (Qualisys, Gothenburg, Switzerland) and a fore-aft split belt instrumented treadmill (AMTI, Watertown, Massachusetts) were used to collect motion capture (120Hz) and loading (1440Hz) data, respectively. Participants wore form fitting shorts, a shirt, and Nike Zoom neutral cushioning athletic running shoes. Reflective markers were placed bilaterally on lower extremity bony landmarks. Participants completed a five minute walking trial at 1.5m/s on the instrumented treadmill. All spatial and temporal time-series data was calculated using Visual 3D software (C-Motion, Bethesda, Maryland).

Step length, single support time (% stride), and swing time (% stride) asymmetry was quantified using a limb symmetry index (Equation 1) [3]. Stride-to-stride standard deviation was calculated for step length, stride length, step width, stride time, support time (% stride), and swing time (% stride). Standard deviation was used to quantify variability on the dominant (D) and non-dominant (ND) limbs.

$$\text{LSI} = \frac{|X_D - X_{ND}|}{0.5*(X_D + X_{ND})} * 100\% \qquad (1)$$

Pearson correlation coefficients between each pair of asymmetry and variability metrics were calculated in JMP Pro 13 (Table 2). An alpha level of 0.05 indicated significance and coefficients of below 0.34, 0.37-0.67, 0.67-0.9, and above 0.9 were considered poor, moderate, high, and very high respectively.

RESULTS AND DISCUSSION

Gait asymmetry and motor variability were significantly correlated. Increases in swing and single support time asymmetries were positively correlated with temporal variability. Increases in step length asymmetry were negatively correlated with variability of step length and step width. Spatial and temporal asymmetry were only significantly related to spatial and temporal variability, respectively.

Correlations between temporal measures were stronger than those between spatial measures.

Motor variability has been described as both noise in the motor control system and as serving to increase adaptability [4]. Similarly, gait asymmetry can be both functional and pathologic (**); the context of this observation is crucial. In active young adults, gait asymmetry may allow each limb to be utilized uniquely for propulsion and balance [5]. Results suggest this asymmetry would be correlated with increased temporal and decreased spatial variability. These potential changes in motor variability may also be functional and indicative of increased system adaptability. In a pathologic older adult population, gait asymmetry and related alterations to motor variability are less likely functional and more likely pathologic or reflective of some increased risk. In older adults with lower extremity pathology, higher variability may indicate decreased motor control and compromised balance that may increase fall risk [1].

The main limitation of this study was that only temporal and spatial correlations between gait asymmetry and motor variability were investigated. Spatial and temporal parameters are more commonly studied in variability literature than are kinetic and other kinematic measures, which drove this focus. However, the scope could be expanded to include kinetic and other kinematic measures in future studies. This study also only included healthy young adults. Since variability is so heavily studied in older adults and pathologic patients, this limited population decreases broad applicability back to the populations of interest. A similar study in older adults and individuals with injuries and/or pathology would widen the represented population.

CONCLUSIONS

The relationship between gait asymmetry and motor variability provides additional information to better understand the role of motor variability in gait. This relationship is another tool to differentiate between functional and pathologic asymmetry and variability. Gait retraining based on this relationship may be useful to decrease fall risk in older adults. Gait asymmetry and motor variability should not be thought of independently and should be investigated in tandem when possible.

CHANGES IN FORCE-DEFORMATION PATTERNS OF THE FOOT WITH WALKING SPEED

[1]Thomas Hulcher and [1,2] Elisa Arch

[1] Biomechanics and Movement Science Interdisciplinary Program, [2] Department of Kinesiology and Applied Physiology
University of Delaware, Newark, DE, USA
Email: thulcher@udel.edu

INTRODUCTION

Walking is one of the most important motor abilities a person can possess, allowing for transportation, exercise, socialization and participation in society. Loss of walking ability leads to physical inactivity which has been shown to increase mortality [1]. Depending on the injury or disability, an orthotic device may be prescribed to help an individual regain walking ability. Orthoses are common, with almost 2.5 million orthotic and prosthetic devices approved by Medicare in 2015 [2].

Ankle-foot orthoses are the most commonly prescribed category of orthotic devices [3]. Many foot and ankle-foot orthoses use a solid, rigid footplate which inhibits the natural deformation of the foot. In particular, during the latter part of the stance phase, the forefoot naturally deforms under force. Interestingly, this forefoot deformation absorbs power [4]. Use of a rigid footplate with a toe rocker has been shown to minimize the overall power loss of the ankle-foot complex [5], demonstrating the energetics of the ankle-foot system can be manipulated through control of the foot's deformation. Harnessing this knowledge, we theorize it may ultimately be possible to augment the power profile of the ankle-foot system, particularly for patients with impairments, through a deformable footplate that harnesses the natural loading and unloading pattern of the foot. In order to design such a footplate, the force-deformation patterns of the natural foot need to be characterized, especially in the latter part of stance during which the forefoot (toes) dorsiflex. We hypothesized that, in typical gait, as walking speed increases, the vertical ground reaction force and amount of forefoot foot deformation will both increase. Furthermore, we hypothesized that these increases will be similar in value, leading to a constant forefoot stiffness (ratio of force to displacement/deformation) across walking speeds.

METHODS

Motion capture data from nine healthy subjects walking barefoot, overground at four scaled speeds (0.4, 0.6, 0.8, 1.0 statures/second) were analyzed. These data were captured using a six camera optical motion analysis system (Motion Analysis Corporation, Santa Rosa, CA) and four force plates (AMTI, Watertown, MA, USA). A six-degree-of-freedom marker set was used to track lower extremity segments. Outcome measures were calculated for each subject at each speed for trials that had at least one foot completely in contact with a force plate. Each of these measures were then averaged across trials within each walking speed, for each subject. Primary outcome measures were the change in (1) vertical ground reaction force (GRF) and (2) the vertical center of pressure (COP), referenced to the foot coordinate system, over the period of interest (approximately the phase of toe dorsiflexion in late stance). To indicate the start and end of this period of interest, the time at which the vertical COP had an inflection point during the latter half of stance and the maximum COP value, respectively were used. The change in vertical GRF and vertical COP (forefoot deformation) were calculated as the measure's value at the second time point minus the value at the first time point. Finally, these measurements were used to determine forefoot stiffness according to the function $k = F/\delta$ where k is the stiffness value (N·foot-length/kg), F is the force (N/kg) and δ is the forefoot deformation (1/foot-length).

RESULTS AND DISCUSSION

On average, the forefoot deformation and vertical GRF increased at a seemingly steady rate as speed increased (Table 1.) Average forefoot stiffness increased from 0.4 to 0.8 stat/s. There was a slight decrease in stiffness from 0.8 to 1.0 stat/s (Table 1.)

These data supported our hypotheses across all speeds for the deformation and vertical GRF. Contrary to our hypothesis, the stiffness increased but then decreased as speed changed.

0.8 stat/s is generally considered to be a comfortable walking speed for healthy individuals. Trends in these data were consistent from slow to comfortable walking speeds but seem to change at a faster than comfortable speed (1.0 stat/s). This observation may indicate that the mechanics of the ankle/foot complex is altered at faster-than-comfortable speeds, perhaps as a preparatory transition from walking to running.

CONCLUSIONS

The goal of this study was to characterize how the foot, specifically the forefoot, naturally deformed at various walking speeds in order to take the first steps toward developing an orthotic footplate that mimics that deformation. The results showed that the deformation, GRF, and stiffness changed as walking speed changed although they do not all increase with increased walking speed. This work is the first step towards ultimately aiming to harness energetics of the ankle-foot system to improve gait function and mobility of patients with ankle-foot impairments.

A NEW KINEMATIC-BASED GAIT EVENT DETECTION ALGORITHM DURING TREADMILL LOCOMOTION

[1]Alexander M. Morgan, [1]Stephen Cobb, [1]Emily Gerstle, [2]Bryan Heiderscheit, [2]Mikel Stiffler-Joachim, and [1]Kristian M. O'Connor

email: morgan28@uwm.edu

INTRODUCTION

Detection of gait events is typically reliant upon kinetic data from force plates. However, in the absence of force plate data as is typical for treadmill-based gait, algorithms using kinematic data are necessary to estimate these gait events. Numerous treadmill coordinate-based algorithms for detecting initial contact and toe off during the stance phase of the gait cycle have been developed and assessed for accuracy and reliability [1,2,3]. These algorithms have primarily examined the positions of heel and toe reflective markers, often in relation to a pelvis marker. However, not all motion capture methods utilize these markers. As such, it would be beneficial to be able to identify gait events using a single landmark.

Tracking the anterior-posterior position of the ankle joint center does not require placing markers on specific foot locations, and it is a point that all kinematic methods generally have access to. Such a method could be beneficial across different walking and running speeds if appropriate temporal offsets can be determined with adequate precision. Methods using foot-based markers have been reported for walking [4] and running [5], but no study has established using a single landmark across walking and running speeds. Therefore, the purpose of this study was to examine the validity of a new gait event detection method using the anterior-posterior position of the ankle joint center.

METHODS

Eighty subjects (43 male and 37 female) participated in this study (average: 40.9 years, 1.7 m, 70.5 kg). Written informed consent was obtained from all subjects prior to participation in accordance with the Institutional Review Board of the University of Wisconsin-Milwaukee. Three-dimensional kinematic data were collected using an MPT Series-2.0 motion capture system (Metria Innovation, Inc., Milwaukee, WI) at 180 Hz. Kinetic data were collected using Bertec instrumented force treadmill (Columbus, OH) at 1800 Hz.

Tracking targets were placed on the pelvis and bilaterally on the posterior aspect of the thigh, shank, and heel. Relevant anatomical landmarks, including bilateral ASIS, PSIS, greater trochanters, lateral and medial epicondyles and malleoli, and the head of the first and fifth metatarsals, were identified. The ankle joint center was identified as the midpoint of the malleoli.

Fifteen-second trials for six different gait speeds were collected. Subjects walked on the instrumented treadmill at 2 and 3 mph, and ran at 5, 6, 7, and 8 mph. The anterior-posterior position of the ankle joint center relative to the pelvis was used in the algorithm for detecting gait events. The most anterior and posterior relative positions of the right and left ankle joint center were determined for each step. The instants of initial contact and toe off were determined from the force data using a 20-N threshold. The temporal difference between the most anterior ankle position and initial contact, and the difference between the most posterior ankle position and toe off were determined. Positive reported offsets indicated that the actual gait event occurred later than the kinematic event.

Statistical analyses were performed using SPSS (v19.0 SPSS Inc., Chicago, IL). Within-subject differences in gait event offsets across the six different speeds were assessed using a one-way

repeated measures ANOVA ($p<0.05$). Within subject differences in gait event times between walking and running were assessed using a paired-samples t-test ($p<0.05$).

RESULTS AND DISCUSSION

For both walking and running, initial contact occurred on average between five and six frames after the most anterior ankle position, with a significant difference of a half frame between walking and running (Table 1).

The instant of toe off occurred nine frames after the most posterior ankle position for walking and 14 frames before this event for running (Table 1). For walking, the ankle joint begins to move forward as the ankle plantarflexes before toe off, while for running the leg continues to move backwards after toe off. Within each mode of gait, there were significant differences in gait event detection across speeds for both walking and running (Table 2). However, many of the speed related differences were relatively small.

The between-subjects standard deviations of the offset for walking are less than two frames for initial contact and slightly more than two frames for toe off, which is similar to previous reports [1]. These values for running are about two frames for initial contact and between two and four frames for toe off. These standard deviations are between two to eight times less than previously shown in other studies [1,2,6].

CONCLUSIONS

This study presents a kinematic algorithm using the ankle joint center to detect gait events across gait speed and type. Applying the offsets listed in Table 1 to the times of most anterior and posterior positions of the ankle joint provided an accurate representation of initial contact and toe off. In addition, the present algorithm appears to perform better than other, similar kinematic algorithms with regards to between subjects variation for running [1,2,6]. Furthermore, our findings concur with previous work suggesting that gait type does impact event offsets [5]. These results support the use of this algorithm for walking and running gait studies.

INTRODUCTION

The ankle and subtalar joint (STJ) provide primary dorsiflexion/plantarflexion and inversion/eversion during gait, respectively. Frequently, the subtalar joint is overlooked in biomechanical models. These two joints are often grouped together as one ankle-subtalar-joint complex or the models focus on the ankle, keeping the subtalar joint locked. Further, when the STJ is included in the model, like in the commonly used OpenSim model, Gait2392 [1], the subtalar joint is treated as a one degree-of-freedom joint with the axes orientation angles set at the low range as reported by Inman [2]. According to Inman [2], the subtalar joint lies on an oblique axis with inclination and deviation angles that range from 68.5-20.5° and 4-47°, respectively. In the Gait2392 model, the orientation of the subtalar joint axis is set at 37.2° from the horizontal plane and 8.7° from the midline of the foot. While these lie within the range, these values are lower than the average inclination and deviation angles of 42° and 23° as reported by Inman [2].

The purpose of this study was to determine how varying the subtalar joint axes orientation to reflect Inman's average axes affect kinematics and kinetics of the ankle and subtalar joint during dynamic motion in OpenSim.

METHODS

Three-dimensional marker position and ground reaction force (GRF) data of three dynamic tasks: walking, running, and a one-leg jump, were obtained for five subjects (3 male, 2 female, mean age 23.4 ±3.43, average BMI 26.49 ± 3.48) as part of an IRB approved study after informed consent was obtained. The data were imported into OpenSim (SimTK, Stanford, CA, v3.3) and used to scale the default Gait2392 model for each subject. Marker data were filtered at 6 Hz for walking, running, and jumping prior to dynamics comparisons.

To determine the impact of Inman's axis on STJ dynamics, inverse kinematics and dynamics were computed using OpenSim in two STJ conditions: 1) the standard scaled model and 2) a scaled model with the subtalar joint orientation matching Inman's average inclination and deviation angles. A custom Matlab (The Mathworks, Natick, MA, R2014a) program was used to normalize stance phase of the right leg for all five subjects during walking and running. The one-leg jump task was separated into three parts and normalized for stance, in air, and land phases. A two-tailed paired t-test was used to compare max, min, and range values for kinematics and kinetics of the original Gait2392 subtalar joint axis orientation and Inman's mean axis. Significance was set at $p<0.05$ for all analyses.

RESULTS AND DISCUSSION

The mean ankle and subtalar joint kinematics patterns for both Inman and default Gait2392 subtalar joint models were similar to in vivo bone pin studies for walking [3]. Modifying the subtalar joint orientation from Gait2392 to match Inman's mean inclination and deviation angles resulted in a statistically significant change in the range of ankle angle values ($p=.049$) seen in the kinematics during walking (Gait2392: 28.95° ± 4.41°; Mean Inman: 29.42° ± 4.54°). No other changes in kinematics were seen in other joints or motions.

Varying the orientation of the subtalar joint axes caused a significant increase in peak subtalar joint moments in all three dynamic motions (Table 1): walking (peak 1: $p=.001$, peak 2: $p<.001$), running ($p=.005$), and one-leg jump (peak 1: $p=.009$, peak 2:

p<.001). Looking at the three motions (Figure 1), we can see that Inman's mean subtalar joint axes produce higher average subtalar joint moments throughout each motion. The more dynamic the task, with jumping being the most extreme, we see a larger difference in subtalar joint moment between the two models.

Changing the subtalar joint orientation also resulted in large changes of the subtalar joint moment patterns during walking. The average Inman's mean axes produces two large peaks during the stance cycle, one at 30% stance and the second around 80% of the gait cycle. The axis used by Gait2392 produced a much smaller second peak, seen later at around 90% of the stance (Figure 1a).

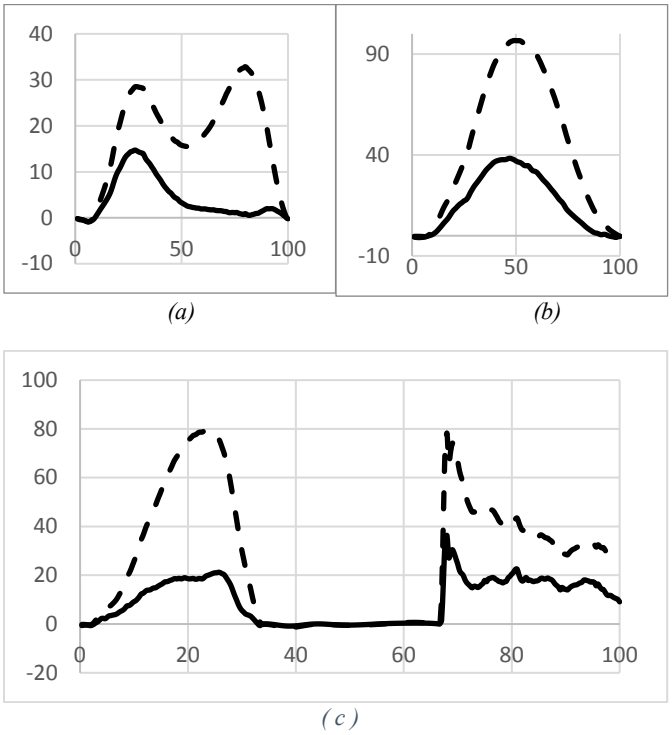

Figure 1: Average subtalar joint moment (Nm) comparing Gait2392 (solid) vs Inman (dotted) subtalar joint orientation during (a) walking (b) running (c) and one-leg jumping tasks.

Comparing the results from all five subjects, the subtalar joint moments during walking show subject-to-subject variability, which is consistent with prior studies [4]. The model with Inman's mean axes has a double-peak curve for all 5 subjects while the model with Gait2392 subtalar joint angles shows a slight double-peak for only 2/5 subjects. This is similar to the literature that showed a double-peak for only 1/3 subjects [4]. A limitation of this study is that due to lack of studies and the variability in subject specific differences, we are not able to verify which model is correct.

Another limitation of this study is that the knee, ankle, and subtalar joint are all modeled as one DOF joints. This restricts the observation to only one plane of motion. In order to see how the changes to the subtalar joint axes affects all planes of motion, the model should include 3DOF in the knee and ankle.

Since the net joint moments affects muscle force calculations, future studies should evaluate how changes to the subtalar joint inclination and deviation angles affect muscle activation and muscle force during dynamic tasks. In this study, walking, running, and a one-leg jump were investigated, but future work should also investigate more complex dynamic tasks like cutting maneuvers, which elicit more motion at the subtalar joint.

CONCLUSIONS

Changing the subtalar joint axes to match Inman's mean inclination and deviation angles produces different subtalar joint moments in various dynamic tasks. Future works should determine how these changes in subtalar joint moments affects muscle forces as well as the kinematics and kinetics at the hip and knee seen in dynamic motions, such as cutting.

DOES LOCAL DYNAMIC STABILITY DURING UNPERTURBED WALKING PREDICT THE RESPONSE TO BALANCE PERTURBATIONS?

Mu Qiao, Kinh N. Truong, and Jason R. Franz

INTRODUCTION

Older adults are at high risk of falls, and most falls occur during locomotor activities such as walking. Reduced local dynamic stability in old age is often interpreted to suggest a lessened capacity to respond to more significant balance challenges encountered during walking and future falls risk [1]. However, it remains unclear whether local dynamic stability during normal, unperturbed walking predicts the response to larger external balance disturbances. Indeed, local dynamic stability quantifies resilience to small, naturally occurring kinematic deviations arising normally during walking, and may not reflect resilience to larger external perturbations that could elicit a fall [1]. Predicting one's resilience to external balance challenges using measurements acquired during normal, unperturbed walking may be clinically desirable, enabling the targeted prescription of preventive care. We hypothesized that larger values of local dynamic instability during unperturbed walking would positively correlate with larger changes due to optical flow perturbations – a hypothesis that we tested in subjects coalescing to provide a spectrum of walking balance integrity: young adults, older non-fallers, and older fallers.

METHODS

We recruited 11 young (5M/6F), 11 older adult non-fallers (5M/6F), and 11 older adults with at least one fall in the last year (4M/7F) to walk on an instrumented dual-belt treadmill (Bertec, Corp.). Young adults walked at 1.25 $m \cdot s^{-1}$ while both older fallers (1.03±0.22 $m \cdot s^{-1}$) and non-fallers (1.19±0.20 $m \cdot s^{-1}$) walked at their preferred overground speed. While walking, subjects watched a speed-matched, virtual hallway rear-projected onto an immersive semi-circular curved screen surrounding the treadmill (Fig. 1A) both with and without continuous oscillations of optical flow designed to elicit the visual perception of lateral instability [2]. In randomized order, subjects walked for 2 min normally and with optical flow perturbations at amplitudes of 20, 35, and 50 cm. A 14-camera motion capture system (Motion Analysis Corp., 100Hz) recorded the 3D trajectories of heel markers and the C7 vertebrae (filtered with a low-pass cutoff of 8 Hz). We quantified local dynamic stability by estimating maximum exponential rates of divergence (*i.e.*, λ, bits·stride^{-1}) from 3D C7 marker velocity time series (Eqn. 1). We constructed a state space, $\boldsymbol{S}(t)$, as:

$$\boldsymbol{q}(t) = (\dot{x}, \dot{y}, \dot{z}) \quad (1)$$

$$\boldsymbol{S}(t) = [\boldsymbol{q}(t), \boldsymbol{q}(t + 1 \cdot \tau), \cdots, \boldsymbol{q}(t + (d_E - 1)\tau)] \quad (2)$$

where, $\dot{x}, \dot{y},$ and $\dot{z}$ are the C7 velocity components in the anterior-poster, medio-lateral, and vertical directions, respectively. By convention [1,2], we computed the maximum rates of divergence of initially neighboring trajectories from $\mathbf{S}(t)$ using an embedding dimension (d_E) of 4 and a time delay (τ) equal to one quarter of subjects' average stride time. We time normalized the divergence curves to account for differences in stride period and calculated short-term (i.e., λ_S, 0 to 1 stride) and long-term (i.e., λ_L, 4 to 10 stride) divergence exponents for each condition, where larger positive values indicate larger local dynamic instability. A mixed 2-way factorial ANOVA first tested for main effects of group and condition on λ_S and λ_L using α=0.05. Linear regressions then estimated the relation

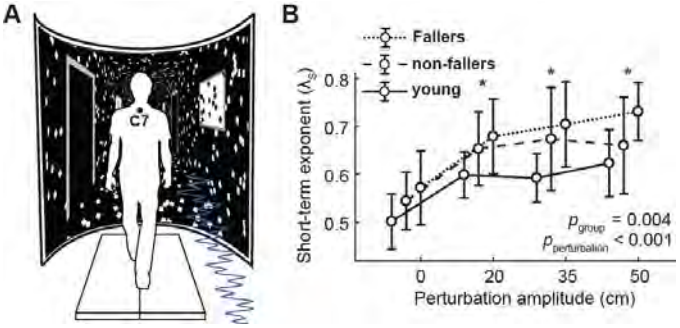

Figure 1: (A) Virtual environment. (B) The effects of group (*e.g.,* young adults, non-fallers, and fallers) and perturbation amplitude on short-term local divergence exponents (λ_S).

between local dynamic stability during unperturbed walking ($\lambda_{unperturbed}$) and the average change thereof in response to perturbations (i.e., $\bar{\lambda}_{perturbed}$-$\lambda_{unperturbed}$).

RESULTS AND DISCUSSION

Aging and falls history effects on dynamic instability

We observed a significant effect of group on short-term (λ_S, p=0.004, Fig. 1B) but not long-term local dynamic instability - an effect governed by instability due to age, independent of falls history. However, neither age nor falls history significantly affected dynamic instability during unperturbed walking. Compared to unperturbed walking, optical flow perturbations significantly increased short-term (λ_S, p<0.0001, Fig. 1B) local dynamic instability – which affected all subject groups (young: p<0.001, non-fallers: p=0.009, fallers: p<0.001, Fig. 1B).

Perturbations revealed between-group differences in local dynamic instability that were not apparent during unperturbed walking. Age alone did not increase local dynamic instability during walking for any optical flow perturbation amplitudes. In contrast, fallers exhibited larger local dynamic instability than young adults for all three perturbation amplitudes (fallers *vs*. young: p<0.009, Fig. 1B). We observed no difference in local dynamic instability between fallers and non-fallers for the two smallest amplitude perturbations (p≥0.445, Fig. 1B). However, although not statistically significant, fallers tended to have larger local dynamic instability than non-fallers at the largest amplitude (50cm: p=0.059, Fig. 1B).

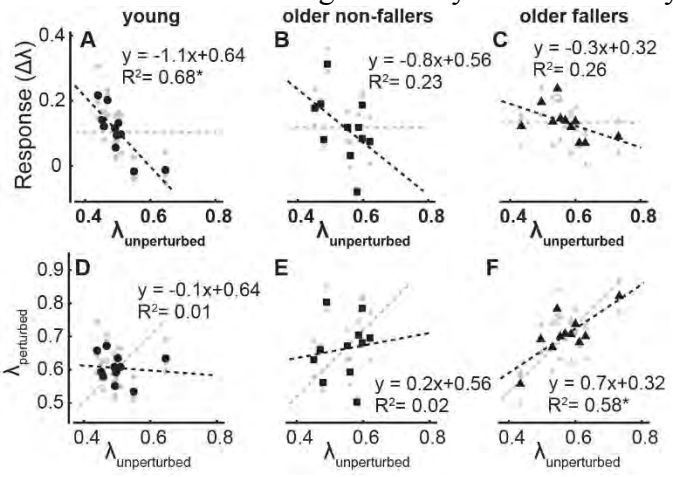

Figure 2. Top row; correlations between λ_S during unperturbed walking ($\lambda_{unperturbed}$) and the average change thereof in response to perturbations ($\Delta\lambda$=$\lambda_{perturbed}$-$\lambda_{unperturbed}$) for (A) young adults, (B) older non-fallers, and (C) older fallers. Bottom row; correlations between $\lambda_{unperturbed}$ and the average in response to optical flow perturbations ($\lambda_{perturbed}$) for (D) young adults, (E) older non-fallers, (F) and older fallers. The black dashed line is the best linear fit; the solid gray line has a slope of zero (top row) or one (bottom row) indicating, in both, a response to perturbations that is independent of subjects' baseline stability.

Predicting the response to balance perturbations

The relation between λ_S during unperturbed walking and changes due to optical flow perturbations differed across individual groups (Fig. 2). Young adults had the only significant. and by far the strongest and steepest, negative correlation between local instability during unperturbed walking and response to perturbations (R^2=0.68, Fig. 2A). Compared to young adults, this relation was similarly steep but much less well correlated in older non-fallers (R^2=0.23, Fig. 2B). Finally, older fallers exhibited by far the most shallow regression between λ_S during unperturbed walking and changes thereof due to optical flow perturbations (R^2=0.26, Fig. 2C). Indeed, the relation between λ_S during perturbed and unperturbed walking reached significance and approximated the line of unit only for older fallers, indicating a uniform response that emerged only in older adults with a history of falls (Fig. 2F).

CONCLUSIONS

Although modest, our data first suggest that older adults with a history of at least one fall have a more pervasive susceptibility to optical flow perturbations than older non-fallers during walking. Second, in surprising contrast to our hypothesis, a significant negative correlation indicated that young adults with higher local dynamic instability during unperturbed walking exhibited *smaller* responses to optical flow perturbations. One interpretation is that young adults may self-regulate their response to balance perturbations based on a self-perception of risk guided by their baseline level of dynamic instability. In contrast, particularly among older fallers, the response to optical flow perturbations appeared completely independent of their baseline level of dynamic instability. We conclude that understanding the response to balance perturbations, especially among older fallers, may require measuring that response directly rather than relying on measures collected during normal, unperturbed walking

PREDICTING MEASURES OF PHYSICAL PERFORMANCE FROM GAIT MECHANICS IN PATIENTS WITH ANKLE OSTEOARTHRITIS

[1,2] Robin Queen, [1]Kristen Renner, [1]Shyam Ranganathan and [1]Divya Srinivasan

[1] Virginia Tech, Blacksburg, VA, USA

INTRODUCTION

Measures of physical performance are often used in orthopaedic patient populations and older adults to understand function and determine changes over time [1, 2]. Two measures of physical performance which are often used in the clinical and older adult settings are the timed up and go (TUG) and the sit to stand (STS) tests. These two measures have been used extensively to monitor both functional decline in adults as well recovery following surgical interventions. Gait mechanics have also been used to assess post-operative recovery and functional status in these same populations. Although measures of physical performance and gait mechanics are both important for understanding functional changes, the association between these two paradigms has not been assessed on orthopaedic patients.

In order to examine the association between gait mechanics and physical performance, this study examined an end-stage ankle osteoarthritis (A-OA) cohort. A-OA has been associated with limitations in gait mechanics and physical performance [3]. Therefore, the purpose of this study was to determine whether, and which, gait mechanics measures during self-selected speed level walking can predict physical performance on the TUG and STS tests in an A-OA cohort.

METHODS

A prospective cohort study was completed during which 112 end-stage A-OA patients (**Table 1**). A-OA Patients were included in this study if they had unilateral disease and were able to walk without the use of an assistive device. All patients provided informed written consent prior to participation in this study.

Each patient completed a standard gait assessment with a modified Helen-Hayes marker set using an 8 camera motion analysis system (120Hz) (Motion Analysis Corporation, Santa Rosa, CA) and 4 embedded force plates (1200Hz) (AMTI, Watertown, MA) [3]. Seven barefoot walking trials were collected at a self-selected walking speed. Visual 3D (C-Motion, Bethesda, MD) was used to calculate joint kinematics and kinetics. In addition to the gait assessment, each participant completed a 5 time STS test and a TUG [3].

STS and TUG scores were sorted, and patients in the bottom 25% and the top 25% were identified independently and their data were used for further analysis (**Table 1**). A total of 200 variables characterizing gait including averages, peaks, and stride-to-stride variability (SD) on the affected side, and asymmetry (ASYM) using the formula from Herzog et al [5], were computed:

1. Spatiotemporal characteristics (28 variables - means and variability);
2. Joint Kinetics (60 variables quantifying peak flexion (FLEX)/extension (EXT) as well as abduction (ABD)/ adduction (ADD) of hip, knee, and ankle moments and powers, SD of moment and power trajectories, and ASYM in peak FLEX/EXT and ABD/ADD moments and powers)
3. Stance phase joint kinematics (56 variables characterizing FLEX/EXT and ABD/ADD peaks, range of motion (ROM), SD of joint trajectories and ROM, ASYM across limbs in FLEX/EXT and ABD/ADD peaks and ROM, mean coordination and SD of hip-knee and knee-ankle joint couples quantified through vector coding in sagittal and frontal planes);
4. Swing phase joint angle kinematics (same 56 variables as stance phase)

Four different regression models were used to predict performance on the TUG from gait characteristics from each of the above categories. Due to the large number of potential predictor variables, regularized regression is required to avoid overfitting. Least Absolute Shrinkage and Selection Operator (LASSO) was used to fit logistic regression models

to the data. Five-fold cross-validation was used to ensure low out-of-sample prediction error. Since the high number of variables may result in instability of the results, an additional variable selection step was used by iterating the LASSO algorithm multiple times and selecting only those variables that were selected in more than 95% of the model iterations. The same approach was implemented to predict STS performance using the same four gait variable categories. All statistical analysis was completed using R (R Foundation for Statistical Computing, Vienna, Austria).

RESULTS AND DISCUSSION

The full Ankle-OA cohort of 112 participants was divided into the top and bottom 25% on the STS and the TUG test independently (**Table 1**).

Performance on both the TUG and STS tests could be predicted with 0% mis-classification error, meaning that a logistic regression LASSO model could correctly classify all 55 subjects into the lower or upper quartile. TUG was predicted best using the joint kinetics variables: 7 of the 60 variables input into the model achieved 100% classification accuracy (**Table 2**). Models using stance and swing kinematics performed poorly (i.e. less than 50% classification accuracy), and the best model using gait spatiotemporal characteristics achieved only 65% accuracy.

STS performance was predicted best by swing phase kinematics: 14 of the 56 variables input into the model achieved 100% classification accuracy (**Table 2**). STS was predicted poorly by the stance phase kinematics and gait spatiotemporal models (less than 50% accuracy) but 88% accuracy using 11 variables was achieved through the joint kinetics model.

These results indicate that variability in measures of physical performance were high in A-OA patients. The best 25% of these A-OA patients were able to achieve similar physical performance outcomes to age matched healthy control for both the TUG 5.6 ± 1.0s and the STS 9.9 ± 1.4s tests.

Table 2: LASSO model selected variables for 100% accuracy in physical performance prediction

TUG	Joint Kinetics	Sagittal Knee Extension Moment Sagittal Knee Flexion Moment Frontal Hip ADD Moment Frontal Hip ADD Power Sagittal Hip Moment SD Sagittal Ankle Power SD Sagittal Hip Power Asymmetry
STS	Swing phase kinematics model	Sagittal Knee Extension Sagittal Knee Flexion Sagittal Ankle ROM Sagittal Hip-Knee coordination Frontal Knee SD Frontal Hip SD Frontal Ankle SD Sagittal Knee SD Sagittal Ankle ROM SD Sagittal Knee-Ankle Coordination SD Sagittal Ankle dorsiflexion Asymmetry Sagittal Knee Extension Asymmetry Sagittal Hip Flexion Asymmetry Sagittal Hip ROM Asymmetry

CONCLUSIONS

While the STS and TUG are clinically accessible and reliable methods for physical performance testing, they do not provide mechanistic insights on the source of a patient's deficits. Our work demonstrates that STS and TUG are able to be predicted by different sets of biomechanical variables, which might serve as good targets for therapeutic intervention.

INTRODUCTION

Motor control of gait is thought to be governed by a reduced set of principal activation patterns (modules) [1]. Musculoskeletal modeling and simulation techniques are commonly used to characterize the underlying muscle activation patterns that control gait. Modular control of gait has been identified from electromyography (EMG) in young and older adults [1,2] and a combination of EMG and simulation-derived activation patterns in older adults [2,3]; yet, it remains unknown if activations derived from simulation alone would reduce to the same set of modules as those derived from EMG. Therefore, this study explored the modular control estimated from experimental and simulated muscle activation patterns in young and older adult gait.

METHODS

Ten young (23.9±2.8 years) and ten older (63.1±2.6 years) adults provided IRB-approved written informed consent prior to walking at a self-selected speed while 3D kinematic and kinetic data were collected. Surface EMG was collected from rectus femoris, vastus lateralis, vastus medialis, biceps femoris, medial hamstrings, lateral gastrocnemius, medial gastrocnemius, and soleus on the dominant leg. The EMG was demeaned, passed through a sixth order Butterworth bandpass filter (10-300 Hz), rectified, and then passed through a sixth order Butterworth low-pass filter (6 Hz).

Simulations of one gait cycle were generated for each subject in OpenSim 3.1 [4]. A generic model with 23 degrees-of-freedom and 92 musculotendon actuators [4] was scaled using a least squares approach to minimize the distance between the experimental and corresponding virtual model markers [5]. A least squares approach was used to determine the model's generalized coordinates that reproduced the experimental gait marker data [5]. A residual reduction algorithm slightly adjusted model mass properties and joint kinematics to achieve more dynamically consistent kinematics and kinetics [5]. Static optimization resolved the joint torques into individual muscle forces using an objective function that minimized the sum of the squared muscle activations [6]. The agreement between the normalized EMG and static optimization's simulated (SIM) activation patterns was quantified using RMS error. Each muscle's EMG was normalized by scaling the EMG pattern by the ratio of the muscle's peak SIM activation to the peak EMG activation in the trial [7,8]. A 40ms delay was applied to the EMG to account for electromechanical delay [9].

For each subject, separate non-negative matrix factorizations (NMF) [10] extracted modules from the original activation patterns (EMG_o; SIM_o). The number of modules required to produce adequately reconstructed activation patterns (EMG_r; SIM_r) was determined by the variability accounted for (VAF) by the modules. The VAF is calculated as, for example, $VAF=1-((SIM_o-SIM_r)^2/SIM_o^2)$. The NMF began by extracting one module. If VAF was greater than 0.9 for each muscle, additional modules were not needed to represent the data. Otherwise, the number of modules extracted by NMF was increased by one until VAF of all muscles was greater than 0.9 or until VAF was greater than 0.8 and adding another module did not increase the VAF of the muscle with the lowest VAF by more than 5% [11]. Each subject's principal patterns were normalized to the peak value. Muscle weights were normalized to the maximum weight of the muscle across all modules. Principal patterns and muscle weights were averaged within each age group for each activation source.

RESULTS AND DISCUSSION

All RMS errors between SIM_o and EMG_o were less than 0.31, with soleus having the largest errors in both age groups (Figure 1).

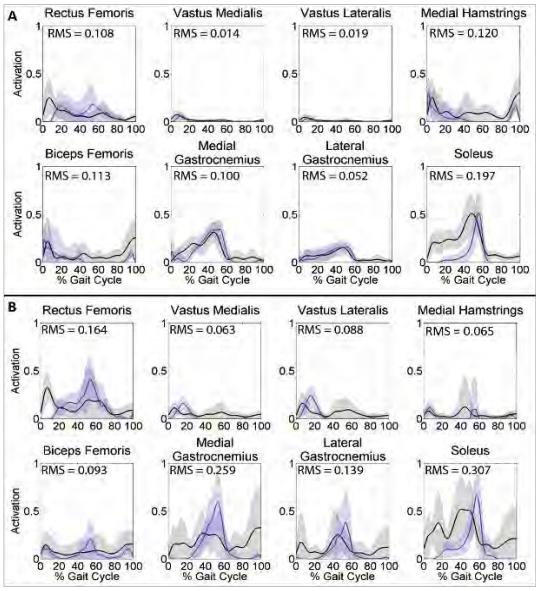

Figure 1: Average EMG_o (grey) and SIM_o (blue) activation patterns in A) young and B) older adults. Shaded areas represent ± one standard deviation.

The number of modules required to reconstruct the original activation patterns was greater with SIM_o (young: 6.8±1.2; older: 5.2±1.0) than EMG_o (young: 3.6±0.7; older: 3.6±0.8). Five young adults' SIM_o could not be reduced to a modular organization (8 modules required to represent the activation of 8 muscles). Therefore, young SIM modules could not be defined and compared to their EMG modules.

The principal patterns of older adult SIM Modules 1, 2, and 4 were qualitatively similar to their EMG modules (Figure 2A); however, no SIM module was similar to EMG Module 3. The muscles primarily associated with each module differed between SIM and EMG (Figure 2B). In contrast to EMG modules, hamstring activity governed SIM Module 1, vasti activity governed SIM Module 4, and separate modules were required to capture plantarflexor activity (gastrocnemius in SIM Module 2; soleus in SIM Module 3). The additional SIM module (5) was required to capture SIM rectus femoris activity.

CONCLUSIONS

Modules extracted from SIM_o differed from those extracted from EMG_o and previously derived modules [1–3], suggesting muscle activations estimated by static optimization, without any activation constraints [12], are not ideal for deriving the modular control of gait. The static optimization objective function was chosen because it is associated with minimizing energy expenditure [13]. However, the discrepancies between the EMG and SIM modules in both young and older adults suggests an optimization function that prioritizes minimizing energy expenditure may not fully capture the neuromuscular control of gait and an alternative objective function may be needed to estimate muscle function. Future work should determine if modules identified from muscle activations estimated by an alternate optimization method or objective function are more consistent with EMG modules.

AUDITORY AND VISUAL EXTERNAL CUES HAVE DIFFERENT EFFECTS ON SPATIAL BUT SIMILAR EFFECTS ON TEMPORAL GAIT VARIABILITY

INTRODUCTION

Sensorimotor synchronization deals with the coordination of a movement with an external rhythm. Specifically, external auditory or visual cues have been implemented in several populations: Stroke[1], Parkinson's Disease[2] and Aging[3]. Typically, the patient is instructed to synchronize their steps to an invariant stimulus that lack any temporal variability in their presentation. However, there is recent evidence indicating that such stimulus may not be optimal, as it does not incorporate the natural variability that is observed in the stride-to-stride fluctuations of the gait patterns of healthy adults[3]. Gait variability, the natural stride-to-stride fluctuations that are present in walking, is essential for adaptation and safe interaction with the ever-changing environment. Therefore, it has been recommended[3,4] to be incorporated in external cueing interventions. The selection of the type of cueing is also an important issue. In this study, we hypothesized that this selection should be based on our goal. We believe that if one would intend to alter stride length variability, spatial cueing should be provided (visual stimulus). Conversely, to manipulate stride time variability, temporal cueing (auditory stimulus) should be used. Therefore, we aimed to investigate the differences between a visual and an auditory stimulus on stride time and length variability. We also aimed to investigate the effect of incorporating the natural stride-to-stride fluctuations in the temporal structure of the stimulus used. We implemented a variable (pink-noise; a spectra/distribution that characterizes healthy natural gait[3]), a random (white-noise), an invariant, and a non-stimulus condition.

METHODS

Twenty subjects volunteered to participate in this study. The subjects were randomly assigned to an Auditory (AUD) or a Visual (VIS) group. Both groups started with a preferred walking speed familiarization trial. This was followed by four 10-min trials on an instrumented treadmill starting with a no external stimulus trial. From this trial, the preferred cadence was determined and embedded in the stimulus to be provided for the three stimulus conditions. The order of the three stimulus conditions was randomized: invariant (INV), variable (VAR) and random (RND). The VAR was generated using an approximation of a -10dB/decade filter with a weighted sum of first order filters; RND was generated using a normal distribution of random numbers. The subject's preferred cadence and standard deviation was incorporated in the stimulus. The INV stimulus was generated using each subjects' mean self-paced cadence and a standard deviation of zero. The auditory stimulus was provided through speakers as a single beat per step, and the visual stimulus was provided through the screen's projection of horizontal bars (GRAIL, Motek). For the latter, each subject's virtual footsteps were visible during the task on the screen. A high speed 8-camera Vicon system was used for spatiotemporal data calculations. Reflexive markers were placed on the heel, lateral malleolus and 2nd metatarsal. Means and SDs of stride time (ISIs) and stride length (ILIs) intervals were determined. The $\propto$-scaling of stride time ($\propto$-ISIs) and length ($\propto$-ILIs) time series was also calculated through Detrended Fluctuation Analysis (DFA)[5]. DFA estimates the autocorrelation behavior of the time series. An $\propto$ less than 0.5 indicates anti-persistence and greater than 0.5 indicates statistical persistence. To determine differences between groups and stimulus conditions a two-way ANOVA (group x conditions) was used. *Post hoc* analyses with Tukey's tests were used to highlight specific differences between conditions.

RESULTS AND DISCUSSION

A stimulus main effect was found for both ISIs (p<0.001) and ILIs (p<0.001). Further analysis revealed that the stimulus effect was present only for

the AUD group where INV was significantly lower compared to all the other conditions (p<0.05) (Table 1). A stimulus x group interaction was found for ∝-ILIs (p<0.001) but not for ∝-ISIs (p=0.887). A main effect was observed for stimulus both in ∝-ISIs and ∝-ILIs (p<0.01). Pairwise comparisons shown a significantly greater ∝-ISIs in non-stimulus compared to INV (p<0.001) and RND (p=0.010). Likewise, VAR showed greater ∝-ISIs compared to INV (p<0.001) and RND (p<0.001). For ∝-ILIs, significant differences were observed between non-stimulus compared to INV (p<0.001); and VAR compared to INV (p<0.001) and RND (p<0.001). A main effect of group was observed for ∝-ILIs (p=0.03). Further analysis revealed that the differences between groups were observed in INV (p<0.001) and RND (p<0.001) conditions, where ∝-ILIs was significantly smaller for VIS (Fig.1 and 2).

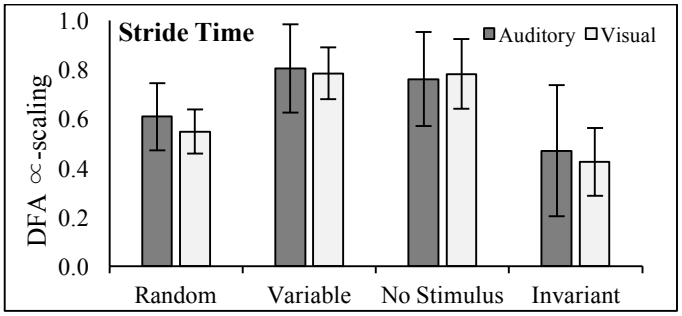

Figure 1. DFA ∝-scaling exponent of stride time (*ISIs*) for the all stimuli conditions for both auditory and visual groups.

The present study results showed that regardless of the type of stimulus provided (AUD or VIS), the variability of stride time and length was altered in a similar fashion. The structure of the RND and INV stimuli decreased the fractal scaling while VAR stimulus showed values similar to what was observed in the non-stimulus condition. A similar effect was previously observed with invariant cueing with both AUD and VIS cues [6]. We also found that the effect of the type of the stimulus on stride length variability was more evident when a VIS stimulus was provided, which partly corroborates our hypothesis that a VIS stimulus would affect the stride length more compared to an AUD stimulus. However, no differences between groups were observed in stride time variability. This finding can be partly explained by possibly the treadmill adding a temporal cueing effect. Therefore, the VIS group received both temporal and spatial cueing. Additionally, we also found that linear measures of ISIs and ILIs were altered in AUD group, particularly for INV condition.

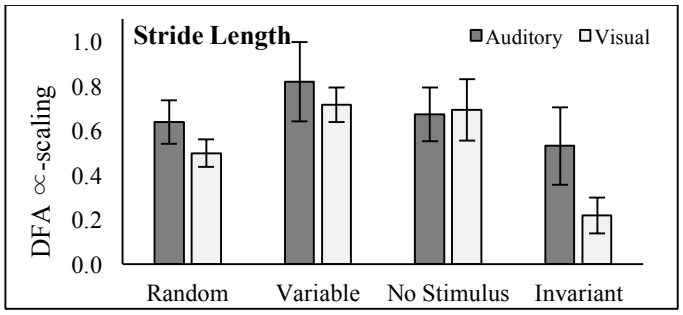

Figure 2. DFA ∝-scaling exponent of stride length (*ILIs*) for the all stimuli conditions for both auditory and visual groups.

CONCLUSIONS

This study shows that regardless of the stimulus (auditory or visual), the fractal scaling of stride time and length was decreased in the presence of a random or invariant stimulus, as compared to no stimulus. Interestingly, the modality of these stimuli affect the statistical persistence of spatial but not temporal gait variability. Conversely, the use of variable stimulus did not alter the variability of these spatiotemporal gait parameters. This further suggests that gait rehabilitation programs should incorporate this type of stimulus to achieve healthy values of gait variability.

REGULAR RUNNING IN MIDLIFE MAY BE PROTECTIVE OF PLANTARFLEXOR FUNCTION AFTER A PROLONGED WALK

INTRODUCTION

Aging is associated with declines in mobility and alterations in gait [1,2]. Muscle function and control may be a contributing factor to these mobility changes as midlife adults are shown to have altered muscle activation and co-activation patterns compared to young adults [2,3]. Greater muscle activation and co-activation may increase the economic cost of walking for midlife adults [2] and may also increase contact forces within the joint [4] increasing the risks for fatigue related falls and musculoskeletal injury.

There remains a need for a better understanding of factors influencing muscle activation with aging to develop targeted interventions for mobility. There is evidence to suggest that highly active midlife adults may be protected against both increases in cost of walking [5] and slowing gait speeds [6], as well as against knee extensor muscle fatigue from extended bouts of walking [7]. These findings may be explained by a mitigating effect of physical activity on altered muscle activation, but this has not been examined. Comparing midlife adults' muscle activation across physical activity level and in response to a bout of exercise may yield insight into how highly active midlife adults maintain the gait speed, cost of walking, and possibly gait mechanics of young adults.

Therefore, the aim of this study was to quantify the differences in muscle activity at the beginning and end of a prolonged treadmill walk in healthy young (Y), highly active midlife (RUN), and sedentary midlife (SED) females. It is hypothesized that sedentary midlife females will have longest duration of activation and greatest peak activation of the knee extensor and plantarflexors, and these differences will be larger following the prolonged walk.

METHODS

Twenty-eight female participants: 10Y (Age: 27.0 ± 3.5yrs; BMI: 23.19 ± 2.1kg/m^2; Speed: 1.41 ± 0.15m/s); 10 RUN who ran ≥15mi/wk (Age: 60.5 ± 3.9yrs; BMI: 21.2 ± 2.2kg/m^2; Speed:1.43 ± 0.12m/s;); and 8 SED exercising ≤ 2 times/wk (Age: 61.8 ± 1.4yrs; BMI: 23.9 ± 1.7kg/m^2; Speed: 1.34 ±0.10m/s); participated in this study. All participants completed an IRB approved informed consent prior to completing any study procedures.

Participants completed a 30 minute treadmill walk (30MTW) with intermittent "challenge" periods to simulate a bout of daily activity [8]. Electromyography (EMG) was collected during the 2nd and 30th minute of. Electrodes (Trigno, Delsys, Inc., Natick MA) were placed over 8 lower extremity muscles: vastus lateralis (VL), vastus medialis (VM), rectus femoris (RF), biceps femoris (BF), semitendinosus (ST), lateral gastrocnemius (LG), medial gastrocnemius (MG), and Tibialis Anterior (TA). EMG were bandpass filtered at 20-500Hz, full-wave rectified and then lowpass filtered at 20Hz to produce a linear envelope. Linear envelopes for each muscle were expressed as a percentage of the average stance phase signal for 10 consecutive strides from the 2nd minute of the 30MTW.

Peak, and duration of activation were calculated for each muscle from minutes 2 and 30 of the 30MTW. EMG time on/off for each muscle was determined by using a threshold set at 2 standard deviations from baseline. Duration was then calculated as the total time above this threshold throughout stance. A 2x3 (time*group) repeated measures ANOVA was used for each muscle to compare EMG peak, time of peak, and duration of activation between the three groups at the beginning and end of the 30MTW.

RESULTS AND DISCUSSION

Duration of activation in the knee extensors and flexors were not significantly different between groups across time. Peak activation of VM (Table 1) decreased significantly in SED ($p=0.041$) during early stance and in RUN during midstance ($p=0.033$). No differences were found between SED and RUN in VM peak activation throughout stance indicating that these changes are likely due to age rather than activity level.

Peak activation of the MG during late stance and LG in early stance decreased across time in all groups, with no difference between groups. In both early and midstance a group by time interaction was found for the MG ($p=0.034$ and $p=0.029$ respectively). Post-hoc testing showed no difference in peak activation of the MG between groups at the beginning of the walk, however, at the end, RUN had an increased peak activation while SED and Y decreased or had no significant change in the peak activation. These results suggest that regular running in midlife may protect women against the commonly observed distal to proximal shift in joint power during walking, thereby potentially limiting both slowing gait speed and increasing cost of walking.

The difference in response to the 30MTW for Y and SED as compared to RUN may be related to the onset of muscle fatigue at the end of the 30MTW. In a prior analysis of these participant groups we found both the Y and SED groups experienced knee extensor fatigue (defined as a decline in power) following the walk, while RUN did not [7] suggesting regular running in midlife adults may mitigate muscle fatigue in response to the 30MTW. While changes in plantarflexor power were not quantified in this prior study, a similar decrease in MG activation has been reported in a study [9] examining the gait and muscle activity of young adults following a unilateral plantarflexor fatigue protocol.

CONCLUSIONS

Peak activation in VM decreased throughout the walk in both early and midstance in midlife women regardless of activity level when compared to young women suggesting that this is an effect of aging rather than disuse. Peak activation of MG and LG show differences throughout stance for RUN when compared to both young and sedentary midlife women. This suggests that regular running in midlife may be protective against changes in plantarflexor function following a prolonged moderate intensity walk and should be explored more in future studies.

LOWER LIMB JOINT ANGLE VARIANCE AS A FUNCTION OF OBSTACLE HEIGHT DURING OBSTACLE CROSSING

INTRODUCTION

Tripping is a main contributor to falls and fall related injuries. To ensure crossing an obstacle without tripping, one has to elevate the foot higher than the upper edge of the object. Typically, the trail foot (the foot that crosses second) contacts visible stationary obstacles more frequently than the lead foot (the foot that crosses first) [1].

The variability of foot clearance has been commonly used to quantify the risk of tripping during obstacle crossing [2]. During swing phase, lower limb segments from stance foot to swing toe form an open kinematic chain with multiple joint angles that influence the configuration of the swing foot. Foot variability clearly arises from the variability in joint angles. Although mean foot clearance and joint angles during obstacle crossing have been studied extensively, it is essential to study joint angle variances to understand toe height variability.

The purpose of this study is to (a) quantify the lead and trail toe height variability when crossing obstacles of different heights, and (b) investigate the source of the toe height variability by examining the lower limb joint angle variance.

METHODS

Ten young adults (age: 23.8±3.4 years, 3 females) walked along a 15 m walkway and stepped over an obstacle. Four obstacle heights were examined: unobstructed (no obstacle), 3, 10, and 26 cm. 10 trials of each condition were performed in block randomized order. Kinematic data were collected using the Qualysis Track Manager at 100 Hz.

Measures were calculated at the frame where tripping was most likely to occur: when the lead toe and the trail toe were above the obstacle, and at minimum toe clearance for unobstructed trials for both limbs.

We computed the across-trial standard deviation of the toe height (henceforth toe variability), the variances of lower-limb joint angles (sagittal hip, knee, and ankle of stance and swing limb), and the total joint angle variance as the sum of all six joint angle variances (henceforth total joint variance). Two-way mixed model ANOVA was conducted with *obstacle height* (unobstructed, 3, 10, 26 cm) and *limb* (lead, trail) as fixed factors. Tukey post hoc pairwise comparisons were conducted.

RESULTS AND DISCUSSION

Six of the 10 subjects contacted the obstacle one time (contact rate 2%; all with the 26 cm; five with the trail toe). Since contacting the obstacle modified gait in subsequent trials [3], data from the 26 cm condition was excluded from statistical analyses.

There was a significant interaction (*obstacle height by limb)* observed for toe variability ($F_{2,57}$=3.27; p=0.04; Fig. 1). Post hoc comparisons revealed that toe variability was not different for the lead and trail limbs for unobstructed and the 3 cm obstacle trials, but it was 72% higher for the trail limb for the 10 cm obstacle. Toe variability was 273% higher for 3 cm obstacle versus unobstructed ($p<0.01$). It was 80% higher for the 10 cm obstacle than the 3 cm obstacle, but only for the trail limb ($p<0.01$).

A significant interaction *(obstacle height by limb*) was observed for total joint variance ($F_{2,57}$=4.82; p=0.01; Fig. 2). Post hoc comparisons revealed that total joint variance with the trail crossing was 98% higher than the value of lead crossing for the 10 cm obstacle ($p<0.01$), whereas no difference for lead and trail crossing was observed for the unobstructed and 3 cm obstacle conditions. Total joint variance for trail

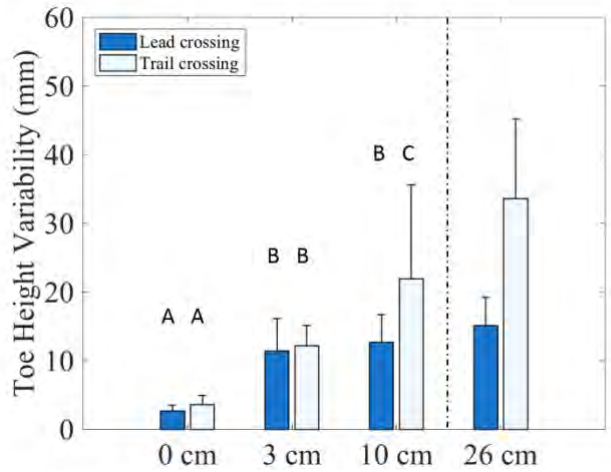

Figure 1: Effect of obstacle condition and limb for toe variability. 26 cm shown but not included in statistical analysis due to obstacle contacts. Letters A, B, C distinguish significantly different conditions.

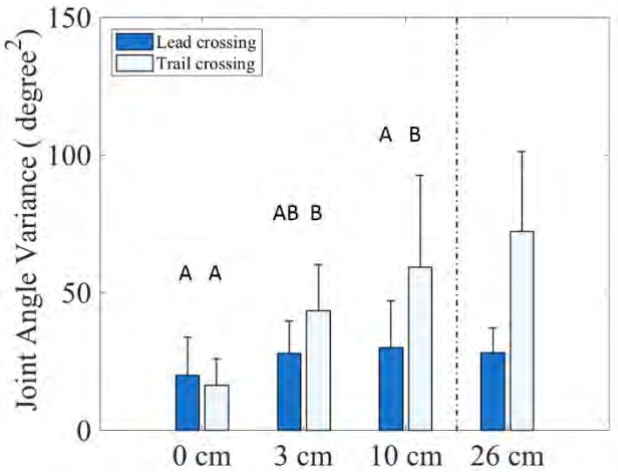

Figure 2: Effect of obstacle condition and limb for total joint angle variance.

crossing increased 164% for the 3 cm obstacle ($p<0.01$) and 259% for the 10 cm obstacle ($p<0.001$) compared with unobstructed walking; no significant obstacle effect was observed for lead crossing.

Overall, similar patterns were observed in toe variability and total joint variance (Fig. 1,2) as a function of obstacle height and limb: higher toe variability generally corresponded to higher total joint variance, consistent with the idea that total joint variance prescribes toe variability. There is an important exception – while toe variability and joint variance for the trail limb increased as a function of obstacle height, only toe variability increased for the lead limb. Future research should determine if the joint angles covary in a task-specific manner to control the variability in the toe height.

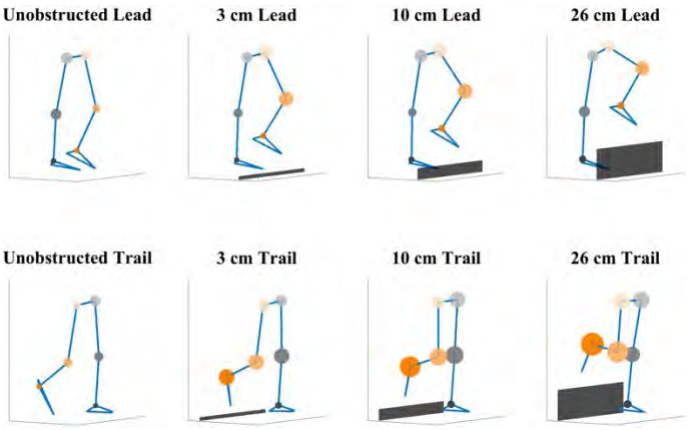

Figure 3: Individual joint angle variance marked on illustrative lower limb stick figures as circles. The area of circle reflects the amount of variance. Black rectangles are the obstacles.

We examined variances in each joint angle to locate the source of the toe variability. Qualitatively, variances in joint angles tended to be larger (quantified as larger circles on each joint, Fig. 3) during the trail crossing than lead crossing, and this pattern became more apparent for larger obstacles. The contribution from the stance limb joint angles to the toe variability is substantial. Although most research on obstacle crossing focus on the swing limb, stance limb behavior cannot be ignored.

CONCLUSIONS

Larger toe variability and total joint variance for the trail limb, especially for taller obstacles, is consistent with observations of greater failures with the trail foot [1]. Furthermore, the joint angle variances are distributed over the joints of both the swing and stance limb, indicating that the contribution of the stance limb to obstacle contacts must be considered. This suggests existence of compensatory covariance in the lower limb joint angles to control toe height. Further investigation into coordination between the individual joints of both limbs is necessary.

ESTIMATING GAIT EVENTS AND LOCOMOTION STATE WITH A BETA-PROCESS AUTO REGRESSIVE HIDDEN MARKOV MODEL

[1,2] Seth R. Donahue, [1,2] Li Jin, [1,2]Michael E. Hahn

[1] Bowerman Sports Science Clinic, [2] Neuromechanics laboratory, University of Oregon, Eugene, OR, USA
email: sethd@uoregon.edu, web: https://bssc.uoregon.edu/

INTRODUCTION

Identification of gait phase is important for many applications including control of active lower limb prostheses. One challenge for adaptive prostheses is accurate prediction of initial contact, toe off with minimal sensors and low sampling frequency. Previous work has used acceleration-based thresholds to identify initial contact and toe off [1]. These algorithms lack adaptability to different locomotion states and speeds. The beta-process auto-regressive hidden Markov model (BP-AR-HMM) has been shown to accurately identify different human movement patterns from motion capture data at low sampling frequency (10 Hz) [2]. Unlike other classification algorithms the BP-AR-HMM provides a statistical model for classification. The purpose of this exploratory data analysis is to determine the feasibility of the BP-AR-HMM to identify and estimate gait events and locomotion states from a single simulated accelerometer sampling at low frequency during two different gait transitions.

METHODS

Ten able-bodied subjects participated in the study (51 ± 6.0 years, 173 ± 11.4 cm, 70 ± 15.0 kg) (5 male, 5 female). Ground reaction force (GRF) and marker trajectory data were collected at 1200 Hz and 120 Hz, respectively. Subjects were asked to perform two different transitions: walk to run (WRT) and run to walk (RWT) transition on a force-instrumented treadmill (Bertec, Inc., Columbus, OH). The WRT protocol began with walking at 1.8 m s^{-1} for 30 seconds, then the treadmill was constantly accelerated at 0.1 m s^{-2} to 2.4 m s^{-1}. Subjects were asked to transition to running gait whenever they felt ready during the acceleration stage. After transitioning to a running gait, they ran at 2.4 m s^{-1} for another 30 seconds. The RWT protocol was the inverse of the RWT, starting at 2.4 m s^{-1} for 30 seconds, then the treadmill was constantly decelerated at -0.1 m s^{-2} to 1.8 m s^{-1}.

The GRF data were filtered with a low pass fourth order Butterworth filter (50 Hz cut off frequency). Ground contact state was determined when the vertical GRF values were above a threshold of 50 N. Motion trajectory data from a single marker on the dorsum of the left foot were extracted from a larger data set [3]. Three-dimensional (3D) acceleration values were calculated by taking the second derivative of the raw marker position data. The GRF and acceleration data were then down-sampled to 20 Hz. The algorithm was tested on a set of 17 trials. One trial was removed from the data set because the GRF data were incomplete for the present analysis

The BP-AR-HMM is composed of three major parts (2). The beta process determines the number of states available for each time series, based upon a Bernoulli probabilistic model. Vector autoregression implies acceleration throughout the gait cycle at any given time is a function of the previous acceleration values and random variation. The use of auto-regression also allows for features to be shared across different time series via the beta process. The hidden Markov model assumes a set of distributions and transitions between them follow a Markov process. The assumption of the Markov process is the probability of state change from i to j has a set probability π_{ij}, which does not depend on prior state. The algorithm also contains a parameter to limit state transitions at each time step. This parameter helps to ensure the estimated states are biomechanically relevant. The BP-AR-HMM algorithm used a data driven model to estimate and share states across each time-series.

The temporal differences between the change in the estimated state and the measured initial contact (IC) and toe off (TO) of the left foot were calculated. Duration of a state was calculated from the first

instance of desired state to the first instance of a different state. The duration of the state indicating stance phase was calculated to estimate whether the current gait was walking or running. With an effective sampling frequency of 20 Hz, the difference between two time steps corresponds to 50 msec. All analyses were performed post hoc.

RESULTS AND DISCUSSION

Example accelerations, foot contacts and estimated states are shown for a RWT and WRT condition in Figure 1. At Point 1 is the estimated event where swing phase terminates, and stance phase begins. State A occurs every gait cycle and is used as an estimator of stance phase. Transition out of State A is the time point used to determine the time until TO. Point 2 is indicative of the estimated termination of stance phase. State B occurs every gait cycle, indicating swing phase. The first point after State B is used to determine the time until IC.

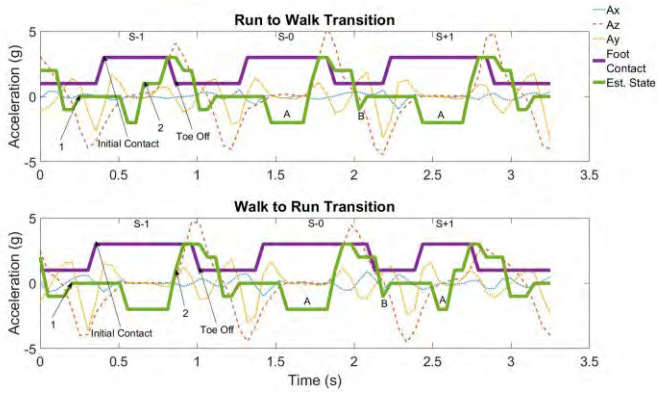

Figure 1: Accelerations, foot contacts and estimated states for RWT (top panel) and WRT (bottom panel) are shown for a single exemplar subject.

Figure 2 shows the natural transition points between walking and running locomotion states. Transition steps were verified by ground reaction force waveforms. The shaded area indicates foot ground contacts classified as running. The contacts in the unshaded area are classified as walking contacts.

Initial analysis indicates initial contact and toe off can be estimated for both the WRT and RWT from a single source of acceleration on the dorsum of the foot sampled at 20 Hz. Previous work has estimated that approximately 40 ms are required to adjust the prosthesis state [1]. The duration of state A, representing foot contact provides a basis to estimate the locomotion state of the subject as seen in Figure 2.

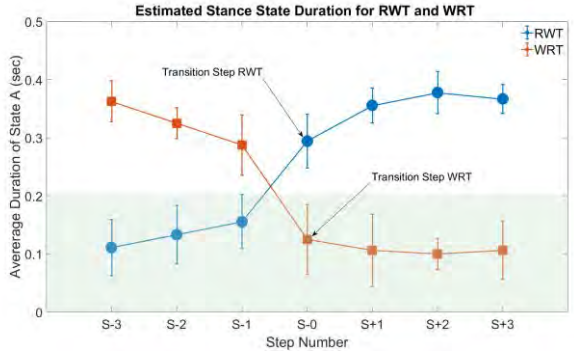

Figure 2: Average contact duration for WRT and RWT conditions. S-1 is the last step before the transition and S-0 is the actual transition step.

Table 1: Average time (sec) of estimated state change prior to actual gait event; mean (SD). The average duration of the states that approximate mid stance and mid swing are also shown; mean (SD).

	Initial Contact	Toe off	State A Duration	State B Duration
Walk	0.156 (0.037)	0.147 (0.068)	0.359 (0.048)	0.102 (0.036)
Run	0.180 (0.031)	0.126 (0.028)	0.103 (0.055)	0.081 (0.031)

CONCLUSIONS

The BP-AR-HMM provides a suitable basis for estimating initial contact, toe off, and locomotion state. Future directions of this work will include comparison of these results to over-ground transitions with self-selected accelerations, and a larger range of speeds. The final application of this work will be for use in a microcontroller of a lower limb prosthesis.

A Novel Approach for Evaluating Compensatory Gait Strategies Using Mechanical Energetics

Anahid Ebrahimi, Jill S. Higginson, and Steven J. Stanhope

University of Delaware, Newark, DE, USA
E-mail: anahide@udel.edu

INTRODUCTION

Mechanical work is done about joints of the lower limb to move the body, subsequently changing the body's energy state. In gait, the limbs do mechanical work to rotate the center of mass (COM) upwards then downwards in a semicircular arc, theoretically following pendular mechanics [1]. Consequently, this leads to changes in gravitational potential energy and kinetic energy of the body.

With a joint impairment, mechanical work is redistributed among the limb yielding a compensatory gait strategy [2]. This is especially true for individuals with ankle impairment due to the key role of the ankle musculature in gait [3]. However, characterizing a compensatory strategy as "good" is complicated by the operational definition of the term.

Assessing if a strategy's energetics (work and energy) differ from the theorized pendular mechanics of gait in single support phase can help us to understand how and why certain gait strategies are used when there is an impairment. To explore compensatory gait strategies, we compared the mechanical energetics of healthy individuals walking with an artificially impaired ankle joint unilaterally and bilaterally to their typical gait (in shoes).

METHODS

Motion and force data were collected on 17 healthy subjects (8M/9F, 1.7 ± 0.2 m, 75.7 ± 15.1 kg) walking at 0.8 statures/s (1.4 ± 0.1 m/s) with shoes only, and with a custom ankle-foot orthotic on one limb (RiAFO) and on both limbs (BiAFO) which partially restricted ankle motion in dorsiflexion and plantar flexion. The summed net work and rate of change in energy for all segments of the body were integrated over two halves of single support: "single support rise" from left toe off to right midstance, and "single support fall" from right midstance to left heel strike. Average net work and change in gravitational potential energy, translational kinetic energy, and rotational kinetic energy of the whole body (W_{wb}, ΔGPE_{wb}, ΔTKE_{wb}, and ΔRKE_{wb}) are presented in bar charts with standard deviation bars.

Considering that the magnitude of energetics metrics would differ across conditions, relative metrics were calculated. Work or energy forms were calculated as a percentage of the largest energetics metric (see Fig. 1 for example). Statistical differences between conditions were assessed using one-way repeated measures ANOVA with Bonferroni corrections ($p < 0.05$). A † and ‡ denote a significant difference between Shoes and RiAFO conditions, respectively ($p < 0.05$).

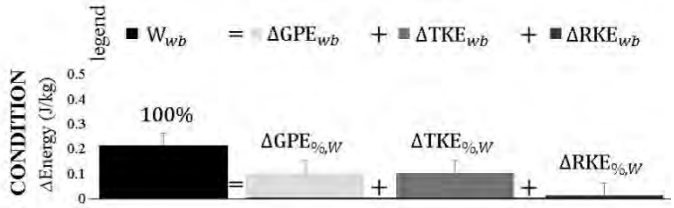

Fig 1. Example bar chart of energetics data. Note percentage values above bars are relative to the largest energetics metric (in this case W_{wb}).

RESULTS AND DISCUSSION

Subjects walked at the same scaled speed and did not significantly change their step lengths ($p = 0.065$) across conditions. The AFO successfully reduced the ankle work by an average 37-40% in the AFO conditions compared to shod walking.

In single support rise, ΔGPE_{wb} was the largest energy form. Individuals walking in the BiAFO condition had a significantly larger $W_{\%,\Delta GPE}$ (86%) compared to the Shoes condition (75%). In a conserved inverted pendulum, the $\Delta TKE_{\%,\Delta GPE}$ would be 100% such that translational kinetic energy and potential energy were equal in magnitude and opposite in sign. However, Fig. 2 shows 25% of the negative ΔTKE_{wb} was transferred to positive ΔGPE_{wb} to raise the COM in the Shoes condition, but only 14% transferred in the BiAFO condition.

Therefore, the BiAFO condition used less pendular mechanics (as evidenced by a smaller $\Delta TKE_{\%,\Delta GPE}$) to raise the COM compared to the Shoes condition.

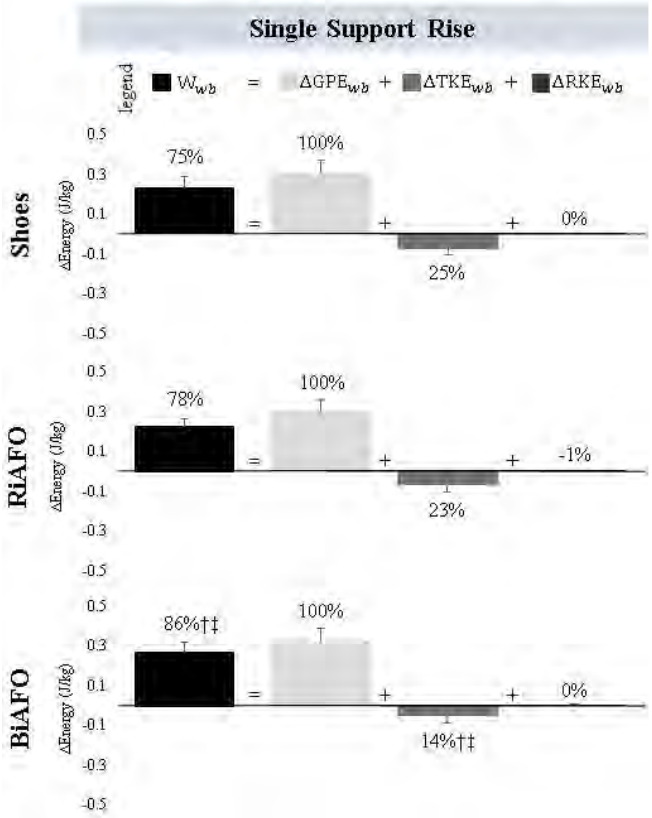

Fig 2. During single support rise, percentages are relative to ΔGPE_{wb}. The BiAFO condition results in significantly less $\Delta TKE_{\%,\Delta GPE}$ compared to Shoes.

In single support fall, W_{wb} was the largest metric. Individuals walking in the RiAFO condition had a significantly smaller $\Delta GPE_{\%,W}$ (-83%) compared to the Shoes condition (-87%). Interestingly, there is no evidence of pendular mechanics during this interval since ΔTKE_{wb} is not net positive. Thus, Fig. 3 shows that nearly all of the net work went into the form of negative ΔGPE_{wb} in all three conditions. While the body is doing a majority of net negative work to control the "fall" of the COM in all three conditions, the RiAFO condition led to altered energetic patterns (as evidenced by a smaller $\Delta GPE_{\%,W}$) to lower the COM compared to the Shoes condition. These results may support the necessity for lower limb prosthetic device design to provide control during this interval to reduce the risk of falls in individuals with amputations.

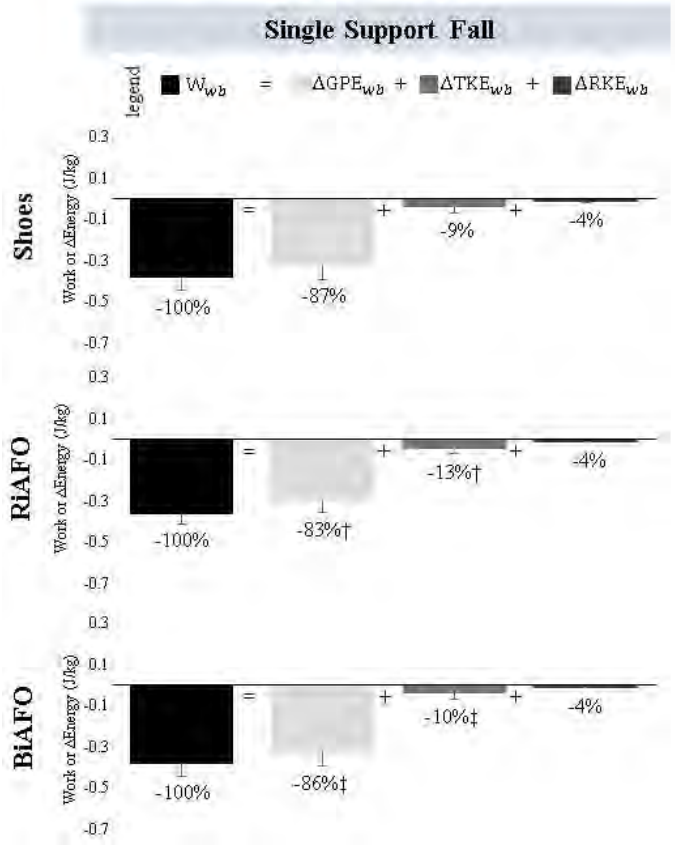

Fig 3. During single support fall, percentages are relative to W_{wb}. The RiAFO condition results in significantly less $\Delta GPE_{\%,W}$ compared to Shoes.

CONCLUSIONS

Individuals compensated with ankle impairment by walking with a similar stride length, yet evaluating the energetics revealed walking with an impairment required more work (as in the BiAFO condition in single support rise) and resulted in altered energy forms (as in the RiAFO condition in single support fall) compared to without impairment. Also, this analysis demonstrated that the limbs do not act like a conserved inverted pendulum, but rather do work to assist the rise and control the fall of the COM.

INTRODUCTION

Staircases are frequently associated with falls, over a million people were treated after falling on stairs in American emergency departments annually [1]. Injuries for the older individuals are more severe and require more hospitalisation [1]. In the UK, approximately ten fatalities per week are result from stair falls [2]. Treatment is costly for health care providers such as the National Health Service (NHS).

Inconsistent staircase dimensions are very common and are frequently associated with serious falls [3, 4]. Inconsistencies in rise result in an increased risk of tripping during stair ascent, where individuals are more likely to catch their toe. During stair descent variations in going (horizontal distance between the step edge and the next step) result in errors in stepping-length or over-stepping, which increases the potential for a slip to occur [4]. It is likely that inconsistencies in going also influence safety during ascent, and inconsistencies in rise also affect safety in descent. However, little is known about these and how they could affect fall risk [4].

The aim of this study, therefore is to investigate the influence of a small 1 cm change in going during ascent and 1 cm change in rise during descent on stepping parameters and risk factors for younger and older adults negotiating stairs. The local university's and NHS Ethics Committee approved this study (IRAS project ID: 216671).

METHODS

Twenty-six younger adults (YA; 24.4±3.4 yrs, 1.74±0.08 m, 71.4±11.0 kg, including of British, European and Asian origin, 15 male, 11 female) and thirty-three older adults (OA; 70.7±4.2 yrs, 1.68±0.08 m, 67.9±14.1 kg, of White British origin, 10 male, 23 female) negotiated a custom-built staircase set to three different dimensions: CONSISTENT, inconsistent GOING and inconsistent RISE. 1) The CONSISTENT staircase had uniform dimensions, where all steps had a 20 cm riser height and a 25 cm going length. 2) For the inconsistent GOING condition, Step3 was moved 1 cm inward, lengthening Step2 and shortening Step3 (Figure 1A). 3) For the inconsistent RISE condition, Step3 was raised 1 cm decreasing the riser height of Step4 and increasing the riser height of Step3 (Figure 1B). Participants were asked to leave the room and were not aware how the staircase had changed. GOING and RISE conditions were randomised.

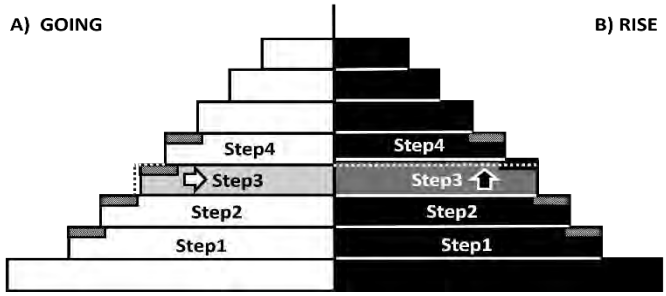

Figure 1: A) Ascent: GOING, Step3 moved 1 cm inward compared to CONSISTENT condition (dotted grey step edge. B) Descent: RISE, Step3 raised 1 cm compared to CONSISTENT condition (dotted white line).

Full-body 3D kinematics and kinetics were recorded (26 camera system: Vicon & 4 force plates: Kistler). Five CONSISTENT trials were averaged and only the first GOING trial during ascent and RISE trial during descent were used for analysis. Only leading limb foot clearances (Foot Clearance) and percentage of foot contact length (Foot Contact) were compared by mixed-methods ANOVAs. Alpha level, $P<0.05$.

RESULTS

There were no significant differences in Foot Clearances between the CONSISTENT and either RISE or GOING trials.

During stair ascent, there was a significant interaction effect between age group and stair configuration on Foot Contact on Step2 ($p = 0.004$), Step3 ($p = 0.013$) and Step4 ($p = 0.010$). YA increased their percentage of foot contact on Step2 in GOING whereas OA did not make this adjustment (Figure 2A). The OA however had a slight decreased Foot Contact on Step3 and the YA a slight increased Foot Contact (Figure 2B). Both groups had increased Foot Contact on Step4, YA more so than the OA (Figure 2C).

During stair descent, there were main effects of staircase configuration on Foot Contact (no age*step interactions). Main effects were recorded between CONSISTENT and inconsistent RISE conditions where both groups had less Foot Contact on Step3 and increased Foot Contact on Step2 ($p = 0.005$ & $p < 0.001$, respectively) (Figure 2D-E).

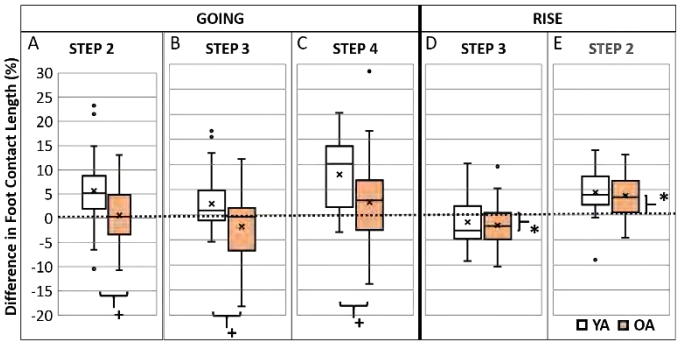

Figure 2: Difference in Foot Contact Length (%) during ascent GOING (A-C) and descent RISE (D-E) compared to CONSISTENT condition for YA (white box) and OA (shaded orange box). Dotted line = 0 % change, X = mean, middle line = median, * = condition effect; $p < 0.05$, $^{+}$ = age by condition effect; $p < 0.05$.

DISCUSSION

In stair ascent YA appear to make use of the longer going of Step2 by placing more of their foot on to the step, which carries forwards to a Foot Contact similar to CONSISTENT on Step3 (shorter going). However, OA did not make adjustments to increase Foot Contact on the longer Step2, nor appear to change their stepping pattern over the inconsistent step. Thus, they had a reduced Foot Contact and have an increased risk of slipping off the shorter Step3. On Step4 both groups had a positive increase in Foot Contact, potentially reducing their risk of slipping, but this could be too late. The interaction effect may be caused by the previously more forward position for the YA compared to the older adults. At this stage, the mechanism behind the YA adjustment on Step2 is unknown.

During stair descent, there were no apparent differences prior to the inconsistent step. Both groups had a reduced Foot Contact on the inconsistent Step3; creating a larger over-step. This in itself is associated with a higher fall risk [4]. Older individuals with larger variability in their stepping behaviour could be at greater risk from a fall.

Analysis of visual behaviour, full body kinetics and kinematics of both groups will help determine the mechanisms behind the changes to Foot Contact and the extent that a person's safety is compromised. The initial results presented could influence staircase regulations on tolerances, it could also justify the need to remodel existing staircases or develop visual cues that make inconsistencies more identifiable.

CONCLUSIONS

Inconsistencies in rise dimensions could increase the risk of over-stepping and slipping off the inconsistent step in descent, in a similar way to over-stepping onto a step with a shorter going dimension. In ascent, the OA did not adjust their stepping pattern to the inconsistent staircase which could increase the risk of slipping off the shorter step. This could be particularly dangerous for older adults' safety.

A FULL-STATE CONTROLLER FOR THE SIMPLE INVERTED PENDULUM BIPED DERIVED FROM HUMAN PERTURBATION EXPERIMENTS

Varun Joshi and Manoj Srinivasan
The Ohio State University, Columbus, OH, USA
email: joshi.142@osu.edu

INTRODUCTION

Humans walk stably by using neural feedback control and perhaps some feedforward control. Characterizing the feedback controller might inform our understanding of falls and movement disorders, and inform the design of prosthesis and exoskeleton controllers. Here, we seek to characterize how humans balance themselves when subject to perturbations. We describe how human-subject response to Anterior-Posterior (AP) and Medio-lateral (ML) pulls applied at the hip [1] may be used to derive a full-state controller for a simple model of bipedal walking. We evaluate the feedback controller's perturbation rejection ability by determining the basin of attraction for this controller (set of perturbations that do not result in a fall). We also analyze the robustness of the feedback controller to noise in the control gains and biped body parameters.

METHODS

Subjects walked on a treadmill at constant speed for 10 bouts of 4 mins each. During each walking bout, the subjects were perturbed randomly, either in the AP direction (9 subjects, only backward pulls) or in the ML direction (7 subjects, randomly selected leftward or rightward pulls).

We collected kinematic data from 13 markers placed on the subject - 5 around the hip, 4 on each foot using 8 motion capture cameras (Vicon T20, 100 Hz). Subjects were manually pulled by the experimenters via cables tied at the hip. Forces from these cables were recorded using a load cell in series with them (Phidgets S-type 100Kg, 1000 Hz). A loose harness connected to the ceiling was provided for safety. Subjects wore blinders to block peripheral vision and headphones to muffle noise so that visual and audio cues could not be used to anticipate the onset of a perturbation. 20% of all perturbations were randomly assigned to be "fake" perturbations where the experimenter went through the action of pulling on the cable but the perturbing force was very small. These fake perturbations were used to prevent proprioceptive cues from being used to detect oncoming perturbations.

To determine the controller, we first calculate a linear equation that relates mid-stance state deviations of the human to the subsequent foot-placement deviation as outlined by Wang and Srinivasan [2]. Next we determine the Poincare map that relates mid-stance states for the human from one-step to the next:

$$\Delta\begin{bmatrix} X_{\text{torso}}(n+1) \\ \dot{X}_{\text{torso}}(n+1) \\ \dot{Y}_{\text{torso}}\ (n+1) \end{bmatrix} = J_1.\Delta\begin{bmatrix} X_{\text{torso}}(n) \\ \dot{X}_{\text{torso}}(n) \\ \dot{Y}_{\text{torso}}(n) \end{bmatrix}$$

For the simple inverted pendulum model shown in Fig. 1, we can write an equation relating the n+1th mid-stance states for the biped as a function of the mid-stance states during the nth step and the control actions during the nth step:

$$\Delta\begin{bmatrix} X_{\text{torso}}(n+1) \\ \dot{X}_{\text{torso}}(n+1) \\ \dot{Y}_{\text{torso}}\ (n+1) \end{bmatrix} = J_2.\Delta\begin{bmatrix} X_{\text{torso}}(n) \\ \dot{X}_{\text{torso}}(n) \\ \dot{Y}_{\text{torso}}(n) \end{bmatrix} + J_3.\Delta\begin{bmatrix} x_{\text{foot}}(\text{n}) \\ y_{\text{foot}}(\text{n}) \\ I_{\text{pushoff}}(\text{n}) \end{bmatrix}$$

If we select a biped controller of the form:

$$\Delta\begin{bmatrix} x_{\text{foot}}(\text{n}) \\ y_{\text{foot}}(\text{n}) \\ I_{\text{pushoff}}(\text{n}) \end{bmatrix} = J_4.\Delta\begin{bmatrix} X_{\text{torso}}(n) \\ \dot{X}_{\text{torso}}(n) \\ \dot{Y}_{\text{torso}}(n) \end{bmatrix}$$

Combining these equations, we get the following equation:

$$\Delta\begin{bmatrix} X_{\text{torso}}(n+1) \\ \dot{X}_{\text{torso}}(n+1) \\ \dot{Y}_{\text{torso}}\ (n+1) \end{bmatrix} = (J_2 + J_3.J_4).\Delta\begin{bmatrix} X_{\text{torso}}(n) \\ \dot{X}_{\text{torso}}(n) \\ \dot{Y}_{\text{torso}}(n) \end{bmatrix}$$

We solve for the value of J_4 that minimizes

$$J_1 - J_2 - J_3J_4$$

Since we already know the foot-placement gains from human data, the minimization only solves for the 3 impulse gains within J_4.

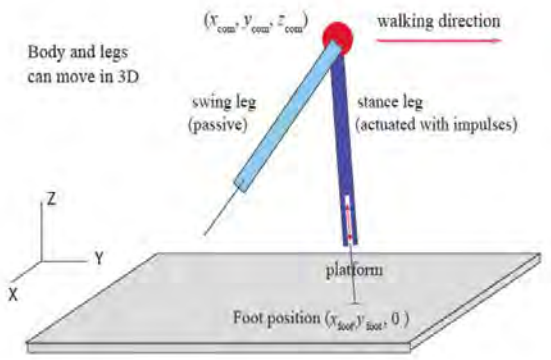

Figure 1: The inverted pendulum biped model

Once the gains are calculated, we simulated the biped for 20 steps with varying initial perturbations to determine the basin of attraction. Similarly, we simulated the biped with fixed initial perturbation and varying parameter noise to determine the parameter sensitivity of this controller.

RESULTS AND DISCUSSION

The feedback controller gains were determined to be as follows in non-dimensional terms:

$$J_4 = \begin{bmatrix} 1.85 & 1.99 & 0.22 \\ -0.49 & -1.65 & 0.85 \\ -0.18 & -0.69 & -0.52 \end{bmatrix}$$

This controller was found to be robust to changes in the gains and parameters, at least 10% in each non-zero parameter value, generally much more. The basin of attraction of the controller, seen in figure 2, was found to be 30-40 times larger than the standard deviation of mid-stance kinematic variability in normal walking. Such basins of attraction predictions can be tested in further large-perturbation experiments.

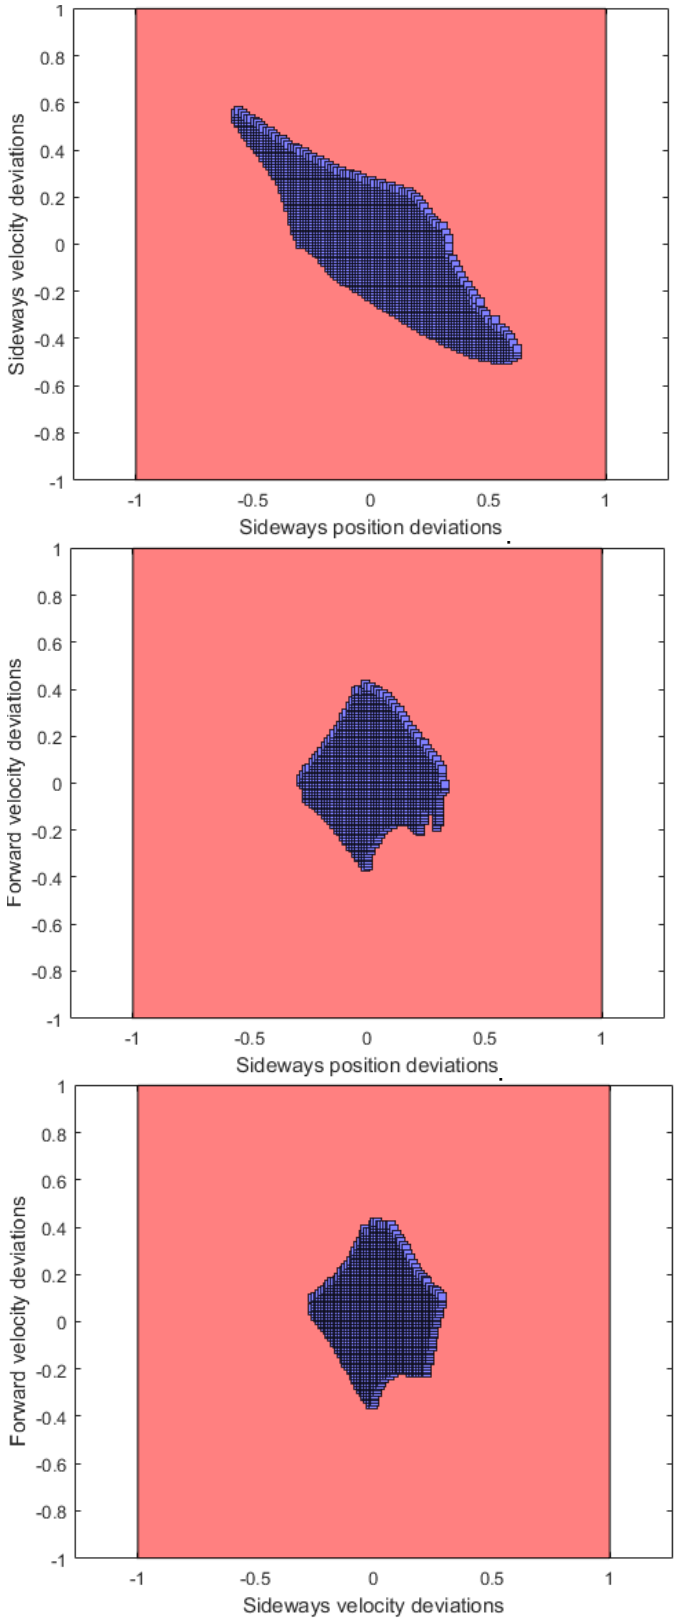

Figure 2: Basin of attraction for the simple inverted pendulum walker with a controller derived from human perturbation experiments. The dark patch represents the set of perturbations that do not result in a fall. All quantities non-dimensionalized.

EFFECTS OF A NEW ADAPTIVE ANKLE PROSTHESIS ON LEVEL AND SLOPED WALKING

Erik P. Lamers, Maura E. Eveld and Karl E. Zelik

Vanderbilt University, Nashville, TN, USA
email: erik.p.lamers@vanderbilt.edu

INTRODUCTION

Sloped terrains can be challenging for individuals with lower limb amputation to navigate, in part because conventional prosthetic feet are aligned at a fixed angle and lack biological ankle joint articulation. The lack of ankle articulation may cause prosthesis users to adopt compensatory strategies on slopes [1]. To address this issue, various prosthetic feet have been developed to adapt their ankle angle based on the slope, partially restoring ankle articulation. There is evidence that this ankle articulation may help normalize certain gait biomechanics during level [2] and incline walking [3]. However, objective performance data on adaptive ankle prostheses is still limited, and the extent to which these devices benefit users on slopes requires additional investigation.

In this study we investigated a new microprocessor-controlled prosthetic ankle (MPA, Ossur premarket device), which uses a low-power motor to adapt its ankle angle to sloped terrain and to dorsiflex the ankle during swing to enhance toe clearance. We quantified the biomechanical effects of the MPA on unilateral transtibial prosthesis users during level and sloped walking, compared to the MPA with the ankle locked at the neutral position, and also compared to each user's prescribed prosthesis. The first comparison served as a controlled scientific study to isolate effects due specifically to ankle angle adaptation (since all other aspects of the MPA were unaltered). The latter comparison provided a more clinically-relevant assessment of the MPA against prostheses that users wear each day.

METHODS

Eight individuals with unilateral transtibial amputation participated in this study of level, incline and decline walking. These individuals (7 male, 1 female, height 1.78 ± 0.1 m, weight 92 ± 15 kg, age 45 ± 14 years) were all K3-K4 level ambulators, at least 6 months post amputation surgery. Six healthy controls (4 female, 2 male, height 1.78 ± 0.1 m, weight 69 ± 10.6 kg, age 21 ± 1.8 years) also performed identical walking conditions, to assist with results interpretation. All participants provided informed consent, according to Vanderbilt Institutional Review Board procedures.

Prosthesis users were fitted with the MPA by a certified prosthetist, and then users were educated on the functions of the device. After the fitting, prosthesis users wore the MPA for 2-3 weeks of at-home acclimation before returning for formal gait analysis testing.

Prosthesis users (and healthy controls) performed level (0°) and sloped (±7.5° incline/decline) walking on a treadmill at a fixed speed (either 0.8 or 0.9 m/s). Prosthesis users walked on: (i) the MPA, (ii) the MPA with the ankle locked at the neutral position (hereafter referred to as the MPA-locked condition), and (iii) their prescribed prosthesis (primarily higher profile energy storage and return prostheses). Ground reaction force data were collected under each foot at 1000 Hz using a split-belt force-instrumented treadmill (Bertec), and lower-body kinematics were recorded at 200 Hz via a synchronized motion capture system (Vicon). Joint level kinematics and kinetics, as well as center-of-mass power, were calculated using common gait analysis methods. Prosthesis power was estimated using a previously published method that computes power due to all structures distal to the prosthetic socket [4]. Statistical significance was evaluated via repeated measures ANOVA, α=0.05.

RESULTS AND DISCUSSION

This study resulted in a comprehensive biomechanical characterization of lower-limb kinematics and kinetics, and center-of-mass power. Various changes were only observed in prosthetic-side biomechanical outcomes. However, in many cases, these changes were observed within a subset of users. Changes in sound limb kinematics and kinetics across the prosthesis conditions were generally small in magnitude, and inconsistent across participants. For brevity, the focus of this abstract is limited to (i) reporting key trends that were observed to be consistent among multiple, or a majority of participants, and (ii) reporting on a subset of outcome metrics of interest based on previously published prosthetics studies. Additional/extended results and discussion will be presented at the conference itself.

MPA vs. MPA-locked Results

The MPA adapted its ankle angle by the programmed amount on slopes (6.0 ± 1.5° dorsiflexion for 7.5° incline, 2 ± 0.4° plantarflexion for 7.5° decline) and provided more toe clearance (minimum height of toe above ground between 75% and 85% of gait cycle) than the MPA-locked condition during level (1.39 ± 0.44 cm, $p<0.001$), incline (1.99 ± 0.40 cm, $p<0.001$) and decline walking (0.81 ± 0.46 cm, $p=0.005$).

MPA vs. Prescribed Results

The MPA provided more toe-clearance than prescribed prostheses during level (1.46 ± 0.7 cm, $p<0.001$), incline (1.84 ± 1.0 cm, $p=0.001$) and decline walking (1.17 ± 1.06cm, $p=0.012$. During incline walking, four users switched from a toe-landing gait pattern on their prescribed prosthesis to a heel-to-toe gait pattern on the MPA, which was more consistent with the gait pattern of the controls. The MPA stored and returned less elastic energy for 6 of 8 subjects during level walking, and for 5 of 8 subjects during both incline and decline walking.

Discussion

The MPA may provide benefits by reducing trip risk due to increased toe-clearance. This was anecdotally supported by one user who reported less "toe-catching" during the at-home acclimation period with the MPA compared to his prescribed prosthesis. For half the prosthesis users, the MPA also appeared to promote a more typical heel-to-toe gait pattern for incline walking (i.e., more similar in appearance to the controls); however, a trade-off was that elastic energy return was generally reduced relative to prescribed prostheses. One limitation of this study was that K2 users (limited community ambulators) were not tested, a group for whom large elastic energy storage/return may be less important, and for whom ankle articulation has been shown to benefit walking performance [2].

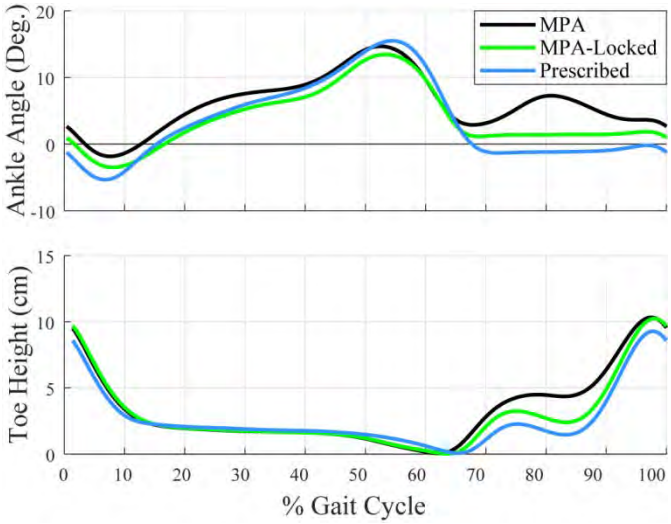

Figure 1: The MPA dorsiflexes the ankle during swing (~80% gait cycle) (top) to provide increased toe clearance (bottom), which may reduce trip risk. Representative subject depicted.

RELIABILITY AND FEASIBILITY OF AN INERTIAL MEASUREMENT UNIT BASED DUAL-TASK GAIT BALANCE ASSESSMENT

[1]Will Pitt and [1]Li-Shan Chou

[1]Department of Human Physiology, University of Oregon, Eugene, OR, USA
email: chou@uoregon.edu, web: http://choulab.uoregon.edu

INTRODUCTION

Concussion in athletics, workplace, and everyday activities continue to occur at high rates leading to impaired dynamic balance control persisting up to two months post-injury [1]. Prolonged gait imbalance is currently detected using costly and time consuming camera-based whole body motion analysis under a dual-task paradigm (walking while performing a concurrent cognitive test). However, advances in commercially available wearable inertial measurement unit (IMU) technology offers an opportunity to perform objective post-concussion gait stability analysis in the clinical setting.

At present a clinically feasible dual-task gait balance assessment utilizing sensitive whole body center of mass (COM) biomechanical markers is not available. The development of such a clinical assessment requires design of a testing protocol, determination of its consistency in non-laboratory settings and across time, and establishment of inter-rater reliability and clinical feasibility.

This study has two main purposes: first, to examine the internal consistency and interrater reliability of an IMU-based dual-task gait balance control assessment. Second, to establish the clinical feasibility of the instrument in a Division I collegiate sports programs.

METHODS

This two part study consisted of 1) assessment of internal consistency and interrater reliability, and 2) assessment of clinical feasibility with a Division I female soccer team. Instrumentation consisted of an APDM OPAL IMU system (sensor placed over the L5 vertebrae as a COM proxy [2]) for kinematic data collection, Bluetooth headset/microphone for assessment instruction and cognitive test application, and Superlab 5 software for protocol automation. All hardware and software were controlled with a single MacBook Air laptop. In part one of the study subjects performed four walking trials in each of three conditions: walking only, walking while performing an auditory Stroop test, and walking while spelling a five letter word backwards or subtracting from a given number by 6s or 7s. Individuals walked at a self-selected pace over an eight meter level path, performed a 180° turn around a cone, and returned to the start. The conditions were repeated in two environments (laboratory and hallway representing a typical medical clinic), by two different raters, and on two separate days (separated by 7-10 days). The order of environment, rater, and walking condition was randomized for each testing session.

IMU data was sampled at 128Hz and filtered with a 2nd order, low-pass, Butterworth filter, with a 12Hz cutoff. The gait cycles beginning with the 5th heel strike during the walk out and the returning walk were analyzed. Peak linear accelerations along the vertical axis (10-30%, 30-50%, and 50-60% gait cycle) and medial-lateral axis (30-50%, 50-60%, and 60-75% gait cycle) were identified (Fig. 1).

The second part of the study consisted of a shortened clinical protocol implemented with the University Women's Soccer team. The protocol consisted of three walking trials in each of the three testing conditions with the conditions presented in a random order. Testing was performed in the University athletic medicine facility by a team athletic trainer. Total assessment time per athlete was collected to assess clinical feasibility. Additionally, the 10 linear acceleration metrics were collected and compared to our healthy, non-athlete female subjects from part one of the study.

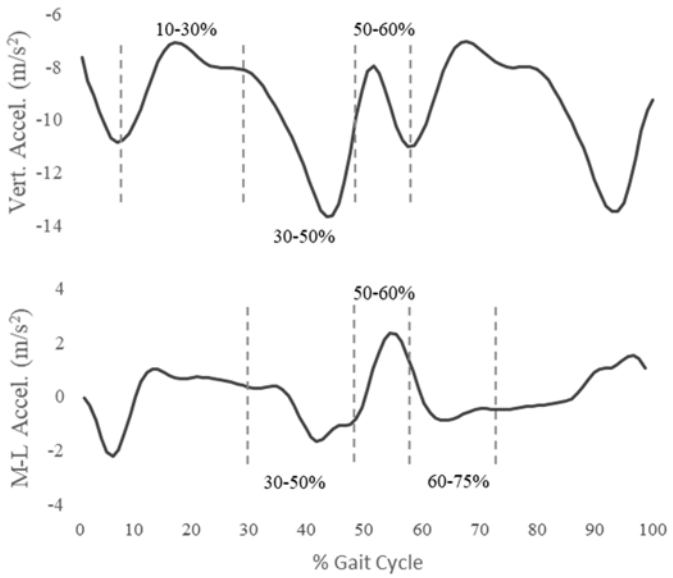

Figure 1: Representative plot of the A-P and M-L linear accelerations and 6 peak accelerations

An eight item Cronbach's α was used to establish the consistency of the measurement tool across time, environments, and raters. An Intraclass Correlation Coefficient and 95% CI was used to establish interrater reliability. Paired t-tests were performed for each outcome measure between female athletes and non-athlete controls. Statistical analyses were performed with SPSS version 24 (SPSS Inc., Chicago, IL).

RESULTS AND DISCUSSION

Twenty healthy subjects (10F) completed part one of the study (Age 22.2±2.8yrs, Wt. 71.0±12.0kg, Ht. 175.8±8.1cm). Internal consistency for the six outcome measures was excellent as established by Cronbach's α values between .904 and .980. Interrater reliability was also very good with ICC values ranging from .868 to .941 (Table 1).

Fourteen uninjured female athletes participated in part two of the study (Age 19.3±1.3yrs, Wt. 64.6±4.0kg, Ht. 168.4±7.1cm). Total assessment time including sensor placement and verbal instructions was 8:30 minutes ±35 seconds, demonstrating its clinical feasibility. Female athletes were compared to 10 non-athlete females from part one (Age 21.4±3.5, Wt. 62.5±7.6kg, Ht. 169.0±4.8cm). The magnitude of all M-L peak accelerations in all three walking conditions was

Table 1: Cronbach's α and ICC values for the 6 COM kinematic outcome measures

	Cronbach's Alpha			ICC	
Metric	Walk	Stroop	Q&A	r	95% CI
Vert. Accel 10-30%	.976	.942	.976	.920	.918±.022
Vert. Accel 30-50%	.951	.955	.980	.868	.865±.033
Vert. Accel 50-60%	.911	.914	.933	.876	.872±.034
M-L Accel 20-40%	.931	.963	.969	.931	.928±.020
M-L Accel 40-50%	.933	.904	.925	.902	.898±.027
M-L Accel 50-70%	.976	.969	.970	.941	.939±.016

greater than non-athlete females, however, only M-L Accel 20-40% and M-L Accel 50-70% reached a significant level (Table 2). This demonstrates the ability of the instrument to detect subtle differences in dynamic balance control.

Table 2: M-L peak accelerations (m/s^2) presented in mean±SD for non-athlete females and female soccer players. An * indicates $p < .05$

Metric	Group	Walking	Stroop
M-L Accel 20-40%	Non-Athlete	-2.24±0.52	-2.07±0.42
	Soccer	-2.91±1.14	-2.77±1.10 *
M-L Accel 40-50%	Non-Athlete	2.79±1.08	2.75±1.22
	Soccer	3.47±1.39	3.36±1.45
M-L Accel 50-70%	Non-Athlete	-1.39±0.70	-1.45±0.47
	Soccer	-2.07±1.01	-2.24±1.04 *

CONCLUSION

The high Cronbach's α and ICC values indicate our testing apparatus and protocol have excellent consistency and interrater reliability in a non-laboratory environment, across time, and with different evaluators. Furthermore, the instrument is both clinically feasible and sensitive to subtle differences in dynamic balance control. The results provide the necessary foundation for the development and implementation of a low-cost, accurate and sensitive, post-concussion gait stability assessment that is reliable in the clinical setting by minimally trained evaluators.

Exploring Movement Variability and EEG Correlates During Motor Learning with a Smartpen: A Novel Method

[1,2] Jo Shattuck, [2] Matthew R. Johnson and [1]Jack W. Ransone

INTRODUCTION

The optimal degree of movement variability during practice in the role of motor learning and ultimate performance outcome has been vigorously debated since Bernstein's degrees of freedom theory [1]. However, measuring movement variability with motion capture systems can be cumbersome, cost prohibitive and not suitable for smaller movements. Digital graphical tablets and touchscreens present one solution to capture smaller movements, but may not offer the flexibility of study design and the naturalistic feel of traditional pen and paper. Our solution was the use of an Echo Smartpen, which digitally stores every stroke of the pen on specialized LiveScribe paper, and image processing code with Matlab to record and analyze the movement variability over a timed drawing task with multiple training sessions spread over four days. Continual EEG data collection during the task was recorded with an EPOC 14 portable Bluetooth headset. The currently known neural substrates of motor learning have yet to offer a clear model of neural changes that occur over various brain regions through the learning stages. We intend to use the data collected via this novel method with non-linear analysis to pursue neural markers of performance outcomes and movement variability. This abstract describes the procedures, analysis and initial performance results in the timed drawing task.

METHODS

Nine females and eleven males from 19 to 30 years (M=21.35±3.65), completed 14 sets of a timed trail-making task. This timed drawing task required connecting 25 numbered circles on a page in a specific sequence. A 3-ring binder and timer button (Fig. 1) sat on the desk. The timer button and binder were attached; the left and right pages were equidistant to the timer button even if the subject repositioned the binder on the desk. Subjects were instructed to draw lines with the Echo Smartpen to connect the circles in sequence "as fast as possible without making mistakes." Fig. 2 shows Part A of the Trail Making Task in the Halstead Ralston Battery. (Part A was repeated 140 times over 4 days) Subjects pressed the timer button at the beginning and end of each page (trial), yielding a measure of speed; variability in movement was measured with custom Matlab code.

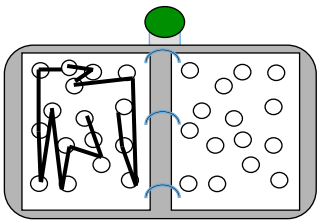

Figure 1: Binder and Timer Button

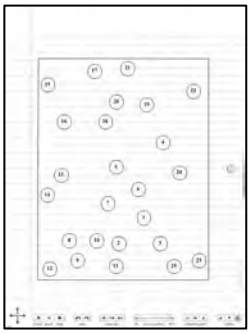

Figure 2: Trail Making Task

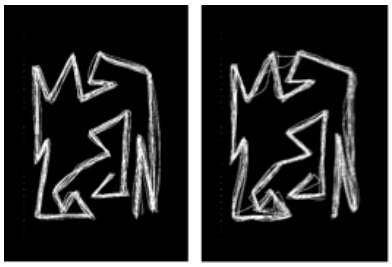
Each set containing ten pages (trials) was exported as a portable document format file (pdf), converted to black and white, inverted to show pen strokes as white, background as black, then overlaid into a single image. Fig. 3 shows the overlaid trials of Set 1 and Set 14.



Set 1 Set 14

Figure 3: Overlaid Sets

Our variability code compared the distance of each white pixel to every other pixel to capture a quantitative measure of variability or Efficiency of movement. Figure 4 shows a low variability circle (top right inset), and a high-variability (bottom left

inset) for two 50 x 50 pixel areas (gray box) surrounding the numbered circles (dashed lines).

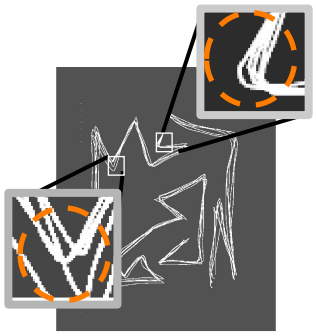


Figure 4: Examples of Different Levels of Variability

Each circle's coordinates surrounding the 23 circles (first and last were omitted) had been pre-determined from the original trail-making task. Variability was calculated on each circle in each set, from an image of the 10 overlaid trials in the set. Each subject completed 14 sets: four sets per day in Visits 1, 2, and 3, which all occurred on consecutive days, plus two sets in the Retention Visit, which occurred four days after Visit 3.

RESULTS AND DISCUSSION

Trial time retention (from set 1 to set 14) in the motor sequence improved 45%, in 4 days over 14 sets (M = 44.59±9.20). Variability improved 1.8% (M = 1.76±3.84). T-tests on the raw *variability scores* showed the mean difference in variability was significant (M=0.3212), p = 0.039). Recall variability (between set 12 to set 14, during which there was a four day delay) was not significantly different, suggesting the -1.06% efficiency gains were maintained and did not worsen over the delay, (M=-1.84, SD=4.74.)

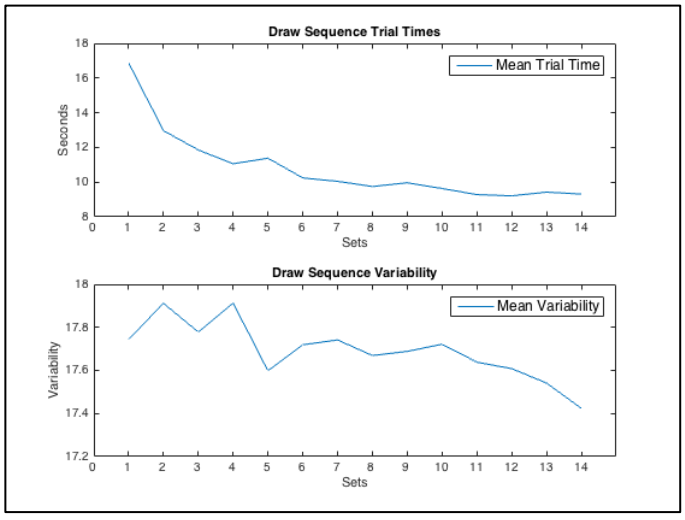

Figure 5: Trial Times (top) and Variability (bottom) per Set, n=20

Trial times decreased according to the law of practice, and the maximum speed/efficiency tradeoff occurred within the first 5 sets, the early (fast) stages of learning. The greatest change in trial times occurred in 1, after which trial times began to plateau; however, variability continued to decrease, (i.e. Efficiency improved, see Fig.5)

This method combined kinematics, a grapho-motor task and pen stroke capture, to produce a novel motor learning task and analysis method. While unable to capture force or pressure information as traditional digitizing tablets can, this method was a suitable alternative for studying 2 dimensional motor learning. The method was designed for a larger project for which the primary goal is to find neural correlations for different performance features of motor learning. Further analysis on continually recorded EEG data throughout the sessions was required to determine if neural activity shifts with movement variability and trial times. We intend to use a repeated measures non-linear multilevel model to examine between-set variability over the learning stages.

CONCLUSIONS

Stergiou and Decker stress the importance of studying variability to understand human movement: "Far from being a source of error, evidence supports the necessity of an optimal state of variability for health and functional movement" [2]. We explored the role of variability and its relationship with neural activity with this novel method in an attempt to improve movement pedagogy. Improved teaching techniques can benefit motor learning fields such as physical therapy, vocational training, and recreational and elite sport coaching.

GAIT VARIABILITY TO PREDICT MOTOR LEARNING OF A NOVEL MOTOR TASK

INTRODUCTION

Motor variability (MV) is a fundamental feature of movement that refers to the variation observed in the spatiotemporal dispersion of joint movements, inter-joint coordination patterns, and muscle activities, when an individual completes the same task numerous times. While variability is natural and inherent in any human movement, it was traditionally assumed to be undesirable, as it was thought to contribute to less accurate performance. However, basic motor control research has progressed in recent years, and now suggests that movement variability has important functional implications for the preservation of motor performance, both with respect to short-term adaptations of movement strategies and longer-term motor learning. Existing evidence of motor variability being predictive of motor learning has been reported during simple reaching tasks [1]. Whether this concept is generalizable to other kinds of movements such as gait is currently unknown.

The goal of this study was to assess whether motor variability in normal gait at a self-selected speed (baseline condition) was associated with motor learning in a young healthy population performing a novel motor task. The novel motor task involved clearing an obstacle course within a designated time while performing a dual task. We hypothesized that inter-individual differences in motor learning ability in the novel task would be explained by differences in baseline gait variability. As a secondary objective, we also aimed to determine which variability measures (stride characteristics. lower limb joint kinematics and inter-joint coordination as quantified by vector coding) were most discriminative of inter-individual differences in learning ability in our cohort of young healthy adults.

METHODS

Thirty-two participants (16 F, 16 M), aged 21.28 (SD 1.76) years, with no known history of musculoskeletal disorders or injuries were recruited. Each participant was asked to walk barefoot continuously at a comfortable, self-selected pace for six minutes in order to reliably capture baseline motor variability [2]. Gait kinematics were collected using a 10-camera motion capture system (Qualysis INC, Gothenburg, Sweden), and passive reflective markers placed at select anatomical landmarks on the pelvis and lower limbs. After baseline over-ground walking, each participant was asked to walk through an obstacle course barefoot while holding a bowl of colored water. In order to complete the course successfully, they needed to finish the course within a specified time constraint while not spilling the bowl of water. The course consisted of directional cones, an agility ladder, a low balance beam, and stepping stools to step over. “Performance” in the novel task was quantified by the number of trials taken by each participant to achieve success, i.e. obstacle course completion within the pre-set time.

Marker data were exported into Visual 3D (C-motion Inc., USA) for data processing. Spatiotemporal stride characteristics and hip, knee, and ankle joint angles in the sagittal and frontal planes, during the stance and swing phases of gait, were extracted for further analysis. Standard deviation of each joint angle trajectory was calculated as the root mean square of standard deviation obtained at each normalized time point across all trials, during the stance and swing phases (~35-40 strides). Inter-joint coordination was quantified through vector coding [3]: hip-knee and knee-ankle couples in the sagittal and frontal planes during stance and swing were computed, and the stride-to-stride SD of joint coupling angles were used to quantify coordination variability. Two stepwise linear regression models were estimated to assess the association between performance (response variable) and the following predictor variables:

1. Stride characteristics (mean and stride-to-stride SD);
2. Joint trajectory variability of hip, knee and ankle joints, and stride-to-stride SD of hip-knee and knee-ankle joint couples in the frontal and sagittal planes during stance and swing phases.

JMP (SAS Inst. Inc., USA) was used for all statistical analyses, and a type I error rate of 5% was considered to be acceptable for statistical significance in tests of each variable in the regression models.

RESULTS AND DISCUSSION

On average, the participants took 10.97 (range 2-21) trials to learn to clear the obstacle course. A model using only stride characteristics of baseline gait (top panel in table 1) to predict performance was not statistically significant. However, when joint kinematic variability measures were used as predictor variables (bottom panel of table 1), 95.6% of the variance in performance could be explained by the model. Thus, our results support the functional significance of joint kinematic variability in over-ground walking even for a homogenous group of young and healthy adults: inter-individual differences in the rate of learning a novel motor task was predicted by differences in kinematic variability between individuals. Specifically, individuals with the fastest learning rate exhibited increased variability in knee frontal and ankle sagittal joint angle trajectories during the stance phase, and increased knee-ankle coordination variability during the swing phase. Our results are also novel from the perspective of showing that swing phase joint kinematic variability is also meaningful to study in gait, as hip and knee joint variabilities as well as inter-joint coordination variabilities are predictive of performance.

CONCLUSIONS

Although the functional significance of motor variability has been demonstrated in various clinical populations and among older adults, ours is one of the first studies showing strong association between gait variability and short-term motor learning in a cohort of young and healthy individuals.

REAL-TIME MUSIC-BASED BIOFEEDBACK TO REDUCE IMPACT LOADING DURING OVER-GROUND RUNNING

INTRODUCTION

Running retraining through biofeedback on a measure of impact loading combined with simple instruction can decrease running related injuries [1]. Running retraining through real-time biofeedback on a direct measure of impact loading has been exclusively executed on treadmill [1,2]. For example, Peak Tibial Acceleration (PTA) was reduced by provision of simple auditory biofeedback within a single, treadmill-based retraining session [2]. Ecological validity could be improved by conducting retraining programs in an over-ground environment outside the laboratory and with a motivational bio-feedback approach.

In this 'proof of concept' study, retraining by means of real-time auditory biofeedback happened over-ground on an indoor running track in runners with elevated PTA. Impact loading was expected to be reduced within a single session.

METHODS

After screening 80 uninjured runners on PTA, 5 (3♂-2♀) high impact runners (height: 1.74 ± 0.02 m; weight: 71 ± 7 kg; age: 38 ± 11 years; weekly running volume: 25 ± 10 km; mean ± SD) were recruited in this ongoing study. These recreational, habitual rearfoot runners ran at least 15 km/week in non-minimalist footwear, were injury-free in the last 6 months and had no experience with gait retraining. They were instrumented with a wearable accelerometry system able to continuously detect PTA in real-time. Tibial skin was bilaterally pre-stretched before low-weight accelerometers (LSI 331, Sparkfun; 1000 Hz) were attached over the distal, anteromedial aspect of both tibia [3]. At an indoor track-and-field site (Flanders Sports Arena, 289 m/lap), participants were instructed to run at 3.2 ± 0.3 m/s. A warm-up of 4.5 min without bio-feedback was given while the average axial PTA was automatically determined for the leg bearing the highest tibial shocks. Lap times were used to give feedback on running speed. Real-time, music-based biofeedback was then provided for 20 min. in total (2*10 min. with ~ 5 min. intermittent rest). Music of a preferred genre was continuously synchronized to the runner's step frequency and was non-linearly distorted by superposition of pink noise according to the magnitude of elevated PTA [4]. To lower impact loading, runners were instructed to run with maximum music clarity and were not given any instructions on possible gait modifications. To account for any within-subject change in PTA during running, all PTAs were exported for further analysis using a custom MATLAB program. Wilcoxon signed-rank tests compared the mean running speed and mean PTA level between the no biofeedback and biofeedback (last 10 min. phase) conditions. The data were determined to be significant if $p < 0.05$. Mean ± SD are reported.

RESULTS AND DISCUSSION

Running speeds during the no biofeedback and biofeedback conditions were respectively 3.2 ± 0.1 and 3.1 ± 0.1 m/s ($p = 0.416$, $z = -0.813$), and thus speed had no confounding effect on PTA. Supporting our hypothesis, one retraining session with real-time biofeedback was enough to temporary decrease PTA in an over-ground setting (Table 1). The PTAs experienced by a representative runner during the over-ground running session are shown in figure 1. All subjects could decrease impact loading while listening to real-time biofeedback, and this without

any instruction on gait modification but simply by means of impact sonification. The reduction of -2.7 g or -26 % in PTA was more than the achieved reduction in other single retraining sessions by auditory biofeedback on treadmill [2, 5].

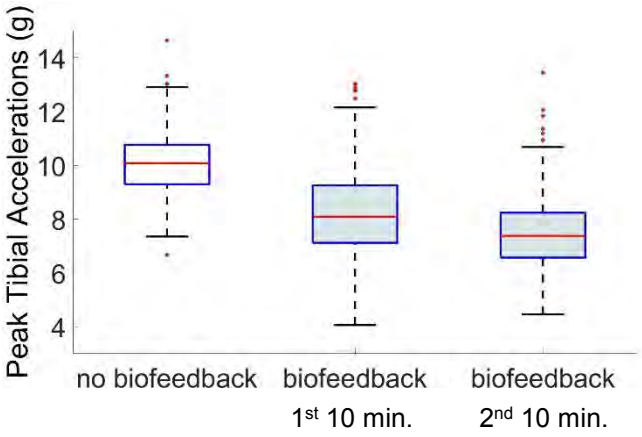

Figure 1: A Box-and-Whisker plot showing the distribution of peak tibial accelerations experienced by a representative participant.

The achieved reduction is arguably due to the more motivating form of the provided augmented feedback [6], consisting of music continuously synchronized to the runner's step frequency instead of simple beeps, and the cohort exhibiting high impacts along the lower leg's axial axis at baseline. Although other studies [2,5] demonstrated the effectiveness of auditory biofeedback by generating simple beeps for impact loading reduction on treadmill, this study is the first to show reduction in axial PTA in runners at-risk for the development of tibial stress injuries by applying more advanced and motivating real-time audio biofeedback and this in a non-lab environment. Besides the PTA acting along the axial axis, the impact shock severity along the other axes may also have altered and should be investigated in future and ongoing studies.

The feasibility of providing auditory information about clinically relevant biomechanical data per wearable biofeedback system eliminates the need of retraining exclusively in laboratory or clinic settings. This allows people to engage in gait retraining by means of impact sonification in their regular running environment (e.g. track-and-field, trail running) and is expected to increase the effectivity of and the adherence to a running retraining program.

CONCLUSIONS

High impact runners were able to temporarily decrease their PTAs during over-ground running by actively listening to and acting on music-based biofeedback without any instructions on gait modifications. Running retraining aiming at impact loading reduction by provision of augmented feedback on a direct measure of impact loading is possible in an ecologically valid environment.

INTRODUCTION

Modern warfare requires warfighters to carry increasingly heavy loads that include, for example, body armor, gear, electronics, food, and water. To optimize the magnitude and configuration of the load, the Marine Corps Load Effects Assessment Program (MC-LEAP) was developed to assess variations in soldier performance due to clothing and individual equipment (CIE) [1]. The program consists of an obstacle course representative of tasks warfighters encounter in combat. Historically, performance in the MC-LEAP (and variations of it) is quantified solely by the time required to complete each obstacle as often measured via timing gates. Although the time to complete an obstacle is one measure of performance, completion time alone does not reveal the technique(s) used or underlying biomechanics contributing to performance. As an alternative to video motion capture, recent studies employed inertial measurement units (IMUs) to measure underlying biomechanics that define performance for obstacles in the MC-LEAP [2-8]. The goal of this follow-up study is to understand how the IMU-derived performance metrics change when subjects carry different loads.

METHODS

A set of 22 subjects (7 females, 15 males) were recruited to complete a 10 obstacle abbreviated version of the LEAP-A a total of four times with a weight vest with 0% (2 repetitions), 15% (1 repetition), and 30% (1 repetition) of their body weight. All subjects wore an array of 13 IMUs (Opal, APDM, Portland OR) attached to the head, upper arms, forearms, sternum, sacrum, thighs, shanks, and feet. In addition, the subjects carried a mock plastic rifle (3.4 kg) with another attached IMU. The University of Michigan IRB approved the study and all subjects gave informed consent. The IMU data (accelerometer and angular rate) for each of the 14 IMUs was parsed into segments for each obstacle with custom activity identification code. The data for each obstacle was further analyzed with custom algorithms identifying key biomechanical measures of performance with examples detailed in [2-8].

Performance metric changes for a subset of obstacles is reported as a function of load. Thus, a repeated-measures analysis of variance (ANOVA) was conducted. Several subjects' data were eliminated because the subject did not complete all four testing sessions, data for one or more sensors was lost due to technical difficulties, or data was not properly parsed (i.e. falsely identified as another obstacle or failed to find anything). For the present analysis, the total number of subjects for the wall, window, and high crawl were 15, 13, and 14, respectively.

For each obstacle-specific performance metric, the normality assumption for the residuals is confirmed with Shapiro-Wilk normality tests, skewness and kurtosis calculations, and Q-Q plots. After conducting the repeated-measures ANOVA, a Mauchly's test for sphericity was conducted. Depending on the severity of the violation of this assumption, the ANOVA F-statistic was evaluated with adjusted degrees of freedom using a Greenhouse-Geisser correction. Then, Tukey post hoc analyses were conducted for performance metrics with significant results. All statistical tests are evaluated with a significance level of $\alpha = 0.05$.

Results are presented from the chosen subset of obstacles: 1) wall, 2) window, and 3) high crawl. The wall obstacle requires subjects to lift themselves up and over a 4ft tall wall. The window obstacle similarly requires subjects to lift themselves through a 3ft x 3ft opening 4ft off the ground. The high crawl requires subjects to crawl 30ft on elbows and knees while keeping their bodies as low as possible. The

ANOVA results include the F-statistic (and degrees of freedom), p-value, and effect size (η^2). For η^2, an effect size that is small is 0.01, medium is 0.06, and large is 0.14 [9]. The Tukey post hoc test results include the p-value and effect size (Cohen's **d**) for each pairwise comparison. Cohen's **d** indicates both the magnitude and direction of the comparison. (A negative **d** value indicates that the first group's average is less than that of the second group.) For Cohen's **d**, an effect size that is small is 0.2, medium is 0.5, and large is 0.8 [9].

RESULTS AND DISCUSSION

Performance on each obstacle is described by several performance metrics and a subset of three important metrics/obstacle are reported in Table 1 (all of which have normally distributed residuals). The ANOVA results show that load has a significant and large effect on the performance metrics in this subset of obstacles, whereas the post hoc results show these effects vary across metrics. As expected, the effect sizes for the 0%-30% comparison are larger in magnitude than either of the other two comparisons. However, there does not appear to be a common trend between the other two comparisons. For example, adding 15%BW from 0%BW has a larger effect on the wall's *Average take-off power* than adding 30%BW from 15%BW whereas adding 15%BW from 0%BW has a smaller effect on the wall's *Take-Off Speed* than adding 30%BW from 15%BW. These results imply potential metric-specific non-linear effects of adding weight. These differences could be the result of altering the underlying technique selected for the obstacle.

CONCLUSIONS

Load has large, significant effects on several performance metrics in this obstacle subset. The post hoc analyses indicate the increased load degrades performance, but in directions and magnitudes that vary across metrics and load conditions. These results suggest the IMU-derived metrics can be used to discriminate performance and technique in an outdoor setting that could potentially be extended to applications beyond warfighter performance.

CHANGES IN DYNAMIC MOTOR CONTROL FOLLOWING NEUROREHABILITATION FOR TRAUMATIC BRAIN INJURY: TREADMILL VS OVERGROUND WALKING

INTRODUCTION

Chronic gait deficits are often present in persons who have sustained a mild to moderate traumatic brain injury (TBI)—they tend to walk more slowly, take shorter steps and exhibit greater mediolateral sway [1]. Non-invasive neuromodulation of the cranial nerve has shown promise to enhance balance and gait in chronic TBI when coupled with rehabilitation exercises [2]. It is theorized this neuromodulation enhances neuroplasticity during rehabilitation, and thus improves the brain's ability to functionally compensate for damaged neural tissues [2]. However, it is unknown if the improvements in balance and gait arise from fundamental changes to the underlying motor control as a result of the neuromodulation.

One way to examine the underlying motor control during walking is with muscle synergy analysis. This has emerged as a quantitative tool to characterize the complexity of neuromuscular control patterns in neurologically impaired populations. The analysis typically involves the use of matrix factorization algorithms to identify low-dimensional patterns, or synergies, that can describe the variability inherent in an individual's measured muscle activations. A synergy then represents a group of muscles that are generally co-activated, which may represent simplified control. Hence, the variance in muscle activity accounted for by a given number of synergies can provide a measure of the complexity of control used by an individual. Prior synergy analysis studies have identified diminished complexity in the gait EMG patterns of stroke [3] and cerebral palsy [4] patients. Our previous work suggests that complexity is reduced for TBI subjects as well [5].

The objective of this study was to investigate if non-invasive cranial nerve neuromodulation during rehabilitation for a prior TBI can induce fundamental changes to the neuromuscular control of walking. We hypothesized that fundamental changes would manifest across a variety of walking tasks, such as walking overground and walking on a treadmill.

METHODS

Twenty healthy adults (25±3 years, 10 female) and forty-four ambulatory adults with a balance disorder due to a non-penetrative TBI participated in the study (53±9 years, 28 female). Each TBI participant was at least one year post-injury, had previously completed a focused physical rehabilitation program for their TBI, and were no longer seeing improvements from their gait rehabilitation. All TBI subjects had a dynamic posturography score at least 8 points below normal (Sensory Organization Test, NeuroCom®). The TBI subjects participated in 14-week neurorehabilitation program to train gait and balance. A portable electrotactile device stimulated cranial nerves V and VII throughout training via an electrode array placed on the human tongue, delivering three 0.4-60μs wide electric pulses at 5 ms intervals every 20 ms [2]. The rehabilitation program involved exercises 3x per day for two weeks in the clinic and then continued the exercises for 12 more weeks at home with the device.

Lower extremity electromyographic (EMG) signals were collected bilaterally from six muscles (tibialis anterior, medial gastrocnemius, soleus, vastus lateralis, rectus femoris, semitendinosus) during treadmill and overground walking (60 seconds). EMG was collected before rehabilitation (week 0), after the in-clinic training (week 2), after at-home training (week 14), and after a washout period without stimulation or exercises (week 26). Each chronic TBI subject walked at his/her pre-rehabilitation preferred speed (1.0±0.2 m/s). The

protocol was repeated on the healthy young adults walking at a speed of 1 m/s. EMG signals were rectified and then low-pass filtered at 10 Hz. Ensemble EMG patterns were created by averaging signals over all gait cycles and normalizing the data to each muscle's root-mean-squared EMG. Non-negative matrix factorization was used to derive the synergies. The walking dynamic motor control index (Walk-DMC) was then used to measure the complexity of neuromuscular control during gait [4]. A two-way repeated measures ANOVA tested for the effects of time (weeks 0, 2, 14, 26) and walking activity (treadmill, overground) on Walk-DMC score. For normative comparisons, exploratory Mann-Whitney tests compared Walk-DMC in TBI to the healthy adults.

RESULTS AND DISCUSSION

There was no significant effect of time (p = 0.581) or walking type (p = 0.307) on the Walk-DMC score of the TBI subjects (Fig. 1) During overground walking, the TBI subjects had a significantly lower Walk-DMC score than the healthy adults at every time point (p's < 0.01). However, the Walk-DMC score for TBI subjects on the treadmill was only significantly lower than the healthy adults before training (p = 0.018).

Changes in Walk-DMC for the TBI subjects were not consistent between treadmill and overground walking, suggesting that changes in neuromuscular complexity were different between the two walking tasks. This might suggest that the two walking tasks were sufficiently different and thus did not induce similar muscle activation patterns. Indeed, treadmill and overground walking may require different control strategies in this population [6]. However, as both walking activities have a lot of similarity, we may interpret our findings to suggest that the neurorehabilitation program did not create a fundamental change in the underlying control of walking. Rather, the improvements likely arose from proper training and increased familiarization of the treadmill walking task. Regardless, it is encouraging that neuromuscular complexity during treadmill walking improved to levels similar to the healthy adults after the in-clinic training, and then was maintained through the 12-week washout period. This suggests that the neurorehabilitation program may provide some level of meaningful change in walking control in a population of subjects who were no longer seeing improvements in gait and balance through traditional rehabilitation. Future research will examine individual subjects across time, as many TBI subjects started with healthy levels of neuromuscular complexity.

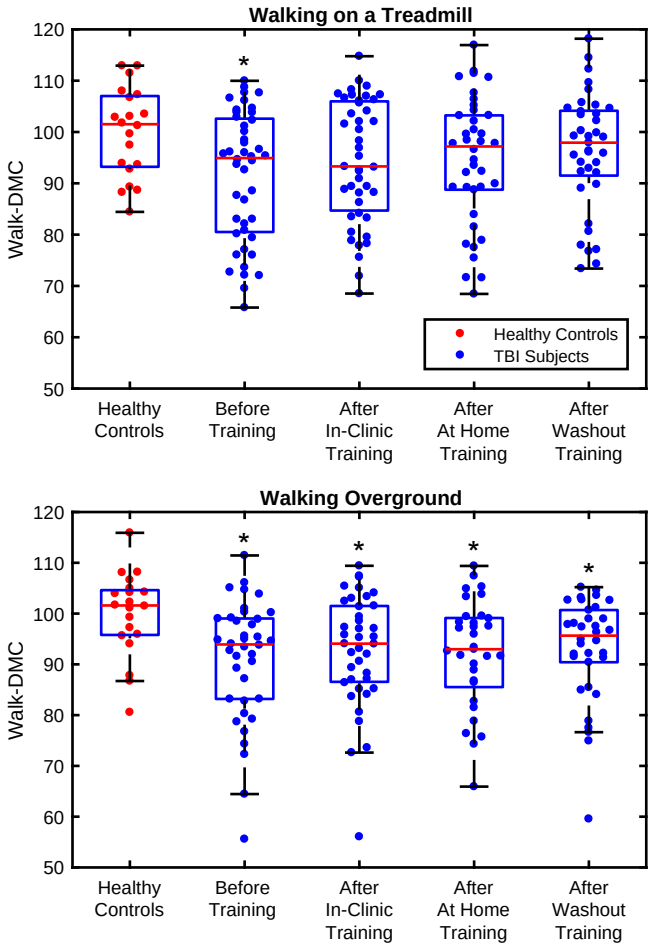

Figure 1: Walk-DMC scores for TBI and healthy controls. Asterisks indicate time points when the TBI subjects had a significantly lower Walk-DMC score than the controls.

INTRODUCTION

Falls are a leading cause of injuries and injury-related deaths among older adults in the United States [1]. Up to half of all falls among older adults occur due to tripping [2-4]. Since the onset of tripping events may not be completely avoidable, enhancing the reactive balance response after tripping may be an effective approach for reducing falls among older adults. Reactive balance training (RBT) is a form of task-specific, perturbation-based balance training that has the potential to improve reactive balance performance. RBT involves repeatedly exposing individuals to trip-like perturbations in a safe, controlled manner to facilitate improvements in reactive balance performance.

The goal of this study was to evaluate the efficacy of RBT as an on-site balance training intervention for improving reactive balance among residents of retirement communities. This was done in comparison with Tai Chi, an active control demonstrated to reduce fall risk.

METHODS

Thirty-five older adults (age 70-92, 24 females) participated in the study. Subjects were initially required to pass a medical screening that included a history, physical, and bone mineral density assessment at the lumbar spine and proximal femur. Subjects were randomized to either RBT or Tai Chi. RBT was performed on a treadmill that was modified to elicit trip-like perturbations. Subjects stood quietly on the treadmill with a foam block placed in front of their feet. Perturbations were generated by accelerating the treadmill belt to a preselected walking speed over ~40 msec. This abrupt acceleration induced a forward fall similar to a trip while walking, and subjects subsequently attempted to take steps to recover balance (Fig. 1). RBT involved 30-minute sessions performed three times a week for four weeks. Each session consisted of 18-40 trials on the treadmill, with direction and speed pseudo-randomized and individualized based upon subject ability and improvement (with speeds between 0.5-2.4 mph). Tai Chi consisted of slow, controlled movements that focused on balance and like RBT, was performed three times a week for four weeks.

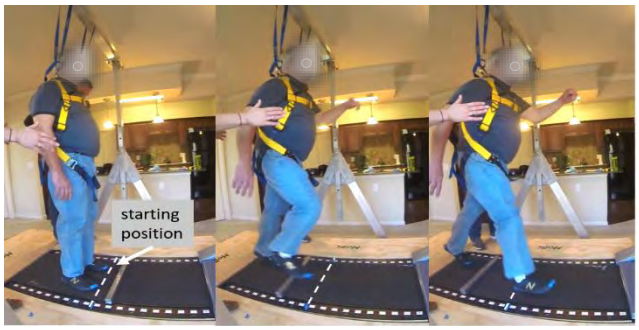

Figure 1. RBT subjects stood still on the treadmill (left) until the motorized treadmill suddenly accelerated, inducing a forward fall (middle). Subjects were asked to step over the block and establish a stable gait (right).

Outcome measures included metrics of reactive balance performance, along with standard clinical tests of balance and mobility. Outcome measures were assessed before (B) intervention, and one week (1W), one month (1M), three months (3M), and six month (6M) after intervention. Reactive balance performance was determined by accelerating the modified treadmill belt backward (to induce a forward fall) to 0.8, 1.6, and 2.4 mph. Outcomes measures were based on characteristics of the initial reactive step (measured from video recording) and sagittal plane trunk angle (measured using an inertial measurement unit). These measures included anterior/posterior length of the first reactive balance

step (step length), time from treadmill onset to lift-off of first recovery step (liftoff time), time from onset to touchdown of first reactive balance step (touchdown time), maximum sagittal plane trunk angle, and a reactive balance rating. Clinical tests included the time-up-and-go test (TUG), unipedal stance time, maximum step length, Berg Balance Scale, Performance-Oriented Mobility Assessment (POMA), and Activities-specific Balance Confidence Scale (ABC). Post-intervention differences between groups were investigated using a mixed model that accounted for fixed and random effects and within subject correlation. A $p \leq 0.05$ indicated significance.

RESULTS and DISCUSSION

RBT subjects performed better than Tai Chi subjects in a subset of reactive balance measures. Maximum trunk angle was 13.5 degrees smaller among RBT subjects one week after intervention ($p < 0.001$; Fig. 2). The reactive balance rating was 24% higher ($p = 0.016$; indicating better performance) at one week, 31% higher ($p = 0.023$) at one month, and 28% higher ($p = 0.029$) at six months after the intervention among RBT subjects compared to Tai Chi subjects. There were minimal differences in clinical tests between groups after intervention, though the POMA score was 5% higher (indicating better performance) among Tai Chi subjects one week after the intervention ($p = 0.040$).

CONCLUSIONS

Improvements in maximum trunk angle and reactive balance rating provide evidence for the ability of on-site RBT to improve reactive balance after trip-like perturbations. These results also support the use of the specificity of training principle among older adults for fall prevention.

PATIENTS WITH MEDIAL KNEE OA VARY IN THE KINETIC RESPONSE TO PLANTAR PRESSURE-BASED FEEDBACK

[1] Jade He, [1] Christopher Ferrigno, [1] Najia Shakoor, [1] Markus A. Wimmer
[1] Rush University Medical Center, Chicago, IL, USA
Email: Markus_A_Wimmer@rush.edu

INTRODUCTION

The knee adduction moment is a surrogate of medial compartment load during gait and is a regular target of conservative therapy for medial knee osteoarthritis (OA). In this study, we explore a gait retraining strategy that utilizes auditory cues based on real-time plantar pressure to inform individuals to medialize their center-of-pressure. After development and successful implementation of a gait retraining protocol on healthy subjects [1], we started a 6-week longitudinal clinical trial (NCT02955225) with patients with OA. This abstract reports on the initial gait retraining and investigates the immediate response of subjects to auditory cues.

The main purpose was to examine if patients were able to lower their knee adduction moment using pressure-based feedback. While 100% healthy subjects in a previous study responded favorably to pressure-based feedback [1], we anticipate that patients with OA will have more varied response with the training, prompting a secondary purpose to investigate gait variables that may differentiate responders from non-responders.

METHODS

Fifteen subjects with Kellgren-Lawrence (KL) grade 2 & 3) were recruited. The pressure-based auditory feedback system comprises a standardized, flexible shoe, a wireless, pressure-detecting shoe insole (Moticon GmbH, Munich, Germany), and a portable device for processing real-time plantar pressure and generating auditory cues (**Fig 1**). On the day of the visit, prior to the marker-based walks, subjects were fitted with the shoe and insole. Baseline plantar pressure was obtained from a 20-m walk at a self-selected, comfortable speed. A percentage (75-95% depending of actual performance of subjects) of the mean maximum of five steps of two lateral sensors were used as training thresholds. The sensors correspond to the time occurrence of the first and second peak of knee adduction moment.

Before gait retraining using pressure-based feedback, a motion capture (Baseline) acquired gait variables of subjects (**Fig 2**). After subjects were given an introduction on the pressure-based feedback system, they practiced walking while responding to the auditory cues under the supervision of a physical therapist. Once subjects were able to medialize center-of-pressure without triggering auditory cues from at least one of the two sensors for a few consecutive steps, they underwent another motion capture (Feedback).

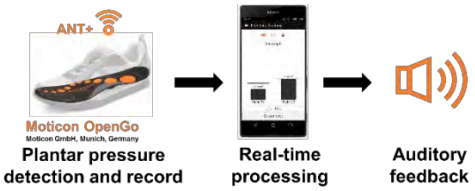

Figure 1: The pressure-based system was comprised of a flexible shoe, a wireless, pressure-detecting shoe insole, and a portable device.

Motion capture was performed using a ground embedded force plate (Bertec, Columbus, OH) to measure ground reaction forces and 12 optoeletric cameras (Qualysis, Gothenburg, Sweden) to capture lower extremities kinematics. A modified Helen Hayes marker-set was used. Raw kinetics and kinematics were processed in Visual 3D (C-Motion, Inc., Germantown, MD).

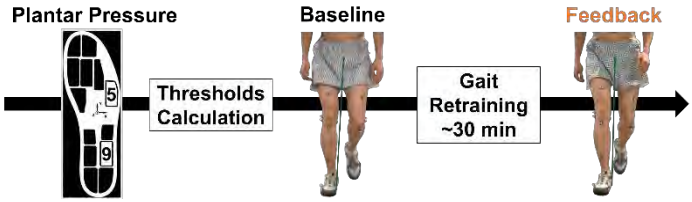

Figure 2: The gait retraining using pressure-based feedback happened between two marker-based walks, which captured gait variables before (Baseline) and after (Feedback) training.

Statistical analyses were performed using IBM SPSS Statistics 22 (SPSS Inc., Chicago, IL). Statistical significance was set to $\alpha = 0.05$. Binomial tests were used to evaluate if subjects were able to reduce the knee adduction moment. Paired t-tests were used to evaluate the training effects of pressure-based

feedback and independent sample t-tests were used to evaluate differences between subgroups. Linear regression was used to gauge a relationship between variables.

RESULTS

Characteristics of subjects recruited were 62 ± 11 yr, 85.4 ± 17.8 kg, 1.67 ± 0.09 m, and knee OA of 7 subjects was classified KL-2 and 8 subjects KL-3.

Ten subjects were able to reduce the overall and first peak of knee adduction moment, which was significant (p = 0.008 & 0.002, respectively). These ten subjects reduced the overall peak by 11.8% (0.31 %BW*Ht, p = 0.001) and the first peak by 12.7% (0.33 %BW*Ht, p < 0.001).

The responders to pressure-based feedback were separated from the non-responders based on whether or they were able to reduce the knee adduction moment (**Fig 3**). Between the subgroups, spatiotemporal variables were investigated since speed and its contributors stride length and cadence were shown to influence the knee adduction moment [2].

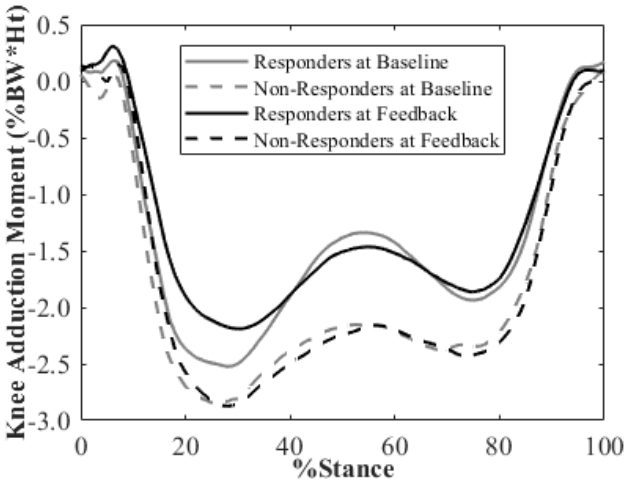

Figure 3: The average knee adduction moment at Baseline and Feedback across those who succeeded (responders) and failed (non-responders) to reduce knee adduction moment using pressure-based feedback.

At Baseline, responders showed longer stride length than non-responders (1.31 m > 1.13 m; t(13) = -2.13, p = 0.053). At Feedback, responders reduced stride length by 3.2% (0.41 m, p =0.001) (**Fig 4**) and increased cadence by 5.6% (3.13 step/min, p = 0.014). Reduced speed (8.9%, 0.11 m/s, p = 0.003) was also found in responders; however, there was no relationship between the reduction in speed and the reduction in knee adduction moment (r = 0.263, p = 0.464). In contrast, non-responders increased stride length by 9.7% (0.10 m, p = 0.336) without a significant change in cadence or speed at Feedback.

DISCUSSION

Two thirds of the OA subjects were able to follow auditory cues and lower their knee adduction moment within the 30-40 min training. According to Bernoulli statistics, it is unlikely that this happened by chance. A recent study revealed that stride length and cadence can have an impact on knee joint moments [2]. Starting with longer stride length, the responders might have more room of improvement, but by adjusting stride length a majority of the subjects with knee OA redistributed knee loads using pressure-based feedback.

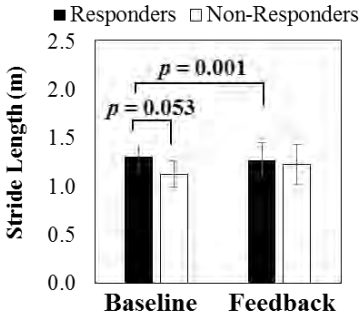

Figure 4: The responders who reduced knee adduction moment significantly reduced stride length after gait retraining using pressure-based feedback.

CONCLUSIONS

Pressure-based feedback was effective for a majority of subjects with medial knee OA to redistribute knee loads in the beginning of the clinical trial. How these subjects responded to pressure-based feedback to reduce knee adduction moment awaits more analyses. Difference in stride length at baseline and change in stride length and cadence that reflect a potential change in speed-regulating strategy post-training should deserve more attention when evaluating knee moments.

INTRODUCTION

Current clinical assessment and diagnostic imaging techniques are unable to capture dynamic, three-dimensional (3D) motion of the spine at the segmental level. Understanding motion at the segmental level may help to better inform diagnosis, prognosis, and treatment for those with various musculoskeletal conditions. Biplane fluoroscopic imaging is a non-invasive and valid technique for quantifying 3D, dynamic bone motion at a segmental level in the spine [1,2]. Despite this technology being validated in other laboratory environments, it is important to validate each individual system's accuracy due to the complexity and customization of this developing technology. Moreover, because of the nature of radiographic imaging, the potential risk of radiation exposure must be balanced appropriately with the accuracy of the system, making the need for verification of each system's accuracy even more essential. Additionally, processing biplane fluoroscopic images into meaningful osteokinematic output (shape-matching) is manual and exceedingly labor-intensive with individual labs developing proprietary code to automate the process [1-3].

The purpose of this study was to validate our lab's biplane fluoroscopic system against the gold standard of radiostereometric analysis (RSA) for cervical spine kinematics using a custom, automated algorithm for shape-matching a cadaveric specimen.

METHODS

Data Collection

A fresh-frozen cadaveric specimen (male, 55 years of age), fully intact from the pelvis superiorly, was obtained for collection. Four tantalum beads were implanted into each of the anterior vertebral bodies of the cervical spine (C4-C6). Computed tomography (CT) images were obtained (Siemens Somaton Sensation 64; Germany; 120 kVp; voxel size: 0.23×0.23×0.60mm) from which bead centroids were identified and 3D bone models were reconstructed at each level (Mimics; Materialise, MI, USA). Anatomic-coordinates were labeled in Mimics: anterior, superior vertebral body and left and right lateral, superior vertebral notches (Figure 1). Bead traces were masked in the bone volumes to avoid shape-matching bias (ImageJ, NIH, MD, USA).

The specimen was thawed and dynamic fluoroscopic imaging was collected with our custom biplane system (Imaging Systems and Services Inc., OH, USA) using a long-handled apparatus to passively simulate neck motion from extension to flexion and from right to left lateral bending. The biplane system utilizes two 16″ image intensifiers (Thales 9447 QX; North American Imaging, OH, USA) and two high-speed cameras (Xcitex ProCapture, MA, USA). Figure 1 illustrates the system configuration with a 55-degree interbeam angle with one system parallel to the horizontal (flexion: lateral; bending: oblique) and the other oriented eight degrees above the horizontal inferior to superior (flexion and bending: oblique). Source-to-Image Distance (SID) was 152cm and the technique for acquisition was 70-74kV, 250-320mA, 3.5ms, 60Hz with a radiographic, wedge filter used for all trials (Ferlic Filter Co. LLC., MN, USA).

Data Analysis

Fluoroscopic images were undistorted, calibrated and dynamic bead positions were tracked for all visible frames using RSA (XMALab, Brown University, RI, USA). Prior to analysis all data were filtered with a low-pass, 4th order Butterworth Filter with a 3 Hz cutoff frequency [2]. To facilitate the automated shape-matching process, the position of

each vertebra (C4-C6) was manually set for the initial frame. All subsequent frames were tracked using an automated shape-matching algorithm, which incorporates a standard ray casting approach to generate digitally reconstructed radiographs (DRRs) and a 2D-3D image registration algorithm (Nelder-Mead Simplex optimization) which maximizes a correlation similarity measure to shape-match the DRR's onto the biplane radiographic projections (MATLAB, R2016B, The MathWorks, Inc., MA, USA). Three trials of flexion (565 total frames) and three trials of lateral bending (520 total frames) were analyzed. Output of the automated shape-matching algorithm was compared directly to RSA for rotations and translations at C4-C6 and for intersegmental kinematics (C4/C5, C5/C6). Bias, precision, and root mean square error (RMSE) were calculated at each level, averaged across all levels for that trial, then averaged across all three trials for each motion.

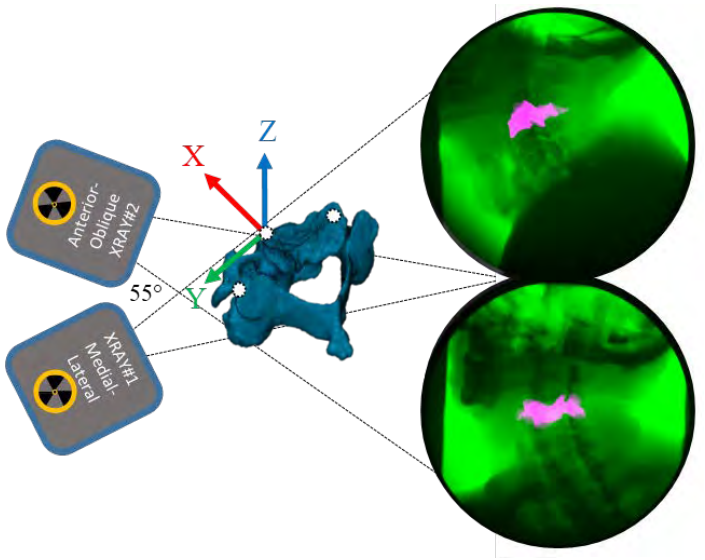

Figure 1: Biplane fluoroscopic set-up for flexion motion with reconstructed C4 CT bone model inset with local coordinate system and anatomic landmarks (white).

RESULTS AND DISCUSSION

Results of bias, precision, and RMSE calculations are displayed in Table 1. Briefly, average segmental RMSE for all levels (C4, C5, C6) of flexion trials was 0.78° rotation and 0.30 mm translation and average intersegmental RMSE (C4/C5, C5/C6) was 1.13° rotation and 0.33 mm translation. Average RMSE for all levels (C4, C5, C6) of lateral bending trials was 0.61° rotation and 0.21 mm translation and average intersegmental RMSE (C4/C5, C5/C6) was 0.85° rotation and 0.31mm translation. Rotations about the Y-axis (flexion/extension) demonstrated the greatest amount of error for both motions. Total RMSE was found to be below 1.70° degrees (rotation) and 0.50 mm (translation). Bias and precision values were similar to previously published works [1-3].

CONCLUSIONS

The results of this study demonstrate the appropriate accuracy of our biplane system, fluoroscopic technique, and the utility of an automated shape-matching algorithm for cervical motion analysis.

THE EFFECT OF SCAPULOTHORACIC UPWARD ROTATION ON SUBACROMIAL PROXIMITIES

[1] Rebekah L. Lawrence and [1] Paula M. Ludewig
[1] Department of Rehabilitation Medicine, University of Minnesota, Minneapolis, MN, USA
email: lawre354@umn.edu

INTRODUCTION

Rotator cuff pathology is a prevalent finding on magnetic resonance (MR) images in individuals with shoulder pain. Subacromial rotator cuff compression has long been thought to be a primary mechanism of rotator cuff injury. Clinical theory suggests decreased scapulothoracic upward rotation (ST UR) increases risk for subacromial rotator cuff compression as it positions the acromion downward and presumably in closer proximity to the rotator cuff tendons. However, this clinical theory has not been fully tested *in vivo*. Therefore, the purpose of this study was to determine the impact of decreased ST UR on subacromial proximities.

METHODS

Sixty subjects were recruited to participate in this study. Of these, 30 had current shoulder symptoms consistent with a clinical diagnosis of "impingement syndrome" (32.4 ± 8.8 years, 46.7% male, 40% tested on dominant side) and 30 had no prior history of shoulder pain (32.7 ± 8.3 years, 46.7% male, 40% tested on dominant side).

Subjects underwent kinematic motion analysis using single plane fluoroscopy synced to a five-camera motion capture system. The camera system was used to track thorax motion, while the fluoroscopy was used to track humeral and scapular motion. Data was collected while subjects performed arm raising in the scapular plane. MR scans were also acquired, which was used to create 3D anatomical models of the humerus and scapula. Scapulothoracic and glenohumeral kinematics were tracked via manual 2D/3D image registration in JointTrack software. Kinematics were described using published recommendations [1, 2]. Subjects were ranked based on their magnitude of ST UR at 30° humerothoracic elevation, which corresponds to the range of closest subacromial proximities [3]. The 20 participants with the highest ST UR were classified as having "high" ST UR, while the 20 participants with the lowest ST UR were classified as having "low" ST UR. Classification in this manner allowed for the effect of ST UR on subacromial proximities to be tested directly. Demographic data for these subjects are provided in Table 1.

Table 1: Demographic Data for High and Low ST UR Groups (mean ± SD, or %)

	High (n=20)	**Low (n=20)**	**p-value**
Age (years)	30.7 ± 5.2	34.1 ± 10.1	0.20
Gender (% male)	25%	65%	0.01
Group (% asymptomatic)	45%	40%	0.75
Rotator cuff tendon thickness (mm)	5.5 ± 1.2	5.7 ± 0.9	0.59

The thickness of the rotator cuff tendon was measured at the articular margin on each subject's MR scan on the slice corresponding to the anterior/posterior midpoint of the tendon insertion. A plane was fit between the coracoid and acromion representing the coracoacromial ligament according to published anatomical descriptions [4].

Each subject's arm raising task was re-created by animating their humeral and scapular models using their glenohumeral kinematics. Subacromial proximities were quantified at 10° intervals of humerothoracic elevation by calculating the minimum distance between each pairwise set of vertices on the coracoacromial arch (i.e. acromion and the plane representing the coracoacromial ligament) and along the articular margin (**Fig. 1**). The minimum distance measures were constrained to the articular margin coinciding to where the rotator cuff thickness was obtained because the thickness cannot be assumed constant across the surface of the insertion site. All minimum distances were normalized to the subject's rotator cuff thickness value, which facilitated interpretation. For each

subject, the humerothoracic elevation position at which the normalized minimum distance was smallest was defined as the position of absolute minimum distance. Contact between the rotator cuff and coracoacromial arch was defined as a normalized minimum distance of <120%. This threshold accounts for approximately 1 mm of error in quantifying the minimum distance due to errors during 2D/3D image registration.

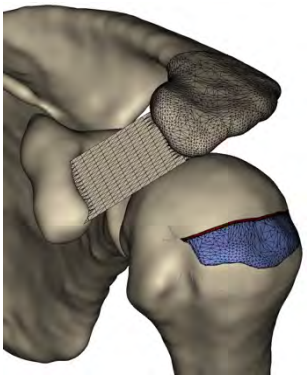

Figure 1: Definition of: 1) rotator cuff insertion (blue surface); 2) Articular surface region of interest (maroon line); and 3) coracoacromial ligament.

Data normality was tested prior to statistical analysis. The normalized minimum distance was skewed and subsequently log transformed for statistical analysis. The effect of ST UR on subacromial proximities was assessed using a two-factor mixed-model ANOVA with Toeplitz covariance structure. The model included a between-subject factor of group (low, high) and a within-subject factor of angle (arm at side, 30°, 60°, 90°). Follow-ups were calculated using Tukey adjustments. The position of absolute minimum distance was compared between groups using a two-sample independent t-test. The frequency of contact between the tendon was tested between groups using Chi-square analysis.

RESULTS AND DISCUSSION

Consistent with group assignment, the subjects in the low ST UR group had on average 11.9° less UR at 30° humerothoracic elevation than the subjects in the high ST UR group. In both groups, the normalized minimum distance was generally smallest below 90° humerothoracic elevation. There was a significant group-by-angle interaction, suggesting the difference between ST UR groups was dependent on the angle of humerothoracic elevation (p=0.047) (**Fig. 2**). However, group follow-ups were not significant at any angle of humerothoracic elevation. Although not statistically significant, the normalized minimum distance for the subjects in the low ST UR group was 15.2% lower than those in the high UR group at the minimum position, and 20% higher at the 90° humerothoracic elevation. The rotator cuff was closest to the coracoacromial arch an average of 8° lower in the range of motion in subjects in the low ST UR group. In total, only 38% of subjects had at least one humerothoracic position where the normalized minimum distance was <120% suggesting contact occurred.

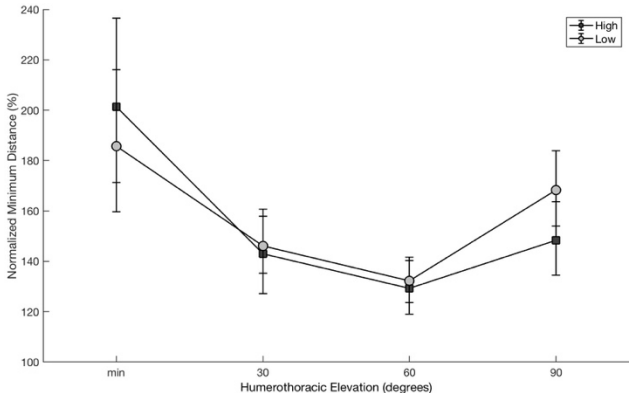

Figure 2: The normalized minimum distance for the high and low ST UR groups across angles of humerothoracic elevation.

CONCLUSIONS

Decreased ST UR shifts the range of risk for subacromial rotator cuff compression to lower angles. However, the clinical meaningfulness of the small magnitude of change in normalized minimum distance is unclear. Subacromial rotator cuff compression occurs in less than 40% of individuals during unweighted, non-fatigued arm raising, suggesting it may not be a predominant mechanism for rotator cuff injury.

Changes in Hip Mechanics During Gait Modification to Reduce Knee Adduction Moment

INTRODUCTION

First peak internal knee abduction moment (PKabdM) has been associated with knee osteoarthritis (OA) progression [1]. Gait modification strategies using real-time biofeedback (RTB) including lateral trunk lean (TL), medial knee thrust (MKT), and decreased foot progression angle (FPA) have reduced PKabdM in both healthy and OA populations [2]. Despite the success of these interventions in reducing PKabdM, the potential biomechanical effects on the kinetic chain remain poorly understood [3]. There is evidence suggesting that PKabdM partially depends on the magnitude of hip abduction moment [4, 5]. Greater internal hip abduction moment has been shown to be protective of medial knee OA development, reducing the odds of OA progression 50% for every additional unit of hip abduction moment [6]. Previous authors have suggested that increased hip abductor strength can be beneficial in controlling knee joint loads which is supported by reduction of knee OA symptoms after a hip strengthening intervention [7]. However, limited evidence suggests that common strategies to reduce PKabdM can reduce hip abduction moment [8]. Therefore, the purpose of this study was to investigate biomechanical changes at the hip during three previously studied gait modifications designed to reduce PKabdM.

METHODS

Twenty healthy individuals volunteered for this study (28.4 ± 3.8 years, 1.73 ± 0.1 m, 75.3 ± 12.5 kg). Mean and standard deviation (SD) for trunk angle, knee angle, and foot angle during stance was calculated from ten baseline trials using eight high-speed motion analysis cameras and four floor embedded force plates. Gait trials were conducted on a 6m long walkway with the last 2.4 meters containing the force plates. Trials were only valid with two full foot contacts of the experimental limb on the force plates and gait speed within ±5% of baseline speed. Five trials were completed for each gait strategy using RTB so that joint angles fell within a range of 3-5 SD greater than (FPA and TL) or less than (MKT) baseline. Visual 3D was used to project RTB on a 4.8m by 3.3m projection wall facing the walkway as a line graph displaying real-time joint angle during stance. Participants were instructed to modify their gait so that the line fell within a highlighted bandwidth representing the target ranges. Visual 3D was used to calculate joint angles (°) and internal moments (Nm/kgm) measured at PKabdM. Although, external joint moments are most commonly reported in knee OA literature, internal moments are equal but opposite. Repeated measures ANOVA was used to assess differences in hip moments and angles between conditions. Pairwise comparisons were conducted to compare changes between baseline walking and modification strategies ($p<0.05$).

RESULTS AND DISCUSSION

On average PKabdM was reduced in all strategies from baseline, however, significance was only reached for FPA ($p<0.05$) and MKT gait ($p<0.01$; Table 1). Compared to baseline, participants significantly reduced frontal plane hip angle during TL gait ($p<0.01$) and sagittal plane hip angle across all strategies ($p<0.01$; Table 1). Hip abduction moment was significantly decreased during TL and MKT gait compared to baseline ($p<0.01$) while hip extension moment was unchanged (Table 1). During TL gait participants walked with a more abducted and flexed hip and demonstrated decreased hip abduction moment at PKabdM (Figure 1).

Previous studies have shown that hip abduction moments are greater in patients with less severe medial compartment knee OA [4, 5, 6].

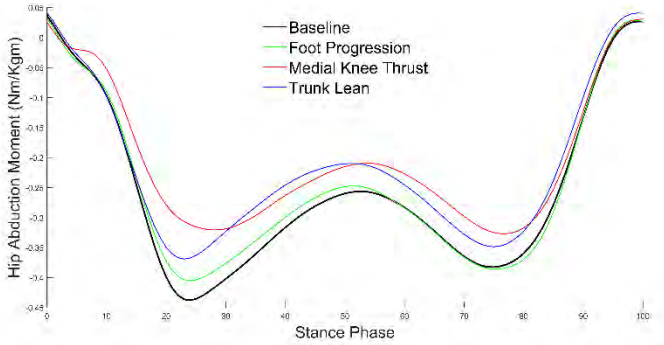

Figure 1: Mean hip abduction moment (Nm/kgm) across the stance phase.

A common gait strategy adopted by knee OA patients includes shifting the center of mass (COM) towards the involved limb while moving the trunk laterally [4]. This compensatory mechanism is similar to the TL strategy used in this study and has shown success in reducing medial knee joint load by shifting the GRF vector laterally, decreasing the magnitude of the moment arm [4].

Patients with more severe OA, however, may lack the hip abductor strength to maintain this altered trunk position during stance causing excessive pelvic drop in the contralateral leg. This shifts the COM away from the stance leg, increasing the PKabdM and subsequent medial compartment joint load [4, 6]. Even in patients with the prerequisite hip strength, this strategy may not be beneficial in the long-term as it decreases demand on the hip, weakening the musculature. This reduces the ability of the muscles to regulate medial/lateral knee load distribution, decreasing frontal plane stability [6]. Similar to TL gait, MKT gait resulted in participants walking with a more flexed hip and reduced hip abduction moment at PKabdM (Figure 1). The mechanism between the two strategies was similar; increased hip and knee abduction angle with reduced peak hip abduction moment potentially due to the shift of the COM closer to the joint centers.

CONCLUSIONS

Gait modifications designed to reduce PKabdM significantly changes hip mechanics in healthy individuals. TL and MKT strategies resulted in reduced hip abduction moment at PKabdM which may be detrimental to patients with more advanced knee OA. Therefore, future studies investigating gait modifications designed to slow the progression of OA should consider the effects on hip as well as knee mechanics.

COMPARISON OF JOINT KINETICS USING COMMON MODELS FOR BASEBALL PITCHING

Michael P. McNally, James A. Oñate, Ajit M.W. Chaudhari

The Ohio State University, Columbus, OH, USA
email: Michael.mcnally@osumc.edu

INTRODUCTION

Biomechanical analyses are more frequently being utilized to aid in achieving improved baseball pitching performance while minimizing joint loads on the body. Increased potential for injury at the shoulder and elbow have been associated with certain kinetic risk factors, which are calculated using standard inverse dynamics from a known force applied by the ball [1]. However, because of the complexity in measuring the pitching motion, different underlying modeling approaches have been used with varying constraints. In particular, three common models have been used in research, and are suggested for use in clinical throwing analysis, which include a 6 degree of freedom model (6DOF), an optimized model using inverse kinematics (IK), and a model that does not allow intersegmental translations (ASMI) [2]. Understanding the differences between these models is critical for understanding the biomechanics of the pitching motion, and how to interpret data relative to normative data expressed in the literature.

The purpose of this study was to determine the relationships between joint kinetic parameters as estimated by three different biomechanical models for baseball pitching, both in the absolute estimates as well as in the relative predictions of which individuals have elevated loading. We hypothesize that differences will exist in absolute joint kinetics between models, but that kinetic parameters will be correlated between models.

METHODS

15 right-handed male baseball pitchers from high school (n = 8), collegiate (n = 4), and professional (n = 3) baseball, who all learned to play in the United States, were analyzed for this study as part of an overarching study (age = 19.2±4.9 years, height = 1.85±0.06 m, mass = 83.5±12.1 kg, hand velocity = 23.6±1.38 m/s). After performing a self-selected warm-up, pitchers were recorded using an optical motion capture system (Vicon Inc., Oxford, UK) capturing at 300 Hz while throwing five fastballs from an instrumented pitcher's mound [3] at "game like effort" towards a target placed approximately 13m away. The first three pitches which contained complete marker data for the upper extremity were analyzed for each pitcher.

All analyses were performed using Visual3D software (C-Motion Inc., Germantown, MD, USA). Marker trajectories were filtered using a low-pass Butterworth filter with a cutoff frequency of 13.4 Hz [2]. Shoulder and elbow kinematics and kinetics were calculated in the global reference frame, and reported using 3 different methods. The first method utilized a 6 degree of freedom model, defined using recommendations of upper extremity kinematics described by the International Society of Biomechanics [4], and tracked each segment allowing full translation and rotation in all planes for each segment (6DOF model) [5]. The second method defined the upper extremity and the resulting kinematics and kinetics using the same ISB model, but utilized a global optimization technique to eliminate any translation at the wrist and elbow joint, varus/valgus motion at the elbow, and rotation at the wrist (IK model) [6]. The third method defines the distal end of the proximal segment and the proximal end of the distal segment to be coincident at the shoulder, elbow and wrist, thereby eliminating translations. It constrains the shoulder reference frame using the cross product of the long axis of the arm and vertical axis of the trunk to define the anterior axis, and the elbow reference frame using the cross product of the long axis of the forearm and long axis of the upper arm to define the anterior axis (ASMI model) [2]. As one of the critical instants, maximum shoulder external rotation (MER) was calculated as the point

when the shoulder is maximally externally rotated relative to the trunk.

Four kinetic variables were calculated using each method based on evidence suggesting a relationship to shoulder or elbow injury risk. Specific variables included peak elbow varus torque and elbow varus torque at MER, internal rotation torque at MER, and peak shoulder distraction force. A one-way ANOVA was used to detect a main effect of model for each kinetic variable, with Tukey's post hoc analysis to determine individual differences for any main effects. All variables were confirmed to be normally distributed, so Pearson correlation coefficients were calculated to determine the relationship in kinetic calculations between models. Significance for all statistical tests was set *a priori* at $p < 0.05$.

RESULTS AND DISCUSSION

Descriptive statistics and a summary of ANOVA's are listed in Table 1. Main effects of model were identified for all kinetic variables ($p < 0.001$). Peak elbow varus torque was significantly greater for IK and ASMI models compared to 6DOF ($p < 0.001$). Elbow varus torque at MER was different between all methods, with ASMI model estimating greater torque at MER than 6 DOF, which is greater than IK ($p < 0.001$). Shoulder internal rotation torque at MER was greater for IK and ASMI compared to 6DOF, and peak shoulder distraction force is greater for 6DOF and IK compared to ASMI ($p < 0.001$).

Elbow varus torque showed moderately strong correlations between methods (R = 0.696-0.777). Elbow torque at MER was moderately correlated between 6DOF and IK (R=0.541) and between 6DOF and ASMI (R=0.631), with no association between IK and ASMI models (R=0.078). Shoulder internal rotation torque at MER was weakly correlated (R=0.283-0.514), while peak shoulder distraction force showed only a strong correlation between 6DOF and IK, with no association between 6DOF and ASMI (R=0.137) and IK and ASMI (R=0.140).

While this research cannot differentiate which model is most accurate, it does suggest that results may not be generalizable between models, often making conclusions from research dependent on the model used. These differences are likely a result of both differing constraints and definitions of anatomical reference frames, as well as any resulting differences in the timing of MER using each method. When evaluating research or conducting performance evaluations on pitching, clinicians need to match the model they use to the available literature and normative values, otherwise inaccurate conclusions may be reached. Further study may help to better assess the validity and reliability of each model as it pertains to the pitching motion, identifying pitchers at risk, and in assessing interventions to improve performance while minimizing risk.

INTRODUCTION

Occupational injuries are commonly observed among the workers involved in material handling tasks such as lifting. An important criterion to identify the non-ergonomic lifting task is the net force and moment values at L5/S1 joint. These values are mainly calculated in a laboratory environment, which utilizes marker-based motion capture systems and force plates. However, this method is usually a time-consuming process and needs expensive equipment. In this study, we propose and validate a novel marker-less method for L5/S1 joint load estimation, which address aforementioned limitations. The proposed method uses computer vision approaches, in particular Deep Neural Network (DNN), to estimate the 3D body pose from multi-view images and calculate the joint loads by an inverse dynamic algorithm. The results of our proposed method are compared with results obtained from a marker-based system as a reference and it is shown that the proposed method achieves promising results.

METHODS

Participants and Procedure. A group of 12 healthy males (age 47.50±11.30 years; height 1.74±0.07 m; weight 84.50±12.70 kg) participated in the experiment. Each participant performed various lifting trials in a laboratory while being filmed by two camcorders (positioned at 90 degree and 135 degree views) and a synchronized motion tracking system to measure the body movement. They lifted a plastic crate weighing 10 kg and placed it on a shelf without moving their feet. Each subject performed three vertical lifting heights (floor to knuckle, knuckle to shoulder, and floor to shoulder) combined with three end-of-lift angles (0, 30 and 60 degree). Lifting trials of subjects 1 to 10 were used as training dataset and subjects 11 and 12 were used for testing.

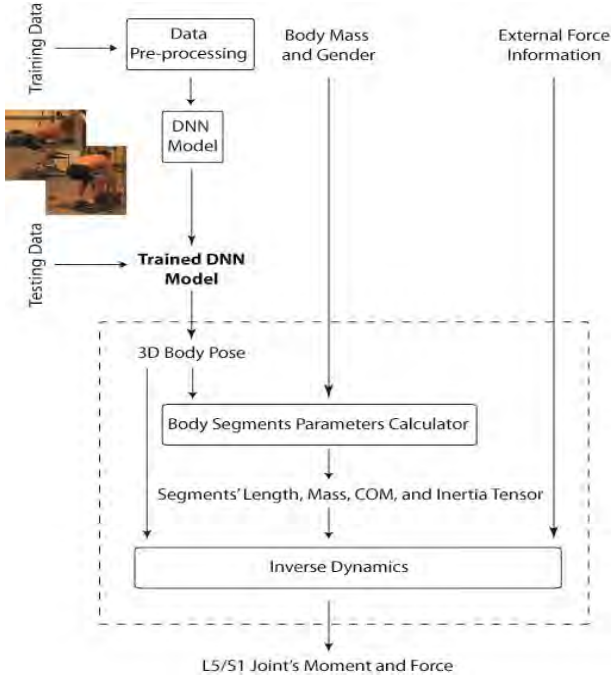

Figure 1: Workflow of the proposed DNN based method.

Methods. In this work, we aim to predict the 3D L5/S1 joint kinetic from a multi-view RGB image. As shown in figure 1, in the offline phase, the training dataset images are preprocessed and used to train a DNN model. In the online phase, given a new multi-view image (testing dataset), the trained DNN estimates its corresponding 3D body pose. The network architecture of the DNN model comprises of encoder and decoder. The encoder processes the input image with convolution and pooling layers to generate low resolution feature maps and the decoder processes low resolution feature maps with up-sampling and convolution layers to construct 2D joints coordination maps. The constructed 2D joints maps for each view are concatenated together and are processed more by another encoder. The neural network is ended with a fully connected output layer, which output the 3D coordination of each joint.

Next, the estimated 3D body pose along with the subject's anthropometric information are utilized to calculate body segments parameters including segments length, mass, position of the center of mass (COM), and inertia tensor based on the suggested values by [1].

Finally, L5/S1 joint kinetic is determined by a top-down inverse dynamic algorithm according to the estimated 3D body pose, body segments parameters and external force information. We applied a global equation of motion to estimate the net L5/S1 joint kinetic, as described by [2].

RESULTS AND DISCUSSION

L5/S1 Joint Moment. Results show a good agreement between the estimated L5/S1 joint moments in each of the three planes and the references (fig. 2). The grand mean (±SD) of the moment absolute errors across all the subjects and trials was 9.06 (±7.60) Nm. The R coefficient for all the lifting trials were high (above 0.94) and RMSE were small (mostly below 20 Nm).

Furthermore, Absolute peak values extracted from the moment time series of the proposed method were compared to the corresponding values of the reference across the whole lifting trials. In line with the small RMSE (6.14 Nm) and high R coefficient value (0.96), t-test showed no significant differences between the reference and the proposed method.

L5/S1 Joint Force. For all of the lifting trials, the correspondence between 3D L5/S1 joint force obtained from the reference and estimated from the proposed method was good with R values mostly above 0.90 and RMS mostly below 10 N (fig. 2). The grand mean (±SD) of the force absolute errors across all the subjects and trials was 4.85 (±4.85) N.

Absolute peak values extracted from force time series of the proposed method were also compared to the corresponding values of the reference across the whole lifting trials. In line with a small RMSE value (4.45 N) and high R coefficient value (0.99), t-test showed no significant differences between the reference and the proposed method.

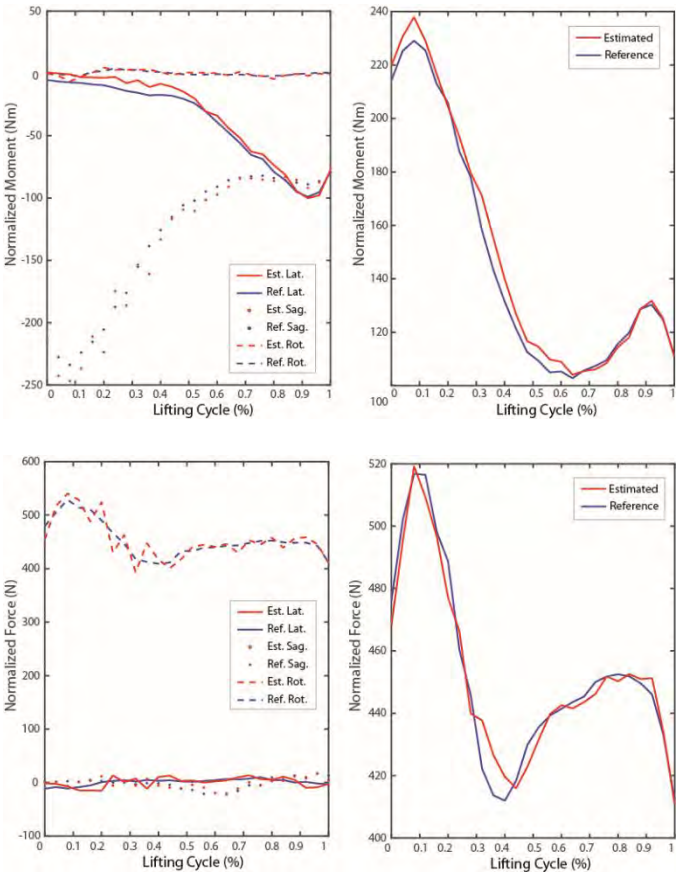

Figure 2: Estimated versus reference L5/S1 joint moment (top row) and L5/S1 joint force (bottom row) for floor-to-knuckle-height and 60 degree end-of-lift angle lifting trial. The total moment/force is the vector summation of the L5/S1 moments/forces at each three planes (right).

CONCLUSIONS

This study demonstrates the applicability of deep learning techniques in the context of biomechanical analysis and can provide a reliable tool for detecting the risk of lower back injuries during occupational lifting.

GAIT ASYMMETRIES 6 MONTHS POST-ACLR ASSOCIATE WITH INTER-LIMB T1ρ RATIOS 12 MONTHS POST ACLR

[1]Steven J. Pfeiffer, [1]Jeffrey Spang, [1]Daniel Nissman, [1,2]David Lalush, [1]Kyle Wallace, [3]Matthew S. Harkey, [1]Laura Stanley, [4]Randy Schmitz, [1]Troy Blackburn, [1]Brian Pietrosimone

INTRODUCTION

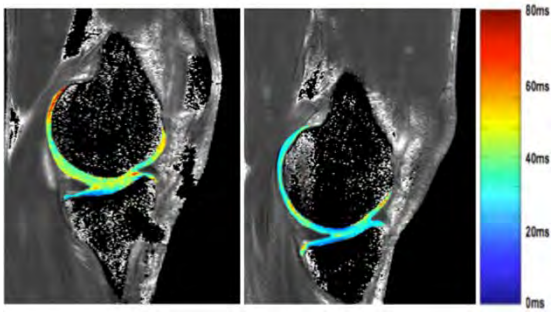
Individuals who sustain an anterior cruciate ligament injury and reconstruction (ACLR) are at heightened risk for posttraumatic knee osteoarthritis (PTOA).[1] The progression to PTOA following ACLR is theorized to result from an interaction between aberrant joint biomechanics during walking and deleterious biological changes to the knee cartilage.[2] Alterations in proteoglycan density within the cartilage matrix are hypothesized to be one of the initial cartilage changes that may be related to PTOA development.[3] T1ρ magnetic resonance imaging (MRI) relaxation times are sensitive to proteoglycan density changes and are elevated, indicating worse proteoglycan density, as early as one year post-ACLR.[4] The purpose of this study was to determine the associations between limb symmetry indices (LSI) for gait biomechanics measured six months post-ACLR and femoral T1ρ relaxation times twelve months post-ACLR. We hypothesized individuals with lesser loading of the ACLR limb six months following ACLR would demonstrate greater T1ρ MRI relaxation times on the ACLR limb twelve months following surgery.

METHODS

Twenty-four individuals (50% female, 21.92 ± 3.61 years old, 178.13 ± 11.30 cm, 75.35 ± 12.60 kg) with a unilateral bone-patellar-bone autograft ACLR participated in this study. Walking biomechanics [peak vertical ground reaction force (vGRF), vGRF loading rate (vGRF-LR), and peak internal knee extension moment (KEM)] were extracted from the first 50% of stance phase in both limbs during five trials of walking at self-selected speed six months following ACLR. LSI were used to normalize the biomechanical outcomes of the ACLR limb to the uninjured limb (ACLR Limb / Uninjured limb). Peak vGRF (BW) and vGRF-LR (BW/s) were normalized to body weight. vGRF-LR was calculated as the peak of the first derivative of the force-time curve. KEM was calculated using an inverse dynamics approach and was normalized to the product of body weight and height (BW*m). KEM was expressed as an internal moment and a negative value.

A 3-Tesla scanner was used to acquire images following 30 minutes of unloading the knee joint. T1ρ relaxation times were calculated (Figure 1) for the medial and lateral femoral condyles (MFC & LFC) using a five-image sequence created with a MatLab program with the following equation: $S(TSL) = S0 \exp(-TSL/T1\rho)$ where TSL is the duration of the spin-lock time, S0 is signal intensity when TSL equals zero, S corresponds to signal intensity, and T1ρ is the T1 relaxation time in the rotating frame. Prior to segmentation, affine and non-rigid deformable registration techniques were utilized to align the ACLR limb to the uninjured limb. The weight bearing portions of the cartilage of the MFC and LFC was manually segmented into posterior, central, and anterior regions of interest (ROI) based on the location of the meniscus in the sagittal plane.[5] Inter-limb T1ρ relaxation time ratios (T1ρ ILR = ACLR limb T1ρ / uninjured limb T1ρ) were calculated for each ROI.

Figure 1: Representative map of T1ρ relaxation times of an ACLR (L) and contralateral (R) knee.



Separate, stepwise linear regressions were used to determine the unique associations between knee biomechanical outcomes and ILR for each ROI (ΔR^2, β, $P \leq 0.05$). Self-selected gait speed and the presence of a meniscal injury may influence T1ρ MRI relaxation times following ACLR. Therefore, these variables were entered into the regression model first followed by the biomechanical variable of interest. The presence of a medial or lateral meniscal injury was entered when specifically evaluating ILR of cartilage in either the medial or lateral compartment, respectively.

RESULTS

Lesser peak vGRF LSI six months following ACLR significantly associated with greater Posterior-LFC T1ρ ILR (ΔR^2=0.20, β=-0.48, P=0.04) twelve months following ACLR. Similarly, lesser peak vGRF-LR LSI six months following ACLR significantly associated with greater Posterior-MFC T1ρ ILR (ΔR^2=0.19, β=-0.45, P=0.05) twelve months following ACLR. Additionally, lesser peak KEM LSI six months following ACLR significantly associated with greater Central-MFC T1ρ ILR (ΔR^2=0.19, β=0.46, P=0.04) twelve months following ACLR.

DISCUSSION

Consistent with our hypothesis, individuals with lesser peak vGRF LSI, vGRF-LR LSI, and peak internal KEM LSI during walking six months following ACLR, demonstrated greater T1ρ ILR in the medial and lateral femoral condyles. These findings suggest that lesser mechanical loading of the ACLR limb compared to the uninjured limb early (i.e. 6 months) following ACLR may be related to deleterious changes in proteoglycan density of the ACLR limb compared to the uninjured limb at a later time point following ACLR (i.e. 12 months).

Both excessive and insufficient mechanical loading of the knee can lead to breakdown of tibiofemoral cartilage within the joint. Recent evidence[6,7] has demonstrated that excessive mechanical loading during walking early following ACLR associates with increased T1ρ relaxation times at early and later time points following ACLR. The findings of the current study are contrary to these studies but are consistent with previous findings demonstrating that lesser mechanical loading during walking following ACLR associates with changes in cartilage metabolism,[8] structure,[9] and future PTOA development.[10] Future work is needed to further understand the association between joint loading and deleterious changes to joint tissue metabolism following knee joint injury in order to develop interventions to optimally load the joint for the purpose of improving long-term joint health.

CONCLUSIONS

The findings of the current study illustrate that mechanical loading, specifically lesser loading, between limbs during walking early following ACLR may be related to deleterious changes of the cartilage matrix at later time points following ACLR, which may be related to the development of future PTOA. These findings illustrate the need for establishing optimal mechanical loading patterns during walking early in the rehabilitation process.

RUNNING-SPECIFIC PROSTHETIC MODEL AFFECTS TOP SPRINTING SPEED IN ATHLETES WITH UNILATERAL TRANSTIBIAL AMPUTATIONS

INTRODUCTION

Running-specific prostheses (RSPs), which are made of carbon fiber and passive-elastic, enable athletes with transtibial amputations (TTAs) to compete in running events. The stiffness and height of RSPs can be adjusted and likely affects users' performance. Additionally, RSP models are either C-shaped or J-shaped. C-shaped RSPs are attached beneath the socket and typically used for distance running, while J-shaped RSPs are attached posterior to the socket and more commonly recommended for sprinting. Despite the different attachments, both types of RSPs act in-series to the residual limb.

Faster sprinting speeds are achieved by applying greater average vertical ground reaction forces (vGRFs) to the ground during briefer contact times (t_c) for non-amputees [1]. However, athletes with unilateral TTAs who use an RSP have lower peak and stance average vGRFs for their affected leg (AL) than their unaffected leg (UL) [2], resulting in asymmetric forces between legs. Further, the use of a taller RSP results in more asymmetric peak vGRFs, which suggests that taller RSPs could prohibit faster sprinting speeds [3]. The purpose of our study was to quantify how RSP model, stiffness, and height affect top sprinting speed, stance average vGRF, and t_c in athletes with a unilateral TTA. We hypothesized that RSP model, stiffness, and height would affect top sprinting speed. We also hypothesized that stance average vGRF and t_c would be greater and shorter, respectively, and more symmetric using the optimal RSP configuration.

METHODS

Ten athletes with a unilateral TTA (7 M, 3 F; mean ± s.d. age: 28 ± 5 yr, mass: 76.0 ± 12.4 kg, height: 1.77 ± 0.12 m) gave written informed consent according to the COMIRB and USAMRMC Human Research Protection Office prior to participation. Each subject performed sets of running trials consisting of at least 10 strides per trial at a given speed on a 3D force measuring treadmill (Treadmetrix, Park City, UT). Each set of trials began at 3 m/s, rest was provided between trials, and each successive trial incremented treadmill speed by 1 m/s until the athlete approached top speed, when smaller speed increments were used. For each set of trials, subjects used 15 different combinations of RSP model, stiffness, and height. Models included the Freedom Innovations Catapult FX6 (FDM), Ottobock 1E90 Sprinter (OBK), and Össur Cheetah Xtend (OSR). FDM is C-shaped, while OBK and OSR are J-shaped. Stiffness conditions were the manufacturer recommended category (based on body mass) and ±1 stiffness categories. Height conditions were prosthetist-recommended and ±2 cm. For each model, height was only adjusted for the stiffness category that enabled the fastest speed.

We measured GRFs at 1000 Hz and filtered them using a 4th order low-pass Butterworth filter (30 Hz). We used these filtered data and a 30 N threshold to calculate stance average vGRF ($vGRF_{StA}$) and t_c for each step. For these variables (var), we calculated the average (AVG) of both legs (AL and UL) and the absolute value of the symmetry index (SI) between legs (Eq. 1):

$$SI = \left|\frac{var_{AL}-var_{UL}}{0.5(var_{AL}+var_{UL})}\right| * 100 \qquad Eq.\ 1$$

We used a linear mixed model to analyze the influence of RSP model, stiffness, and height on top sprinting speed. We used additional linear mixed models to analyze the influence of significant RSP configuration variables (model, stiffness, and/or height) on AVG and SI for the $vGRF_{StA}$ and t_c. We used a significance level of $p<0.05$.

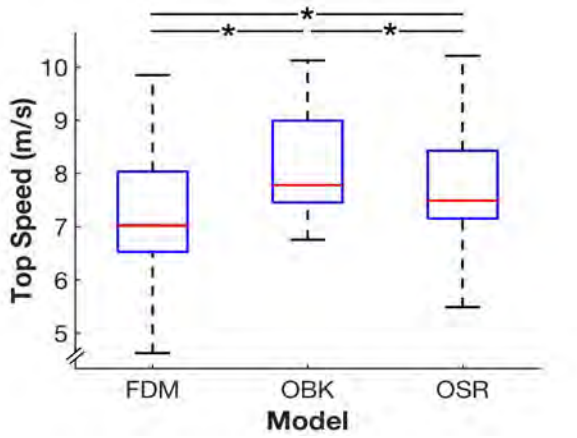

Figure 1: Mean ± s.d. top sprinting speed for each RSP model at all stiffness and height configurations. * indicates a significant difference between models.

RESULTS AND DISCUSSION

Compared to FDM, OBK and OSR resulted in 0.82 m/s ($p<0.0001$) and 0.37 m/s ($p<0.0005$) faster top sprinting speeds, respectively (Fig. 1). Additionally, OBK resulted in 0.46 m/s ($p<0.0005$) faster top sprinting speeds than OSR. Neither stiffness nor height influenced top sprinting speed ($p=0.72$ and $p=0.11$, respectively). There were no significant interactions among model, stiffness, and height for top sprinting speed.

RSP model had a significant effect on AVG and SI $vGRF_{StA}$ (Table 1). When controlling for speed, OBK resulted in 0.040*Body Weight (BW) greater $vGRF_{StA}$ than FDM ($p<0.01$). OSR resulted in 0.040*BW and 0.080*BW greater $vGRF_{StA}$ than OBK and FDM (both $p<0.005$). Additionally, OBK and OSR resulted in 5.1% and 6.7% lower SIs (more symmetric), respectively, for $vGRF_{StA}$ compared to FDM (both $p<0.001$). RSP model also had a significant effect on AVG and SI t_c (Table 1). When controlling for speed, OSR resulted in 0.003 s shorter t_c than both FDM ($p<0.005$) and OBK ($p<0.05$). In addition, OBK resulted in 2.5% and 3.5% higher SI (more asymmetric) for t_c than FDM and OBK, respectively (both $p<0.005$).

CONCLUSIONS

The data partially support our hypothesis that RSP model, stiffness, and height affect top sprinting speed. RSP model, but not stiffness or height, affects top sprinting speed in athletes with unilateral TTAs. Specifically, use of OBK resulted in the fastest top sprinting speed and use of FDM resulted in the slowest top sprinting speed.

We reject our hypothesis that stance average $vGRF_{StA}$ and t_c would be greater and shorter, respectively, using the optimal configuration. OSR resulted in the highest AVG $vGRF_{StA}$ and shortest AVG t_c, but did not elicit the fastest top sprinting speed. We partially reject our hypothesis that $vGRF_{StA}$ and t_c would be more symmetric using the optimal configuration. $vGRF_{StA}$ was more symmetric for OBK and OSR compared to FDM, and also elicited faster top sprinting speeds than FDM, suggesting that $vGRF_{StA}$ is important for top speed. In contrast, t_c was more asymmetric with OBK compared to FDM and OSR. Since OBK elicited the fastest top sprinting speed, this suggests that t_c symmetry may not influence top speed.

The underlying mechanisms for how J-shaped RSP models enable faster top sprinting speeds than a C-shaped RSP model could be due to relatively greater mechanical energy return, wider blades that enable greater stability, or a different alignment with respect to the residual limb [3,4]. Future studies are planned to assess the influence of prosthetic model on joint mechanics during top speed sprinting.

Table 1: Mean ± s.d. top sprinting speed, AVG and SI $vGRF_{StA}$, and AVG and SI t_c for each model.

		FDM	OBK	OSR
Top sprinting speed (m/s)		7.92 ± 1.53	8.78 ± 1.39	8.24 ± 1.42
$vGRF_{StA}$	AVG (BW)	1.88 ± 0.21	1.94 ± 0.19	1.96 ± 0.19
	SI (%)	15.18 ± 9.53	9.34 ± 7.39	8.44 ± 6.31
t_c	AVG (s)	0.13 ± 0.02	0.12 ± 0.02	0.12 ± 0.02
	SI (%)	5.87 ± 4.67	8.67 ± 4.76	5.15 ± 3.71

LONGITUDINAL CHANGES IN CARTILAGE COMPOSITION ARE ASSOCIATED WITH ABNORMAL *IN VIVO* KNEE MECHANICS FOLLOWING ACL RECONSTRUCTION

INTRODUCTION

Residual abnormalities in knee mechanics following ACL reconstruction (ACLR) may contribute to the high incidence of post-traumatic osteoarthritis (PTOA) in this patient population [1]. This theory is supported by *in vivo* studies that report abnormal kinematics in ACLR knees, which would lead to altered cartilage contact patterns [2]. Further, *ex vivo* cartilage testing and animal studies have shown that altered cartilage loading is related to the initiation and progression of PTOA [3]. However, prior studies have been unable to establish a direct link between altered knee mechanics and cartilage degeneration in ACLR knees. Thus, the objectives were (1) to determine bilateral differences in knee mechanics in ACLR patients using dynamic MR imaging, and (2) to investigate a link between altered cartilage contact patterns and signs of cartilage degeneration detected via quantitative MR imaging.

METHODS

We tested six subjects that underwent a primary, unilateral ACLR following completion of post-surgery rehabilitation (time point 1, TP1) (2F, 25.7±8.1 yrs, 14.9±4.2 months post-surgery, 3PT grafts) and at approximately one year after completion of rehabilitation (TP2, 29.7±5.2 months post-surgery). At both time points, bilateral static images were collected and manually segmented to obtain bone and cartilage geometries for the ACLR and contralateral knees. Quantitative MR imaging was then performed on the ACLR knees using an mcDESPOT multi-component T2 mapping sequence to obtain maps of the fraction of water bound to proteoglycan (FBW), with lower FBW representing loss of proteoglycan content in cartilage [4].

Post-rehabilitation (TP1), subjects lay supine in the MR scanner with their lower leg secured to an inertial loading device. They performed cyclic knee flexion-extension at 0.5 Hz, with the device inducing quadriceps loading similar to the weight-acceptance phase of gait. Dynamic 3D MR images were continuously acquired and reconstructed into 60 frames over the motion cycle [5]. Tibiofemoral kinematics and cartilage contact were computed by registering the bone and cartilage geometries to the dynamic images at each frame and measuring cartilage overlap. Contact maps were generated by computing the maximum contact depth across the tibial cartilage during knee extension. The tibial cartilage was divided into regions of interest (ROI). Contact and FBW maps were averaged within ROIs.

A two-factor repeated measures ANOVA (α=0.05) tested for differences in kinematics between ACLR and contralateral knees and across flexion angles (every 2.5°). Separate two-factor repeated measures ANOVAs (α=0.05) tested for differences in contact and changes in FBW. For significant interaction effects (α=0.05), post-hoc Bonferroni comparisons tested for differences across flexion angles (adjusted α=0.004) or ROIs (adjusted α=0.0013). Side-to-side differences (ACLR minus contralateral) in cartilage contact depth and changes in FBW (TP2 minus TP1) were computed across all ROIs for each subject. Geospatial analysis (bivariate local indicator of spatial association, BiLISA) was used to test for correlations between asymmetric cartilage contact and changes in FBW within each ROI (α=0.05) [6].

RESULTS AND DISCUSSION

ACLR knees exhibited abnormal tibiofemoral kinematics relative to contralateral knees (Fig. 1). Specifically, ACLR knees exhibited greater anterior tibial translation, medial tibial translation, and external tibial rotation during extension. We also observed abnormal cartilage contact in ACLR knees with greater contact depth than contralateral knees on both tibial plateaus (Fig. 2A). The greatest contact differences occurred on the posterior aspect of the medial plateau and along the medial tibial spine. We also found longitudinal changes in cartilage

composition in ACLR knees, with a reduced FBW in both plateaus between time points 1 and 2 (medial: TP1 = 22±8.8%, TP2 = 21±11%; lateral: TP1 = 22±8.1%, TP2 = 19±12%) (Fig 2B). The greatest reductions in FBW occurred in the posterior weight-bearing region of the medial plateau and the posterior-medial cartilage on the lateral plateau.

Bilateral differences in cartilage contact were linked to longitudinal reductions in FBW within ACLR knees (Fig. 3). In particular, there were weight bearing regions on both the medial and lateral tibial plateau where significant decreases in FBW were linked to greater contact (i.e. a high-low correlation).

Previous studies found that ACLR knees are externally rotated and medially translated, relative to healthy knees, during functional motion [2]. While we found similar kinematic asymmetries, ACLR knees also exhibited greater anterior tibial translation during knee extension. This may be due, in part, to the open-chain task causing internal kinematics to be more sensitive to changes in the ACL [7].

Many studies have been designed on the premise that a shift in cartilage loading initiates PTOA in ACLR knees [1]. We confirmed this theory by determining that increases in contact were correlated to signs of cartilage degeneration. Additionally, we found reduced contact was linked to degeneration along the lateral tibial spine. While this suggests that unloading of cartilage may also be problematic, it is important

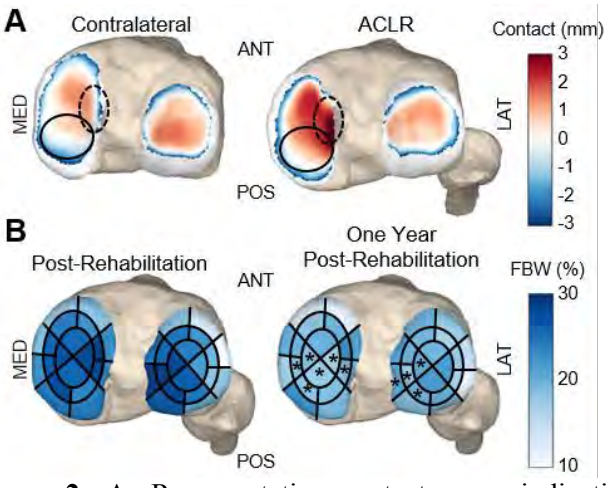

Figure 2: A. Representative contact maps indicating regions with greatest contact differences between ACLR and contralateral knees (ellipses). **B.** Average FBW (%) across all subjects for each ROI at both time points. * = significantly reduced FBW at one year post-rehab.

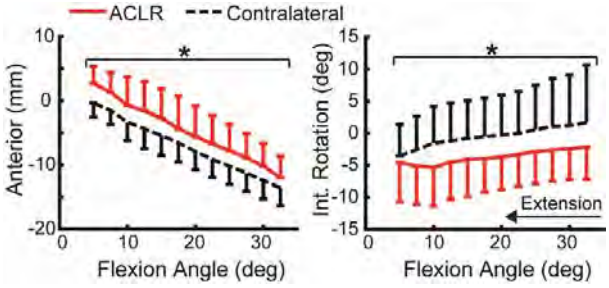

Figure 1: Anterior translation (mean ± SD) and internal rotation of the tibia relative to the femur during knee extension. * = a significant difference between ACLR and contralateral knees across all flexion angles.

to note that additional factors, such as subchondral bone bruising and joint inflammation, may also contribute to PTOA after ACL injury. Further work is needed to assess the sensitivity of the rate of cartilage degeneration to altered knee mechanics to determine the accuracy needed during ACLR.

CONCLUSIONS

This study provides striking evidence of early cartilage degeneration characterized by reductions in FBW one year after completing post-ACLR rehabilitation. Further, we provide evidence of an association between abnormal *in vivo* cartilage loading and cartilage degeneration. Taken together, these results provide evidence that failure to restore normal knee mechanics following ACLR contributes to cartilage degeneration within the knee.

ESTIMATES OF ACHILLES TENDON MOMENT ARM WITH AXIS OF ROTATION DETERMINED FROM ANKLE MOTION VERSUS ANATOMICAL LANDMARKS

[1]Francesca E. Wade, [2]Gregory S. Lewis, and [1]Stephen J. Piazza
[1]The Pennsylvania State University, University Park, PA
[2] Penn State College of Medicine & Milton S. Hershey Medical Center, Hershey, PA
email: piazza@psu.edu web: www.biomechanics.psu.edu

INTRODUCTION

Functional capacity of the ankle joint is influenced by the plantarflexion moment arm of the Achilles tendon (ATma). Experimentally, ATma may be found as the shortest distance from the ankle center of rotation (CoR) to the Achilles tendon line of action on planar magnetic resonance (MR) images [1], or ATma may be determined in three dimensions from MR imaging using ankle axes from instantaneous helical axis decomposition and a tendon path [2].

While MR imaging allows tracking of the bones and tendons, cost and accessibility are barriers to using an MR-based approach. An alternative method for finding ATma locates the Achilles tendon using an ultrasound probe fitted with motion capture markers [3,4]. Previous uses of this approach have typically assumed that the CoR lies at the midpoint between markers placed on the malleoli. This assumption, however, may not accurately represent ankle joint rotation [5].

The purpose of this work is to investigate how three different methods for locating the ankle center (or axis) of rotation influence estimates of 3D ATma during loaded and unloaded movements. We located the center (or axis) of rotation using the malleoli markers and finite helical axis decomposition of ankle motion. In each case the Achilles tendon was imaged with ultrasound. We hypothesized that ATma estimated from ankle motions would differ from those estimated from the malleoli landmarks, and would be more consistent with those previously measured using MR imaging.

METHODS

Fifteen participants (7M, 8F; 26 ± 2 y; 1.7 ± 0.07 m; 71 ± 12 kg) performed sets of three weight-bearing toe-raises in time to a 0.5 Hz metronome. This motion was repeated unloaded at the same frequency. Approval for all procedures was given by the Institutional Review Board of The Pennsylvania State University.

A linear 60 mm ultrasound probe (HL9.0/60.128Z-2; Telemed) imaged the Achilles tendon at the level of the malleoli. Four retroreflective markers were rigidly attached to the probe, with additional markers placed on the femoral epicondyles and the malleoli. Clusters of four markers were attached to the dorsum of the foot and the anterior shank. Ultrasound images were sampled at approximately 60 Hz, while marker motions were captured simultaneously using seven Eagle cameras (Motion Analysis Corp.) at 100 Hz.

Marker data were passed through a 4th order Butterworth low-pass filter with a cut-off frequency of 10 Hz. Image processing routines in MATLAB (Mathworks Inc.) were used to identify the midline of the Achilles tendon. ATma was calculated as the effective distance between this 3D line of action and either 1) a transmalleolar axis (TA), 2) the transmalleolar midpoint (TM), or 3) a 'functional' axis determined by finite helical decomposition of foot motion with respect to the shank (FA).

Moment arms were quantified over the range from 10° dorsiflexion to 20° plantarflexion (in 5° increments) by interpolating a second-order polynomial fit to ATma versus plantarflexion angle data. Ankle joint angles were computed using Cardan angle decomposition and a modified ISB joint coordinate system [6]. A three-way repeated measures ANOVA, followed by Bonferroni-corrected post-hoc comparisons as indicated by ANOVA results, was run to examine the effect of loading condition, ankle joint angle, and rotational axis/center on ATma.

RESULTS AND DISCUSSION

ATma calculated using FA were significantly larger than values calculated using TA or TM across all joint angles considered (all $p < 0.001$). TM values were slightly larger than TA values ($p = 0.008$). Values of ATma obtained with FA were commensurate with those reported in the literature from 2D and 3D MR data [1,2,7], and our TA and TM values were similar to those found by authors using a similar methods [3,4].

We found that ATma computed using FA increased with plantarflexion angle ($p < 0.001$), with an average increase of 7.5 mm over the range of ankle angles tested. No clear angle-dependent relationship was observed for TA or TM (Fig. 1). ATma has been found to increase with plantarflexion in 2D MR studies [1,7] but in 3D MR studies there is an increase from dorsiflexion to neutral followed by a plateau with increasing plantarflexion [2,7]. In studies employing TM, ATma has been found to increase with plantarflexion [3] and to remain constant with joint rotation [4].

Using FA, ATma were approximately 10% larger for loaded movements ($p < 0.001$) but did not differ with loading for TA and TM. Increases in moment arm with loading have been noted previously in MR studies [1,7].

The location of the FA qualitatively agrees with ankle axis of rotation described in previous studies of bone kinematics [5]. This agreement, along with the similarities between our ATma findings with published results from MR studies, suggest that FA may be a better choice when estimating ATma because FA provides a closer approximation of ankle axis of rotation than TA or TM. It must be noted, however, that our FA was a single axis fixed in the foot coordinate system (a choice we made for the sake of simplicity), and it is known that rotational axis of the ankle joint moves throughout a range of motion [5]. Future work will include use of an instantaneous helical axis to compute ATma with an axis of rotation that moves with respect to the local segment coordinate systems throughout the motion.

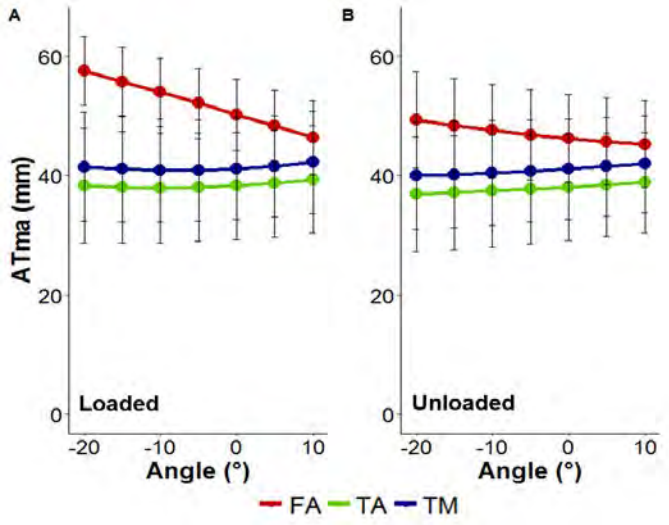

Figure 1: Achilles tendon moment arm, calculated using 'FA' in red, 'TA' in green, and 'TM' in blue, over plantarflexion (-) and dorsiflexion (+) in (A) the loaded condition, and (B) the unloaded condition.

CONCLUSIONS

The plantarflexion moment arm of the Achilles tendon approximated using a functional axis derived from the relative motions of the ankle and foot produces loading- and angle-dependent patterns similar to those with previously reported in MR studies. The results of this study suggest that location of the axis of rotation from measured motion may provide advantages over landmark-based methods when estimating ATma.

FINGER MUSCLES INJECTED WITH BOTULINUM TOXIN DEMONSTRATE INCREASED PASSIVE STIFFNESS AND DECREASED PASSIVE RANGE OF JOINT MOTION IN INDIVIDUALS WITH CHRONIC HEMIPARETIC STROKE

INTRODUCTION

In individuals with chronic hemiparetic stroke, botulinum toxin (BTX) is often used to reduce muscle hypertonicity and spasticity with the goal of improving passive range of motion (ROM), pain, and hygiene in the paretic limb [1, 2]. However, recent evidence suggests that BTX may increase the collagen content within rodent muscles [3, 4]. This could have devastating lasting effects on the passive mechanical properties of the muscle limiting the therapeutic effects of BTX.

Because of these findings in animal studies, we investigated the effects of BTX on the passive properties of the human extrinsic finger muscles following stroke. The extrinsic finger muscles were chosen because they are located in the flexor compartment of the forearm, a frequent target for BTX injection. In addition, we implemented an experimental design that exploits the multi-joint length-dependence of the extrinsic finger muscles across both wrist and finger posture to separate the torque they generate about the metacarpophalangeal (MCP) joints from those produced by other soft tissue structures at the MCP joint [5].

METHODS

The total passive flexion/extension torque generated about the four MCP joints, $T_t(\theta, \omega)$, was quantified in both hands of 16 subjects with chronic hemiparetic stroke and severe hand impairments. Seven subjects had previously received BTX injections in the flexor compartment of the forearm (Table 1).

$T_t(\theta, \omega)$ was quantified as a function of both MCP (θ) and wrist (ω) position using a custom built device [6]. Experimental conditions encouraged a sleep or near sleep state to mitigate hyperactivity of the paretic muscles; EMG monitoring ensured the absence of muscle activity. Data were collected in static 15° increments, spanning the range of motion of the MCP joints; measurements were repeated in 9 different wrist postures, with wrist posture randomized in 15° increments between 60° flexion to 60° extension. The passive ROM of the MCP joints within the torque-measurement device was determined by either the limits of the device or the subject's tolerance; the most extended and flexed postures of the MCP joints were recorded in each wrist posture. PIP & DIP joints were splinted to prevent movement.

For each subject, an exponential analytical model was fit to all of the torque data collected [5]:

$$T_t(\theta, \omega) = T_{sj}(\theta) + T_e(\theta, \omega)$$

The model is comprised of two components. The first component, $T_{sj}(\theta)$, assumes that the torques contributed by the single-joint structures (e.g., intrinsic muscles, skin, ligaments, joint capsules, etc.) vary as a function of MCP joint posture, θ, only. The second component, $T_e(\theta, \omega)$, assumes that torques that vary as a function of both MCP joint posture, θ, and wrist posture, ω, are produced by the extrinsic finger muscles. Data were analyzed using a linear-mixed model analysis.

Table 1: Subject demographics

	N	Age yrs (SD)	Time since Stroke yrs (SD)	CMHS (SD)	Mod. Ashworth (SD)	Time Since BTX yrs (SD)
BTX	7	56.7 (8.3)	10.7 (5.3)	2.8 (0.4)	2.7 (0.5)	4.5 (2.8)
No-BTX	9	60.3 (10.4)	17.1 (7.9)	2.4 (0.7)	2.2 (0.9)	NA

RESULTS AND DISCUSSION

We observed significant inter-limb differences ($p < 0.001$) in both $T_t(\theta, \omega)$ and $T_e(\theta, \omega)$ for both the BTX and the no-BTX groups. The largest differences between paretic and non-paretic limbs were observed in the BTX group when the wrist was extended (Fig. 1A). For the no-BTX group, the MCP passive torques were comparable across limbs in the same extended wrist posture (Fig. 1B).

When the wrist was flexed the differences in $T_e(\theta, \omega)$ between limbs were an order of magnitude smaller (Fig. 1C). In the no-BTX group, smaller inter-limb differences in $T_e(\theta, \omega)$ were observed across all postures (Fig. 1 B&D). No significant differences in $T_{sj}(\theta)$ were observed in either the BTX ($p=0.111$) or no-BTX ($p=0.131$) group in this study.

Large torque increase between limbs were only observed within the BTX group when the wrist was extended and the extrinsic finger flexor muscles were at their longest lengths (Fig 1A). These increases decreased as the wrist was flexed and the flexors shortened (Fig 1C). The increases were only observed in muscles that received the BTX injections and were not observed in muscles that did not receive BTX injections (Fig. 1B,C,&D).

The increased passive MCP flexion torque observed in the BTX group corresponded with a decreased ability to passively extend the MCP joint ($p<0.001$). This was especially evident when the wrist was extended, with an inter-limb decrease in passive extension of 68° for the paretic limb in the BTX group. This decrease in extension ROM was not present in individuals who did not receive BTX ($p=0.360$).

CONCLUSIONS

Paretic muscles located in the anatomical compartment where BTX injections were given demonstrated increased passive MCP flexion torques in joint postures associated with long muscle lengths. These effects were absent in individuals with comparably impaired hands who had never received BTX. These data, together with animal studies revealing increased muscle collagen following BTX injections, suggest that BTX may have long-term consequences opposing the desired treatment effect of increasing ROM.

OLDER ADULTS REVERSE THEIR DISTAL-TO-PROXIMAL REDISTRIBUTION USING BIOFEEDBACK

Michael G. Browne, Sarah N. Fickey, and Jason R. Franz

University of North Carolina at Chapel Hill and North Carolina State University, Raleigh, NC, USA
email: mgbrowne@email.unc.edu, web: http://abl.bme.unc.edu

INTRODUCTION

Compared to young adults, older adults walk slower and with a characteristic decrease in push-off intensity. This decreased push-off intensity stems from large reductions in mechanical power generated by the plantarflexor muscles (i.e. ankle power, P_A) and propulsive ground reaction forces generated during push-off (F_P) [1]. Seemingly in response to this decreased push-off intensity, older adults also rely more on positive mechanical power generated by the hip musculature. This phenomenon, known as the distal-to-proximal redistribution [2], may also contribute to increased metabolic energy costs during walking in older adults [3]. Conventional resistance training for improved mobility in older adults successfully improves maximal muscle strength and fast walking speed (FWS) but has minimal functional impact on habitual walking performance (i.e. preferred walking speed; PWS) or gait biomechanics (e.g., mechanical power generation).

Rehabilitative approaches that go beyond resistance training alone are needed, toward more direct means to elicit favorable biomechanical adaptations during habitual speed walking. As an important first step, we previously attempted to enhance push-off intensity in older adults using biofeedback to increase propulsive forces. While effective - older adults increased F_P with potentially favorable reductions in hip flexor power generation [4] – we were surprised to observe no concomitant increase in P_A. However, older adults can increase P_A in order to walk faster or uphill, revealing a translationally important gap in our understanding. Motivated by these findings, we tested here the primarily hypothesis that real-time ankle power biofeedback during walking can directly increase P_A in older adults. We also hypothesized that doing so would: (*i*) alleviate mechanical power demands at the hip and (*ii*) increase preferred but not fast walking speed.

METHODS

10 healthy older adults (mean±SD; age: 74.8±5.4 years, 3 males/7 females) participated in this study. We first assessed subjects' PWS (1.28±0.20 m/s) and FWS (1.79±0.20 m/s) using an instrumented walkway. Subjects then walked normally for 1-min on a dual-belt instrumented treadmill at their PWS. A custom Matlab script running a surrogate inverse dynamic model of the lower legs and feet estimated bilateral step-by-step P_A. Subjects walked again for 1-min each while watching a screen with visual biofeedback of their instantaneous P_A and targeting increases of +10% and +20% of normal (Fig. 1A). For all trials, a motion capture system recorded the

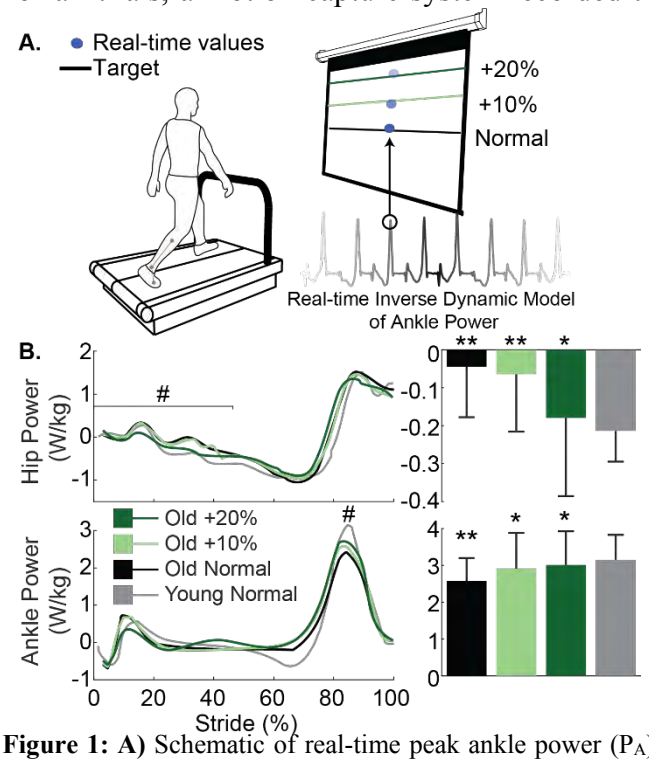

Figure 1: A) Schematic of real-time peak ankle power (P_A) biofeedback. **B)** Group-mean hip and ankle power plotted against an averaged gait cycle. Pound signs (#) denote a significant main effect of P_A biofeedback ($p<0.05$). Each graph is accompanied by bar graphs indicating group mean (±SD) peaks. Asterisks (*) and double asterisks (**) denote a significant pairwise difference from old and young adults walking normally, respectively.

trajectories of markers placed on subjects' pelvis and lower extremities for estimating joint kinetics. Data reported represents the 20 consecutive strides for which participants were most successful matching prescribed targets. Finally, we again assessed subjects' PWS and FWS to investigate recall. We additionally include normal walking data from 9 healthy young adults (age: 25.1±5.6 years, 4 males/5 females, PWS: 1.30±0.12 m/s) to serve as a reference for comparison.

RESULTS AND DISCUSSION

Our older adults walked with 21% lower P_A and 79% greater hip power during early to mid-stance compared to their younger counterparts ($p<0.034$). Older adults increased P_A by 13% and 17% when targeting increases of 10% and 20%, respectively (main effect, $p=0.006$), thereby attenuating their P_A deficit compared to young adults (Fig. 1B). Conceptually, older adults could increase P_A through changes in net moment or angular velocity at the ankle. Our older adult subjects increased P_A through modest (+3%) but significant changes to peak ankle moment ($p=0.008$) and nonsignificant changes to angular velocity (+7%, $p=0.157$) (Fig. 2). We also observed larger net ankle moments developed during early to midstance, which may have indirectly contributed to larger than preferred P_A through greater elastic energy storage and return. Greater P_A was also accompanied by up to a 300% reduction in the demand for positive hip power generation during early to mid-stance ($p=0.015$). P_A biofeedback also increased positive ankle joint work ($p=0.001$), total positive leg joint work ($p=0.002$), and F_P ($p<0.001$) (Fig. 2). This latter finding reveals an interesting disconnect in our understanding of push-off in walking: older adults increase F_P without related improvements in P_A [4], but increase P_A with related improvements in F_P. Finally, subjects walked overground with 11% faster PWS ($p=0.010$) but no change in FWS when recalling P_A biofeedback.

CONCLUSIONS

Our results reveal that older adults are capable of increasing P_A through the use of targeted ankle power biofeedback – effects that are accompanied by potentially favorable shifts in hip power generation during early to mid-stance. Moreover, the associated

increase in PWS suggests a functional benefit to increased ankle power output during habitual speed walking. Further work will investigate whether ankle angular velocity alone may be sufficient feedback to modulate P_A, an approach more immediately translatable to novel rehabilitation approaches via wearable sensor technologies. Ultimately, targeted biofeedback may complement resistance training to reverse age-associated mobility decline.

TRICEPS SURAE MUSCLE-SUBTENDON INTERACTION DIFFERS BETWEEN YOUNG AND OLDER ADULTS

William H. Clark and Jason R. Franz

University of North Carolina and North Carolina State University, Chapel Hill, NC, USA
email: jrfranz@email.unc.edu, web: http://abl.bme.unc.edu

INTRODUCTION

Mechanical power generated via triceps surae muscle-tendon interaction during walking is largely responsible for the total power needed for forward propulsion and swing initiation [1]. This interaction is made complex by the biological architecture of the Achilles tendon (AT), which consists of distinct bundles of tendon fascicles, known as "subtendons", arising from the gastrocnemius (GAS) and soleus (SOL) muscles [2]. Comparative data and our own *in vivo* evidence alludes to a reduced capacity for sliding between adjacent subtendons compromising the AT in old age. This is functionally important, as subtendon sliding could facilitate independent actuation between individual triceps surae muscles, perhaps augmenting contributions to trunk support and forward propulsion. Indeed, our lab recently found that an age-associated reduction in the capacity for sliding between GAS and SOL subtendons correlated with smaller peak ankle moments and positive work performed during push-off, alluding to unfavorable functional consequences [3]. However, it remains unclear whether age-associated changes at the subtendon level unfavorably affect triceps surae muscle contractile dynamics. Recently, we introduced a novel dual-probe ultrasound imaging approach to reveal that length change differences between the GAS and SOL of young adults during force generation positively correlated with non-uniform tissue displacement patterns in the AT.

Therefore, the purpose of this study was to investigate aging effects on triceps surae muscle-subtendon interaction dynamics using dual-probe ultrasound imaging during a series of ramped isometric contractions. We hypothesized that, compared to young adults, older adults will have (*i*) more uniform Achilles subtendon tissue displacements that (*ii*) are accompanied by more uniform GAS and SOL muscle length change dynamics.

METHODS

We report data for 9 younger adults (age: 25.1 ± 5.6 years, weight: 69.8 ± 6.9 kg, height: 1.7 ± 0.1 m, 4 females) and, thus far, 6 older adults (age: 74.3 ± 3.4 years, weight: 67.2 ± 9.0 kg, height: 1.7 ± 0.1 m, 4 females). Subjects completed 3 ramped isometric voluntary contractions at each of 5 different ankle angles (spanning 30° plantarflexion to 10° dorsiflexion) using a Biodex (Biodex System 4 Pro), with the knee flexed to replicate that near the push-off phase of walking (~20º). We synchronized two linear array ultrasound transducers to simultaneously record GAS and SOL fascicle kinematics with tissue displacements in their associated tendinous structures (Fig. 1). A 60 mm Telemed Echo Blaster 128 transducer (LV7.5/60/128Z-2) placed over the medial gastrocnemius and soleus of subjects' right leg recorded cine B-mode images at 61 frames/s. Simultaneously, a 38-mm transducer (L14-5W/38, Ultrasonix Corporation, Richmond, BC) operating at 70 frames/s recorded ultrasound radiofrequency (RF) data from a longitudinal cross-section of the right free AT, distal to the SOL muscle-tendon junction and secured via a custom orthotic. Subjects' right foot was barefoot throughout the experiment to facilitate proper placement of the AT transducer.

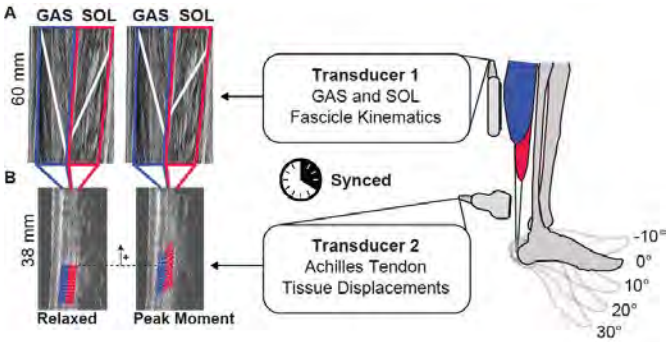

Figure 1. Simultaneous ultrasound imaging of the gastrocnemius (GAS), soleus (SOL), and Achilles free tendon. (A) Fascicle lengths and pennation angles derived from cine B-mode images. (B) Custom speckle-tracking of localized Achilles tendon tissue displacements.

Finally, motion capture tracked right ankle and knee joint kinematics and the positions and orientations of both probes.

Available MATLAB routines based on an affine extension to an optic flow algorithm quantified time series of GAS and SOL fascicle lengths and pennation angles (UltraTrack, [4]), which we combined to compute longitudinal muscle lengths. A custom 2D speckle-tracking algorithm estimated localized displacements of AT tendon tissue, which we averaged in two equally sized tendon depths - superficial and deep - corresponding to tendon tissue thought to arise from GAS and SOL, respectively [5]. A repeated measures ANOVA tested for, in part, significant main effects of and interactions between age and ankle angle on GAS-SOL differences in muscle shortening and tendon tissue displacement at peak ankle moment using an alpha level of 0.05.

RESULTS AND DISCUSSION

For young and older adults, peak isometric plantarflexor moment decreased progressively from dorsiflexion to plantarflexion across the angles tested (p<0.01). On average, older adults generated a 21% smaller peak isometric plantarflexor moment than young adults (p=0.014). Compared to young adults, average peak muscle shortening was 21% greater for SOL and 81% greater for GAS, while average peak tendon displacement was 18% greater for SOL and 50% greater for GAS in older adults (Fig. 2) – findings fully consistent with functional consequences of increased compliance in older tendon. In addition, consistent with our translational premise, GAS versus SOL differences in muscle contractile behavior and those in subtendon tissue displacements were significant in young but not in older adults. Indeed, as hypothesized, differences between peak GAS subtendon and peak SOL subtendon displacement averaged 44% smaller in older versus young adults (e.g., 77% at 0º, p<0.05). Also as hypothesized, differences between peak SOL and peak GAS muscle shortening averaged 58% smaller in older versus young adults (e.g., 65% at 0º, p<0.05) (Fig. 2).

CONCLUSIONS

We reveal that more uniform AT tissue displacements in older versus young adults extend to anatomically consistent and potentially unfavorable changes in muscle contractile behavior – evidenced by smaller differences between GAS and SOL peak shortening during isometric force generation. These findings provide an important biomechanical basis for previously reported correlations between more uniform AT subtendon behavior and reduced ankle moment generation during waking in older adults.

DOES FATIGUE AFFECT WRIST KINEMATICS DURING A REPETITIVE PICK-AND-PLACE TASK?

[1] Sarah P. DeDecker, [2] Bryan Piper, [1] Michele L. Oliver, and [1] Karen D. Gordon

[1] School of Engineering, University of Guelph, ON, Canada

INTRODUCTION

Carpal Tunnel Syndrome (CTS) is a common hand and wrist neuropathy. Increased risk for developing CTS is associated with extreme wrist posture during repetitive tasks, which is associated with some workplace occupations [1]. Ergonomic assessment is used to assess frequent flexion and extension motions of the wrist during repetitive tasks through various scoring methods. However, there is a lack of data regarding wrist kinematic alterations that may or may not occur as a worker becomes fatigued. If detectable differences in wrist kinematics with fatigue were present, this could provide an avenue for biofeedback mechanisms to inform preventative measures in the workplace.

The first objective of this study was to evaluate wrist posture during a repetitive pick-and-place task (e.g. task performed by a grocery cashier). The second objective was to quantify the effect of fatigue on wrist posture. It was hypothesized that wrist kinematics would be altered after fatigue.

METHODS

Ten healthy right-hand dominant subjects (four males and six females, age 21.1 ± 2.81 years) participated in this University of Guelph REB approved study. Seven retroreflective markers were mounted on the subject's right forearm and hand based on a previous model [2]. The markers were placed on the lateral epicondyle of the elbow, the medial epicondyle of the elbow, the ulnar styloid process, the radial styloid process, the capitate bone, the second metacarpal-phalangeal joint, and the third metacarpal-phalangeal joint. An eight camera VICON Bonita Motion Capture System (Vicon Motion System Ltd, Oxford, UK) was used to predict flexion-extension and radial-ulnar deviation angles of the wrist at a sampling frequency of 100 Hz. The subjects were instructed to perform a pick-and-place task. While seated, subjects used their right hand to move five objects (cans) from one end of a waist height table to the other and back (10 total cycles), while turning the cans over approximately 180 degrees each time. The cans weighed less than two kilograms and could be moved in any order selected by the subject. A fatiguing protocol described in [3] was followed to ensure subjects were fatigued prior to performing the pick-and-place task for a second time. Grip force data was collected using a hand dynamometer (Vernier, OR, USA) until grip force dropped to 70% or less of the subject's maximum grip force, as described in [3].

The range of motion (ROM) and mean angle were determined over the middle 5 pick-and-place cycles for both wrist flexion-extension (FE) and radial-ulnar deviation (RUD) angles. FE ROM, FE mean and RUD ROM were transformed using a Johnson transformation to meet data normality requirements prior to statistical analysis. RUD mean data was not transformed as it was normally distributed. A general linear model ANOVA ($p<0.05$) was performed on FE ROM, FE mean, RUD ROM, and RUD mean with factors of subject, sex, cycle, and fatigue included in the analysis. All statistical analyses were performed using Minitab 17 software (Minitab Inc., Chicago, Illinois, USA).

RESULTS AND DISCUSSION

FE and RUD ROM and mean angle for females and males pre- and post-fatigue are shown (Fig. 1 and Fig. 2).

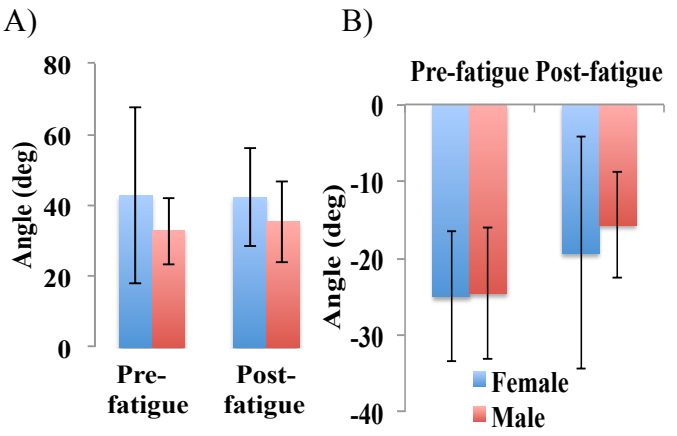

Figure 1: A) Mean ± SD flexion-extension ROM angle pre- and post-fatigue (left) and B) mean ± SD flexion-extension mean angle pre- and post-fatigue (right) for females and males (positive angles represent extension)

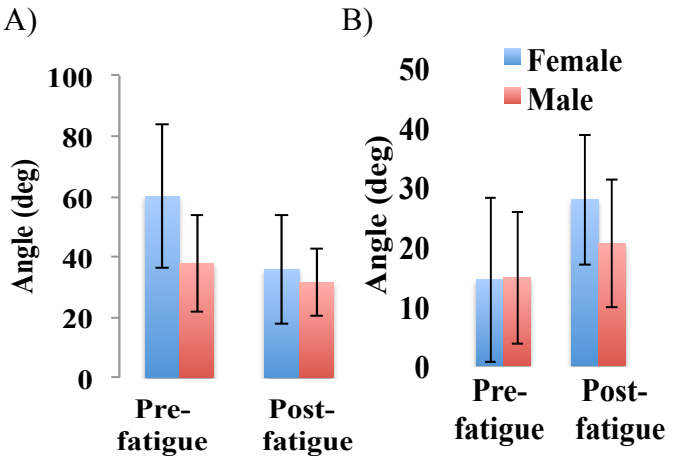

Figure 2: A) Mean ± SD radial-ulnar deviation ROM angle pre- and post-fatigue (left) and B) mean ± SD radial-ulnar deviation mean angle pre- and post-fatigue (right) for females and males (positive angles represent ulnar deviation)

There was a significant difference in pre- and post-fatigue for FE mean ($p=0.046$) and RUD ROM ($p=0.029$). The mean FE angle decreased indicating an increase in flexion angle post-fatigue. The RUD ROM increased significantly post-fatigue in both females and males. There was a significant difference in RUD ROM ($p=0.034$) between sexes. Females had a significantly larger RUD ROM compared to males.

CONCLUSIONS

Wrist posture changes significantly after fatigue during an everyday task for both wrist flexion-extension and radial-ulnar deviation. The changes detected post-fatigue were in the range of 5-10 degrees different for the mean angle measurement and 5-20 degrees for the ROM measurement. This information has potential applications in an ergonomic setting. To determine if wrist kinematic changes due to fatigue occur in the workplace, ongoing work in our laboratory is developing a wearable unobtrusive wrist device that could detect kinematic alterations without the need for motion capture or inertial measurement units. Ultimately, information determined from the current study coupled with an instrumented wrist device could help ergonomists and others improve hand-arm workplace risk evaluation by removing the ambiguity associated with common ergonomic risk assessment tools.

An interesting outcome of this study was that females had a larger RUD ROM than males. This result should be taken with caution due to the low number of subjects and subsequent low power to detect differences due to sex. However, tracking sex differences in biomechanical variables such as kinematics is a variable that has not previously been explored with respect to understanding the etiology of carpal tunnel syndrome. Though preliminary, results from the current work suggest that further work is needed.

PATHOLOGICAL KNEE JOINT CONDITION IN CHILDREN WITH CEREBRAL PALSY IS ASSOCIATED WITH THE ACTIVE STATE MUSCULAR MECHANICS RATHER THAN PASSIVE

INTRODUCTION

In individuals with cerebral palsy (CP), the knee joint is kept typically in a flexed position. Although the mechanism of the related pathological resistance against knee extension is unknown, this is ascribed to passive and active properties of spastic muscles. Yet, spastic muscle's passive forces at various joint angles have not been assessed. Hence, its contribution to the pathological condition cannot be judged objectively. Besides, intraoperative tests in which active state forces of spastic muscles were measured directly at the tendon indicate that spastic knee flexors produce only low forces in flexed knee positions [e.g., 1]. However, if co-activated with an antagonist, spastic Gracilis (GRA) muscle's overall mechanical characteristics change, with the peak force shifting to flexed knee positions hence resulting in a narrowed operational joint range of force exertion [2]. This was ascribed to epimuscular myofascial force transmission (EMFT) [e.g., 3] between activated muscles, which can be relevant for the unknown mechanism of the pathology. Additionally, as, unlike gait analyses, direct spastic muscle force measurements are very rare, the present literature remains insufficient to show the relationship between muscle's mechanical characteristics and the patient's gait.

The aim was to fill these gaps by combining intraoperative experiments with gait analyses and to test the following hypotheses: (i) spastic GRA shows high amplitudes of passive forces even in the flexed knee positions, (ii) active forces of spastic GRA are high, particularly within the gait relevant knee angle range, and (iii) this becomes more pronounced due to EMFT.

METHODS

Seven children with CP (mean age (SD)=9.1 (2.9) years; GMFCS scores level II) participated.

Pre-surgery gait analyses were performed using a motion analysis system (ELITE 2002, BTS Bioengineering, Milan, Italy) with six infrared cameras and two force plates (Kistler Instumente AG, Winterthur, Switzerland). Hip and knee joint angles and moments in the sagittal plane were used to relate the global gait metrics to intraoperative spastic muscle level mechanics.

Intraoperatively 10 limbs were tested. Isometric GRA forces (F_{GRA}) were measured per knee angle (KA) in four conditions: (I) passive state, after spastic GRA was stimulated (II) alone, (III) simultaneously with its synergists semitendinosus and biceps femoris, and (IV) also with its antagonist rectus femoris. Hip angle (HA) was set to 45° and 20°, and KA was changed from 120° to full extension (0°).

Two-way ANOVA (factors: KA and condition) and paired-t or Wilcoxon signed-rank test were used to test the effects of studied conditions on overall mechanical characteristics and Range-F_{GRA} (KA range between 120° and peak force exertion) ($P<0.05$).

RESULTS AND DISCUSSION

Passive and active state forces are shown in (Fig. 1).

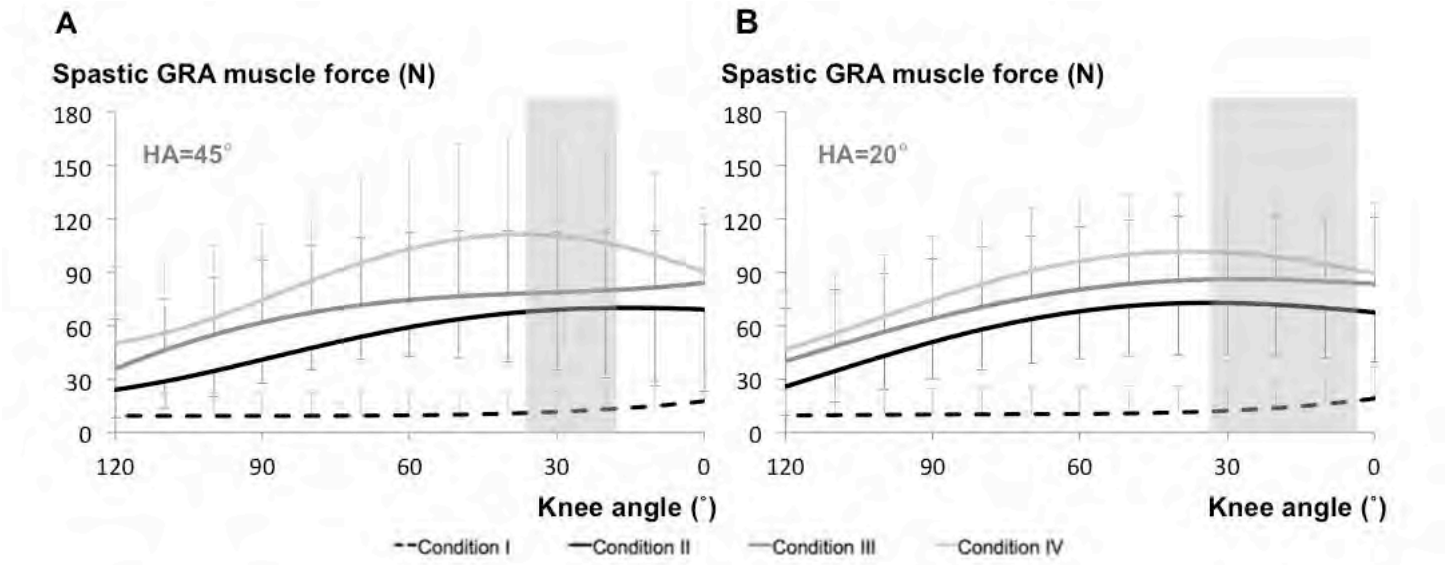

Figure 1: The mean of GRA forces of intraoperatively tested limbs per KA across the conditions tested at HA=45° and HA=20°. The gray shaded areas show the gait relevant KA-positions.

Passive force is low in flexed positions and increases towards knee extension. However, its peak value is only a small fraction of the peak total force (26%) measured in the active state.

ANOVA showed significant main effects of both factors on F_{GRA}, but no significant interaction. Compared to condition II, co-activation of other muscles caused F_{GRA} to increase substantially (on average, for HA=45° and 20°, by 32.8% and 71.9%, and 24.5% and 45.1% in conditions III and IV, respectively). Considering the muscle's overall mechanical characteristics in conditions III and IV, EMFT did cause major increases in spastic GRA forces. However, compared to condition II, no significant change in Range-F_{GRA} was shown in any co-activation condition.

Gait analyses indicated that intraoperative data for KA=36°-18° and KA=33°-3° (for HA=45° and 20°, respectively) are particularly relevant, where F_{GRA} in active state approximates its peak value. The elevated forces shown in conditions III and IV for gait relevant KA-ranges characterize an elevated contribution of the muscle to knee flexor moment during the patients' gait. Hence, the findings reflect an increasing effect on spastic muscle's mechanics of different components of EMFT. Since daily activities involve simultaneous activation of several muscles, such EMFT effects potentially have important implications for the poorly understood pathological joint condition in CP and its treatment.

CONCLUSIONS

The first hypothesis is rejected, while the second and the third are confirmed. Spastic muscle's passive forces measured directly for the first time in patients with CP do not show high amplitudes even in extended knee positions. In contrast, in the active state, the muscle's forces within the gait relevant KA-range are high. This gets much more pronounced due to EMFT. Therefore, the pathological knee joint condition can be ascribed to the active, rather than the passive state mechanics of spastic muscles effects of which, do elevate due to intermuscular mechanical interactions.

HOW DOES ACHILLES TENDON TWISTING INFLUENCE STRAIN AND ENERGY STORAGE?

[1] Katherine R. Knaus and [1] Silvia S. Blemker

[1] University of Virginia, Charlottesville, VA, USA
email: ker4e@virginia.edu, web: http:// bme.virginia.edu/muscle/

INTRODUCTION

The Achilles tendon (AT) transmits force from the triceps surae muscles during walking and other motion. It comprises three subtendons that originate from each muscle, twist around each other, then insert into the calcaneus. A recent investigation in 53 human cadavers sought to characterize the architecture of these subtendons and their variation between subjects [1]. The authors characterized the variation in torsion of the subtendons within the free AT, dividing subjects among three groups with Type 1 as the least twisted, Type 2 as moderately twisted, and Type 3 as extremely twisted. They also measured the torsion of the fibers within individual subtendons, which varied between the soleus (SOL) and the medial (MG) and lateral (LG) heads of the gastrocnemius, and tended to be greater than the twist of the subtendons about each other.

Sliding between subtendons is thought to explain non-uniform deformations of the Achilles observed with ultrasound during walking [2]. Measured differential displacements provide exciting insight into complex loading patterns by the triceps surae. However, conclusions about muscle-tendon behavior drawn from this imaging technique are dependent on several assumptions. Tissue displacements are tracked in a small 2D sagittal plane region of interest in the free AT, and while individual subtendons are not visually discernable, deep tissue is associated with the SOL and superficial tissue with the MG. Subjects exhibit varied amounts of AT torsion, though it is unknown if subtendons visible in the superficial and deep portions of the sagittal plane vary with twist type. In addition, tendon elongation is assumed to be longitudinal and estimated from in-plane displacements; however, this may misinterpret *in vivo* tendon strains due to out-of-plane stretch.

Ultrasound imaging combined with traditional force and motion capture can be used to quantify *in vivo* tendon dynamics, with displacement measurements of the free AT providing a more direct approach for approximating energy stored during walking [3]. These estimates are subject to assumptions about the force in the different subtendons as well as their strain, which may be altered by varied torsion.

The goal of this work is to understand how lengths of subtendon fibers with varied twist compare to free AT lengths. Using finite element models (FEM), we aim to decouple the influence of twisting architecture from other complexities of AT and triceps surae dynamics to assess how this anatomical feature and its variance may influence *in vivo* estimates of tendon stretch and energy storage.

METHODS

Three generic AT FEMs, representing the region of tendon from the calcaneus' superior border to SOL musculo-tendinous junction, were constructed with elliptical cross sections using average lengths and widths [1]. Models were divided into were divided into three parts to represent the subtendon architecture of each twist type. In order to focus on the effect of varied twist, the three models were identical in volume and subtendon proportions with amount of twist as the only distinguishing feature.

Tendon was modeled as transversely isotropic material with fiber direction vectors defined using Laplacian flow simulations [4]. Flow guides were used to match subtendon fiber torsion angles to twist types [1]. Flow results were used to determine subtendon fiber lengths.

Simulations of simplified walking conditions were defined to match deep and superficial measurements by prescribing either displacements [2] or forces [3] as boundary conditions to the proximal end. This end was constrained to only move proximal-distally. Frictionless contact was assigned to allow sliding between subtendons.

Subtendon along fiber strains were compared to longitudinal elongations estimated from proximal end displacements and the starting free tendon length. Subtendon strain energies were compared to stored energy estimated from integrals of force at the proximal end and length changes determined from displacements.

RESULTS AND DISCUSSION

Fiber lengths of all subtendons in each type were longer than the length of the AT. Fibers in the Type 1 model were the shortest while fibers in the Type 3 model were the longest. Fibers in the GM subtendon were shortest and the SOL subtendon were longest.

Along fiber strains were lower than estimated elongation in all subtendons, with Type 1 being the most similar (0.5% error) and Type 3 being the least (10% error) [Fig 1]. Subtendon strain energies were lower than estimated stored energy in the LG and MG and higher in the SOL, with Type 1 being the most similar in total energy stored (5% error) and Type 3 being the least (15% error) [Fig 1].

Larger amounts of twist lead to overestimation of tendon strain and energy storage. Twisting of subtendons created longer fiber lengths for the same give AT length and therefore more out-of-plane alignment. Interestingly, greater twist also contributed to having a greater portion of the LG subtendon in the deep distal region of the sagittal mid-plane [Fig 1], which is typically assumed to be occupied by SOL subtendon. Variations in twist architecture could contribute to higher rates of injury due to greater strains resulting from similar loading patterns.

CONCLUSIONS

While errors are not large enough to discount estimates of tendon dynamics made from sagittal plane ultrasound images, it does illuminate the necessity for considering architectural variation. This work demonstrates the utility of using 3D models to determine possible errors associated with 2D measurements. Models also provide the means to better calculate quantities that cannot be measured readily *in vivo*, like tendon strain energy, from those that can be measured, such as tendon length changes.

INTRODUCTION

The theory of muscle modules (or synergies) suggests that groups of muscles are activated synergistically via a common neural command [1]. While this idea has provided insight into the control of simple tasks like locomotion [2], the clinical relevance of this theory has only recently begun to be explored. For example, patients with higher function at one year following a cruciate-retaining (CR) total knee arthroplasty (TKA) displayed a higher number of muscle modules (n=4-5) compared to patients with lower function (n=2-3) [3]. This relationship between number of modules and function suggests that if muscle modules are able to change over time, it may be possible to develop module-focused clinical programs to improve patient function.

The aim of this study was to determine muscle modules in patients with TKA during gait at 6 & 24 months post-operatively and to compare these modules to patient function. We hypothesized that (i) participants with a higher number of modules would demonstrate higher function and (ii) changes in patient function would be accompanied by changes in the number and characteristics of muscle modules.

METHODS

Fifteen participants (M/F 5/10; 60.3±6.8 y; 97.9 ±23.3 kg; 1.7±0.1 m) provided written informed consent prior to undergoing posterior-stabilizing TKA (Zimmer NexGen LPS Flex Knee) and were tested at 6 & 24 months post-operatively. Each participant performed 5 over-ground walking trials at self-selected speed. We collected passive motion capture data [4] at 150 Hz (10 Vicon MX-F40 cameras; Oxford, UK) and ground reaction force data at 1500 Hz (6 Bertec 4060-10 plates; Columbus, OH). We collected surface electromyography (EMG) data from the rectus femoris (RF), vastus medialis and lateralis (VM, VL), semitendinosis (ST), biceps femoris (BF), medial and lateral gastrocnemii (MG, LG), and soleus (SO) on the TKA-involved limb at 1500 Hz (Noraxon Telemyo DTS System; Scottsdale, AZ). To create linear envelopes for the EMG data , we used a 10-300 Hz 6th order bandpass Butterworth filter, rectified the data, smoothed the signals with a 6 Hz 6th order low-pass Butterworth filter, and normalized the signals to the maximum activations within each respective gait cycle.

For each trial, we used non-negative matrix factorization (NMF) to define muscle modules from the original EMG activations. Each module consisted of a principal activation pattern and weighting factors for the muscles within the module [5]. The product of the principal patterns and weights reconstructed individual muscle activation patterns. In order to ensure these reconstructions represented the original EMG, we calculated the variability accounted for (VAF) by the reconstructed signals and iteratively increased the number of modules from 1 to 8 in separate NMF calculations until the following criteria were satisfied: VAF > 0.9 for all muscles or VAF > 0.8 for all muscles and the addition of another module did not raise the minimum VAF by more than 5% [6].

To compare principal patterns and muscle weights between subjects and time points, we also performed NMF calculations the number of modules equal to the average for all gait trials. The principal pattern of each module was normalized to its peak and the weighting factors were normalized to the maximum within the module. We averaged the principal

patterns and weighting factors over the 5 walking trials to create ensemble averages for each participant at both 6 & 24 months. We used Wilcoxon signed-rank tests to compare muscle weights between 6 & 24 months in each of the modules and Spearman Rho tests to examine correlation in muscle weights in these modules (α=0.05).

We recorded the distance walked by each participant during a six-minute test (6MW) [7] and classified each participant as high- and low- functioning using a regression from Enright et al. that accounts for height, weight, and age [8]. We used paired t-tests to identify differences in 6MW performance at 6 & 24 months (α=0.05).

RESULTS AND DISCUSSION

The number of modules was consistent across time points and functional groups. At 6 months, 4 participants were high-functioning and had 2.5±0.4 modules (n=2, 2 modules; n=2, 3 modules), while 11 were low-functioning and had 2.7±0.6 modules (n=4, 2 modules; n=6, 3 modules; n=1, 4 modules). At 24 months, 6 participants were high-functioning and had 2.9±0.4 modules (n=2, 2 modules; n=4, 3 modules), while 9 participants were low-functioning and had 3.0±0.3 modules (n=2, 2 modules; n=8, 3 modules; n=1, 4 modules). We rounded the average number of modules in each group to 3.

Despite there being no significant change in 6MW tests between 6 & 24 months (p=0.902, 476.4±76.5m vs. 477.9±98.6 m), there were some differences in the modules of individual patients. There was a slight increase in the number of modules for 5 participants and a decrease for 2 participants. After performing the NMF calculations for each gait trial with the number of modules fixed at the average (n=3), each participant demonstrated modules at both 6 & 24 months in which the quadriceps (Q), hamstrings (H), and plantarflexors (PF) were primarily expressed (Fig. 1). However, the weights were related between 6 & 24 months for only 5 module-muscle pairs: the VM (ρ=0.779; p=0.001), BF (ρ=0.581; p=0.023), and LG (ρ=0.561; p=0.030) in the Q module and the VM (ρ=0.521; p=0.046) and LG (ρ=0.732; p=0.002) in the H module. Initial analysis indicated phase shifts in the three principal patterns between 6 & 24 months in individual participants. Such changes in timing and muscle weights contrast Shuman et al. who found greater consistency across modules between days in younger populations with and without cerebral palsy [9].

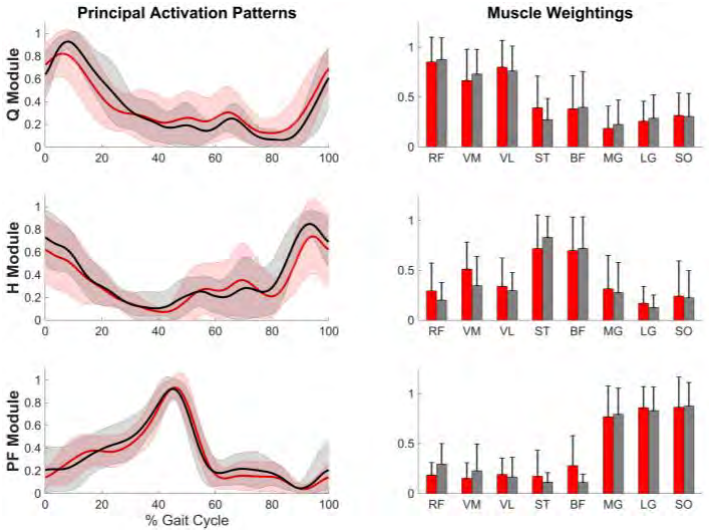

Figure 1. Average 6 month (red) & 24 month (gray) post-TKA principal patterns and muscle weights ± 1 standard deviation.

CONCLUSIONS

Our results did not indicate a relationship between function and either the number or characteristics of muscles modules. As part of a larger study, we have observed greater improvements in function between the pre- and post- TKA conditions. Additional investigation will examine the relationship between modular control and function pre-operatively as well as changes in modular control before and after TKA.

POST-STROKE WALKING MECHANICS USING A SPEED-ADAPTIVE MYOELECTRIC EXOSKELETON CONTROLLER

INTRODUCTION

Reduced ankle function in post-stroke individuals limits the propulsive 'push-off' power of the paretic limb, resulting in asymmetric gait, reduced walking speed and higher metabolic cost [1]. Powered exoskeletons (exos) offer a promising opportunity to restore mechanical deficits by applying torque at the paretic ankle during the propulsive phase of gait. Previously, a proportional myoelectric ankle exo was shown to increase the paretic plantarflexion moment for stroke survivors walking at 75% of their comfortable overground speed [2]. Despite these improvements, the exos did not reduce the metabolic cost of walking. Researchers suggested exo performance could be limited because the walking speed was restricted to a pace at which exo assistance was not needed. In order to assess the impact of exo assistance on walking speed in stroke populations, we developed a novel, speed-adaptive exo controller [3]. This research extends previous work by: (i) exploring the efficacy of a myoelectric exo controller that automatically modulates the magnitude of propulsive assistance with changes in walking speed for post-stroke populations and (ii) assessing the ability of the controller to improve net average mechanical power output at the paretic ankle, knee and hip joints.

METHODS

We implemented a speed-adaptive controller designed to mitigate specific limitations of prior myoelectric controllers by including two independent adaptive gains: (1) a gain to map user's soleus muscle activity to peak exo torque (Koller) and (2) a gain to map peak exo torque capacity to walking speed (Giest) [3,4]. The speed-dependent gain ensures the exo outputs ~25% of the maximum normal biological ankle plantarflexion moment at the instantaneous treadmill velocity. The desired exo torque profile was applied by a benchtop motor (Baldor Electric Co) to the carbon-fiber ankle exo through a Bowden-cable transmission system.

Experimental data were collected from six stroke survivors (3 male, 3 female) walking on an instrumented split belt treadmill with and without an exo on their paretic limb. Subjects started by walking at 60% of their preferred speed (n00). At each consecutive minute, the treadmill speed was increased by 0.1 m/s (n01, n02, etc) until the subject's heart rate reached 60% of their heart rate reserve. Kinematic and kinetic data were processed in Visual3D (CMotion, USA) and MATLAB (Mathworks, USA) to determine joint angles and angular velocities. Inverse dynamics was used to calculate joint moments and powers at the ankle, knee, and hip. Average joint powers were calculated at the ankle, knee and hip for five strides [5]. Indirect calorimetry was used to determine metabolic cost during walking (OxyCon Mobile, Carefusion, USA). Statistical significance of peak average ankle power, and net average ankle, knee and hip powers were determined using paired t-tests (α=0.05).

RESULTS AND DISCUSSION

The speed-adaptive controller successfully amplified exo assistance as walking speed was increased, verifying efficacy of the speed-adaptive gain (Figure 1c). Subject averages for maximum paretic ankle power were significantly higher for the exo compared to the no exo condition at all speeds (Figure 1a and 1b) (paired t-test; p=0.04). Since subjects walked until reaching a specific heartrate, statistical power was reduced at high speeds for which the sample size was small (n<4 for n05-n07).

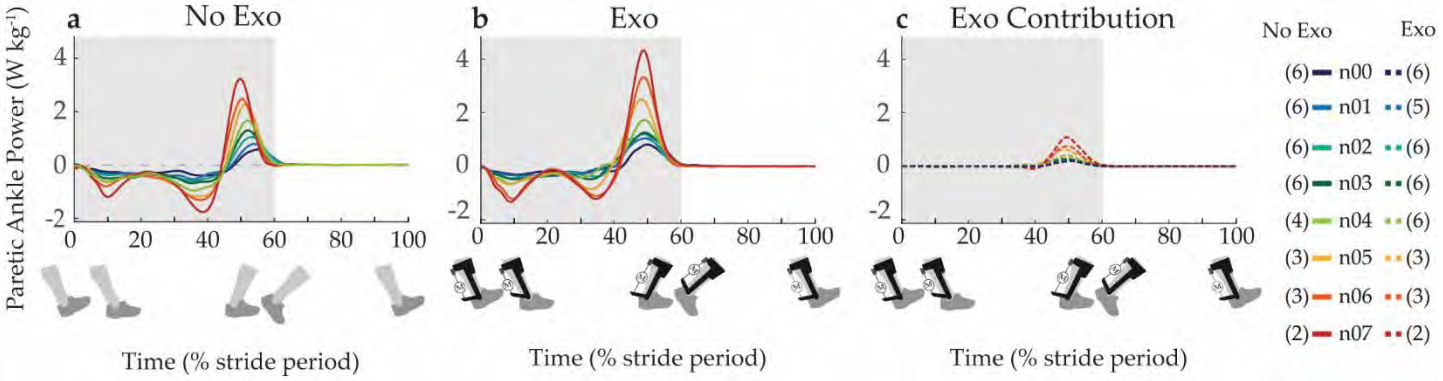

Figure 1.a Paretic ankle power in the no exo condition and **1.b** the exo condition with the **1.c** exo contribution isolated. The number of subjects is indicated in parenthesis. The shaded area represents the stance phase of gait.

Net average paretic ankle power was increased for all speeds while wearing the exo, demonstrating improved delivery of net energy at the ankle (paired t-tests; $p<0.05$ for n00-n04) (Figure 2).

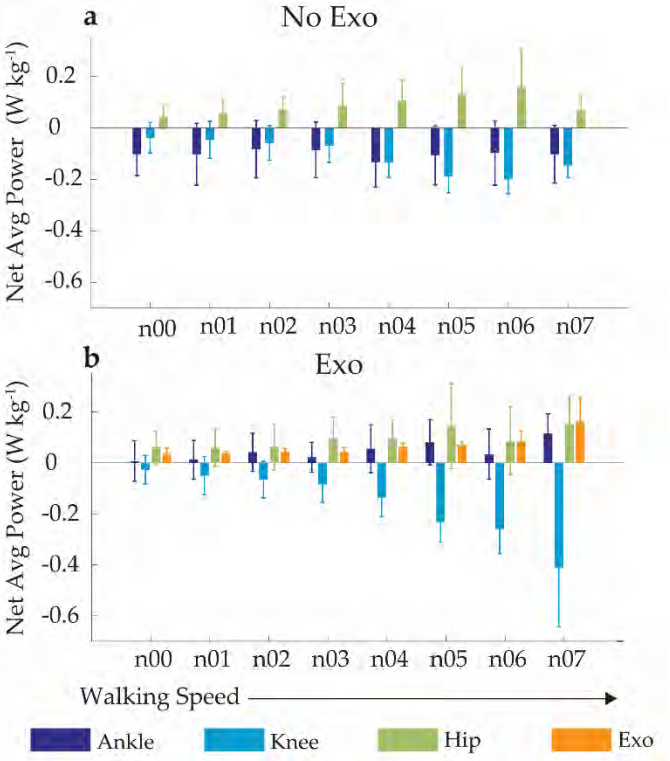

Figure 2.a Net average power averaged across subjects for the no exo and **2.b** exo conditions.

Despite these increases in net average ankle power, only two of the subjects experienced a decrease in metabolic cost while wearing the exo compared to the no exo condition, and no statistically significant change was found. One possible explanation is that assistance applied at the ankle may be absorbed by more proximal joints. This explanation is supported by the decrease in net average power seen at the knee in the exo compared to no exo condition (paired t-tests; $p<0.05$ for n00 and n02) (Figure 2).

CONCLUSIONS

Our speed-adaptive controller successfully increased exo assistance with changes in walking speed for post-stroke individuals. The exo assistance resulted in higher net average power at the paretic ankle. Though we found no significant change in metabolic cost, our exo controller demonstrates the potential of assistive devices to restore paretic limb propulsive power. Future work will examine the interaction between exo assistance, walking speed, distance travelled and gait symmetry between paretic and non-paretic limbs.

INTRODUCTION

Ophthalmologists often maintain static postures of the neck, shoulder, elbow and wrist during their routine clinical examinations, which may lead to work-related musculoskeletal diseases (MSDs) [1] and a decreased capacity for healthcare delivery. Ophthalmologists' posture, ergonomics and occupational discomfort are currently evaluated qualitatively using survey methods, such as the Visual Analog Scale (VAS) pain level reporting [2] or quantitatively using electromyography [3].

A combination of marker-based motion capture and electromyography may provide an objective, quantitative methodology to examine posture and suggest postural adjustments that will reduce the risk of developing MSDs. This study used motion analysis and electromyography to evaluate ophthalmologists' posture during routine exams and with alterations to exam setup.

METHODS

Ten pediatric ophthalmologists (5 male, 5 female, aged 40 ± 9.52 years old) performed retinoscopy, refraction and simulated retina exams using a slit lamp biomicroscope and a 90D lens on a child CPR manikin. Postural kinematics was tracked using 14 Optitrack Flex 13 cameras, with participants donning a conventional 27-marker upper body marker set [4]. Neck and shoulder muscle activity was recorded using Delsys Trigno surface electromyography electrodes placed bilaterally on the upper trapezius and anterior deltoid muscles.

Retinoscopy and refraction examinations were performed as is, and under a postural alteration which involved reclining the manikin to simulate patient viewing a raised eyechart. Non-neutral neck flexion (percentage of procedure time that neck flexion was outside 3 S.D. of upright neck posture) was compared among the postural alterations.

Slit lamp examinations were performed under 3 conditions: no postural adjustments, postural adjustment by altering slit lamp platform height and patient position, and postural adjustment with an elbow rest under arm holding the 90D lens. Sagittal plane neck flexion angle, upper trapezius muscle activation area and the percentage of procedure time that the anterior deltoid was active were compared among these 3 conditions for all ophthalmologists.

Neck flexion angles were calculated using the head and shoulder marker data and a Cardan rotation sequence. EMG data was rationalized using baseline data taken from upright static sitting. Muscle activation area was calculated as the area under the rectified EMG profiles. Paired t-tests were used for all comparisons (presented as mean ± 1 SEM).

RESULTS AND DISCUSSION

For the retinoscopy and refraction examinations, percentage of procedural time with non-neutral neck flexion decreased after reclining the manikin for loose lens retinoscopy (81.39 ± 2.57% vs. 69.45 ± 3.91%, $p = 0.038$*), lens bar retinoscopy (81.29 ± 1.83% vs. 70.62 ± 5.29%, $p = 0.095$), loose prism refraction (66.54 ± 3.80% vs. 64.47 ± 3.93%, $p = 0.741$) and prism bar refraction (74.57 ± 1.38% vs. 60.94 ± 7.54%, $p = 0.203$). These results are displayed in Fig. 1.

For the slit lamp examination, sagittal plane neck flexion angle range of motion decreased significantly after postural adjustment (41.4±3.3° vs. 36.4±2.8°, $p = 0.023$*) and elbow rest placement (41.4±3.3° vs. 35.8±2.8°, $p = 0.025$*). Upper Trapezius muscle

activity (procedural activation area) decreased after postural adjustment (106.1±52.9mV vs. 88.3±46.0mV, p = 0.137) and elbow rest placement (106.1±52.9mV vs. 87.6±45.0mV, p =0.186). Percentage of procedural time that the anterior deltoid was active decreased slightly after postural adjustment (38.8±3.7% vs. 37.43±4.3%, p = 0.756) and decreased significantly after elbow rest placement (38.8±3.7% vs. 31.37±3.9%, p = 0.037). These results are displayed in Fig. 2.

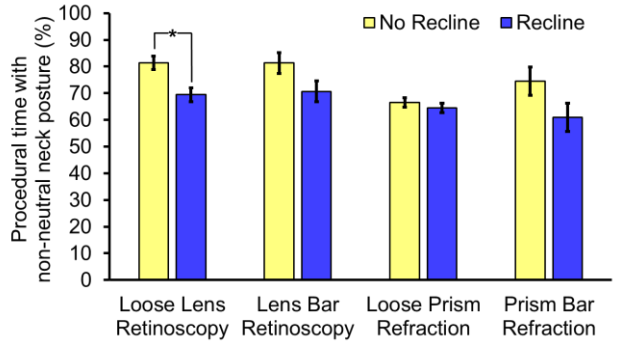

Figure 1: Percentage of procedural time with non-neutral neck flexion (no patient recline vs. recline).

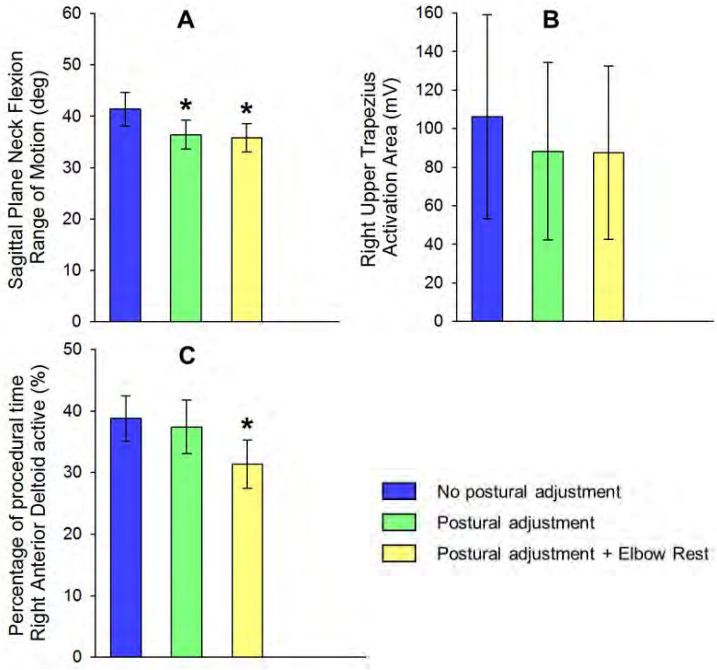

Figure 2: Sagittal plane neck flexion range of motion **(A)**, Activation area of the Right Upper Trapezius **(B)**, Percentage of procedural time that the Right Anterior Deltoid was active **(C)**.

The observed reduction in the percentage of procedural time with non-neutral neck flexion in the retinoscopy and refraction exams and the observed reduction in neck flexion and upper trapezius activity after postural adjustments in the slit lamp examination may indicate lower exposure to sustained non-neutral neck postures that can cause MSDs. The decrease in anterior deltoid activation after installing an elbow rest in the slit lamp examination may also indicate a practice that could lead to reduced stress related to prolonged, unsupported arm raise.

CONCLUSIONS

Easily implemented postural adjustments may decrease the possibility of occupational MSDs by reducing time spent by ophthalmologists in un-ergonomic postures. Preliminary analyses from this and future studies may help establish a quantitative standard for ergonomic postures in ophthalmic practice, lead to a wide scale re-design of ophthalmic equipment, and facilitate the development of postural ergonomics-focused training curriculums for current and future ophthalmologists.

This study only focuses on pediatric ophthalmologists, wherein a generalization of the procedural postural characteristics observed may not necessarily be accurate when applied to all practicing ophthalmologists. Future studies will include a wider subset of ophthalmologists as participants, leading to a more generalizable study and a larger sample size.

IN VIVO RELATIONSHIP BETWEEN JOINT STIFFNESS, JOINT-BASED ESTIMATES OF MUSCLE STIFFNESS, AND SHEAR WAVE VELOCITY

[1] Andrew D. Vigotsky, [2] Elliott J. Rouse, and [1] Sabrina S.M. Lee

[1] Northwestern University, Evanston, IL, USA
[2] University of Michigan, Ann Arbor, MI, USA
email: vigotsky@u.northwestern.edu

INTRODUCTION

The underlying properties governing human joint mechanics, such as stiffness, are constantly regulated for effective, safe, and efficient interactions with the external environment. Joint stiffness (k_{joint}) is, in part, determined by the properties of the muscles surrounding the joint. The muscle-joint relationship can be thought of hierarchically, since there exists a lower level, muscle, and a higher level, joint. In light of this hierarchy, investigators often assess joint properties to make inferences about muscle-level changes. However, such approaches lack the specificity needed to understand the role of individual muscles.

Shear wave ultrasound elastography—which measures the velocity at which shear waves travel through tissue—has been increasingly used to assess the mechanical properties of muscle [2]. However, how shear wave velocity (SWV), measured at the muscle level, relates to k_{joint} and muscle stiffness *in vivo* remains poorly understood [2, 3]. Therefore, the purpose of this work was to quantify the relationships between 1) SWV of individual primary plantar flexors and ankle k_{joint}, and 2) SWV and joint-based estimates of muscle stiffness (k_{muscle}) in two muscles, medial gastrocnemius (MG) and soleus (SOL).

METHODS

Ten healthy, young adults (6 females, 4 males; age = 26 ± 4 years; body mass = 69 ± 16 kg; height = 171 ± 10 cm) participated in this study, which was approved by the Northwestern University Institutional Review Board. Ankle k_{joint}, SWV_{MG}, and SWV_{SOL} were measured in two positions (knee flexed, 90°; knee extended, 0°) and at three activation levels (0%, 20%, and 40% of maximum voluntary contraction, MVC) on two separate days. The ankle was positioned at 90° for all trials. The two knee positions permitted independent investigation of the MG, a bi-articular muscle, and the SOL, a uni-articular muscle.

Joint stiffness was measured using a custom dynamometer, by recording joint moment responses to 1° perturbations, collected over 27, 10-second trials for each activation. System identification analyses were used to isolate stiffness contributions to the ankle joint's resistance to rotation [4]. This approach differs from calculating the slope of the moment-angle curve, such that the measures are not strictly a function of the net moment demands of the task and are robust to inertial and damping components [1, 5]. Shear wave velocity was measured from the MG and SOL over six isometric trials for each condition (Aixplorer SuperSonic Imagine, Aix en Provence, France).

A biomechanical model was used to estimate k_{muscle} (Fig. 1). The ankle joint was modeled as a pin joint with two springs (k_{muscle} and k_{tendon}) acting in series about its center of rotation. Literature values for moment arm were used [6, 7], and k_{tendon} was measured experimentally by tracking the MG muscle-tendon junction with B-mode ultrasound during ramp (0–60%MVC), isometric contractions.

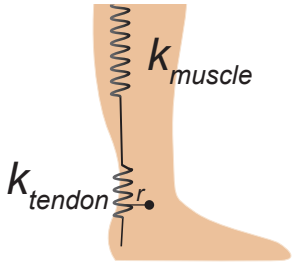

Figure 1: Biomechanical model to estimate muscle stiffness.

To understand the relationships between 1) SWV and k_{joint}, and 2) SWV and k_{muscle}, hierarchical linear statistical models were used. Trials were nested within participants, such that all relationships were within-subject.

RESULTS AND DISCUSSION

A strong, linear relationship was found between SWV_{MG}, SWV_{SOL}, and k_{joint} (R^2 = 0.96; RMSE = 14.6 N·m/rad) (Fig. 2A). SWV_{SOL} (when controlling for SWV_{MG}) had a greater slope in its relationship with k_{joint} than SWV_{MG} (when controlling for SWV_{SOL}). For example, if SWV_{SOL} and SWV_{MG} are 9 and 3 m/s, then $k_{joint} \approx 211$ N·m/rad. However, the inverse produces $k_{joint} \approx 113$ N·m/rad. Low collinearity between SWVs ($r = -0.331$) suggests that SOL and MG were independent regressors.

Shear wave velocity in both SOL and MG increased with ankle joint moment (Fig. 2B and C, R^2 = 0.88, R^2 = 0.95, respectively). The difference in slopes between flexion and extension in SWV_{MG} but not SWV_{SOL} reflect the biarticular nature of MG; SWV_{MG} increases more when it is in a kinematic position that facilitates greater force generation.

The strong relationship observed between SWV and k_{joint} is noteworthy and clinically relevant. Weak relationships between SWV and k_{joint} have been observed when assessed passively, between subjects, and using the moment-angle relationship to estimate k_{joint} [2]. However, our data suggest that *changes* in SWV are reflected on the joint level when assessed using more sophisticated measures of k_{joint} and taking into account inter-individual differences. Thus, researchers and clinicians may be able to use SWV as a guidepost for understanding joint stiffness changes with muscle-level specificity.

Surprisingly, no relationship was observed between SWV and estimates of k_{muscle} (R^2 = 0.10; RMSE = 10537.9 N/mm). Model outputs were highly sensitive to moment arm and k_{tendon} parameters. Moreover, the k_{tendon} estimates measured experimentally were likely low, as just the MG subtendon was assessed; low k_{tendon} inflates k_{muscle}. This is evidenced by non-monotonic within-subject k_{muscle} estimates over increasing activations. Future investigations may wish to model each triceps surae muscle-subtendon unit, while considering the specific properties of each, as has been done in the upper extremity [8].

CONCLUSIONS

Our results indicate that changes in muscle SWV are indicative of changes in k_{joint} in healthy, young adults, and suggest that SW ultrasound elastography may be useful for assessing the etiology of changes in k_{joint} by providing muscle-level specificity.

INTRODUCTION

Muscle fatigue is commonly defined as a reduction in the maximal force capacity of muscles, and can impair postural balance [1,2], possibly leading to injuries in not only sports but also leisure settings.

Control of posture is a complicated mechanism requiring efficient and effective muscular activation using the visual, somatosensory, and vestibular information. As the center of body's mass locates in front of the ankle joint during quiet standing, plantar flexor muscles play a primary role in maintaining balance, and many previous studies have assessed how these muscles are organized using time and frequency analyses. Mochizuki and colleagues, for example, have revealed that common input to motor units within soleus (SL) muscle as well as common input to motor units of bilateral SL muscles are stronger during standing than voluntary contraction [3]. Furthermore, recent studies have found electromyography (EMG)-EMG coherence, that quantifies common input to muscles, between bilateral homologous plantar flexor muscles and unilateral plantar flexor muscles in delta band (0-5 Hz) [4,5]. The origin of the comodulation has been suggested to be the subcortical systems [3].

Given a finding that muscle fatigue can influence the firing rate of motor units [6], this study examined whether localized muscle fatigue would affect the comodulation of bilateral and unilateral plantar flexor muscles during quiet standing, using the coherence analysis. It was hypothesized that muscle fatigue would decrease the delta-band coherences between bilateral homologous plantar flexor muscles and within unilateral plantar flexor muscles.

METHODS

Eleven healthy young male adults (mean age ± SD = 22.2 ± 0.8) participated in this study. They were asked to quietly stand on a force plate (Tec Gihan, Kyoto, Japan) with their bare feet parallel to each other for 40 seconds. The task was performed before and after fatigue protocol. The fatigue was induced by asking the subjects to raise their heels with knees extended until exhaustion.

The center of pressure (COP) was recorded from the force plate. EMG signals from bilateral medial gastrocnemius (MG) and SL muscles were also recorded using Trigno system (Delsys, MA, USA).

A customized Matlab script (Mathworks, MA, USA) was used to analyze the recorded data. We calculated SD and mean speed of COP displacement. Also, coherences between bilateral homologous plantar flexor muscles (MG-MG and SL-SL pairs) and within the unilateral muscles (MG-SL pair) for the right leg were estimated using the following equation:

$$|C_{xy}(f)|^2 = \frac{|P_{xy}(f)|^2}{P_{xx}(f) \cdot P_{yy}(f)},$$

where $P_{xx}(f)$ and $P_{yy}(f)$ are the auto-spectra of the signals x and y, and $P_{xy}(f)$ is the cross-spectra at the frequency f. They were calculated with a discrete Fourier transform of non-overlapping segments of 1024 data points. The coherence function is a number ranging from zero to one: zero indicates that two signals are completely independent, and one indicates that two signals are identical. For each analysis, 95% confidence limit was applied to identify the significant coherence.

Statistical analysis was performed with R. We compared the SD and mean speed of COP displacement between pre- and post-fatigue using a

paired t-test. In addition, we averaged z-transformed coherence over frequency ranges of 0-5 Hz (delta band). We compared the effect of fatigue on the bilateral coherence between the muscle pairs (MG-MG and SL-SL) using a two-way repeated measure analysis of variance (ANOVA). The effect of fatigue on the unilateral coherence (MG-SL) was assessed using a paired t-test. The significant level was 0.05.

RESULTS AND DISCUSSION

Results of COP parameters are presented in Figure 1. There was no significant difference in the SD of COP displacement between pre- and post-fatigue. The mean speed was greater in post- than pre-fatigue ($p = 0.0016$).

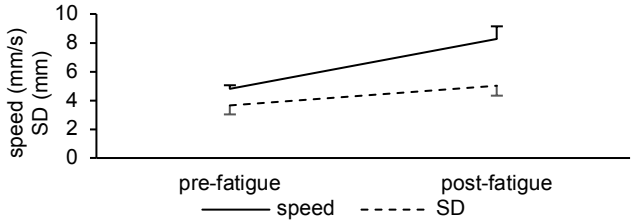

Figure 1: Effects of fatigue on COP parameters.

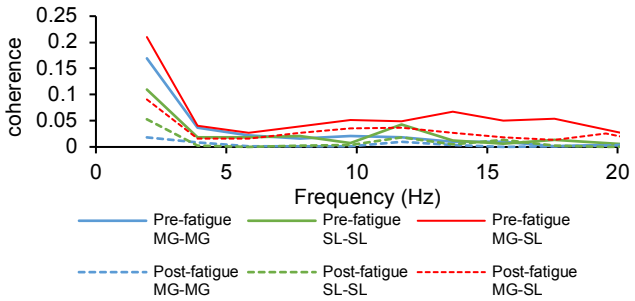
Pooled coherence spectra (95% confidence limit = 0.0047) and results of the z-transformed coherence are shown in Figure 2. A two-way repeated measure ANOVA on the delta-band coherence revealed a main effect of fatigue ($F_{1,10} = 11.0$, $p = 0.0078$) and interaction between fatigue and muscle pair ($F_{1,10} = 6.2$, $p = 0.032$). Post-hoc analysis showed that the delta-band coherence for the MG-MG pair was smaller in post- than pre-fatigue ($p = 0.0041$). There was no significant difference in the delta-band coherence for the SL-SL pair. Also, a paired t-test revealed that the delta-band coherence for the MG-SL pair was significantly smaller in post- than pre-fatigue ($p = 0.044$).

Consistent with a previous study [2], the speed of COP displacement was increased by the local muscle fatigue. The results regarding the coherence partly supported our hypothesis. The insignificant effect of muscle fatigue on the delta-band coherence for the SL-SL pair may be attributed to the fatigue protocol having the subjects raise their heels with knees extended. The gastrocnemius muscles might have been mainly fatigued by the protocol. The significant decrease in the delta-band coherence for the MG-MG and MG-SL pairs could be ascribed to an increase in the variability of motor unit firing rate [6]. This could have caused the comodulation less likely. Alternatively, it is also possible that a shift from ankle to hip postural control strategy has occurred after the muscle fatigue [8]. The ankle muscles could have been utilized less after the fatigue protocol.

A.



B.

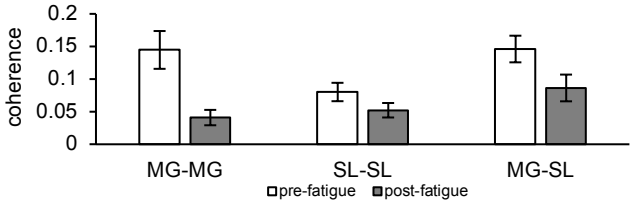


Figure 2: Pooled coherence spectrum (A) and effect of fatigue on coherence (B).

CONCLUSIONS

The local fatigue of plantar flexor muscles could decrease the low-frequency common input to these muscles. The current findings may provide guidance for developing interventions that mitigate fatigue-related problems, potentially in clinical populations.

COMPUTATIONAL MODEL OF MUSCLE INJURY VALIDATED WITH IN SITU EXPERIMENTS

INTRODUCTION

Volumetric muscle loss (VML) injuries occur where there is a permanent loss of muscle function, and treatment of these injuries is challenging because the type of injuries and wound locations varies widely [1]. Regenerative medicine is a promising method for the treatment of VML injuries; however, within the literature, there is variability in the *in vivo* models used to study these injuries and the methods used to assess functional repair [2,3]. *In silico* analysis is a tool that can capture the variability of VML injuries' sizes and locations as well as simulate different experimental conditions.

In this study, we aimed to couple a finite element (FE) model with *in vivo* muscle functional analysis. The latissimus dorsi (LD) of rodents is a large flat muscle on the back that allows for a range of VML injury sizes and locations to be tested. Additionally, its complex muscle architecture of parallel and pennate fibers makes it complicated to understand the relationship between injury magnitude, location, and functional loss. Functional assessment of the LD can be tested using an *in situ* setup, which maintains the physiological conditions of the LD and captures the force of both parallel and pennate fibers. We developed a finite element model of the rat latissimus dorsi (LD) and used it as a predictive tool to focus our *in vivo* study and understand the complex biomechanics of force loss resulting from different injuries.

METHODS

The three-dimensional FE model of an intact rat LD was created based on measurements from dissected LDs of rats and was simplified to have a shape of one rectangle plus one fan [4]. The LD was modeled as a transversely isotropic, hyperelastic and quasi-incompressible material [5], and it was assigned fiber direction from the origin along the spine to the insertion at the humerus using computational fluid dynamics [6]. Boundary conditions were assigned to replicate *in situ* experimental testing conditions, and maximum muscle activation was set for all simulations. The native LD model was calibrated to fit native experimental data using a sensitivity analysis of the peak isometric stress parameter (Fig. 1C). Then an injury 11x15 mm was created at various locations within the muscle model and isometric contractions were simulated (Fig. 1A).

Experimentally, two injuries (11x15 mm) were created – the original injury and high injury – and then immediately tested using the *in situ* setup [3]. In this method, the LD muscle was minimally dissected and maintained in its native environment with blood supply and nerve innervation. A nerve cuff was placed around the motor nerve and the muscle's distal tendon was attached to the lever arm of a force transducer. The nerve was then stimulated and the peak isometric forces were measured at a range of stimulation frequencies.

RESULTS AND DISCUSSION

The isometric simulations of five different injuries demonstrated that the location of an injury has a dramatic impact on the LD's total force of contraction (Fig. 1B). The 36% reduction in force of the original injury compared to native LD was validated experimentally, as seen in Fig. 1C. An injury near the top of the muscle, labeled high injury, generated the largest decrease from native at 50% (Fig. 1B). The *in situ* testing of the high injury confirmed the model's force prediction (Fig. 1C). Using the FE model as a predictive tool, we were able to determine the preferred injury location to maximize the decrease between native and injured force production. For the development of novel therapies, an increased difference would help to

increase the margin of difference between treatments and better aid development.

The FE model can also be used to better understand the biomechanics of force production and the difference between the original and high injuries. A breakdown of the force production from each component of the LD showed that the original injury fan generated 3.204 N compared to only 2.269 N from the high injury fan portion. The increased number of intact fibers present in the original injury likely contributed to the increased force production of the original injury location. Analysis of along-fiber stretch shows that the high injury LD generated a larger along-fiber stretch within the region of intact fibers of the fan compared to the original injury. This indicates that the fibers of the high injury LD operate on the descending limb of the force-length curve and are unable to generate maximum force.

CONCLUSIONS

Using a computational and experimentally coupled framework, we were able to determine the best injury location to see the largest difference between native and injured rat LD muscles by creating, validating, and testing a model with three different data sets. This work demonstrates that combining these tools allows more focused and efficient *in vivo* studies to be designed which saves valuable time, money, and resources and has the potential to accelerate the development of regenerative therapies.

HIP EXTENSOR FATIGUE ALTERS HIP AND KNEE COUPLING DURING STEP DOWNS: A RANDOMIZED CONTROLLED TRIAL

Nicholas J. Beise, Michelle L. Fischer, Taylor L. Stecklein and John H. Hollman

email: hollman.john@mayo.edu

INTRODUCTION

Impaired hip muscle function may contribute to movement coordination deficits (e.g., altered hip adduction or knee valgus) that increase lower extremity injury risks. In previous work [1] we reported hip extensor fatigue as a model of hip extensor impairment has little to no effect on hip and knee kinematics, as measured with linear measurement tools (mean and SDs of joint angles). Nonlinear measures of coupled hip and knee joint kinematics, however, may provide different insights into the effect of impaired hip muscle function on coupled lower extremity movement patterns.

We examined whether coupled dynamics of sagittal plane hip and frontal plane knee motion are altered during single-limb step-downs following a protocol that fatigues the hip extensors.

METHODS

30 healthy adults participated (10 men, 20 women, age = 23.5 ± 1.5 years, BMI = 24.3 ± 3.1 kg/m^2) in this randomized controlled trial. Each participant performed 20 repeated single-limb step-downs from a 19-cm step before and after completing either a Biering-Sorensen fatigue protocol or a sham fatigue protocol (push-ups to exhaustion).

Hip and knee kinematics during the step-down tests were acquired at 100 Hz with a Vicon MX motion analysis system and five MX20+ cameras. We used Vicon's Plug-in-Gait marker system to model lower extremity segments and Nexus software to quantify pelvis and lower extremity kinematics. Marker trajectories were filtered with a Woltring quintic spline filter (20-mm mean square error).

We analyzed peak sagittal and frontal plane hip and knee angles (i.e., hip and knee flexion, hip adduction, knee valgus or varus) across 20 repetitions of the step-down tests, including means and SDs.

To examine hip and knee coupling dynamics, we created cross recurrence plots and used cross recurrence quantification analyses (cRQA) as described by Webber & Zbilut [2]. Briefly, cRQA examines structural characteristics of two time series embedded in a reconstructed phase space containing sufficient dimensions to define the state of the system. According to Takens [3], that phase space may be reconstructed with time delayed copies of the series. We used a time delay of 60 samples based on average mutual information functions, 3 embedding dimensions based on global false nearest neighbors analyses, and set the radius at 20% of a SD to yield recurrence rates between 1% and 5%.

The following measures were quantified:

- Determinism (DET): proportion of recurrent points that fall on diagonal lines of 2 or more points; represents the predictability of coupling between two signals.
- Maximum line (L_{MAX}): length of the longest diagonal line of recurrent points; an indication of attractor strength between signals.
- Divergence (DIV): inverse of L_{MAX}, also related to the maximum positive Lyapunov exponent, estimates rates at which coupled trajectories in the phase space diverge; an indication of chaos in coupled signals.
- Mean line (L_{MEAN}): average length of diagonal recurrence lines; estimates average period during which signals are coupled.
- Shannon entropy (ENT): probability the length of diagonal recurrence lines will be repeated in the recurrence plot; estimates variety of patterns in which two signals are coupled.

Pre-to-post fatigue change scores in the linear hip and knee angle measures (means & SDs) and in the nonlinear coupled sagittal plane hip and frontal plane knee coordination measures were analyzed inferentially with independent t-tests ($\alpha = .05$).

RESULTS AND DISCUSSION

Overall, participants performed the step-downs with 52.9 ± 10.1° of hip flexion, 18.3 ± 5.9° of hip adduction, 72.2 ± 7.2° of knee flexion and 5.2 ± 13.0° of knee valgus. Neither the magnitude nor variability in sagittal and frontal plane hip and knee kinematics changed following the fatiguing protocol ($p > .05$). Based on cRQAs (Table 1), however, the determinism and entropy in coupled sagittal plane hip and frontal plane knee angle displacement patterns decreased in the control group and increased in the fatigue group ($p = .043$ and .044, respectively). Fig. 1 illustrates representative pre- and post-fatigue data.

Changes emanating from the coupled hip and knee angle trajectories can be interpreted. Namely, participants performed the step-down tests with altered coordination patterns in the fatigued state. Control participants performed the task with less irregularity, implying a learning effect in which they became more efficient at completing the task. Fatigued participants, in contrast, performed the step-downs with longer periods in which hip flexion and knee valgus were coupled (increased DET) and concomitantly performed the task with greater irregularity in the variety of patterns in which hip flexion and knee valgus were coupled (increased ENT). In the fatigued stated, overall hip flexion and knee valgus coupling was increased but that coupling occurred in a more irregular manner.

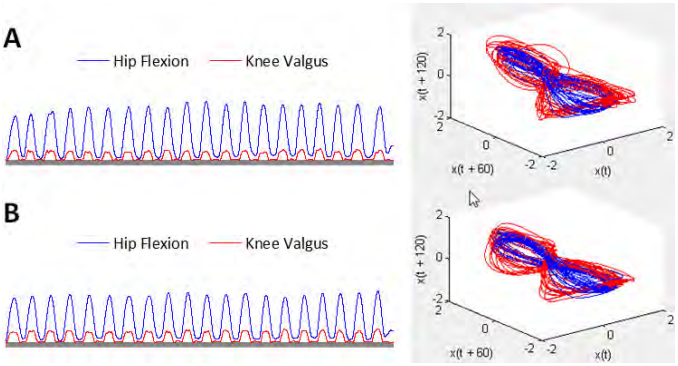

Figure 1: Time series of sagittal plane hip and frontal plane knee angles in (A) pre- and (B) post-fatigue conditions, with reconstructed phase spaces.

CONCLUSIONS

Fatiguing the hip extensors as a model of impaired hip muscle function altered coupled hip and knee motion patterns, suggesting that inter-joint coordination was impaired. This may have implications for pathomechanics that elevate lower extremity injury risks when hip extensor function is impaired. Furthermore, dynamical measures of inter-joint coordination may be more sensitive to examining consequences of changes in hip extensor function than are traditional linear measurements of lower extremity kinematics.

INTRODUCTION

Control of lateral stability is essential to prevent loss of balance and consequential falls during locomotion. This control is complex, demanding not only appropriate limb trajectories for foot placement, but also maintenance of a constantly shifting body center of mass (COM) [1]. Currently, our understanding of how and what the nervous system controls to create lateral stability during walking is poor.

Experiments utilizing robotic force fields to probe the sensorimotor system have been instrumental to our understanding of how the nervous system controls stable reaching movements [2]. When preforming a repetitive reaching task in a novel and consistent environment, people select motor control strategies that predict the effects of the force field. When the force field is unexpectedly removed, people exhibit movement errors, known as after-effects, which provide strong evidence that they have formed a predictive model of their environment.

While there is evidence that people form predictive models to control limb trajectories during walking, the same has not been shown for COM trajectories. Considering that previous research suggests that people plan walking paths in terms of COM trajectory it is likely that the nervous system also utilizes control strategies that predict COM dynamics [3]. Therefore, the purpose of this study was to investigate how people control COM trajectory while walking in a novel environment.

Specifically, we challenged stability by applying a laterally directed force field to participants' COM during a goal-directed walking task. We hypothesized that when lateral stability is altered by a novel but consistent force field, healthy young adults would form a predictive model of the environment that will be used to control lateral COM dynamics during walking.

METHODS

13 healthy young adult subjects (6 male, 7 female, 22.8 ± 2.1 years and 65.9 ± 8.5 kg, mean ± SD) participated in the study. Northwestern University's Institutional Review Board approved the protocol.

Participants preformed repetitions of a discrete walking task, moving from a static standing position to a 0.3 x 0.3 m target located 1.5 leg lengths in front of the start position. A cable robot was used to apply a novel external force field to the participant's COM. The applied forces were proportional in magnitude to forward walking velocity and directed laterally towards the participant's right side. Participants always began the task by stepping with their right foot first. A motion capture system recorded 3D coordinates of markers on the pelvis. This data was used to estimate COM dynamics.

Participants performed 110 total trials of the discrete walking task; 20 **Baseline** trials (no applied forces), 70 **Adaptation** (in the force field), and 20 **Washout** trials (no applied forces).

We quantified signed area deviation of the COM trajectory relative to a straight forward path originating from the lateral COM position at first toe-off (Fig. 1). Signed Deviation reflects directional biases in COM trajectory by taking the difference between areas on either side of the straight path.

We evaluated changes in COM trajectory by comparing COM Signed Deviation across the last

three trials of Baseline, the first three (early adaptation) and last three (late adaptation) trials of Adaptation, and the first three trials of Washout using a one-way repeated measures ANOVA with a Bonferroni correction.

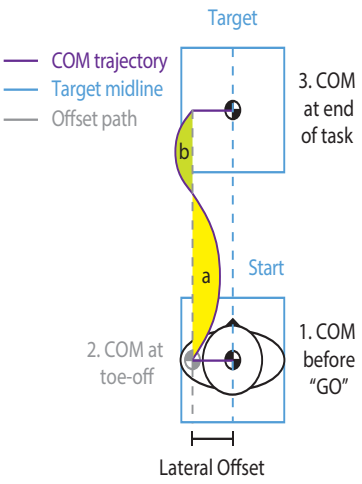

Figure 1: Lateral COM Offset calculated as the shift in COM position between the trial start and first toe-off. Signed Deviation is the net deviation of the COM from a straight path aligned with the Lateral COM Offset (the difference between areas "a" and "b").

RESULTS AND DISCUSSION

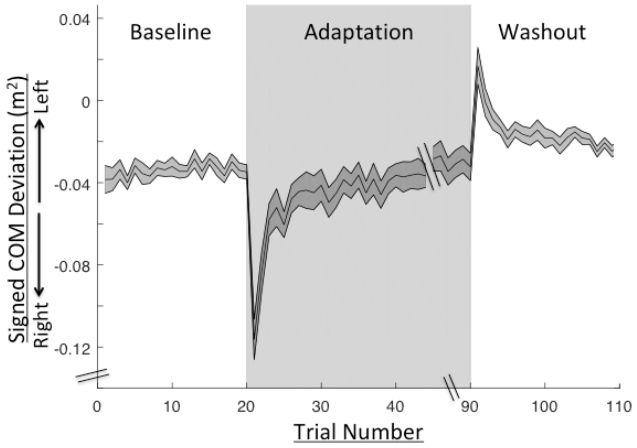

Figure 2: COM Signed Deviation and lateral offset. Mean and SEM calculated across all participants. During Early Adaptation COM Signed Deviation increased in the same direction as the force field. By Late Adaption, Signed Deviation was not different than Baseline. During Washout Signed Deviation increased in the opposite direction of the force field.

Our results revealed a significant difference in Signed Deviation across conditions (ANOVA; $p< 0.001$) (Fig. 2). Post hoc testing found that Signed Deviation was significantly different between Baseline and Early Adaptation ($p<0.001$), but not between Baseline and Late Adaptation ($p>0.99$). In addition we found that Signed Deviation was significantly different and in opposite directions between Early Adaptation and Washout ($p<0.001$). Overall, Early Adaptation movement in the perpendicular force field directed toward the participant's right side resulted in lateral deviations to the right. By Late Adaptation, participants had adjusted their control strategy such that lateral COM deviations were no longer different than Baseline. When the force field was unexpectedly removed during Washout, participants displayed large lateral COM deviations to their left, and after-effects that suggest that individuals were using predictive control strategies to offset the effects of the force field.

CONCLUSIONS

In support of our hypothesis we found that healthy young adults formed a predictive model of a novel-walking environment and used the model to adapt and control their COM trajectory during discrete goal-directed walking tasks. This finding suggests that people plan and control COM locomotor trajectories. Using force fields to probe sensory motor control of walking trajectories will be valuable for evaluating gait stability and identifying the underlying control objectives used to maintain COM stability.

CONTACT STRESS OVER-EXPOSURE CORRELATES WITH OA DEVELOPMENT IN ACETABULAR FRACTURES

Kevin N. Dibbern, Tai C. Holland, Holly D. Thomas-Aitken, Tyler CarlLee, Michael C. Willey,
Jessica E. Goetz, J. Lawrence Marsh, Donald D. Anderson
University of Iowa, Iowa City, IA
email: kevin-dibbern@uiowa.edu

INTRODUCTION

Posttraumatic osteoarthritis (PTOA) is a common debilitating sequela of intra-articular fracture (IAF) [1]. Surgical reduction of IAFs aims to restore congruity of the disrupted joint surface to decrease articular contact stress and mitigate PTOA risk [2]. Elevated contact stress in mal-reduced IAFs of the ankle reliably predicts PTOA risk [3]. The effect of acetabular fracture on chronic hip contact stress and PTOA risk, however, is less well established. With up to a quarter of acetabular IAFs leading to PTOA, an investigation into the pathomechanical development of this condition is warranted.

Computational modeling of articular contact derived from CT images has been well validated for contact stress assessment. Discrete element analysis (DEA) is a specific modeling technique well suited for determining relationships between contact stress exposures and clinical outcomes, such as PTOA, in larger patient populations [6]. Mapping of the cumulative contact stress over-exposure on the articular surface across a complete gait cycle provides a means to identify those joints most prone to eventual development of PTOA.

METHODS

Eleven patients with operatively managed acetabular fractures were enrolled in this IRB-approved study. Patients were selected for having post-operative CT imaging and minimum two-year radiographic follow-up available. Femoral and pelvic anatomy for each patient was segmented from post-operative CT scans to produce DEA models using the validated method of Townsend et. al., 2018. The models were then aligned to the coordinate system defined by Bergmann et al. The walking gait data obtained in that study of instrumented total hips was discretized into 13 evenly spaced time increments. Patient specific forces were applied to each model based on body mass at the time of injury. DEA was used to compute deleterious contact stress exposure above a damage threshold ($P_d \geq 5$ MPa – defined as over-exposure) at each step in the gait cycle. For each patient, only the deleterious contact stress over-exposure was considered in our evaluation. These deleterious contact stresses were then computed at each of the 13 steps of the gait cycle and multiplied by the time spent in each of the steps to obtain a stress-time over-exposure metric. Summed over the gait cycle, the cumulative contact stress over-exposure experienced by the articular surface was compared to KL grades at 2 years post-operatively.

RESULTS AND DISCUSSION

Maximum values of contact stress over-exposure per gait cycle ranged from 0.23 - 2.91 MPa*s in the 11 acetabular cases analyzed in this study (Fig. 1). By design, KL grades were evenly distributed with 2 cases per grade except for grade 1 with 3 cases. Maximum per gait cycle contact stress over-exposure stress had a moderate positive correlation with KL grade ($R^2 = 0.426$). Qualitative assessment of the DEA derived post-operative models of this subset (cases 07, 08, and 10) reveals acetabular fractures with readily apparent joint incongruities flanked by areas of high contact stress over-exposure (Fig. 2). Cases with minimal or no radiographic evidence of osteoarthritis tended to exhibit better articular surface congruity. This corresponded with lower maximum contact stress over-exposure.

To our knowledge, this is the first study investigating the relationship between cumulative contact stress over-exposure and PTOA in acetabular fractures. The maximum per-gait cycle contact stress over-exposure cycle exhibited a

threshold above which all acetabular fractures progressed to PTOA.

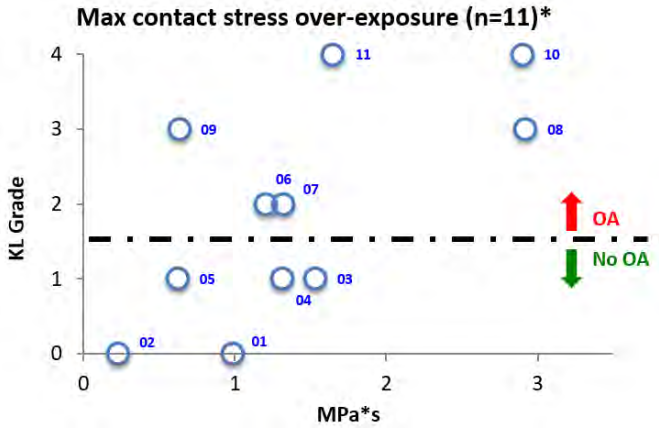

Figure 1: Maximum per gait cycle contact stress over-exposure.

CONCLUSION

The rate of PTOA development after surgical reduction and repair of acetabular fractures has remained stagnant over the years. Major efforts have focused on improving surgical technique to prevent PTOA, despite limited success and poor understanding of the pathogenesis of PTOA. Investigating how disruptions of articular surfaces can cause PTOA will likely provide insight on how to properly reconstruct them. The methods developed in this work allow precise and objective determination of the quality of acetabular fracture reduction. DEA techniques can quantify the mechanical impact of imperfect reduction via calculation of contact stress elevations throughout articular surfaces.

SIGNIFICANCE

The application of these techniques to acetabular fractures highlights the clinical value of this methodology in the hip joint. By identifying hips likely to degenerate due to a high level of residual incongruity, DEA-contact stress analysis may provide early prediction of joint failure and subsequent consideration of conversion to total hip arthroplasty.

KNEE ADDUCTION MOMENT IS GREATER WITH TIME SINCE INJURY IN INDIVIDUALS WITH LOWER LIMB LOSS

INTRODUCTION

Individuals with unilateral lower limb loss often develop osteoarthritis (OA) in the knee of their contralateral limb [1]. OA is a leading cause of knee pain and disability, and is characterized by the progressive loss of articular cartilage, resulting in joint space narrowing. The high prevalence of OA in the limb loss population is posited to be due to large or abnormal loads on the contralateral limb during activities of daily living [1]. Specifically, features of the knee adduction moment (KAM) such as its peak, loading rate, and impulse during walking have been associated with narrow joint space [2] and cartilage volume loss [3].

In individuals with limb loss, we might therefore expect abnormal KAM profiles. For example, individuals living with limb loss for many years (14±10 yrs) demonstrate greater loading on the intact vs. prosthetic limb [4]. However, individuals with more recent limb loss (2±1 yrs) do not display unusually high KAM magnitudes [5], suggesting that individuals with limb loss may not alter their gait mechanics until there is a reason to do so (e.g., loss of fitness, pain from cartilage loss), which may occur years after sustaining the injury and after the joint has already begun to structurally deteriorate. These statements are largely speculative, but speculation serves to emphasize that fact that it is currently unknown how time since injury relates to joint space and knee mechanics during gait. This gap in knowledge is important because OA is not reversible, so we need to better understand how modifiable factors like joint mechanics affect joint health, prior to the initiation of OA.

Therefore, the purpose of this exploratory data analysis was to examine the cross-sectional relationships between time since injury vs. KAM peak, loading rate, impulse, and medial joint space in individuals with lower limb loss.

METHODS

Eleven individuals with unilateral lower limb loss (three transfemoral, eight transtibial; mean±SD age: 36±7 yrs, stature: 1.82±0.05 m, body mass: 100.9 ±14.1 kg, and time since injury: 10±2 yrs, range = 7-13 yrs) participated after providing written informed consent to study procedures approved by the local IRB. Participants walked at self-selected speed (1.34±0.15 m/s) along a 15-m walkway with biomechanical data captured using an 18-camera system and six force platforms embedded within the walkway. KAM was calculated using Visual3D software and scaled by bodyweight and height.

Outcome variables were KAM peak, impulse, and loading rate, the time since injury resulting in amputation, and joint space of the medial knee.

Figure 1: Example of radiographic assessment of joint space at the medial border of the knee (white arrows).

KAM impulse was calculated as the area under the moment-time curve. KAM loading rate was calculated as the slope during 20-80% of time from minimum KAM to first KAM peak.

Weight-bearing radiographs of the intact knee were obtained and evaluated by a trained musculoskeletal radiologist. Medial joint space was measured at the most medial border of the tibiofemoral joint (Fig. 1).

Pearson correlation coefficients (r) were used to examine relationships between time since injury vs. KAM peak, impulse, and loading rate, and medial joint space ($p < 0.05$). 95% confidence intervals on r (CI) were calculated via Fisher transformation. Due to the exploratory nature of these tests, reported p-values were not adjusted for multiple comparisons.

RESULTS AND DISCUSSION

Time since injury positively correlated with KAM peak ($r = 0.64$, $p = 0.03$, CI = [0.07, 0.90]; Fig. 2a) and impulse ($r = 0.62$, $p = 0.04$, CI = [0.03, 0.90], Fig. 2b). There was no correlation between time since injury and KAM loading rate ($r = 0.60$, $p = 0.05$, CI = [0.00, 0.90]; Fig. 2c) or time since injury and medial joint space ($r = 0.53$, $p = 0.09$, CI = [-0.10, 0.90]; Fig. 2d).

The significant correlations between peak KAM and KAM impulse with time since injury suggest that these individuals exhibit greater knee joint loading over time. Further, the insignificant correlation between time since injury and joint space suggests that changes in gait mechanics may precede cartilage degeneration and the resulting loss of joint space. Ongoing longitudinal data collection will further consider temporal relationships between knee joint loading, joint space narrowing, and the initiation/progression of OA.

CONCLUSIONS

The present study is the first to relate features of the KAM, joint space, and time since injury in the limb loss population. These exploratory results suggest a positive relationship between medial knee joint loading (as measured by KAM peak and impulse) and time since injury, but do not support an association between joint space narrowing and time since injury in this population. In other words, individuals with greater time since injury exhibit greater knee joint loading, which may place them at increased risk for future development of knee OA.

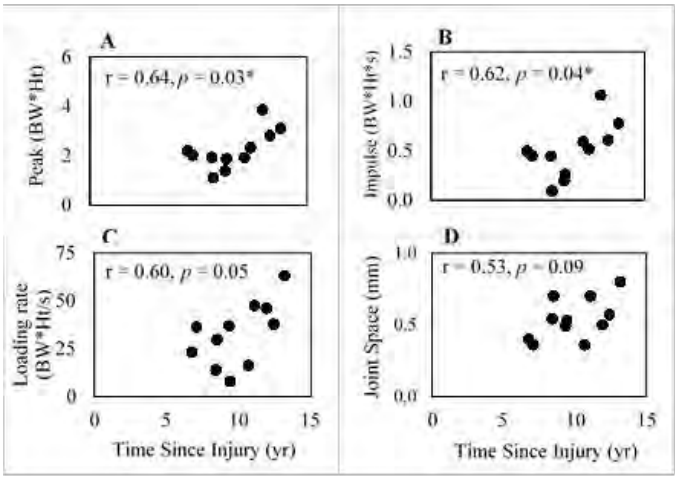

Figure 2: Correlations between time since injury and (A) KAM peak, (B) impulse, (C) loading rate, and (D) medial joint space. *p<0.05

BREAST CANCER TREATMENT TYPE AND POST-TREATMENT DURATION INFLUENCE PECTORALIS MAJOR RECRUITMENT

Department of Kinesiology, University of Waterloo, Waterloo, ON, Canada
email: tlulic@uwaterloo.ca

INTRODUCTION

Pectoralis major is necessary for many daily tasks. It consists of two insertions: clavicular and sternal region, which contribute to shoulder adduction, flexion and humeral internal rotation. In women, this muscle is located beneath overlying breast and subcutaneous tissue and thus, it is commonly damaged iatrogenically during breast cancer treatment [BCT; 1-3]. BCT such as radiation therapy and mastectomy directly affect the pectoralis major [1], while the effects of chemotherapy affect the entire body and may cause indirect, widespread damage to the muscle. Subsequently, this damage contributes to upper limb disability in ~72% of breast cancer survivors [BCS; 4].

Most prior work quantified pectoralis major activity across patient groups and did not investigate the effect of treatment type and time post treatment on pectoralis major recruitment. This information is invaluable as the effects of treatment may differ between groups and mandate specific rehabilitative strategies. Additionally, the time post treatment may affect clavicular and sternal region engagement.

The purpose of this preliminary study was to investigate the effects of treatment type and time post treatment on pectoralis major activity in BCS during maximal voluntary contractions (MVC).

METHODS

50 female breast cancer survivors (59.4 ± 9.7 years) previously diagnosed with stage I, II or III unilateral breast cancer participated in this study. Participants completed treatment including surgery, radiation and/or chemotherapy at least 3 months prior to participation. 47 participants were right-hand dominant and 27 had cancer on the left breast. The average time since diagnosis was 74.9 ± 59.6 months.

Surface electromyography (sEMG) was collected from the clavicular and the superior part of the sternal region of the pectoralis major muscle bilaterally using disposable Ag/AgCl surface electrodes. EMG was collected at 3000 Hz using a Noraxon Telemyo 4200 T G2 telemetered system (Noraxon 2 USA Inc., Arizona, USA), with a band pass filter from 10-1500 Hz, input impedance > 100 MΩ, common mode rejection ratio > 100 dB and a base gain of 500.

Two sets of researcher-resisted maximal voluntary exertions (MVIC) were performed bilaterally against a dynamometer (ergoFET300TM, Utah, USA) using published techniques [5]. The duration of MVICs was 3 s with at least 2 minutes of rest between trials.

sEMG signals were high pass filtered at 30 Hz. A 200 ms RMS was calculated for both limbs and maximal values were extracted for clavicular and sternal regions. The data were then consolidated by quantifying the ratio of affected to unaffected limb peak sEMG for each region. Activations over 100% were defined as hyperactivated, while activations less than 100% were considered reduced. Participants were divided based on treatment type: a) radiation therapy only (9 BCS); b) mastectomy + chemotherapy (7 BCS); c) radiation + chemotherapy (12 BCS); and d) radiation, mastectomy and chemotherapy (13 BCS). Nine BCS received other treatment combinations and were excluded. Time post treatment was self-reported.

Spearman correlations were run for both, clavicular and sternal regions of the pectoralis major, to determine if a relationship existed between duration following treatment and muscle activation. Significance was set to $p = 0.05$.

RESULTS

A significant negative relationship existed in the radiation only group between the time post treatment

and sternal region muscle activation (r = -0.653, p = 0.05; *d* = -2.13). The sternal region of pectoralis major was overactivated in the first ~2 years following treatment, but this was reduced with increased duration following treatment (Fig. 1). This relationship did not exist for the clavicular region (r = - 0.084, p = 0.831). No relationship between time following treatment and regional muscle activity existed in the other treatment types (p > 0.05).

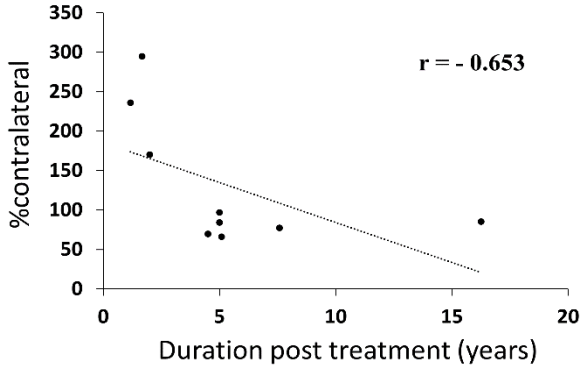

Figure 1: Significant moderate relationship between duration following radiation therapy and pectoralis major sternal activity ratio of affected: unaffected limb.

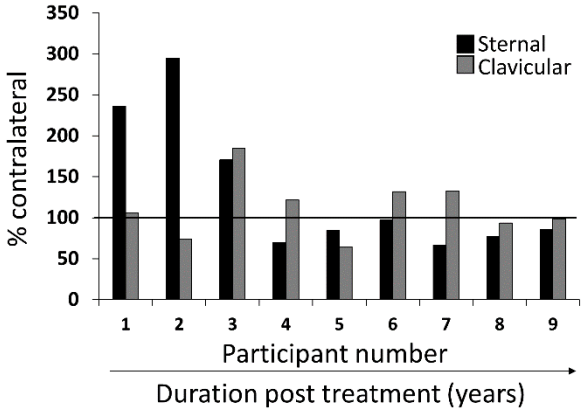

Figure 2: Representation of sternal and clavicular region activity in breast cancer survivors who received radiation therapy only.

Closer examination of the individual data showed that while the sternal region is hyperactive, the activity of the clavicular region is normal. However, when the sternal activity is reduced, the clavicular region became more active (Fig. 2).

DISCUSSION

A relationship existed between altered pectoralis major activity and duration post treatment only for the radiation therapy group. The hyperactivation of this region in the early stages following treatment may indicate fatigue sensitivity or inflamed and damaged tissue. With increased years following radiation therapy, the activity of the affected sternal region reduced relative to the unaffected side, supporting previous literature [2-3; 6]. The effects of radiation therapy on muscle and nerve tissue can continue up to 10 years following treatment [7-8]. Further, muscular scar tissue and fibrotic vasculature may result in decreased underlying muscular activity.

Additionally, preliminary findings suggest that the clavicular region may become hyperactive in some BCS in the later stages following treatment. This may partly be due to the reduction in the activity of the sternal region. However, the exact mechanism is ambiguous.

CONCLUSIONS

Treatment type and duration post treatment are factors that should be considered when investigating pectoralis major activity in BCS who underwent radiation therapy as a form of treatment. Specifically, rehabilitation in the earlier stages post BCT should focus on reducing activity of the sternal region of the pectoralis major, while later stages should focus on increasing activity of the sternal region while reducing activity of the clavicular region.

GLENOHUMERAL JOINT STABILITY DURING DYNAMIC PUSHING AND PULLING

Daniel C. McFarland, Emily M. McCain, Michael N. Poppo, and Katherine R. Saul

North Carolina State University, Raleigh, NC, USA
email: dcmcfarl@ncsu.edu

INTRODUCTION

The glenohumeral joint is the most mobile joint in the human body and depends on active contributions of muscles to stabilize the resultant joint reaction force (JRF) within the glenoid fossa [1]. JRFs composed of large ratios of transverse to compressive forces destabilize the joint and pose a greater risk for shoulder dislocations. Prior dislocations can damage the fibrous structures surrounding the glenoid fossa [1] and reduce the stability index during hand-positioning tasks [2]. Therefore, to prevent degenerative wear to the joint, workspace design should consider glenohumeral instability to avoid motions that naturally place the shoulder at higher risk for instability. Pushing is a common industrial task that has been shown to have increased transverse to compressive forces [2,3]. Knowledge of whether these risks are spatial dependent with task target could be used to design safer workspaces. Our goal was to evaluate how task direction and task target during dynamic push-pull tasks influence joint reaction loads.

METHODS

Prior experimental data of 18 subjects (9M/9F) performing a series of push and pull tasks were used to inform computed muscle control (CMC) [4] simulations in OpenSim [5] to determine resultant JRFs at the glenohumeral joint. CMC tracked experimental kinematics of subjects pushing and pulling submaximal loads to 4 horizontal targets (0^o, 45^o, 90^o, and 135^o) at a sagittal angle of 90^o and 3 sagittal targets (20^o, 90^o, and 170^o) at the 90^o horizontal target for a total of 6 independent task targets (Figure 1). Individualized musculoskeletal models were developed for each subject by scaling a previously developed and validated upper extremity musculoskeletal model [6] to individual joint strength and anthropometry.

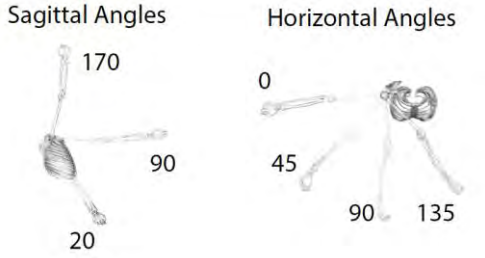

Figure 1: Task target location

Experimental electromyogram (EMG) recordings of surface muscles was used to inform on/off timing of the respective muscles, and thereby improve calculated activations for deep muscles. Furthermore, a penalty term was added to the static optimization stage of the CMC algorithm to constrain the resultant JRF to remain close to experimental limits of glenohumeral stability to prevent theoretical subluxation [7,8]. Differences in stability index, the ratio of transverse to compressive joint reaction forces at the glenohumeral joint, were analyzed across task direction and task target using a two-way ANOVA ($\alpha = 0.05$). If an interaction was present, simple main effects test was performed at each factor level.

RESULTS AND DISCUSSION

An interaction between task target and task direction was present ($p=0.0037$). Pulling stability index was more spatially dependent than pushing (Figures 2 and 3). However, pushing was significantly less stable than pulling for all task targets ($p<0.001$) except for the sagittal target of 20^o ($p=0.1113$) (Figure 3).

Pushing was found to result in less stable joint reaction forces, which agrees with previous studies [2,3]. However, the results suggest that there are limited stability benefits to optimizing push task location. Greater stability benefits would be seen by converting push task to pull tasks where possible

since pulling, except from the low target, was inherently more stable than pushing. Workspaces involving pulling tasks, however, could benefit from optimizing task location, mainly by avoiding placing pull tasks at low targets. Placing pulling tasks at more centrally located targets along the horizontal plane improves task stability.

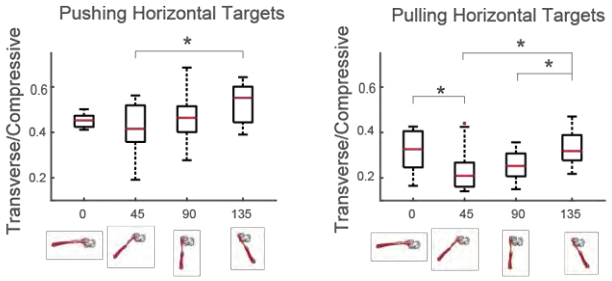

Figure 2: Stability index (transverse/compressive JRF components) across horizontal targets

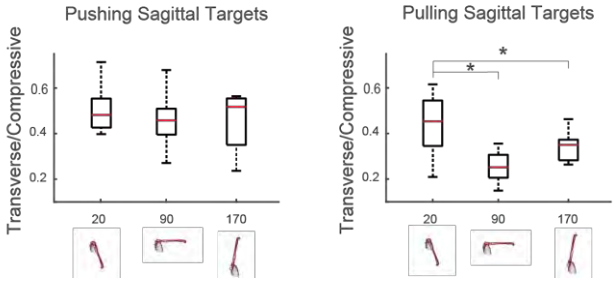

Figure 3: Stability index (transverse/compressive JRF components) across sagittal targets

Inherent task stability may influence muscle demand at the glenohumeral joint. Task targets identified as less stable in this study (i.e 20° for pulling and 135° for pushing) were reported to be significantly more demanding than other task targets [9]. Stabilization of the glenohumeral joint depends on active contributions of muscles, and this increase in demand may, in part, be due to an increased need to control the direction of the resultant joint reaction force.

One limitation of this research is that the kinematics of the handle in the experiment were not recorded. The direction of the applied loads was approximated from initial and final position of the hand's center of mass. Furthermore, strength data was only collected for shoulder abduction and elbow flexion, so strength scaling was limited to these measurements.

CONCLUSIONS

The primary findings have possible implications for arm function throughout the workspace:

1. Pushing places the glenohumeral joint at increased risk for instability; however, the stability index for pushing is similar across targets. Therefore, larger stability benefits may be seen from converting tasks like lever operation from push tasks to pull tasks rather than optimizing task layout.
2. Inherent glenohumeral stability may contribute to increased task demand. Additional work is needed to fully understand to what degree these features are linked.

WHAT ARE THE EFFECTS OF MUSCLE WEAKNESS ON THE SIT TO STAND TRANSFER?

INTRODUCTION

Muscle strength declines in the elderly [1] and those with pathologies such as knee osteoarthritis [2], which leads to difficulty in performing daily tasks like rising from a chair [3]. The degree of weakness that can be tolerated, globally or in individual muscles, before the ability to rise from a chair is compromised is unknown. Previous work investigated this question for gait using dynamic simulations [4], but similar work has yet to be done for the sit to stand (STS) transfer. Such information could allow for better targeted rehabilitation for populations with muscle weakness. The purpose of this study was to investigate the effects of global and individual muscle weakness during the STS transfer and how other muscles compensate for the weakness.

METHODS

As part of a previous study by Caruthers et al. [5], six healthy individuals (4 males and 2 females, age: 23.0 ± 3.0 years) participated after providing IRB-approved informed consent. Each participant rose from a 55.2 cm high, hard-backed, armless chair three times with their arms crossed over their chest and each foot on a different force plate (Bertec, Inc); the chair did not contact the force plates. Motion data were collected at 150 Hz using an 8-camera Vicon MX-F40 system and the Modified Point Cluster Technique [6] while ground reaction forces were obtained from the force plates at 600 Hz. Bilateral surface EMG data were collected on the gluteus maximus, gluteus medius, rectus femoris, vastus lateralis, biceps femoris, tibialis anterior medial, gastrocnemius, and soleus at 1500 Hz using a 16-channel device (Noraxon Telemyo DTS).

Those data were previously used to create dynamic simulations that tracked one STS transfer per participant with the Full Body Model 2016 in OpenSim 3.1 [5, 7]. Muscle forces and activations were estimated by using static optimization (SO), which uses the cost function of minimizing the sum of muscle activations squared [7].

In this study, we began with full-strength simulations and weakened muscles by changing their peak isometric force for two cases. First, all lower extremity muscles were globally weakened by increments of 5% up to 70%. Second, the following individual or groups of muscles were weakened: gluteus maximus (GMAX), gluteus medius (GMED), iliopsoas (ILPS), hamstrings (HAM), rectus femoris (RF), vasti (VAS), quadriceps (QUAD, incl. RF and VAS), tibialis anterior (TA), gastrocnemius (GAS), soleus (SOL), and plantar flexors (PF, incl. GAS and SOL), in 5% increments up to 100% weakness, indicating the absence of a muscle. Using SO, we re-estimated muscle forces as the adjusted model tracked the original kinematics and kinetics, resulting in 932 simulations total.

A simulation was considered to have tracked the original STS transfer if: a) the simulation did not fail and b) the reserve actuators on any joint were less than 5% of peak joint moments [4]. For the simulations that met these criteria, changes in muscle forces and activations from the full-strength simulations were examined in the weakened muscle(s) and the remaining muscles in the dominant leg, which was the leg that had the largest peak vertical ground reaction force during the task. The overall demand placed on all muscles due to the respective muscle weakness was calculated across both legs by the muscle cost metric over time [4]:

$$\text{Muscle Cost} = \sum \text{Muscle Activation}^2$$

In this abstract, we only report global weakness and weakening of the QUAD, GMAX, and PF since Caruthers et al. demonstrated that they produce the largest forces and are main contributors to accelerating the COM up and out of the chair [5].

RESULTS AND DISCUSSION

The amount of global weakness that could be tolerated varied between participants. While three participants could not tolerate more than 35% weakness, the range of tolerable global weakness across all six participants was 20-65%. In all cases, the STS transfer was impaired due to insufficient torque at the knee. For the one participant who failed at 65% global weakness, muscle cost increased by 55% to 617% (relative to 0% weakness) as global weakness increased from 20 to 65%.

For individual weakness, muscle forces changed to maintain the same task kinematics and kinetics. For QUAD weakness, GMAX, biceps femoris long head (BFlh), and GAS reduced in force to oppose the weak QUAD less; the ILPS compensated for a weak RF (Figure 1). For 60% GMAX weakness, the BFlh and GMED forces increased by 183 ± 127% and 49 ± 23% to compensate for a weak GMAX; the RF and VAS forces changed by -5 ± 26% and 24 ± 13% to compensate for the change in BFlh and GMED forces. For 60% PF weakness, the TA decreased in force by 17 ± 23% to oppose the weak PF less.

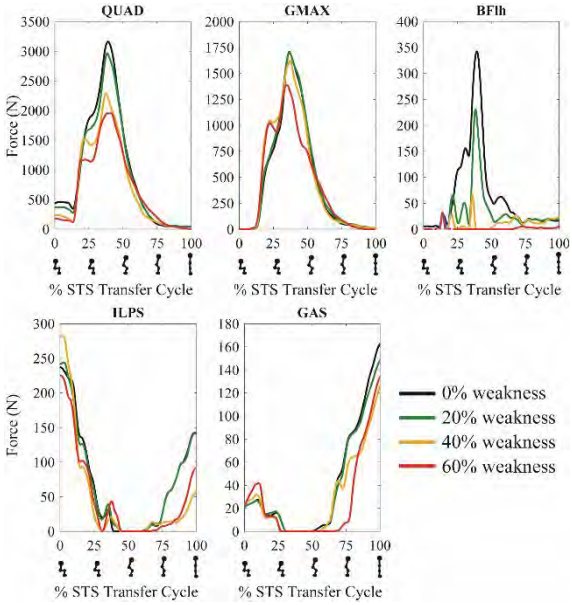

Figure 1. Example of the Effects of 0 – 60% QUAD Weakness on Muscle Forces in the Dominant Leg. Values were averaged across the dominant leg of the participants whose simulations passed the failure criteria for that weakness level.

The compensations that occurred with QUAD, GMAX, and PF weakness led to higher muscle cost, with the QUAD's increase in muscle cost being the highest (Table 1). Simulations with GMAX and PF weakness did not fail or failed later (60-80%) than those with QUAD weakness (20-60%).

Our findings contrast a study that examined how muscle weakness affects gait [4]. While 20-65% of global weakness could be tolerated during the STS transfer, 40-60% could be tolerated during gait [4]. In contrast to the STS transfer, gait was sensitive to PF weakness, but not to GMAX or QUAD weakness [4], which was reflected in muscle cost since the PF's change in muscle cost was the highest. These differences between studies are likely due to larger hip and knee torques but smaller ankle torques during the STS transfer in comparison to gait [9], demonstrating that task kinematics influence how a weakened muscle can contribute to the motion. In addition, more demand is placed on the weakened muscles to maintain the same kinematics and kinetics, which may lead to fatigue and make the task more challenging.

CONCLUSIONS

To our knowledge, this is the first study to examine the effects of muscle weakness on the STS transfer. Our results suggest this task may be most sensitive to weakness of muscles that span the knee, specifically the QUAD muscles, since they are the only muscles that can provide the necessary knee extension to rise from a chair [8]. While strengthening the knee extensors has been suggested to only add to their excess strength capacity during gait [4], such training appears to be essential to maintain a normal chair rise motion. The effects of muscle weakness on other tasks should be explored to inform rehabilitation programs for various populations.

INTRODUCTION

Falls among the elderly (aged ≥ 65) occur frequently, often resulting in injury and increased morbidity and mortality [1]. Most falls occur while walking, and sideways falls are especially hazardous [1-2]. Increased fall risk may be caused by greater gait variability, associated with walking situations that involve uneven terrain or perturbations [3]. Walking surface and visual field perturbations increase gait variability of young, healthy adults, particularly in the mediolateral (ML) direction [3-4]. It is not known how these ML perturbations affect gait parameters of older adults, who may be more susceptible to falls as the result of increased gait variability. Here, we examined the effects of ML visual and surface perturbations on the variability and step-to-step regulation of lateral stepping in healthy young and older adults.

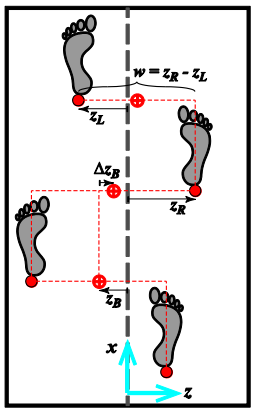
METHODS

Thirteen healthy Young adults (5M/8F; aged 18-29) and thirteen healthy Older adults (6M/7F; aged 61-69) walked in a virtual-reality environment, on a treadmill at 90% of their preferred overground walking speed. Participants completed 3-min walking trials under 3 conditions: (i) Walking with no perturbations (NOP), or walking with continuous, pseudo-random oscillations of either the (ii) treadmill platform (PLA) or (iii) visual field (VIS), all in the ML direction (as in [3]). Participants were instructed to try to walk normally throughout all trials.

Kinematic data of participant and treadmill motion were recorded (Vicon) to compute ML stepping parameters (Fig. 1). Time series of left and right foot placements (z_L and z_R) were used to calculate means and standard deviations of absolute lateral position (z_B) and step width (w). We used Detrended Fluctuation Analysis (DFA) to compute scaling exponents (α) for each time series, $\alpha(z_B)$ and $\alpha(w)$, which quantified the amount of statistical persistence/ anti-persistence in each stepping parameter. Less statistical persistence is implied by α close to 0.5, and indicates stronger correction of deviations in the given stepping parameter from step-to-step [5].

Figure 1: Time series lateral stepping parameters:

- $\{z_L, z_R\} \equiv$ Left & Right lateral foot placements
- $z_B = (z_L + z_R)/2 \equiv$ Absolute lateral position of the body
- $w = z_R - z_L \equiv$ Step width
- $\Delta z_B = z_{Bn} + z_{Bn-1} \equiv$ Change in lateral position of the body (a.k.a., "heading").



RESULTS

There were no significant differences in mean lateral position (z_B) between Young and Older adults, nor between conditions. Mean step widths (w) were not significantly different between Young and Older participants (p = 0.492; not shown), consistent with [6].

Participants exhibited significantly greater w variability during VIS and PLA perturbations than NOP ($p<0.001$; Fig. 2), also as expected [5]. Older adults tended to have slightly more variable step widths than Young adults, but not significantly (p = 0.089; Fig. 2). Participants exhibited significantly greater variability in z_B during both VIS and PLA perturbations compared to NOP ($p < 0.001$; Fig 2), but Young and Older adults were not significantly different (p = 0.192; Fig. 2).

All participants exhibited significantly decreased DFA α exponents during both VIS and PLA perturbations compared to NOP, for both step width (w; p

< 0.001) and lateral position (z_B; p < 0.001; Fig. 3). There were no differences between Young and Older adults for statistical persistence of either w (p = 0.526) or z_B (p = 0.573; Fig. 3).

DISCUSSION AND CONCLUSION

It was expected that mean step widths would be greater for perturbation conditions VIS and PLA, as increasing step width helps maintain lateral stability [3-4]. This is particularly relevant for fall prone populations [1-2]. Participants also demonstrated increased variability in w and z_B, confirming that young and older adults are far more variable in the lateral direction when subjected to perturbations [3].

DFA exponents $\alpha(z_B)$ were closer to 0.5 for PLA and VIS conditions than for NOP, suggesting that during these trials, participants more strongly corrected step-to-step lateral position-specific deviations with the subsequent stride. Thus, participants exhibited tighter step-to-step control [5] over their lateral position when perturbed (Fig. 3). These indications of greater lateral stepping variability and reduced statistical persistence are consistent with our predictions. It is noteworthy that, for all conditions, the $\alpha(w)$ were close to 0.5 than the $\alpha(z_B)$, demonstrating that participants exhibited stronger control of w than z_B. This suggests that participants prioritized maintaining step width for lateral stability [3-4]. Perturbations of the walking surface and visual field did increase Young and Older participant lateral gait variability, closely related to lateral balance control and sideways falling [2-4]. Further, perturbations encouraged a tighter stepping control strategy [5] for correcting w and z_B (Fig. 3).

The lack of significant group effects for variability (Fig. 2) may appear surprising, but was consistent with prior results from similarly *healthy* Older adults [7]. Likewise, the DFA results (Fig. 3) indicate that healthy older adults adopt similar strategies to regulate lateral stepping movements as young adults, despite slightly increased gait variability, consistent with what we found for sagittal plane stride-to-stride stepping control [8].

ACKNOWLEDGEMENTS

NIH / NIA Grant #: R01-AG049735

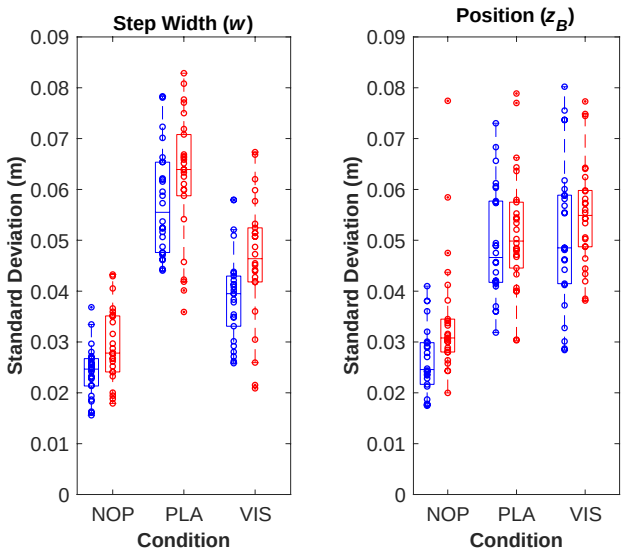


Figure 2: SD as a measure of Young (blue) and Older adult (red) stepping variability for w and z_B. Variability was greater for VIS and PLA compared to NOP.

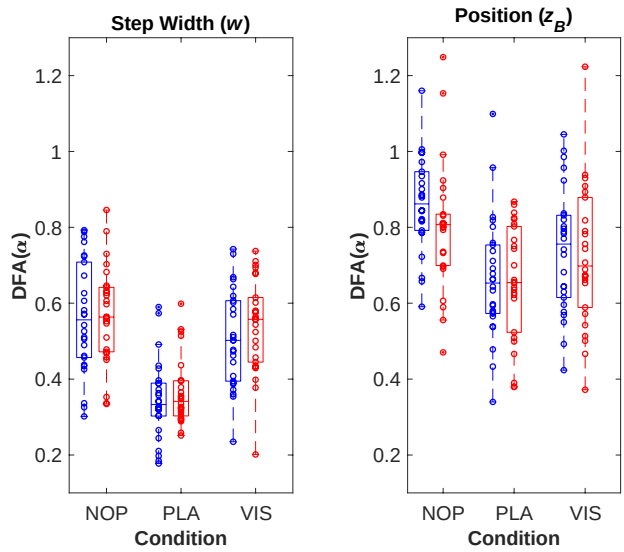

Figure 3: Statistical persistence of Young (blue) and Older adult (red) w and z_B. Group and condition DFA exponent values were closer to 0.5 for w, suggesting tighter regulation of this parameter for lateral stability.

EFFECTS OF WEARING AN UPPER LIMB PROSTHESIS ON STANDING BALANCE

[1,2] Matthew J Major, [1] Tara Shirvaikar, [2] Rebecca Stine, and [1,2] Steven A Gard

INTRODUCTION

Whole-body composition influences the motor behavior required for controlling posture, with the arms playing a key role in standing balance [1, 2]. Consequently, this relationship has important implications for individuals who have lost all or part of an arm. Previous research has suggested that use of an upper limb prosthesis (ULP) can increase the likelihood of falling by six times [3], and that low levels of prosthetic embodiment can cause a postural disturbance to those with upper limb loss (ULL) [1]. A better understanding of the effects of wearing an ULP on balance may inform intervention strategies to enhance postural control. The purpose of this study was to evaluate the acute effects of wearing an UL prosthesis on standing balance, particularly the impact of matching the mass of the prosthetic limb to the sound limb. We hypothesized that this matching would improve bilateral weight symmetry, but have a negative effect on balance. We also expected persons with ULL who fell in the past 12 months to display worse standing balance than non-fallers based on similar observations in elderly persons [4].

METHODS

Eleven individuals with unilateral ULL (8 transradial level, 3 transhumeral level; 50±18 yrs; 175.1±7.4 cm; 79.6±22.6 kg) stood quietly and faced straight ahead for 30 seconds with each foot on a single force plate (AMTI, Watertown, MA) while instantaneous ground reaction forces and center-of-pressure (COP) were recorded. Three trials were collected under three conditions: 1) not wearing a prosthesis; 2) wearing their customary prosthesis; and 3) wearing a mock prosthesis which matched the mass and inertia of the sound limb (Fig 1). Subjects were classified in the 'Faller' group if they reported at least one fall in the 12 months prior to data collection, otherwise they were classified as 'Non-fallers'.

Data for the last 20 seconds of the trials were averaged for each condition and limb side (prosthetic, sound). A mixed three-way ANCOVA (side*condition*group, covariate: body mass index, stance width) was performed on anterior-posterior (AP) COP range, medial-lateral (ML) COP range, and COP sway area. Sway area was estimated using the Khachiyan Ellipsoid Algorithm with a tolerance of 0.001 cm. A mixed two-way ANCOVA (condition*group, covariate: body mass index, stance width) was performed on a Symmetry Index (= (sound side load - prosthetic side load) / (0.5*(sound side load + prosthetic side load))*100) to assess weight distribution symmetry for each condition. A Bonferroni adjustment was used for all multiple comparison post-hoc analyses. Natural log transformations were performed on AP COP range and sway area due to violations of normality as determined by the Shapiro-Wilk test. The critical α for all analyses was set at 0.05.

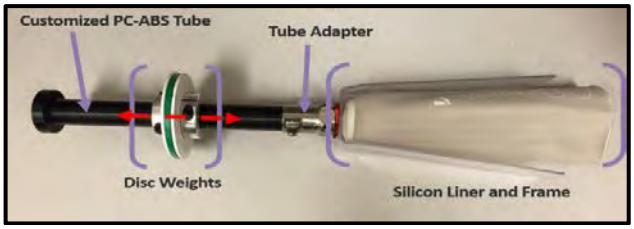

Figure 1: Image of the mock prosthesis allowing for addition and translation of distal mass.

RESULTS AND DISCUSSION

The main effect of prosthesis condition was significant for all COP parameters ($p \leq 0.028$), but post-hoc analyses were not significant ($p \geq 0.506$). COP range was greatest in the AP direction for the customary prosthesis condition, while COP range was greatest in the ML direction for the mock prosthesis condition (Fig 2). The sway area was generally larger for the mock and customary prosthesis conditions compared to not wearing a

prosthesis. Four subjects did not own a prosthesis and so the customary prosthesis was the mock prosthesis without added weight. The main effect of side was not significant for any parameter ($p \geq 0.315$). The main effect of prosthesis condition on weight symmetry was significant ($p=0.008$), with the mock prosthesis creating greater symmetry but a slight bias on the prosthetic limb side (Fig 3). The interaction effect of condition*group on symmetry was also significant ($p=0.042$) with differences between condition greater for the Faller group. There was no significant difference for any parameter between Fallers and Non-fallers ($p \geq 0.070$). Notably, 46% of subjects reported falling within the past year, which exactly matches the prevalence in a larger observation study on persons with ULL [3].

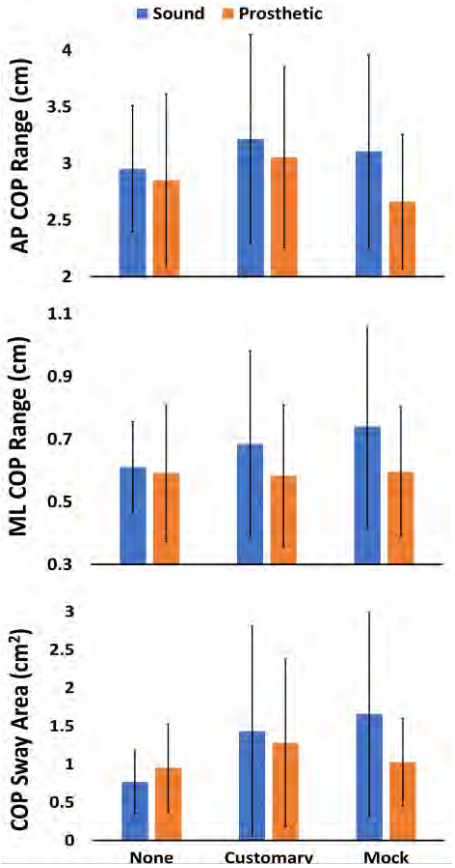

Figure 2: Average AP COP range (top), ML COP range (middle), and COP sway area (bottom) separated by side and condition. Error bars=95% CI.

The results support our hypotheses. Wearing an ULP with mass matched to the sound limb created more symmetric weight distribution, but wearing a prosthesis generally increased COP excursion. Increases in COP excursion represents greater sway of the whole-body center-of-mass and additional demands for postural control [5]. Accordingly, greater COP excursion has shown to be related to greater balance impairment in the elderly [4]. However, there was no significant difference in COP parameters between Fallers and Non-fallers. Given these inconsistent findings, further research is needed to define the relationship between COP excursion and fall risk in persons with ULL. Subjects in this study may have perceived wearing the ULP as a postural disturbance [1], which may help explain the observed acute increase in COP excursion.

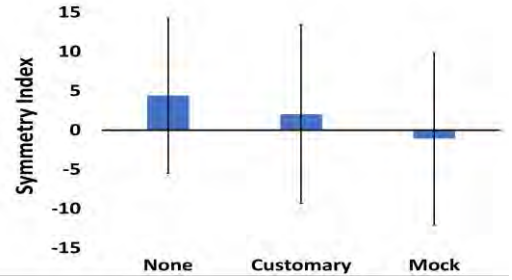

Figure 3: Average Symmetry Index separated by condition. Error bars=95% CI. 0=perfect symmetry, >0=sound side bias, <0=prosthetic side bias.

CONCLUSIONS

Wearing an ULP with mass matched to the sound limb may improve bilateral weight symmetry in persons with unilateral ULL, but acute periods of ULP wear may encourage need for greater postural control. The results do not suggest that an ULP should not be used given the functional benefits of these devices for reaching and grasping activities.

TIME-VARYING NATURE OF POSTURAL CONTROL DURING EYES CLOSED QUIET STANCE

[1] Scott M. Monfort, [2] Lise C. Worthen-Chaudhari, [3] Kimberly E. Bigelow, and [2]Ajit M.W. Chaudhari

email: scott.monfort@montana.edu website: http://www.montana.edu/biomechanics/

INTRODUCTION

Quiet stance with eyes closed (QEC) is an easy-to-implement and informative test condition for various neuromuscular impairments. Several descriptive balance measures (e.g., medial-lateral root-mean-squared excursion – RMS_ml) have been linked to fall risk, supporting their clinical relevance [1]. These descriptive center of pressure (CoP) measures typically analyze time-series data from entire trials; however, reports of CoP signal nonstationarity and acquisition time-dependency raise questions about what aspects of postural control are being analyzed (e.g., transient vs. quasi-steady-state vs. fatigue) [2]. Recommendations for longer acquisition durations are largely based on improving CoP measure reliability [3], without regard for potentially valuable transient characteristics. Identifying an initial transient response to the loss of visual information may be insightful for test design and interpretation of these clinically-relevant balance parameters. It may also provide new postural control outcomes to complement existing methods.

The purpose of this study was to investigate the dependence of clinically-relevant postural control parameters on acquisition time during QEC.

METHODS

Forty-five individuals participated in this study after providing IRB-approved informed consent. Data were collected at the 2017 American Society of Biomechanics Annual Meeting in Boulder, CO. Participants were generally healthy, without known neurological impairment, prior joint replacement, or lower extremity injury within the preceding 3 months (f/m=16/29; 29.3±7.8yr; 77.3±16.1kg; 1.76±0.10m).

Three 60-second QEC trials were collected. Participants stood as still as possible with the medial borders of their feet separated by 5 cm, looking forward with their arms at their sides. Participants counted down aloud '3-2-1-GO', where they closed their eyes as they said 'GO', which also marked the start of each 60 second trial. CoP data were recorded at 1000 Hz using a balance plate (Bertec Corp.), and low-pass 4th-order Butterworth filtered at 20 Hz.

Descriptive CoP parameters of RMS_ml, medial-lateral mean velocity (MVEL_ml), and 95% confidence ellipse area (EA) were calculated for 5-second epochs (n=12), with filtered CoP data demeaned separately for each epoch. Increases in these balance measures indicate worse balance.

Linear mixed models were used to identify the effects of epoch and trial number on these balance parameters (MINITAB). Participant was considered as a random effect, with epoch, trial number, and epoch*trial number as fixed effects. Natural logarithms were taken of balance parameters to satisfy normality and equal variance assumptions. Tukey post-hoc comparisons were made with a family error rate of α=0.05.

RESULTS AND DISCUSSION

The effect of epoch was significant for all balance measures (Table 1). The initial transient period following eyes closure was associated with worse balance for all three balance measures (Figure 1). The first 5 to 10 seconds (depending on the balance parameter) were significantly different from the remainder of the trial ($p<0.05$). The balance measures appeared to reach quasi-steady-state after 15 to 35 seconds, marked by epochs that were statistically similar to the final epoch (all pairwise comparisons, $p>0.05$).

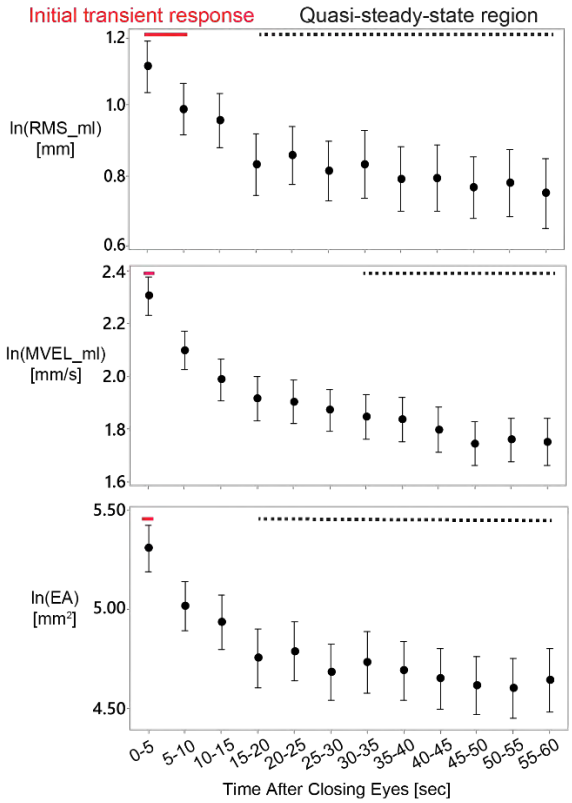

Figure 1. Time-varying behavior after closing eyes during quiet stance. **Solid red line** and the **dotted black line** correspond to epochs statistically similar to the first 5 seconds or last 5 seconds of the trial, respectively. Values correspond to mean ± SD.

Additionally, trial number had a significant effect on all measures, with worse balance observed during the first trial compared to the third (Table 1). An epoch*trial interaction was also observed for MVEL_ml. The greatest discrepancies between trials were during the transition from the transient to quasi-steady-state regions (Figure 2), with no differences detected between trials within the first or last epochs.

Table 1. P-values for model fixed effects.

	RMS_ml	MVEL_ml	EA
Epoch	**0.03**	**<0.001**	**0.02**
Trial	**<0.001**	**<0.001**	**<0.001**
Epoch*Trial	0.71	**0.03**	0.63

These findings demonstrate the transient effects that are prevalent in commonly used descriptive CoP measures during QEC. Increasing acquisition time may improve the reliability of these measures by increasing the relative weight of the reproducible quasi-steady-state response, but consequently removes the initial transient response. Notably, while the transition between the first epoch and quasi-steady-state was somewhat variable, all balance parameters gave repeatable estimates for the initial epoch.

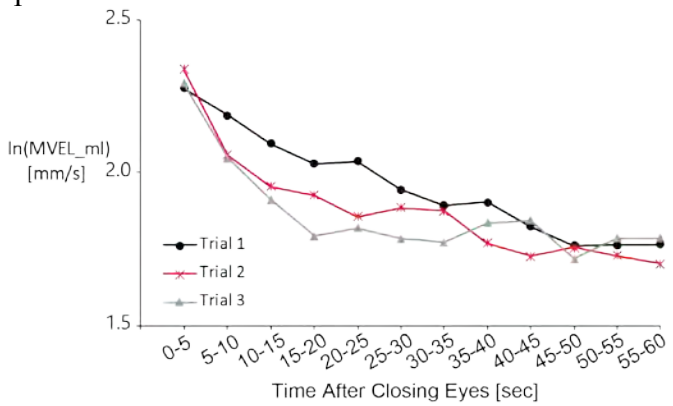

Figure 2. Effect of trial number on time-varying behavior of MVEL_ml. Mean values are presented.

The results of this study indicate that care should be taken when comparing descriptive CoP measures obtained using varying acquisition times, as the relative contribution of transient versus quasi-steady-state may influence estimates. Our ongoing work is investigating whether isolating aspects of the transient response (e.g., estimate for epoch 1, rate of decay to steady-state) provides valuable information.

CONCLUSIONS

Commonly used descriptive CoP measures demonstrate a repeatable transient period of relatively worse balance following closing one's eyes. Acknowledging this behavior may aid researchers in making decisions on acquisition time. Further work is needed to understand the potential value in isolating characteristics of the transient response when assessing postural control.

ENVIRONMENT-DEPENDENT MODULATION OF HUMAN ANKLE STIFFNESS DURING UPRIGHT POSTURAL BALANCE

[1] Varun Nalam, [1] Tanner Bitz, and [1] Hyunglae Lee

[1] School for Engineering of Matter, Transport, and Energy, Arizona State University, Tempe, AZ, USA
email: hyunglae.lee@asu.edu, web: http://faculty.engineering.asu.edu/hlee

INTRODUCTION

Robotic lower limb exoskeletons have gained prominence in many fields including industrial, military, and clinical applications, for performance enhancement, assistance, and rehabilitation. For such devices, proper control of the robotic ankle joint in accordance with human ankle behavior is essential to achieve seamless and stable interaction of the human-robot system. Thus, it is imperative to understand how human ankle mechanics are controlled during interaction with the physical world, which is the main goal of this study.

Two main objectives of this study are: 1) to investigate how ankle stiffness, an integral component of ankle mechanics, is modulated when humans maintain upright posture against a wide range of physical environments, from compliant to rigid environments, and 2) to identify underlying mechanisms or contributing factors of environment-dependent modulation of ankle stiffness. Ankle stiffness was quantified in 2 degree-of-freedom (DOF) of the ankle, specifically, in dorsiflexion and plantarflexion (DP) in the sagittal plane and in inversion and eversion (IE) in the frontal plane.

METHODS

Five healthy male individuals (age: 18−28, height: 170−191 cm, and weight: 56−85 kg) with no reported history of neurological or biomechanical disorders were recruited for this study. This study was approved by the Institutional Review Board of Arizona State University and all experiments were performed after informed consent of the subjects.

In this study, a novel multi-axis robotic platform was used, which is capable of simulating a wide range of mechanical environments as well as providing precise perturbations to the ankle in 2 DOFs [1]. Surface electromyographic (EMG) signals of tibialis anterior (TA), soleus (SOL), peroneus longus (PL), and medial gastrocnemius (GAS), were also measured to estimate activation of major, superficial ankle muscles.

Each subject participated in two sets of experiments. First, subjects interacted with environments having different levels of compliance in order to investigate the environment-dependent modulation of human ankle stiffness. Next, subjects maintained upright posture in a rigid environment with different levels of muscle co-contraction in order to analyze the underlying mechanisms of stiffness modulation.

In the first experiment (compliant trials), subjects were instructed to stand upright in the simulated compliant environments and maintain the platform in a horizontal position. Three levels of compliant environments were simulated in each DOF of the ankle: 50, 150, 450 Nm/rad in DP and 16.7, 50, 150 Nm/rad in IE. These ranges were approximately from one third to three times the ankle stiffness in that particular DOF. When a compliant environment was simulated in one DOF, a rigid environment was implemented in the other DOF.

In the second experiment (rigid trials), in order to control the level of muscle co-contraction during standing, subjects were instructed to simultaneously maintain the target activation level of TA and the neutral position of the center-of-pressure (CoP) measured during quiet standing. Target muscle activation levels for TA were selected as 0, 10, and 20% of its maximum voluntary contraction (MVC).

For the quantification of ankle stiffness, brief ramp-and-hold perturbations (amplitude: 3°, speed: 40°/s) were applied to the ankle. Perturbations were applied in dorsiflexion, inversion, and eversion in a random order. Ten repeated trials were completed for each of 9 experimental conditions: 3 compliance levels x 3 perturbation directions for the first experiment, and 3 muscle co-contraction levels x 3 perturbation directions for the second experiment.

Ankle stiffness was quantified by fitting a linear 2nd order model, consisting of ankle stiffness, ankle damping, and foot inertia, to the measured ankle kinematics and torques.

RESULTS AND DISCUSSION

In the first experiment, ankle stiffness in DP (DP stiffness) was modulated in an environment-dependent manner. It linearly increased (from 56.4 to 90.1 Nm/rad) with increasing compliance of mechanical environment (Fig. 1A), which was highly correlated with notable increase in TA muscle activation (Fig. 2A). On the other hand, ankle stiffness in IE (IE stiffness) was not significantly influenced by the compliance of mechanical environment (Fig. 1B and 1C), consistent with no significant changes in activation of major, superficial ankle muscles (Fig. 2B).

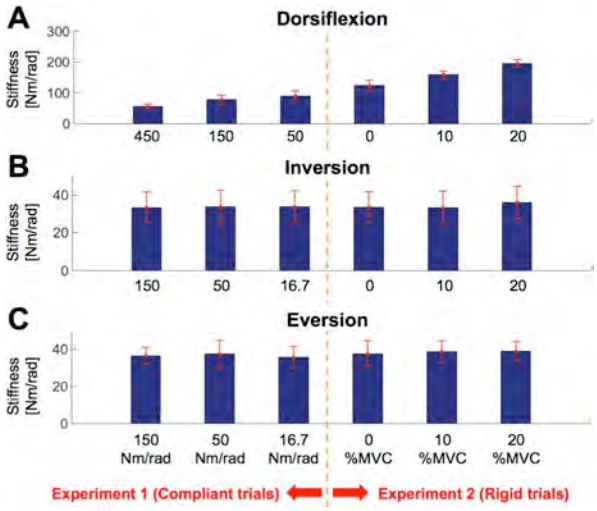

Figure 1 Ankle stiffness in compliant and rigid trials. **A**: dorsiflexion, **B**: inversion, **C**: eversion.

In the second experiment, co-contraction of ankle muscles effectively increased DP stiffness (Fig. 1A). It linearly increased (from 123.4 to 195.8 Nm/rad) with increasing muscle co-contraction. In contrast, IE stiffness was relatively invariant in all muscle co-contraction levels (Fig. 1B and 1C).

Notably, DP stiffness values in all compliant trials were lower than those in the rigid trials. Even the stiffness in the most compliant trial was lower than in the rigid trial during quiet standing (Fig. 1A), while overall activation of ankle muscles was significantly higher in the compliant trial than the rigid trial (Fig. 2A vs. 2C). This suggests that there exists additional factor involved in the modulation

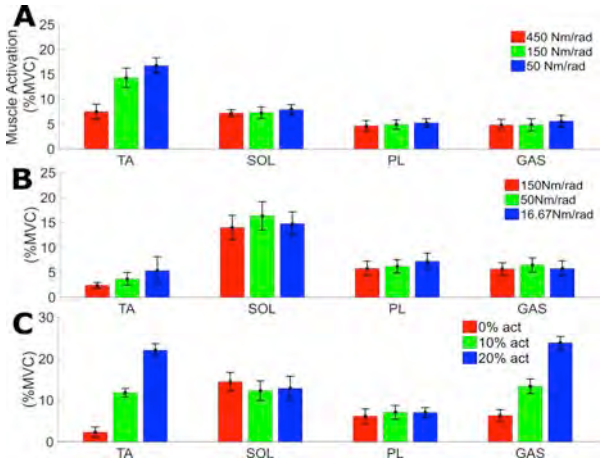

Figure 2 Muscle activation prior to the perturbation during (**A**) compliant DP trials, (**B**) compliant IE trials, and (**C**) rigid trials.

of DP stiffness apart from muscle activation of major, superficial ankle muscles.

Analysis of CoP demonstrated that there exists a positive correlation between DP stiffness and the location of CoP from the DP ankle axis. The CoP was about 53-56 mm in front of the DP axis in the rigid trials, while the CoP was close to the ankle axis (<1.5 mm) in the compliant trials.

Contrary to DP stiffness, IE stiffness values in all compliant trials were comparable to those in the rigid trials. Analysis of CoP in IE further supports the dependency of ankle stiffness on CoP. The location of CoP from the IE ankle axis was close to the ankle axis (<0.5 mm) in both rigid and compliant trials.

CONCLUSIONS

This study demonstrated that DP stiffness is modulated in an environment-dependent manner, while IE stiffness is not, at least in the given experimental conditions. Importantly, activation of superficial ankle muscles cannot fully account for the modulation of ankle stiffness, but it is necessary to incorporate CoP information to explain the modulation of ankle stiffness during upright postural balance. Knowledge gained in this study would aid in the development of a robust model-based controller for the robotic ankle joint.

A PILOT STUDY OF ARGENTINE TANGO TO IMPROVE POSTURAL CONTROL AMONG CANCER SURVIVORS

[1] Lise Worthen-Chaudhari, [2]Marie Lamantia, [3]Scott M Monfort, [1]Ajit MW Chaudhari, [1]Maryam B Lustberg

[1] The Ohio State University, Columbus OH

INTRODUCTION

The most commonly reported serious adverse effect of cancer treatment, called chemotherapy-induced peripheral neuropathy (CIPN), impairs postural control [1] to the point that balance and walking become dysfunctional [2], risk of falling increases [3], and dose intensity of life saving chemotherapy is decreased which negatively impacts survival. CIPN has been reported to affect more than half of individuals who receive a neurotoxic chemotherapy agent and to persist chronically [4].

While balance training represents the best known medicine for neurotoxicity recovery [5], and has been proven feasible for cancer survivors to perform even during treatment [6], adherence and motivation to activity-based medicine represent challenges to participation [6]. Social, creative engagement in balance training has been proposed as an avenue to improve patient participation [7] but has received little study in cancer survivorship. Community-based social dance classes in Argentine Tango (ATango) – adapted for persons with movement disorders – were found previously to improve balance in populations with neurological disorders such as Parkinson Disease [8]. The purpose of this pilot study was to establish feasibility of ATango practice among cancer survivors and to characterize the effect of 5 weeks of practice on biomechanical measures of postural control among cancer survivors with demonstrated balance deficits. As an exploratory aim, we evaluated whether enrolling with a guest (e.g., friend, date, spouse) affected attendance.

METHODS

Participants: Twenty-two cancer survivors enrolled after providing IRB-approved informed consent (age 60.8 (9.2) years; 2 male). Nine enrolled with a partner (e.g., life partner or friend; 2 male). Six demonstrated impaired postural control at baseline (2 male); five completed chemotherapy treatment at least 3 months prior to baseline data collection and were included in this study (age 66.4 (11.7) years; 1 male).

Intervention: Partnered ATango, adapted for individuals with movement disorders [8]

Primary outcome: Postural sway amplitude (Root-Mean-Square amplitude of medial-lateral excursion during quiet standing with eyes closed; RMS_ml) was measured using a portable force platform (1000Hz, Bertec Corp) and custom software written in LabVIEW. Participants were assessed at baseline and at 5 weeks using the protocol reported by Monfort et al. This measure has shown sensitivity to identify changes in balance control associated with cancer treatment [1] and has been found to identify future fallers among elderly with and without neurologic impairment (71% overall accuracy; 81% sensitivity; 58% specificity) [9].

Postural control deficit categorization criteria: Participants were included in postural control change analysis if baseline RMSml was greater than the previously reported mean value for age matched healthy individuals at 75% CI (> 4.54mm) [10].

Secondary outcomes: Participant satisfaction per session; attendance; movement-to-music dose per class.

Statistical analysis: Student's t-test (2 tail, pairwise comparison) was used to evaluate the primary outcome measure (pre vs. post RMSml). Additionally, we report the count of participants for whom individual change exceeded typical within subject variability for the dynamic measure [10]. The MannWhitney U non-parametric statistical test was applied to evaluate the effect of enrolling with a partner on attendance. Descriptive statistics were calculated for secondary outcomes

RESULTS AND DISCUSSION

Participants with postural control deficits (n=5) showed improvement after 5 weeks of ATango practice (mean (SD) pre 7.9 (1.8) mm and post 4.4 (0.6) mm; p = 0.010). Individually, each of the 5 participants improved beyond what could be expected due to healthy, age-matched within-subject variability (Fig1A).

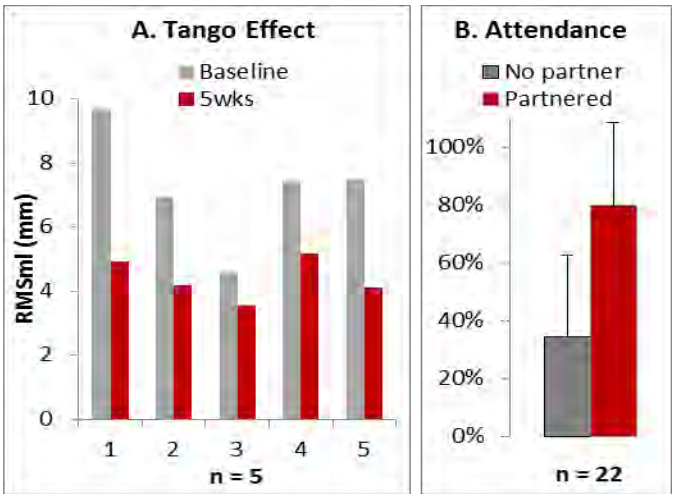

Figure 1: (A) Effect of Argentine Tango practice on postural control (RMSml) for 5 individuals who demonstrated postural control deficits at baseline and (B) effect of enrolling with a partner on attendance.

Those who enrolled with a partner (n=9) attended more classes (p=0.011; *U*-value = 20) with a mean rate of 80 (28) % attendance compared to 35 (28) % attendance for those who did not enroll with a partner (Fig 1B).

Satisfaction with the intervention was high (average = 1.2 +/- 0.5). A majority of participants attended at least half of classes offered (55%). Movement-to-music dose was calculated to be 32.9 (3.9) minutes per one hour class.

CONCLUSIONS

These data provide initial support for the idea that postural control function is recoverable among cancer survivors. In addition, the practice of Argentine Tango may be a candidate intervention for this population and attending with a life partner or friend may be a way to improve participation in the activity-based practice.

GUIDED PRE-CLASS ASSIGNMENTS ENHANCE STUDENT LEARNING AND INTEREST IN UNDERGRADUATE BIOMECHANICS

Hilary Becker and James Becker

Montana State University, Bozeman, MT, USA
email: james.becker4@montana.edu, web: http://montana.edu/biomechanics

INTRODUCTION

Several studies on biomechanics instruction have highlighted the benefits of using active learning strategies such as Just-in-Time Teaching [1], problem or challenge based learning [2], or inquiry based learning [3]. These approaches share the common theme of in-class lecture time being spent engaging students in the learning process rather than passively receiving content from the instructor, and result in improved student performance and learning over the course of the semester. However, to date, studies on the benefits of active learning have mainly focused on what happens during the actual in-class lecture time. In comparison, relatively little attention has been given to best methods for preparing students for in-class activities prior to class. Ensuring students have appropriate content knowledge prior to participating in active learning classes might further enhance the benefits of this approach to biomechanics education.

The purpose of this study was to compare student learning, interest in biomechanics, and perceptions of course difficulty when using two types of pre-class assignments: a traditional approach where assignments consisted of chapter readings and problem sets, and an approach which provided guided content based questions interspersed with applications and problems. We hypothesized the guided pre-class assignments would result in higher student learning over the semester and increased interest in biomechanics.

METHODS

This study was conducted during two successive semesters in an undergraduate biomechanics course. The course is a required component of the Exercise Science curriculum and is typically taken in either the junior or senior years. The course uses a problem based learning approach where the emphasis during in-class lecture time is working in groups to solve problems related to the days' topic.

The first semester used traditional (TRAD) weekly assignments consisting of reading assigned chapters in the textbook and problem sets featuring one or two problems integrating material from the readings and lecture content. Students were instructed to complete required readings before class. During the second semester the weekly readings were replaced with daily guided pre-class assignments (GUIDED). Rather than assign specific chapters from the textbook, these assignments outlined the required content and concepts and allowed students to obtain the information from any source they saw fit, provided they included appropriate citations. Each topic area was loosely grouped into a "chapter" with different sections of the chapter being due each day. The same problem sets used in the first semester were included as the last section of each "chapter".

The Biomechanics Concept Inventory, version 3 (BCI3) [4], was administered during the first and last weeks of both semesters. Student learning during the semester was evaluated by calculating the gain in BCI3 scores from beginning to end of semester, normalized by the maximum possible change [4]. A survey was administered at the end of each semester which, using 5 point Likert scales, asked students to rank their interest in biomechanics at the beginning and end of the semester, the perceived difficulty of the course compared to their expectations prior to the semester, and the extent to which they felt homework assignments contributed to their learning. Paired *t*-tests were used to evaluate differences between TRAD and GUIDED groups in BCI3 scores pre and post class and gain in BCI3 scores. Mann Whitney U tests were used to to compare differences in Likert scale survey

responses. An alpha of $p < .05$ was used for all statistical comparisons.

RESULTS AND DISCUSSION

Thirty eight and forty seven students completed pre and post semester BCI3 assessments and post-semester surveys in the TRAD and GUIDED semesters, respectively. Pre-semester BCI3 scores were not different between groups ($p = .138$). However, post-semester BCI3 scores were higher in the GUIDED group ($p = .005$). Gain in BCI3 scores was also higher in the GUIDED group ($p = .006$).

Table 1. Mean values for pre-semester, post-semester, and gain in BCI3 scores. * indicates significantly different at $p < .05$ level.

	TRAD	GUIDED
Pre BCI3 scores	12.5 (± 2.2)	13.2 (± 2.3)
Post BCI3 scores	14.3 (± 2.9)	15.6 (± 2.2)*
Gain in BCI3	0.22 (± 0.2)	0.35 (± 0.2)*

There were no differences between TRAD and GUIDED groups in student interest in biomechanics at the beginning of the semester ($p = .032$). However, at the end of the semester students in the GUIDED group indicated higher interest in biomechanics ($p < .001$). Students in the GUIDED group also indicated the course was easier than they expected ($p < .001$) and that pre-class assignments contributed more to their learning over the semester ($p = .004$).

There are several possible explanations for these finding. First, the guided pre-class assignments allowed students to organize information in a manner which best suited their individual learning style. There is evidence to suggest that learning improves when instruction is matched with students preferred learning styles [5]. Thus, the guided pre-class learning assignments may have allowed students to utilize their preferred learning style to a greater extent. This could also explain why students indicated the course was easier than expected and the assignments contributed more to their learning than textbook readings and problem sets. A second explanation is the guided pre-class assignments required students to engage with the content rather than passively read a textbook chapter. Numerous studies have shown this type of active engagement improves reading comprehension in college students [6]. Thus, the improved learning with guided pre-class assignments could have resulted from better comprehension and retention of any material students read. Finally, it has been shown that prior domain knowledge plays a role in student learning [5]. Compared to weekly textbook readings, the daily nature of the guided pre-class assignments may have resulted in greater domain knowledge on a day to day basis prior to class, thus resulting in deeper learning of material during in-class time.

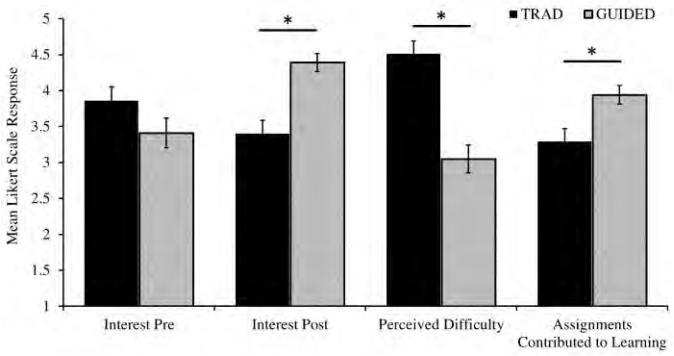

Figure 1. Mean Likert scale results for student interest pre-semester, post-semester, perceived course difficulty, and whether assignments contributed to their learning. Values of 1 indicate little interest, less difficult than expected and little contribution to learning. Values of 5 indicate highly interested, more difficult than expected, and substantially contributed to learning, respectively. * indicates significantly different at the $p < .05$ level.

CONCLUSIONS

Compared to weekly textbook reading and problem sets, daily guided pre-class assignments improve student learning in a problem based undergraduate biomechanics. Such assignments also make the course seem easier to students and increase students' overall interest in biomechanics.

HANDS ON ACTIVITIES CAN IMPROVE LEARNING IN A LECTURE-ONLY QUALITATIVE BIOMECHANICS (FUNCTIONAL ANATOMY) COURSE

Robert D. Catena and Kira J. Carbonneau

Washington State University, Pullman, WA, USA
email: robert.catena@wsu.edu, web: https://labs.wsu.edu/biomechanics/

INTRODUCTION

A qualitative biomechanics (functional anatomy) course is a common course in a Kinesiology curriculum. While only a slight majority of biomechanics courses provide laboratory experiences [1], most instructors believe that laboratory experiences enhance learning outcomes in biomechanics. Even if there were significant evidence to suggest the inclusion of labs in qualitative biomechanics, most courses that don't incorporate a laboratory experience cannot because of administrative constraints (e.g. instructor cost and time) [1].

At the location of this research study, a single graduate teaching assistant will cost the department approximately $15,000 per year, on top of health benefits and tuition waivers provided by the university. Given class sizes, this university would need to offer a minimum of nine lab sections in a year to accommodate all students. That would require 2.25 graduate teaching assistants, putting the lab instructional cost at $33,750 per year.

Many programs may wish to include a hands on laboratory experience, but cannot do so in a cost-effective manner, supported by empirical evidence of the benefits. There is a critical need to determine (1) if hands on experiences do enhance student education in a qualitative biomechanics course and (2) an alternative method for providing hands on experiences applicable to qualitative biomechanics without the use of graduate teaching assistants or expensive equipment?

METHODS

Two hundred and fifty-four students were enrolled in a qualitative biomechanics course over five semesters taught by the same instructor (abstract author). The course has 45 contact hours. The sequential order of topics spread roughly evenly across the semester were: 1. Kinematics, 2. Kinetics, 3. Tissue mechanics, 4. Hand and wrist, 5. Elbow, 6. Glenohumeral, 7. Scapulothoracic, 8. Neck, 9. Thorax, 10. Pelvis, 11. Hip, 12. Knee, 13. Ankle and foot.

The sample of students were separated into two groups. Both groups were comprised of similar proportions of Athletic Training and Sport Science majors. One hundred and fifty-nine students made up the control group. The control group of students received content only through lecture, discussion and video examples. Ninety-five students made up the experimental group. The experimental group was taught by the same methods. However, three additional hands-on experiences were also included. Number 1 below was provided in conjunction with lecture. Numbers 2 and 3 replaced some (not all) video examples during the study semester:

1. Skeletal models corresponding to the joint lecture topic were provided to groups of students during lecture so that they could interact with the surrounding bones of a joint as it was taught. This was an unrestricted hands-on experience.
2. Two-channel electromyography (EMG) units (Backyard Brains) were provided to groups of students so that they could simultaneously measure muscle activity of two muscles during lower-extremity lectures. There were clear instructional procedure and outcome with this hands-on experience.
3. An isokinetic dynamometer (Isokinetic International) activity was used during one lower-extremity EMG activity to demonstrate how muscle activities correspond to joint torque production. There were clear instructional procedure and outcome with this hands-on experience.

The two groups were compared via correct answers from 22 multiple choice and short answer exam questions spread across three semester tests and subjective course evaluation questions completed after all but one test. Analyses were conducted through Chi-square tests with significance level for main effects was set to a p-value of 0.05. Post-hoc analyses were conducted though pairwise comparisons of adjusted residual z-scores with *Bonferroni* corrections.

Exam question results based on upper extremity lectures and lower extremity lectures were compared in the experimental group to determine if guided hands-on lab type experience provide any better education than unguided skeletal model use.

RESULTS AND DISCUSSION

Instructors at this university do not have access to student grade point averages to indicate if the two groups are dissimilar in overall abilities. However, there was no difference in grade point averages between the two groups as they were first certified into our program. There was one indication from student evaluations of potential differences between the makeups of the two groups. The experimental group gave significantly higher rating to the question of if they took responsibility for their learning in the course ($p=0.025$).

The results of the other course evaluation questions indicate that the two groups were not different in what they thought of the quality of the course, how much they learned, the difficulty of the course, or the variety of examples used in teaching. However, the experimental group reported the teacher's effectiveness ($p=0.021$), the encouragement for classroom participation ($p=0.027$), and the effectiveness of activities to encourage learning ($p=0.004$) as significantly higher compared to the control group.

On 22 exam questions, the experimental group did not perform significantly poorer than the control group on any test question. The experimental group performed better than the control group on 8 of the 22 questions, but 7 of the 13 questions specific to the lower extremity. However, when specifically comparing results of lower extremity test questions (EMG and dynamometry were used with skeletal models) and upper body questions (only skeletal model use) there was not a significant difference in test performance ($p=0.117$).

CONCLUSIONS

The findings from this study support the use of hands on activities embedded within a qualitative biomechanics lecture to improve education for kinesiology students and student evaluation of the course. There were some indications that guided hands on activities provide a better learning experience than unguided activities, but students at least have no change, and probably will have some benefit from unguided activities as well. The hands-on activities used in this study were easy to implement in the time allotted through lecture alone, with the exception of the dynamometry activity, which required us to split the classes up during one week.

The interaction of the physical activities and cognition is a theory rooted in cognitive science known as embodied cognition [2]. Having representations that accurately mimic the real thing in shape, and potentially also in force feedback, can significantly enhance learning in sciences foundational to biomechanics.

This study does not make any comparison in educational benefits to the official inclusion of a lab into a course. However, the one-time costs and yearly supply costs associated with the hands-on activities used in this study are significantly less than typical lab supply and instructor costs.

LESSONS FROM THE PAST: LEARNING ANATOMY IN THE ITALIAN RENAISSANCE

M. Melissa Gross

University of Michigan, Ann Arbor, MI, USA
email: mgross@umich.edu

BACKGROUND

Musculoskeletal modeling is an important aspect of contemporary biomechanics, and students need to know muscle attachments and functions to support their work with biomechanical models. Today, students learn musculoskeletal anatomy using print images, interactive digital media, plastic models, and plastinated cadaver materials. Undergraduate students rarely have the opportunity to dissect human cadavers, however, and the time spent in the cadaver laboratory is diminishing even in medical school [1]. As technology continues to advance, it is likely that future students will study musculoskeletal anatomy using 3D digital visualizations.

As the study of musculoskeletal anatomy in the 21st century promises to become even more virtual, pedagogical questions about the relationship between technology and anatomical visualization are inevitable. For example, should educators continue to structure anatomy learning experiences in the same way, in the absence of physical bodies? Are critical aspects of anatomical learning lost if students engage with digital materials exclusively? Scholars are tackling these pedagogical questions, especially with regard to anatomical education in professional schools [2]. These questions are also relevant for biomechanics faculty who want to help students visualize 3D muscle-tendon paths, length changes, moment arms and to understand muscle functions.

Scholars in the 21st century are not the first to grapple with the relationship between emerging technologies and anatomical visualization, and its impact on anatomical education [3]. During the Renaissance in Europe, new print technologies enabled reproduction of both anatomical texts and images on a broader scale, affecting where and how anatomical information was available. The public dissections hosted by prominent universities served both medical students eager to learn anatomy and anatomy professors interested in furthering their academic careers. University administrators invested in the construction of innovative buildings (i.e., anatomy theatres) to attract patrons and funding for their schools [4]. Later, wax anatomical models were introduced, valued for the realism and integrity of the anatomical representations.

Anatomical expertise did not reside solely in the academy, however, as artists played important roles in the advancement of anatomical sciences either through their own artistic work or as collaborators in the technical innovations of the time. Leonardo da Vinci used dissection to discover how the body functioned, and the artistic renderings of anatomy in his notebooks were representations of his thoughts and discoveries. Artists collaborated with anatomical scholars to create illustrations for the new, printed books; among the most well-known are the depictions of anatomy in Vesalius' *On the Fabric of the Human Body* published in 1543. The artists creating the anatomical wax models used for medical education innovated new techniques to form and color the wax, with each model based on dissections of many cadavers.

As the landscape of higher education today is shifting to emphasize hands-on and inquiry-based courses that leverage technological innovations, there may be lessons to be learned from considering how anatomy was studied and visualized in the distant past. Can students get insights into their own approach to learning anatomy by considering the Renaissance context for anatomical studies? With 21st century digital technologies for representing the human body and for teaching and learning anatomy, can students better understand how visualization technologies relate to learning by considering previous times of technological disruptions to established ways of knowing and learning? Exploring these questions may help to improve contemporary approaches to teaching and learning musculoskeletal anatomy.

GLOBAL STUDIES PROGRAM

To provide students with the opportunity to explore these issues while deepening their knowledge of musculoskeletal anatomy, a global studies program "Art and Anatomy in the Italian Renaissance" was created with stops in Rome, Florence, Bologna, Padua and Venice, offered in May 2018 through the School of Kinesiology at the University of Michigan. The goal of the program was to enable students to explore the intersection of art, anatomy and anatomical education during the expansion of humanistic thinking in the Renaissance, and to gain a new appreciation of the roles of art, technology and science in visualizing knowledge, then and now.

The program was designed to provide students with opportunities to: (1) expand their understanding of the cultural context for scientific discoveries while learning about the development of musculoskeletal anatomy knowledge by Renaissance artists and scientists, and (2) deepen their knowledge of surface anatomy by analyzing artworks and skeletal remains in museums, churches and public art. Because the course takes place in a global context, students could also develop important skills of autonomy and self-directed learning, improve their collaboration skills in team-based program activities, and engage with diverse others among program participants and in a global environment while immersing themselves in a non-English speaking culture by traveling in Italy.

Instruction will take place in both face-to-face (on site and in class sessions), and online (brief lectures and assignments) settings. Pre-departure academics included a session on Renaissance anatomy books by a curator from the U-M Special Collections Library, and an introduction to field notes session. In Italy, on site instruction will take place in art museums, anatomy theaters, anatomical wax museums, churches, catacombs, libraries, cultural sites and public places with art. Students participating in the program had basic anatomical knowledge since the prerequisite was a sophomore-level musculoskeletal anatomy course. Because surface anatomy is an important clinical skill [5], students will be encouraged to practice by applying their anatomical knowledge to the drawings, paintings, sculpture and wax models that they will encounter in Italy. To support students' understanding of Renaissance art, a History of Art scholar served as the course co-instructor.

Assignments include field notes, in which students collect, document and make visual records of their observations of musculoskeletal anatomy throughout the program. Students will also be asked to write short reflection papers about their observations and experiences, complete pre-work before visiting sites and give brief presentations to the group. Inspired by Leonardo's notebooks, the final project will be a compilation of their field notes, with embedded written reflections on the intersection of art and anatomy. Student perceptions of their learning will also be gathered using survey questions.

LEARNING ASSESSMENT

Student learning will be assessed on the assignments (IRB Exempt status). Qualitative analysis of their field notes, site-specific assignments and reflection papers will be used to assess the impact of the experience on their understanding of cultural contexts for visualizing musculoskeletal anatomy, especially with regard to technologies used for learning and demonstrating anatomy. It is expected that the students' knowledge of musculoskeletal anatomy will be reinforced by critical examination of artworks for anatomical correctness, as demonstrated in their field notes documents. It is also expected that students will be able to describe how anatomy was learned in the Renaissance, the relationship between anatomy and art in the Renaissance, and how the impact of technology on anatomical education in the Renaissance may relate to learning anatomy today.

INTRODUCING ENGINEERING AND BIOMECHANICS TO PREK-6 STUDENTS THROUGH A SERVICE LEARNING PARTNERSHIP

Stacie I Ringleb, Jennifer Kidd, Rachel Jones, Pilar Pazos
Old Dominion University, Norfolk, VA, USA
Email: sringleb@odu.edu

INTRODUCTION

Engineering education faces many persistent challenges including recruiting and retaining students, teaching engineering students to work successfully in groups, and communicating both within and outside their discipline.

Education majors are facing new challenges relevant to the field of engineering given the recent incorporation of engineering practices and core ideas into the Next Generation Science Standards (NGSS) at the elementary school level. Elementary preservice teachers can flourish if they are exposed to and learn content that is directly relevant to the science and engineering standards that they must teach in their own future classrooms [1].

The purpose of the described project was to tackle these challenges by grouping first year engineering students with pre-service teachers to develop and deliver engineering lessons to preK-6 students in Norfolk, VA. In this abstract, the experiences of three groups of students who developed and delivered lessons on prosthetics to 4-6th graders are described.

METHODS

First year mechanical engineering students were partnered with third year education students as part of existing courses within their disciplines. Small groups of 4-6 students developed prosthetic lessons which were taught to fourth graders (Fall 2016), fifth graders (Spring 2017) and sixth graders (Fall 2017). Google Sites were used to build a collaborative platform for each group that included templates and protocols designed to scaffold the lesson development process and facilitate collaboration and information sharing. The lessons were developed using the 5 E's principles (Engage, Explore, Explain, Extend, and Evaluate). After the lesson plan was drafted, students rehearsed their lessons in front of another group and a faculty member or graduate student. Lessons were finalized after students received feedback on their drafts and met with one of the course instructors. After the lesson was delivered, each student wrote a detailed reflection on the experience. The reflections were qualitatively analyzed to explore perceived benefits and challenges. In particular we wanted to determine what the college students learned from their experience and to ascertain the education students' comfort level teaching engineering.

RESULTS AND DISCUSSION

Three groups, including a total of eight engineering (6 male, 2 female) and nine education students (4 male, 5 female) developed lessons about prosthetics. Each team took a different approach. One team 3D printed prosthetic hands (Fig. 1) from plans obtained from the internet [2], while the other two groups designed their prosthetic hands with used materials such as clay, straws, and string (Fig. 2).

Six engineering and eight education students submitted post-project reflections. When asked what they learned from the experience, most (4/6) engineering students stated that they didn't learn anything about engineering. Few engineering (1/6) and most education (7/8) students discussed the experience of working with a group. Some comments about group work

were positive, for example, how working in groups was beneficial to increased idea generation. However, there were also some drawbacks discussed such as scheduling difficulties and lack of accountability.

Fig 1. Students building prosthetic hands

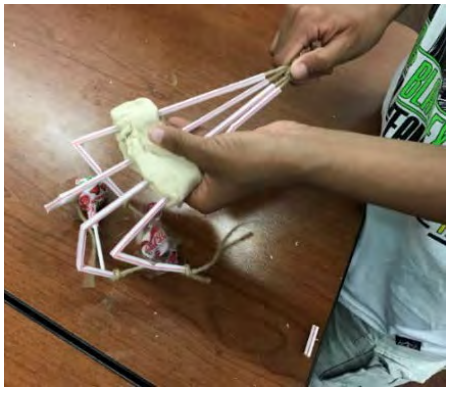

Fig 2. Prosthetic hand made with clay.

Most of the engineering students (4/6) explicitly stated that they had positive reactions to working with the students. One student wrote: "The most valuable part of this lesson was seeing how interested the kids were and how excited they were to try and come up with a solution."

Half of the education students explicitly stated that they have a new understanding and appreciation for engineering. Two students noted the creativity required to be an engineer. One student stated, "I was under the impression that engineers just built bridges and buildings, I was not aware that they also worked in medicine and computers." When asked how comfortable they would feel teaching an engineering lesson in the future, all the respondents said they would be willing to do so, but all but one said they would want support in order to do so.

Several things were learned from examining these groups. First, the engineering students perceived that they did not learn new content in engineering. We believe that is because they were not explicitly taught about the engineering design process and how their lesson development was an example of an iterative design experience. Future classes will receive this instruction, so they can draw a connection between this project and engineering. Secondly, education students were able to gain comfort with engineering from just one collaborative lesson with engineers. Partnerships such as the one described here could increase teachers' confidence with engineering, thereby increasing elementary students' exposure to (and interest in) engineering. Finally, cross disciplinary partnerships have the potential to cultivate communication and collaboration skills and increase understanding of engineering, but group work must be carefully scaffolded and supported. Even with such supports in place, many of these students reported challenges.

REQUIRED MUSCLE ACTIVATION DEPENDENCE ON MOMENT ARM AND MAXIMUM SHORTENING VELOCITY: A COMPUTER SIMULATION STUDY

Lauren J. Hickox and Stephen J. Piazza

The Pennsylvania State University, University Park, PA, USA
email: piazza@psu.edu, web: http://www.biomechanics.psu.edu/

INTRODUCTION

The leg muscle fascicles of sprinters have been shown to be longer than those of distance runners and sprinters have a higher percentage of fast-twitch muscle fibers [1,2]. Both of these properties would tend to reduce the attenuation of muscle force generation during muscle shortening that occurs due to the force-velocity property. In addition, previous studies have found that sprinters have smaller plantarflexor moment arms than non-sprinters, similarly reducing force-velocity effects by decreasing muscle shortening velocity for a given joint rotational velocity and thus increasing force generation [3,4].

Understanding muscle's capacity to produce movement requires knowledge of how limb and joint structure (e.g., muscle moment arm) interacts with muscle architecture and force-generating properties. The purpose of this study was to use computer simulation of a simple submaximal concentric plantarflexion task to determine how demand on the muscle (i.e., muscle activation) is affected by plantarflexor moment arm and composition. We hypothesized (1) that reducing muscle moment arm would reduce demand on the muscle (but only to a point) and (2) that increasing the maximum shortening velocity v_{max} in the force-velocity relation would also reduce the muscle demand.

METHODS

A simple 1-DOF planar musculoskeletal model was developed in Simscape Multibody (Mathworks, Inc., Natick, MA, USA) and used to simulate a submaximal plantarflexion task against an inertial load. The model consisted of two segments, a shank and a foot (properties based on [5]), and two Hill-type muscle-tendon actuators representing lumped plantarflexors (PF) and dorsiflexors (DF) (Fig. 1). The distal end of the foot segment was attached to a 50 kg mass by a revolute and the mass was allowed to slide along an incline. The task was to push the mass a distance of 10 cm along the incline in a fixed amount of time (0.5 s), with zero initial velocity and no constraint on terminal velocity.

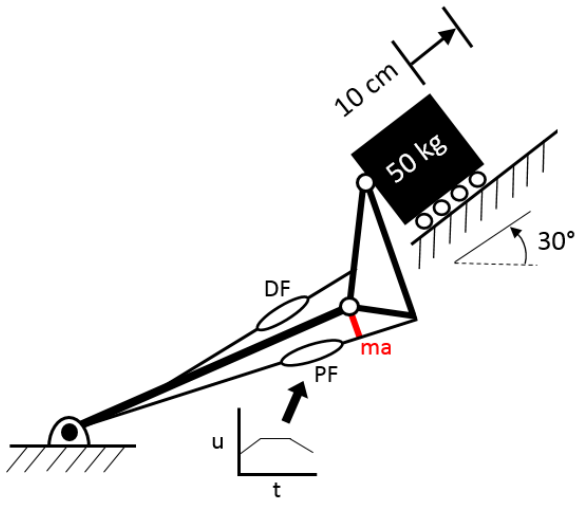

Figure 1: Schematic illustration of the model and the plantarflexion task. Plantarflexor moment arm (ma) was varied along with plantarflexor v_{max}.

Parameter optimization was used to find control strategies that minimized the area under the squared activation curves for both the PF and DF muscles. The fmincon() routine in MATLAB (Mathworks, Inc., Natick, MA, USA) was used to find excitations (11 evenly spaced nodes for each muscle actuator) that minimized activation.

Optimizations were repeated with the length of the plantarflexor moment arm varied from its default value by approximately -8, -4, 0, +4, and +8 mm by altering the length of the heel in the model. Sets of optimizations with these moment arm variations were run for different values of v_{max}, which was used as a surrogate for muscle composition. Increasing v_{max} was intended to represent muscles with a higher

proportion of fast-twitch muscle fibers. When v_{max} was changed (by -20%, -10%, 0, +10%, and +20%) the entire force-velocity curve was scaled in the velocity direction.

RESULTS AND DISCUSSION

Moment arms smaller and larger than the default value caused an increase in the PF activation required to complete the task (Fig. 2a). Minimum activation was achieved with a PF moment arm that was 3-4 mm smaller than the default. When maximum shortening velocities were varied, similar U-shaped patterns were seen over the range of moment arms simulated (Fig. 2b). The dependence of activation on moment arm was found to vary with v_{max}, however: Faster muscles with higher v_{max} produce a less pronounced minimum with lower activations required for the smallest and largest moment arms.

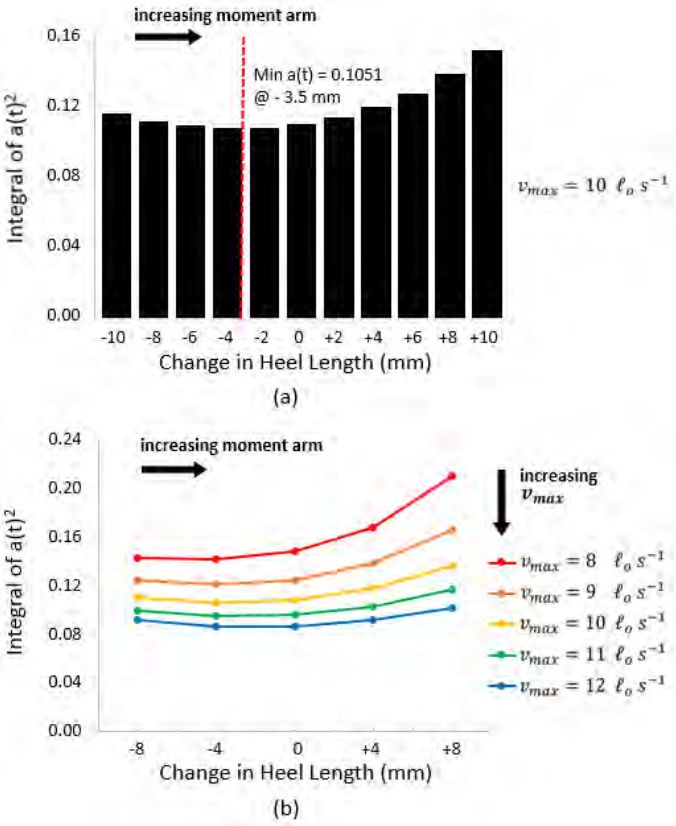

Figure 2: Integrated plantarflexor activation for varying moment arms (heel lengths) and maximum shortening velocity.

The interaction between these two musculoskeletal characteristics may affect the capacity for performing activities requiring rapid plantarflexion under load, such as sprinting. Consider two runners, one born with a high percentage of fast-twitch (faster maximum shortening velocity) fibers and one born with a lower percentage. The relative flatness of the high-v_{max} curves in Figure 2b, suggest that the runner with more fast-twitch fibers would be less affected by variation in PF moment arm. The runner with fewer fast-twitch fibers might still be an effective sprinter, but only with the right PF moment arm. With longer moment arms, this latter runner must activate the plantarflexors with twice the intensity as the first runner, and sprinting performance may thus be substantially limited.

This simulation study demonstrated an interaction between two PF muscle characteristics, moment arm and maximum shortening velocity in terms of their effect on required activation during a submaximal plantarflexion task. The results suggested that runners with a higher percentage of fast-twitch fibers may have greater potential as elite sprinters, regardless of the length of their PF moment arms. Muscle composition was also found to have a larger effect on required activation for runners with larger moment arms. The primary limitation of this study is that it involved only simulations and not experiments. Also, mathematical muscle models such as that used in this study fail to represent several important aspects of muscle-tendon behavior. Future work will focus on determining whether the same dependence on muscle moment arm and muscle composition exist in human subjects.

ACHILLES TENDON STRUCTURE DOES NOT CHANGE IN TRAINED DISTANCE RUNNERS

[1] Todd J. Hullfish, [1] Kenton L Hagan, [2] Ellen Casey, [1] Josh R. Baxter
[1] University of Pennsylvania, Philadelphia PA, USA
[2] Hospital for Special Surgery, New York, NY, USA
email: josh.baxter@uphs.upenn.edu, web: https://www.med.upenn.edu/motionlab/

INTRODUCTION

Achilles tendinopathy is a painful degeneration of the tendon that is ten-times more common in running athletes compared to age-matched peers [1]. Tendon loads in excess of twelve body weights are cyclically applied during running, which may be the driving factor in tendinopathy development in these athletes. However, the progression of asymptomatic and symptomatic tendinopathies is not well understood. Structural changes associated with symptomatic tendinopathy such as decreased collagen alignment – or 'organization' – and increased tendon thickness have both been reported in athletic populations. Previous work by our group has demonstrated that competitive collegiate distance runners have thicker and less organized tendons than their recreationally active peers (**Fig. 1**) even in the absence of signs or symptoms of tendinopathy [2]. However, it is unclear how tendon structure in highly-trained runners changes in response to prolonged bouts of training.

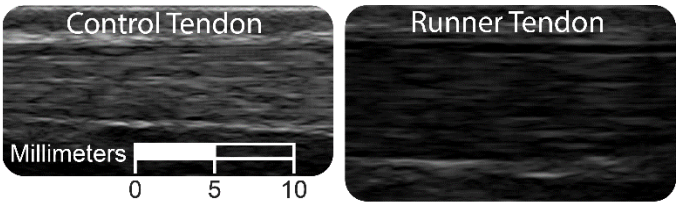

Figure 1. Competitive distance runners have thicker Achilles tendons that are darker in appearance when imaged using ultrasonography and are less organized [2].

Therefore, the aim of this study was to prospectively quantify Achilles tendon structure in competitive distance runners at the beginning and completion of a cross country season. We hypothesized that, in the absence of injury, there would be no significant changes in tendon thickness, organization, or echogenicity for a runner with a habituated tendon.

METHODS

Nineteen collegiate cross country runners (9 females; Age: 19 ± 1.5 years; Height: 172 ± 7 cm; Weight: 60.4 ± 8 kg) provided written consent in this IRB approved study. All participants had no signs or symptoms of Achilles tendinopathy before or after participation. Data were acquired one week prior to and one week following the competitive Division I NCAA Cross Country season. A self-reported assessment of tendon health and a quantitative ultrasound assessment was performed at each study visit. Subjects were asked to fill out a clinical outcome questionnaire (VISA-A [3]) to determine their level of health and function. The structure of the tendon was determined by measuring the level of organization present in its collagen fascicles through ultrasonography.

Longitudinal B-mode ultrasound images of the of the mid-substance of the right Achilles tendon were acquired while subjects lay prone on a treatment table with ankles placed in the resting position off the end of the table. Images were acquired using an 18 MHz transducer (L18-10L30H-4, SmartUs, TELEMED) with a scanning width of 3 cm (scan parameters: Dynamic Range: 72dB; frequency: 18 MHz; gain: 47 dB). Collagen organization was quantified in the ultrasound images using custom-written software [4]. This image processing algorithm is a computational analog to crossed polarizer imaging, which assesses collagen fascicle alignment and quantifies tendon 'organization' as the circular standard deviation (CSD) of these collagen structures and has been shown to be reliable in Achilles tendon [5]. These images were also used to quantify the longitudinal thickness and mean echogenicity of the tendon.

Tendon organization, thickness, and echogenicity as well as VISA-A scores were compared between the two study visits using two-way paired t-tests. This

study was powered ($\beta > 0.8$) to detect ultrasound differences of 15%. Additionally, effect sizes were determined for any differences found to be statistically significant ($P < 0.05$). Effect sizes were reported using Cohen's *d*, calculated as the mean difference divided by the pooled standard deviation.

RESULTS AND DISCUSSION

Achilles tendon symptoms did not develop in any of the runners, which were confirmed by no change in VISA-A scores between the pre- and post-season sessions ($P > 0.1$, **Table 1**). Similarly, tendon organization and echogenicity did not change over the course of the competitive season between the two sessions ($P > 0.05$, **Table 1**). Tendon thickness increased by 7% ($P < 0.001$, **Table 1**) but the effect size of this change was small ($d = 0.36$).

We confirmed our hypothesis that competitive distance runners have Achilles tendon structure that appears to be habituated to prolonged cyclic loading. These findings agree with previous work that showed collegiate distance runners do not undergo Achilles tendon hypertrophy throughout a competitive season [6]. This habituated tendon may be a protective adaptation, allowing trained runners to cyclically load their tendons without injury. Mechanically, the thicker-habituated tendon may undergo strain similar to what is observed in naïve tendon at lower levels of stress. This would result in similar maximal ankle torque generation potential while decreasing the impact of the rapid loading experienced during distance running.

The processes by which tendon remodels from a naïve to a habituated – and from a healthy to a pathologic state – are still not well understood. Exercise has been shown to increase levels of collagen synthesis in humans but the effects of this increase has not been directly linked to tendon remodeling. Additionally, different types of running demands appear to have different effects on tendon remodeling. Sprinters, for example, have stiffer Achilles tendons than distance runners and non-runners, though these findings have not been linked to tendon structure. As a result, there is a need to link the structural differences of habituated tendon with function to better understand the remodeling process and to elucidate the mechanisms that drive pathology.

CONCLUSION

Once habituated to the prolonged cyclic loading of distance running, cross-country athletes do not experience structural changes to the tendon in response to further training. The process by which a tendon becomes habituated remains unclear. Understanding the relationship between tendon structure and function is crucial to anticipating and preventing the development of pathology.

PREDICTION OF SOLEUS MUSCLE FASCICLE BEHAVIOR DURING WALKING USING A MULTISCALE COUPLED OPENSIM AND FEBIO MODEL

Brian K. Jones[1], Emily Y. Miller, Shayn Peirce-Cottler, and Silvia S. Blemker

Dept. of Biomedical Engineering , University of Virginia, Charlottesville, VA, USA
[1]email: bkj3f@virginia.edu

INTRODUCTION

One of the fundamental problems of musculoskeletal biomechanics is the accurate prediction of *in vivo* muscle behavior during whole-body dynamic motion. Recent advances in dynamic ultrasound imaging have allowed *in vivo* measurements of muscle fascicle length changes during movement. These data demonstrate the complex interplay between muscle fiber mechanics and in-series elasticity resulting from tendon and aponeurosis behaviors. Computational models provide a powerful paradigm for understanding muscle and tendon, however current approaches often utilize simple representations of muscle-tendon units that limit their predictive utility. The goals of this study were to: (i) develop a multiscale model of the soleus muscle by coupling the FEBio finite element and OpenSim biomechanical modeling softwares, and (ii) compare predictions from the model with ultrasound measurements [6] and lumped-parameter model predictions [1].

METHODS

OpenSim software (*opensim.stanford.edu*) was used to analyze a previously published [1] dynamic simulation of human walking motion. This model utilizes motion capture and force plate data to predict joint motions and the activations of 76 skeletal muscles in the torso and lower extremity. Results from the right leg of this model were utilized for the present study and included soleus activations, spatial locations of soleus origin and insertion, and kinematics of the pelvis, femur, tibia, talus, and calcaneus bones.

3D geometries of the right-side lower-extremity bones were taken from the OpenSim dataset and imported into the FEBio pre-processor PreView (*www.febio.org*). Each bone's global spatial location was then calculated from the *location_in_parent* field and generalized joint coordinates in the OpenSim model definition file. Predicted orientations and locations of the bones during the gait cycle were then obtained using the OpenSim *Analyze* tool, and a custom Matlab algorithm was written to convert Euler angles to rotation matrices and Euler vectors. This data was then formatted into rigid body translations and rotations for the FEBio model definition file.

Solidworks CAD software was used to create a simplified, unipennate soleus muscle with anterior and posterior aponeuroses based on origin, insertion, and pennation angle from the OpenSim model definition file. Additional soleus architecture and geometry data was taken from previously published literature [2].

Trelis software (*www.csimsoft.com*) was used to mesh the soleus CAD geometry using 8-node hex elements, and the mesh was then combined with the imported bone geometry in PreView. Bones were modeled as rigid bodies, the soleus muscle tissue was modeled as an nonlinear transversely isotropic mixture of muscle [3] and a Mooney-Rivlin material, and tendons were modeled as an elastic mixture of an exponential power law fiber and a Mooney-Rivlin material.

Muscle fiber directions were calculated using our previously published computational fluid mechanics approach [4]. Briefly, the soleus mesh domain was modeled as a Newtonian fluid using the FEBio fluid solver [5]. Aponeurosis attachment faces were given dilatation (pressure) boundary conditions to create a constant laminar fluid flow with Reynolds Number $<< 1$. Remaining exterior boundaries of the mesh domain were treated as slip surfaces (zero viscous traction and zero normal fluid velocity). Select interior mesh faces were also given slip conditions to serve as guides to fine tune the fluid velocity.

Fluid velocity vectors from this CFD analysis were used as muscle material fiber directions in the solid FEA model. In post-processing, a custom Matlab algorithm was used to calculate streamlines using the deformation gradient tensor **F** and this fiber direction vector field. These streamline lengths were reported as muscle fascicle lengths in the results below.

RESULTS AND DISCUSSION

The finite element model, shown in Fig. 1, was comprised of 5871 elements and required 4 minutes of solution time. Average fascicle stretch at a lateral, mid-sagittal, and medial location were calculated for a representative transverse mid-belly section of the soleus (Fig. 2). These calculations were compared with predictions of soleus fiber length changes from the lumped parameter prediction from John et al [1] and ultrasound measurements of soleus fascicle stretch during treadmill walking [6]. While the range of stretch magnitudes for all three datasets were similar, the OpenSim model over-predicts fascicle stretch during the stance phase. In contrast, the FEBio simulation follows the ultrasound measurements more closely, in particular during mid-late stance.

These results demonstrate the potential for finite-element models to predict *in vivo* muscle tissue behavior during whole-body motion. This approach has a wide variety of applications, including understanding how age- and disease-related changes in tendon and aponeurosis properties may influence plantar-flexor function and overall mobility.

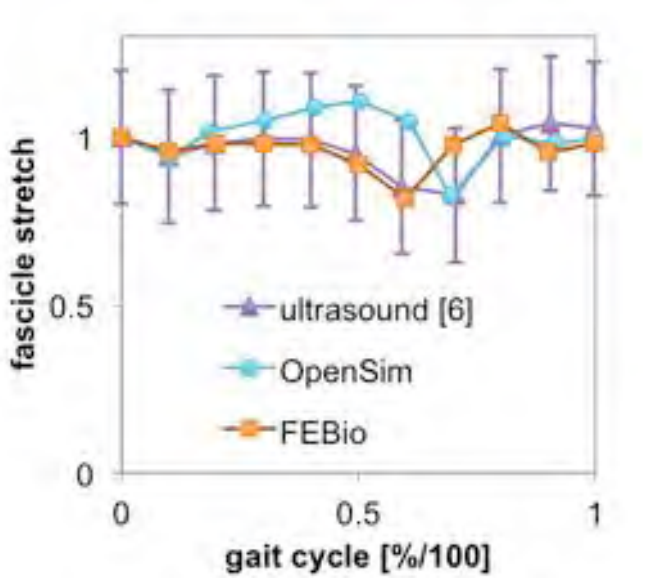

Figure 2: Comparison of fascicle stretch ultrasound data with the present study (FEBio) and the *gait2392* OpenSim model upon which the present model bone kinematics were based.

NON-INVASIVE *IN VIVO* ACHILLES TENDON STRESS MEASUREMENT: POSTURE AND RATE DEPENDENCE

INTRODUCTION

We are working on the development of a non-invasive shear wave sensor that could be used to track tendon loads during dynamic movement. The sensor is based on modeling and *ex vivo* studies that show shear wave propagation speed is directly dependent on axial tendon stress [1]. An *in vivo* version of the sensor uses skin-mounted miniature accelerometers and a tapping device to monitor wave speeds in superficial tendons. Initial collections have found a strong relationship between net joint moments and wave speed during walking [1]. However, to be suitable for use as a load sensor during movement, the relationship between wave speed and stress must be stable across different postures and load conditions. Hence, the purpose was to assess the relationship between Achilles tendon wave speed and loading metrics during voluntary ankle plantarflexion tasks performed at different limb postures and contraction rates.

METHODS

Twelve healthy subjects (6F, age: 23.6±2.8 years, height: 1.8±0.1 m, mass: 72.5±11.9 kg) were tested. Each subject's dominant foot was secured to the foot plate on an isokinetic dynamometer (Biodex System 4 Pro; Fig. 1). Subjects performed cyclic isometric exertions (0.5 Hz) up to maximum effort at eight postures: knee flexion of 20° and 90° and ankle angles of 10° dorsiflexion and 0°, 10°, and 20° plantarflexion. At the 20° knee and 0° ankle angle, exertions were performed at 3 cyclic contraction rates of 0.25, 0.50 and 1.00 Hz. Passive trials were also performed at each knee angle with the dynamometer rotating the ankle through a range of motion. Passive trial data was used to estimate the torque due to the weight of the foot and foot plate. Ankle plantarflexion torque was defined as the measured torque minus the torque due to gravity.

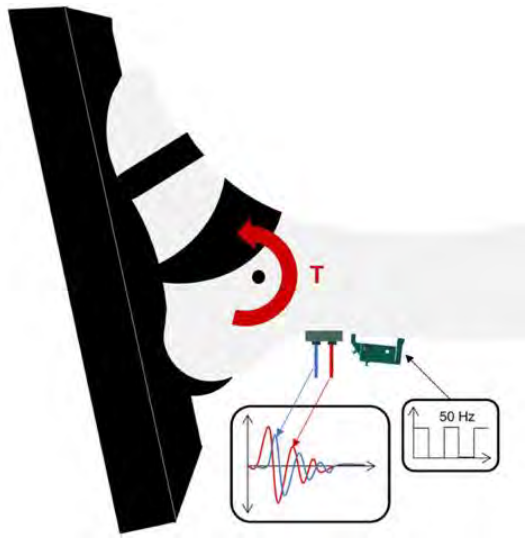

Figure 1: Subjects performed isometric exertions while a tapper induced shear waves that were observable on near (red) and far (blue) accelerometers.

MRI images of the calf and ankle were used to assess the tendon cross-sectional area, **A**. Coupled ultrasound and motion analysis was performed on these subjects to characterize the tendon moment arm, **r**, about the ankle as a function of ankle angle [2]. Tendon stress was then estimated from the ankle torque as $\sigma = \frac{T}{rA}$, which assumes the net torque arises entirely from tension in the Achilles.

Achilles tendon wave speed was measured using a custom shear wave tensiometer, consisting of a piezoelectric-actuated (20μm displacement, Thorlabs PK4JQP1) tapping device and two miniature accelerometers (Piezotronics 352C23) embedded in a platinum silicone mold (Smooth-On – Mold Star® 15 SLOW). The mold maintained constant 10 mm spacing between accelerometers. The tensiometer was strapped over the Achilles tendon, approximately 3.5 cm superior to the calcaneus. The tapper was driven with a 50Hz square

wave. Accelerometer, ankle angle, and torque data were collected at 50 kHz. For each tap, shear wave speed was calculated by finding the time delay that maximized the normalized cross-correlation between the two accelerometer signals [1].

The coefficient of determination (r^2) was used to assess the linear relationship between ankle torque and wave speed squared and was compared for all 12 subjects. Linear regressions of stress and wave speed squared were performed for each posture and contraction rate on the three subjects for which we had complete tendon image and moment arm measurements.

RESULTS AND DISCUSSION

Achilles tendon squared wave speed and ankle torque were highly correlated (r^2=0.95±0.06) at each of the 8 limb postures and 3 rates (Table 1). Correlation was weakest in the most plantarflexed posture where torque capacity is diminished.

Table 1: Coefficient of determination (r^2) mean (±1 s.d.) for posture specific linear regression correlation values over 12 subjects.

	Knee Flexion Angle	
Ankle Angle	**20°**	**90°**
10° DF	0.93 ± 0.08	0.95 ± 0.04
0°	0.96 ± 0.05	0.96 ± 0.03
10° PF	0.95 ± 0.04	0.95 ± 0.04
20° PF	0.91 ± 0.11	0.89 ± 0.11

Theoretical models suggest that wave speed squared should be proportional to tendon stress, as was seen in the three subjects for which this analysis was complete. Further, the slopes of the linear fits of stress to wave speed squared were relatively consistent across subjects, ankle angles, and speeds at the more extended knee posture (Fig 2). However, there tended to be a slight decrease in the computed slope when the ankle was dorsiflexed in the flexed-knee posture (Fig 2).

This observation could, in part, arise from non-uniform tendon stress due to a shortened gastrocnemius muscle. Further study is ongoing to assess if the slope of the stress-wave speed squared relationship remains consistent across additional subjects, or alternatively need to be calibrated by isometric trials of the type described in this study.

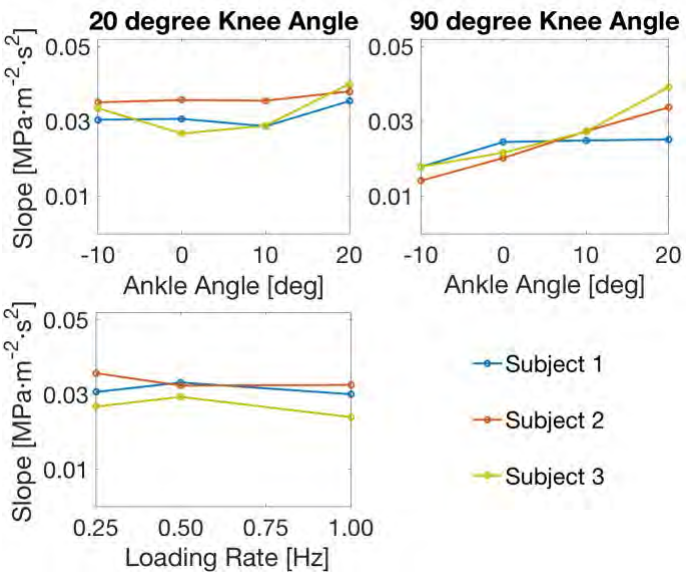

Figure 2: Linear fit slopes from squared wave speed-stress linear regression for three subjects over 8 postures and 3 cyclic contraction rates.

CONCLUSIONS

We observed strong relationships between ankle torque and squared wave speed over a broad range of limb postures and loading rates, supporting the use of shear wave tensiometry to assess internal tissue loading during dynamic movement. We previously showed that tensiometers of the type used in this study can monitor tendon wave speeds during dynamic activities such as running and walking [1]. Hence, shear wave tensiometry represents an exciting new tool that may be applicable for obtaining functional tissue load information that is relevant for a wide variety of orthopedic and rehabilitative applications.

INTRODUCTION

The Achilles tendon is the largest and strongest tendon in the human body, as it is loaded with more than 250%-390% body weight during functional tasks.[1, 2] Aberrant loading is thought to weaken the structure and make it vulnerable to injury. The majority of Achilles tendon ruptures occur as non-contact episodes and the primary location of tendon failure is 2-6 cm proximal to its insertion at the calcaneus.[3] Multiple risk factors are associated with an increased risk of injury, including overuse, age, sex, weight, and biomechanical abnormalities. Previous studies have investigated the mechanical properties of the Achilles tendons by stretching them to failure. However, most of these studies were conducted on tendons harvested from older individuals and used techniques that were not able to assess accurately the strain response under loading. This creates a significant gap in our understanding of the mechanical behavior of healthy tendons.

Digital image correlation (DIC) systems are an emerging state-of-the-art technology used to measure three-dimensional deformation and strains in real time with high precision. In combination with mechanical testing, DIC may provide invaluable insight into the properties of the tissue. Therefore, the purpose of this investigation is to utilize this novel methodology to study the mechanical behavior of healthy, human Achilles tendons.

METHODS

Eleven (n=11) Achilles tendons that included the calcaneus and a third of the gastrocnemius and soleus muscles were harvested from young, human cadavers with no prior history of lower extremity surgery (**Table 1**). The calcaneus was then wrapped in wire and secured in a metal fixture using bone cement such that the enthesis was free. The tendon's posterior surface was then coated with a black and white speckling pattern for the DIC system (GOM, Trillion Quality Systems, King Prussia, PA) to record, calculate, and analyze the strain and deformation response. The samples were then mounted to a servo-hydraulic testing machine (model 312, MTS, Minneapolis, MN) using a custom fixture with the calcaneus at a 30^o angle to simulate the anatomic position of a plantigrade foot in a neutral position. The other end of each sample, which included a third of the proximal muscles, was cryoclamped. Force and displacement data were collected at 128 Hz and the tendons underwent 10 cycles of pre-load to 2% strain. The tendons were loaded until failure at 5 mm/sec. After mechanical failure, standard histological analysis was performed on tissue adjacent to the rupture site to check for pre-existing histopathology. We analyzed the failure method, failure load, stiffness, and overall and regional peak strain.

Table 1: Subject demographics

Subjects (M/F)	Age (yrs±SD)	Weight (kg±SD)	Heigh (m±SD)
11(6/5)	42.1±9.8	83.3±22.3	1.78±0.1

RESULTS

Histological analysis of the tendon tissue showed healthy tissue with no pathohistological changes. There were five mid-substance tears, five calcaneus fractures, and one muscle tear during mechanical testing. The one muscle tear was excluded because it was an artifact of cryoclamping. T-tests were performed to determine differences between failure types (α=0.05). The failure load was significantly greater (p=0.02) in the group that sustained a mid-substance tear than the group that sustained a calcaneus fracture during tensile loading.

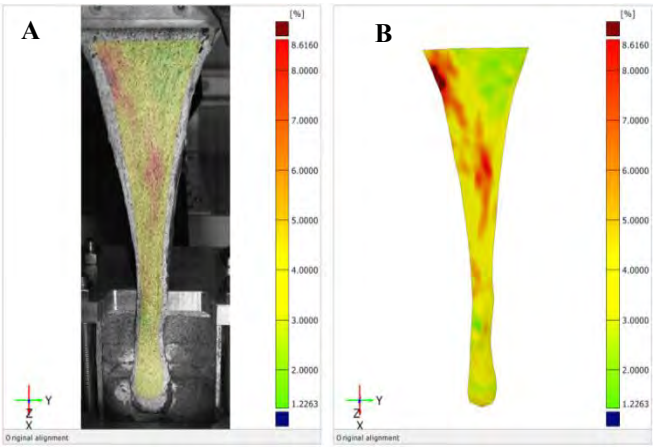

Figure 1: Experimental set-up (A) and percent strain distribution during testing (B).

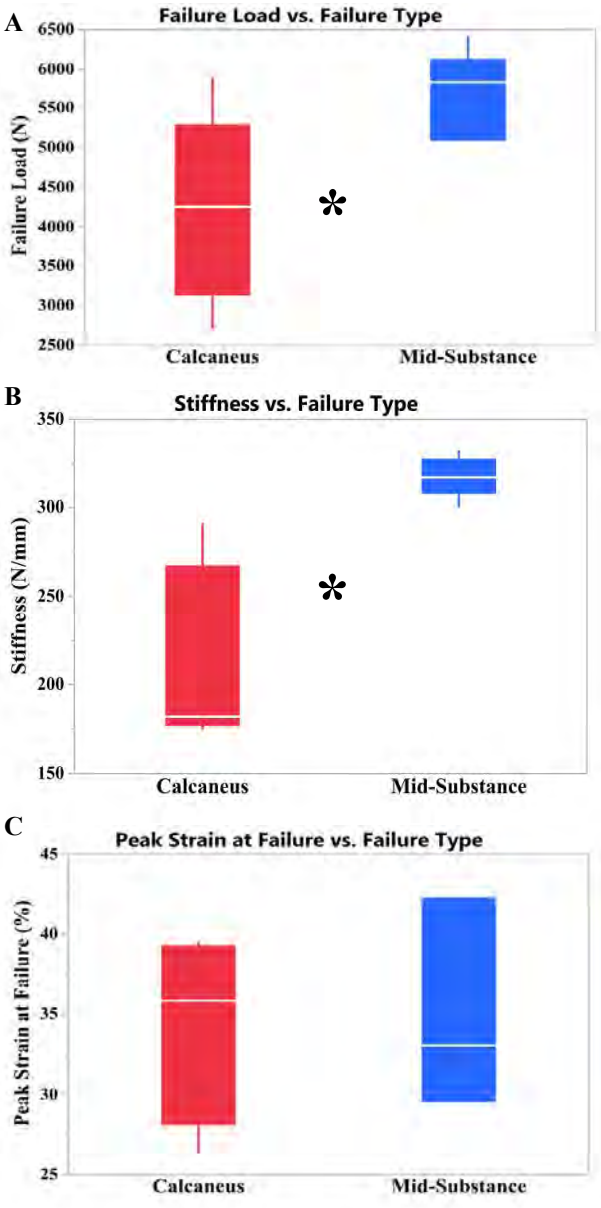

Figure 2: Differences between failure types in Failure Load (A), Stiffness (B), and Peak Strain at Failure (C). *Marks significant differences.

In addition, the mid-substance group was significantly (p=0.004) stiffer than the group which underwent a calcaneus fracture. There were no significant differences in peak strain (p=0.43) between the failure types. Since most Achilles tendons fail at the mid-substance, the tendons were divided into different regions to investigate local strains: distal (insertion to 2 cm proximal), mid-substance (2-4 cm from insertion), and (>4 cm from insertion). There were no significant differences between failure types across the same strain regions. However, within the calcaneus fracture group there were significant difference between the distal region and the mid-substance (p=0.03) and proximal (p=0.04). Also, within the mid-substance group, there was a significant difference between the distal region and the proximal region (p=0.03) (Table 2).

Table 2: Percent strain of the defined regions. Different symbols indicate significance across fracture types.

Failure Type	Distal (% strain)	Mid-Substance (% strain)	Proximal (% strain)
Calcaneus Fracture	17.6±10.0*	30.5±8.6^	34.4±7.4^
Mid-Substance	23.9±9.3*	30.1±8.8	33.7±6.0^

CONCLUSION

This is the first study to use a novel DIC system to measure entire surface deformation of the Achilles tendons. Mid-substance tears occurred at loads approaching 6,000N, which agrees with earlier data of Wren et al.[4] reporting a value of 5,000N. However, overall peak percent strain of nearly 35% observed in our study eclipses the previously reported peak strain values of 8.8% - 14.5%.[4] The results also demonstrate that the strain is not uniformly distributed. Because the tendons used in the present study were obtained from relatively young individuals and the tendons showed no degenerative changes by histology, the results of this study indicate that, healthy tendons are capable to be stretched to failure, despite requiring extremely high forces (700% body weight). This understanding may provide further insight into the load bearing of healthy, human Achilles tendons.

A model for internal elastic energy storage and recovery in deforming muscles

INTRODUCTION

Elastic structures within muscles have the potential to store and recover energy during movement. Intramuscular elasticity is typically represented in Hill-type models as parallel to the contractile element. This arrangement has two important implications. First, it dictates that energy can only be stored in the parallel elastic element when the contractile element is lengthened. Second, it suggests that elastic elements within muscles will be loaded only at long muscle lengths, where passive force is developed. These features of a Hill-type model conception of muscle elasticity have generally led to the conclusion that elastic energy storage and recovery within muscles is limited during normal movement.

Hill-type models typically do not account for muscle architecture. Most limb muscle are pennate, meaning that the fiber operates at an angle to the line of force generation of the whole muscle. As a result a portion of the force generated by the contractile element is oriented orthogonal to the line of action of the muscle (Fig. 1). This force tends to compress the muscle, and must be opposed by forces resisting compression within the muscle. Here we model this resistance as a spring element, and test the idea that compression and recoil of a transverse muscle spring could lead to elastic energy storage and recovery in the "parallel" elastic component of muscle, even when the muscle is not lengthening and not operating at long lengths.

METHODS

The model is constructed as a single muscle fiber operating at an angle (the pennation angle) to the line of action of the muscle (Fig. 1). A spring oriented orthogonal to the muscle line of action acts to balance the component of force tending to compress the muscle. The force and excursions of the model depend on the interaction between fiber force, fiber geometry, and transverse spring forces. Initial values of 30 degrees for theta and 30mm for L_f were used for all simulations.

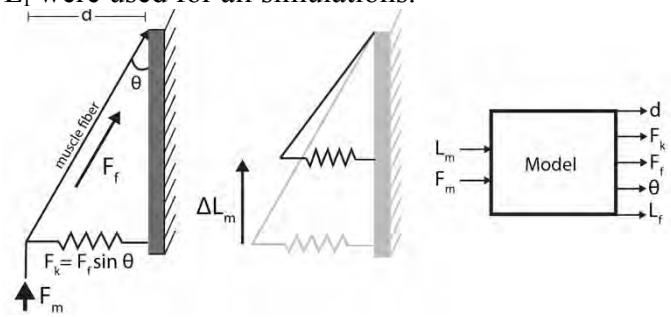

Figure 1. Modeled muscle at two time points, at rest (left) and contracted (middle). The muscle fiber operates at an angle (θ) to the muscle line of action (vertical). A spring generates a force, F_k, acting to resist compression (i.e., reducing of the pennation angle, θ). Simulations operate with an initial fiber length and pennation angle, and take inputs of muscle force and muscle length as a function of time. Outputs include muscle thickness (d), spring force (F_k), muscle fiber force (F_f), pennation angle (θ), and muscle fiber length (L_f).

RESULTS

We first tested whether the simple model could reproduce a phenomenon that has been observed in a number of unipennate muscles: variable gearing. The architectural gear ratio (AGR) of a muscle is defined as the ratio of muscle shortening velocity to fiber shortening velocity, and it has been observed to vary, with low force contractions operating with a high AGR and high force contractions operating with a low AGR. To test whether the model could produce variable gearing, we simulated contraction at a range of muscle forces but the same length trajectory. We optimized the spring stiffness for the high force condition, and then used the same spring constant for all simulations. Results from these simulations are shown in Fig. 2, along with previously measured values for AGR in isolated turkey gastrocnemius [1]. The model reproduced variable gearing (Fig. 2). This observation supports our hypothesis that intramuscular elastic elements

resist muscle compression and result in variable gearing.

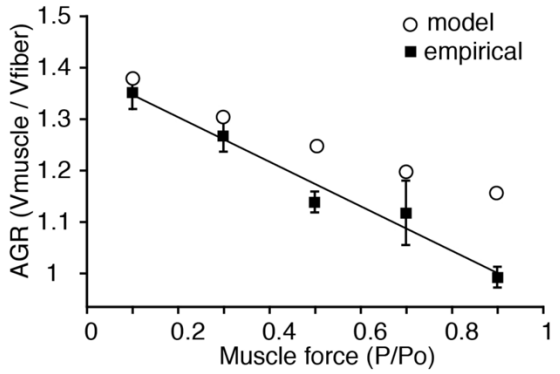

Figure 2. Results from modeled muscle (open circles) and empirical results from published data (closed circles, [1]) show similar patterns of variable gearing with force. Gear ratio was measured as the ratio of muscle velocity to fiber velocity during the constant force period of contraction.

Does the model have implications for elastic energy storage and recovery during ordinary movement? We aimed to test the idea that the springs that resist muscle compression might usefully store and recover energy cyclically by running the simulation with conditions meant to mimic those seen in some muscles during running. We drove the model with a half-sine pattern of muscle force and a half-sine stretch-shorten pattern of muscle length, with the goal of producing stretch-shorten cycles while muscle fibers were near-isometric. Figure 3 shows an example modeled contraction. In this example, nearly all of the excursion of the muscle-tendon unit is provided by fiber rotation (change in pennation angle), while fiber length remains nearly constant. Stretch-shorten cycles in muscles with near-isometric fibers have been observed in a number of systems [2, 3]. Calculated power shows that the majority of the power is associated with the transverse spring, which stores and recovers energy cyclically as the muscle compresses and then recoils.

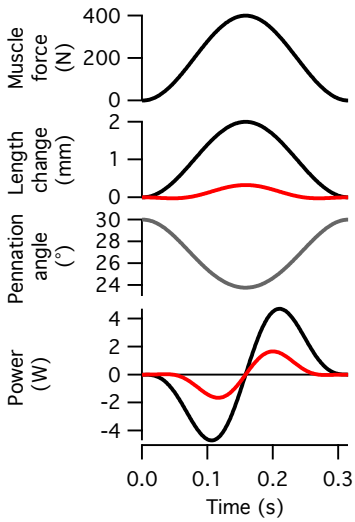

Figure 3. Simulated contractile mechanics for a stretch-shorten cycle. The model allows for significant length change in the whole muscle (black) with minimal length change in the muscle fiber (red). Changes in the pennation angle allow for cyclic energy storage and recover that does not require fiber length changes.

DISCUSSION

Results from a modeled muscle with a pennation angle and transverse spring demonstrate how this arrangement can produce variable muscle gearing. It also shows how a transverse spring can power cyclic stretch-shorten cycles in muscles. Like Hill-type models, our model is a simplified abstraction that does not include the morphological and mechanical reality of the complex, three-dimensional muscle deformations that we propose are associated with the loading of intramuscular elastic elements. It does demonstrate that a very simple modification to typical muscle models – orienting an elastic element orthogonal to the muscle line of action – can allow for the effective use of intramuscular elasticity. The modeled muscle allows for intramuscular energy storage at any muscle length and does not require muscle lengthening. We predict that further empirical measurements of three-dimensional muscle deformations will support the idea that intramuscular springs contribute significantly to muscle performance.

COMPARISON OF 3DOF AND 6DOF WORK AND POWER FOR STANDING LONG JUMP

Blake M. Ashby and Gordon J. Alderink

Grand Valley State University, Grand Rapids, MI, USA
email: ashbybl@gvsu.edu, web: http:// www.gvsu.edu/biomechanicslab/

INTRODUCTION

Work and power measures at the whole body and joint level have commonly been used to study performance of human movements. The standing long jump is a common movement present in numerous sporting events. This movement has been thought to be primarily a 2D, sagittal-plane movement, but recent work has shown that 3D analysis allows for more complete accounting of work and power [1]. Accurate calculation of work and power is important for understanding and describing the fundamental mechanisms of human movement. Six degree-of-freedom (6DOF) joint power/work has been shown to more completely quantify the work and power in movements such as walking [2]. The purpose of the present study was to compare the total body and joint-level work and power in the standing long jump using three degree-of-freedom (3DOF) and 6DOF analyses.

METHODS

Seven healthy, adult, male volunteers (mean ± standard deviation: mass = 78.2 ± 5.5 kg; height = 1.796 ± 0.049 m; age = 24.7 ± 2.5 years) performed six standing long jumps for maximum distance. The 3D positions of 63 passive reflector markers were recorded (120 Hz) throughout the jumping movements using a 16-camera Vicon motion capture system (Vicon Motion Systems Ltd., Los Angeles, CA). Two in-ground AMTI force platforms (Advanced Mechanical Technology Inc., Watertown, MA) recorded (1200 Hz) the 3D ground reaction forces, free moments, and center of pressure locations for each foot during the propulsive phase of the jumps.

The body was modeled using a 12-segment, 11-joint model modified from previous work [1]. Inverse kinematics and dynamics analyses were performed using MATLAB R2017a (MathWorks, Natick, MA) to calculate segment angular velocities and accelerations and joint moments. The over-determinacy of the system of equations resulting from the use of force plate data was resolved by performing "bottom up" calculations for the ankle, knee, hip, and lower back moments and "top down" calculations for elbow and shoulder moments [3].

Traditional 3DOF powers were calculated for each joint according to:

$$P_{3DOF} = \vec{M}_p \cdot \vec{\omega}_p + \vec{M}_d \cdot \vec{\omega}_d \qquad (1)$$

where $\vec{M}_p$ and $\vec{M}_d$ represent the joint moments acting on the proximal and distal segments, respectively, and $\vec{\omega}_p$ and $\vec{\omega}_d$ represent the proximal and distal segment angular velocities. 6DOF powers [2, 4] were calculated for each joint by including terms which allow for relative translation between the segments at the joint with:

$$P_{6DOF} = P_{3DOF} + \vec{F}_d \cdot (\vec{v}_d - \vec{v}_p) \qquad (2)$$

where $\vec{F}_d$ represents the joint intersegmental force calculated from inverse dynamics acting on the distal segment and $\vec{v}_d$ and $\vec{v}_p$ represent the joint center velocities calculated from the distal and proximal segments, respectively.

Work was calculated for each joint by integrating the joint power over the 1.2 seconds prior to takeoff using both 3DOF and 6DOF methods. Total body work was estimated as the sum of the work performed at each of the 11 joints.

Left and right side values were combined for all joints except for the lower back. Two-way, repeated measures, ANOVA models developed with SAS 9.4 (SAS Institute Inc., Cary, NC) were used to compare the power and work values calculated using 3DOF and 6DOF methods. Results are presented as least square means ± 95% confidence intervals. Statistical significance was indicated for $p < 0.05$.

RESULTS AND DISCUSSION

Although the total body work calculated with the 3DOF method (515.3 ± 20.8 J) was not significantly different ($p = 0.3645$) than with the 6DOF method (517.2 ± 20.4 J), there were significant differences in the work done at the joints (Table 1). The lack of significant difference in total body work was due to 35.6 ± 5.4 J more ($p < 0.0001$) work at lower body joints (ankles, knees, hips, and lower back) while 33.7 ± 6.4 J less ($p < 0.0001$) work was calculated at upper body joints (shoulders and elbows) when using 6DOF methods. Looking at the joint powers during takeoff (Figure 1), the differences between 3DOF and 6DOF methods were relatively modest at the ankles, knees, and hips, but were much more apparent at the lower back, shoulders, and elbows.

It has been shown that errors in joint center estimation propagate into the joint power calculations using traditional 3DOF methods, but do not propagate when using 6DOF methods [4]. The large differences demonstrated in the results at the lower back, hip, and shoulder are perhaps reflective of the inherent challenges of properly locating these joint centers using motion capture technology and in modeling the lower back with a single joint.

The large work and power differences for the upper extremity joints might be further explained by the larger joint velocities in the arms just before takeoff. The joint center velocities calculated from the distal and proximal segments and used in Eq. (2) depend heavily on the segment angular velocities, which are considerably larger for the forearm and upper arm segments than for other segments. The results of this study highlight the value of using 6DOF methods for explosive movements such as jumping that involve significant upper body motion.

COUNTERMOVEMENT JUMP HEIGHT AND FORCE – TIME VARIABLES IN HIGH SCHOOL BASKETBALL PLAYERS

Rena Hale, Takashi Nagai, Nathan D. Schilaty, Nathaniel A. Bates, April L. McPherson, Alessandro Navacchia, and Timothy E. Hewett

Mayo Clinic Biomechanics Laboratories & Sports Medicine Center, Rochester & Minneapolis, MN, email: Hale.Rena@Mayo.edu

INTRODUCTION

Due to the increasing affordability and ease of use, force platforms are becoming one of the most commonly used biomechanical testing devices in clinical practice [1]. The countermovement jump (CMJ) is a common portion of athletic testing. It is quick to perform, non-fatiguing, and can inform the clinician of the athlete's neuromuscular control for strength and power training [2]. Plyometric intensity can be determined by calculation of rate of force development during the eccentric and concentric phases of a CMJ from force platform measurements [3]. However, the shape of the force-time curve is dependent upon expertise [2, 3, 4]. For clinical application and interpretation of force plate data, normative values of the CMJ are needed. Thus, the purpose of the study was to calculate Propulsion rate of force development (PRO-RFD), landing rate of force development (RFD), and jump height during a CMJ in high school basketball players. The hypothesis tested was that male athletes would jump higher than female athletes and as athlete's age, PRO-RFD and RFD would be greater in males than females.

METHODS

172 high school basketball athletes (males n=64, females n=108) 14 to 18 years old were recruited (Table 1). This study was approved by the Mayo Clinic IRB. Informed consents were obtained from each player and his/her parent if under 18 years old. Athletes were instructed to place hands on hips, stand feet shoulder width apart with each foot on the center of a force plate, (Bertec, Columbus, OH), and perform a max jump. Force plate data from three CMJs were collected.

Vertical ground reaction force (vGRF) was used to calculate jump height, PRO-RFD, and RFD for the right and left legs. PRO-RFD was calculated as the slope of the propulsion phase (eccentric loading) of the force-time curve. Propulsion phase began when vGRF exceeded body weight and ended when force was zero [3,4]. RFD was calculated as peak vGRF divided by the time from initial contact to peak vGRF during landing phase [4, 5]. Data was averaged by subject, sex, and age.

Table 1: High School Basketball Anthropometrics

	Height (m)		Weight (N)	
Age	Males	Females	Males	Females
14	1.73 (0.06)	1.68 (0.10)	681.13 (89.10)	618.73 (144.61)
15	1.78 (0.07)	1.70 (0.08)	652.84 (120.93)	651.33 (143.49)
16	1.83 (0.10)	1.68 (0.04)	722.20 (103.21)	661.92 (82.44)
17	1.84 (0.08)	1.74 (0.08)	772.36 (121.21)	675.36 (157.74)
18	1.84 (0.03)	1.71 (0.10)	792.04 (80.49)	654.96 (77.53)

Statistical analyses between sexes were performed with JMP 13 (SAS Institute Inc., Cary, NC) with matched pairs and one-way ANOVA with an alpha level < 0.05. A Tukey post hoc analysis was conducted to detect differences among age groups.

RESULTS AND DISCUSSION

Results showed significant differences ($P<0.05$) between male and female jump heights (Table 2), PRO-RFD (Table 3), and RFD (Table 4). Jump height was lower in females than males in all age groups (0.27m ± 0.02 vs. 0.37m ± 0.04). Within males, jump height significantly increased between 14 and 18-year-olds ($P<0.05$). No significant differences in jump height were determined within females. However, a deconditioning trend was seen in 18-year-old females. Results were consistent with previous studies, which report that male athletes jump 26.4% higher than female counterparts [6].

Overall average male PRO-RFD (2200 N/s ± 830) was higher than mean female PRO-RFD (1556 N/s ± 426). PRO-RFD in 16-year-old males was significantly higher than that of females. Significant difference was not found between sexes at any other age or within ages of each sex. PRO-RFD in elite basketball players has been reported as 3,370 N/s, which was 35% greater than the high school male and 66% higher than high school female basketball players analyzed in this study [6].

Table 2: Jump Height

Age	Male (m) mean (SD)	Female (m) mean (SD)	P- value
14	0.33 (0.10)	0.27 (0.08)	0.1401

16	0.37 (0.07)	0.27 (0.06)	0.0002
17	0.35 (0.05)	0.29 (0.07)	0.008
18	0.44 (0.07)	0.24 (0.04)	0.0001

Table 3: Propulsion Rate of Force Development

Age	Male (N/s) mean (SD)	Female (N/s) mean (SD)	P- value
14	2426 (3076)	1625 (983)	0.2544
15	2176 (1879)	1734 (1539)	0.383
16	2098 (1076)	1324 (459)	0.0177
17	1971 (1034)	1580 (705)	0.1926
18	2329 (1612)	1518 (605)	0.1836

Table 4: Rate of Force Development Absorption

Age	Male (N/s) mean (SD)	Female (N/s) mean (SD)	P- value
14	42869 (19366)	26986 (12761)	0.0113
15	46157 (27785)	20769 (6984)	0.0001
16	38737 (13995)	18293 (5629)	0.0001
17	45134 (18460)	24111 (10804)	0.0002
18	45044 (13106)	19371 (5909)	0.0001

Differences in RFD between males and females were significant at all ages ($P<0.05$). Average male RFD was larger than in females (43,588 N/s ± 5,838 vs. 21,906 N/s ± 3,189). RFD was significantly different between males age 14 to 15, 14 to 16, and 14 to 18. No significant differences were found between ages in females. Interestingly, males experienced deconditioning at 16 years old, whereas females experienced deconditioning at 16 and 18 years old.

RFD is typically calculated for the first and second landings of a drop vertical jump (DVJ). Previously reported first and second landing RFD totals are 50,080 and 48,084 [4]. As expected, DVJ RFD values are higher than CMJs, since the DVJ landing is from 31 cm off the ground.

CONCLUSIONS

The purpose of this study was to calculate jump height, propulsion of force development (PRO-RFD), and landing rate of force development (RFD) of a CMJ in high school basketball players. Results demonstrate significantly higher jump height and RFD in males when compared to females. Results can be used to determine appropriate CMJ variables for other high school athlete populations. Coaches should be aware of potential deconditioning of male athletes at 16 years old and female athletes at 16 and 18 years old. Future work should look at the correlation of force-time variables to jump height.

Sport-Specific Wearable: A Jump Monitor for Figure Skating

[1] Sarah T. Ridge, [1]Riley E. Reynolds, [1]Chris Adair, [2]Peter Zapalo, and [1]Dustin A. Bruening

[1] Brigham Young University, Provo, UT, USA

email: sarah_ridge@byu.edu

INTRODUCTION

The sport of figure skating has become more technically demanding since the 1990s. While competitive skaters have increased their off-ice strengthening and training in this time, the number and difficulty of on-ice jumps performed has increased also. While the number of jumps skaters perform daily has never been formally quantified, it has been suggested that skaters perform at least 50, perhaps up to 100 jumps per training day [1].

Forces during performance of skating jumps have been estimated to be greater than 5 times the skater's body weight [1]. The magnitude of force, high loading rates, and frequent repetitions is likely a contributing factor to the injury rate of competitive skaters. As with many athletes, the trade-off between injury prevention and performance enhancement is difficult for skaters. Numerous jump repetitions are required in order to learn and improve technique. However, increasing the number of repetitions of jumps may increase the risk of injury to the skater. Increasing monitoring of the number of jumps performed by skaters may help decrease risk of injury, similar to the institution of pitch counts in youth baseball. In addition, wearable technology could help skaters and coaches monitor fatigue or performance degradation by measuring jump height and/or rotation speed.

Accelerometers are commonly used to monitor physical activity. While they are useful for counting steps during walking and running, figure skating involves a variety of movements that generate similar acceleration profiles, resulting in a number of false positives during jump identification. Figure skating movements are complex and occur in multiple planes, involve changes of direction, and are often performed at high speeds.

Therefore, the purpose of this study was to determine the feasibility of using an inertial measurement unit (IMU) to count the number of jumps performed by figure skaters and estimate flight time of those jumps.

METHODS

Seven healthy competitive figure skaters participated in this study (ages 12-27, 6 female, 1 male). All skaters (and parents, when necessary) signed assent/consent forms approved by the local Institutional Review Board.

Each skater wore an IMU affixed to the lower back while they performed a variety of isolated jumps and a complete competition routine, consisting of jumps, spins, and footwork. The isolated jumps were used to define the jump detecting algorithm, which was then tested on the competition routines. Data from all jumps and routines were recorded by the IMU (128 Hz). A high speed video camera (240 Hz) was used to identify take-off and landing for flight time calculations from isolated jumps.

MATLAB software was used to process and analyze the IMU data. All accelerometer signals were first low pass filtered (6th order Butterworth with 10Hz cutoff) prior to analysis. MATLAB's findpeaks() function was then used to identify jumps and implement jump height algorithms. Jump height was measured from the high speed video using Dartfish and from the IMU data using 4 algorithms - gravitational threshold (GT), peak to peak scaling (PPS), valley to valley scaling (VVS), and vertical/horizontal acceleration intersection (VHI).

RESULTS AND DISCUSSION

The isolated jumps were used to create a jump identification algorithm based on vertical acceleration data and gyroscope data. Using the video as reference, data were analyzed to specify

three factors that could be used in the algorithm to automatically identify jumps in future applications. The three factors were: 1) a jump had to have two acceleration peaks above 25 m/s^2, 2) the two peaks had to be separated by 0.3 – 0.85 s, and 3) a rotation above 688 deg/s had to occur between the two acceleration peaks (Figure 1).

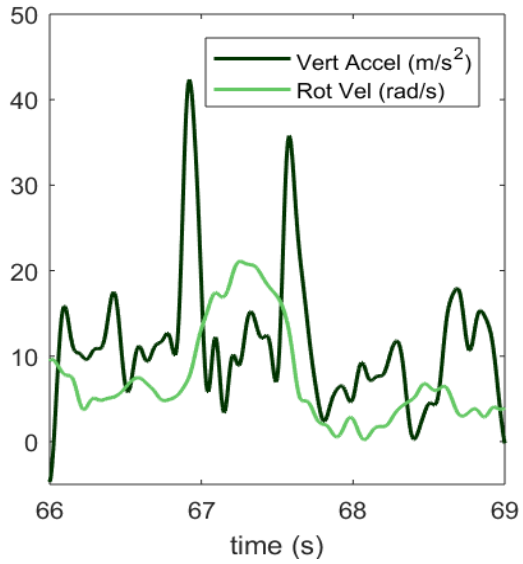

Figure 1. A 3 second section of IMU data from a competition routine. The large vertical acceleration peaks surrounding the rotational velocity peak indicate the jump (double flip).

These specifications were applied to the IMU data from the competition routines. The number of jumps identified by each step of the algorithm is shown in Figure 2. Forty-one total jumps with > 1 rotation in the air were performed during the competition routines. The algorithm performed very well; it identified a total of 40 jumps, missing only 2 jumps that were performed and including 1 ≤ 1 rotation jump.

Flight time and calculated jump height results can be seen in Table 1.

Method	Flight time (s)	Jump Height (cm)
Video	0.44 ± .060	24.4 ± 6.5
GT - error	0.098 ± 0.154	7.81 ± 10.8
PPS - error	0.031 ± 0.025	3.33 ± 2.75
VHI - error	0.165 ± 0.053	4.87 ± 3.87
VVS - error	0.047 ± 0.046	7.81 ± 10.83

Table 1. Algorithm errors for isolated jumps – absolute differences between each method and the gold standard video (mean ± standard deviation).

Further analysis with a greater variety of skaters should be done to determine if there are subject-specific characteristics that could help customize the algorithm to optimize accuracy of jump height calculations. However, it should be noted that, as a tool to monitor fatigue, skaters and coaches are likely more interested in decrease in jump height throughout a training day or session than precision of measurement relative to a gold standard.

CONCLUSIONS

A sport specific wearable to monitor the number and height of figure skating jumps performed during practice sessions is feasible. Future research will focus on finding a consumer-affordable IMU device and developing a user-friendly interface for skaters and coaches.

INTRODUCTION

Physical inactivity is known to contribute to a broad array of health problems throughout the lifespan, but biomechanical factors that limit physical activity are poorly understood. The musculoskeletal system is known to adapt to its activity-dependent loading, and is especially plastic during growth [1]. Studies of animal models have revealed differences in bone shape and joint structure between groups with different levels of physical activity during growth [2]. We have recently demonstrated using an avian, bipedal animal model that optimal fascicle lengths in hip and ankle muscles decrease substantially during growth (by ~15%) in sedentary compared to running-trained animals [3]. The shorter muscle lengths in the sedentary group may limit force generating capacity during dynamic movements due to force-length-velocity constraints [5]. Furthermore, preliminary data on ankle moment arms between these groups support the hypothesis that torque- and power-generating capacity will be compromised [5].

These morphological alterations over the growth span may reduce locomotor performance and increase effort when inactive animals with suboptimal musculoskeletal structure attempt to achieve a locomotor goal. The purpose of this study was to determine (1) the effects of growth-period inactivity upon locomotor performance immediately post-growth and (2) the extent to which these adaptations to inactivity can be reversed after a period of increased activity in adulthood.

This goal was addressed using an experimental design in which guinea fowl were grouped into 1) a control exercise group (EXE) where normal activity, including opportunities for running and jumping, was provided over the growth span and adulthood, 2) a disuse group (DIS) that was subject to limited movement and muscle disuse (using botulinum toxin) during growth and subsequently provided the same access to activity as the EXE group during adulthood.

METHODS

One-day old guinea fowl (*Numida meleagris*) were obtained from a regional breeder (Guineafarm, OH). At 4 weeks of age, guinea fowl were divided into EXE (n = 16) and DIS (n = 16) groups. EXE birds were housed in a large, circular pen that allowed ample room for locomotion and objects for jumping/perching. The DIS group were reared in small, square pens with low ceilings to restrict movement and jumping. Furthermore, the DIS groups was subjected to focal muscle disuse via injection of botulinum toxin-A (BTX-A) into the lateral (LG) and medial gastrocnemius (MG). This protocol created an enhanced disuse signal that was reversible.

Each animal received an initial BTX-A injection (4 units (LD50)/kg) at 7-8 weeks of age under general anesthesia (1.5% isoflurane). The animals received an additional injection every five weeks for a total of 4 injections over 20 weeks, by which time the animals had reached skeletal maturity. The EXE groups received sham injections of saline.

At 27-28 weeks of age (~6 months), a maximal jumping task was used to assess power capacity. Birds were placed on dual-force plates (AMTI 6x6; 20 lb. capacity each) that were surrounded by a vertical box (Fig 1). Birds were given 5 minutes to jump at least 3 times voluntarily or with encouragement. This was repeated across two days. Forces were recorded at 100 Hz and filtered using a

low-pass Butterworth filter with a cutoff frequency of 50 Hz. Peak vertical forces from the top three jumps were averaged and normalized to body weight (BW).

Following the 6 month testing, half of the animals from each group were sacrificed (pentobarbital >1.6 mg/kg) for morphological analyses (to be performed in a companion study). The remaining animals from the DIS group were housed in the same condition as those of the EXE group throughout adulthood. Adult animals were retested at 15 months of age.

Student t-tests were performed to assess group differences at an alpha level $p < 0.05$.

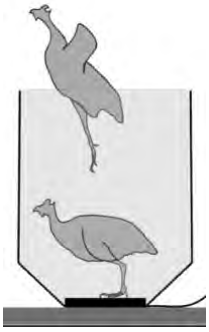

Figure 1. Schematic illustration of jumping task.

RESULTS AND DISCUSSION

The average maximum weight-normalized vertical force at the 6-month post-growth time point was ~6 N/BW in the DIS group vs. ~8 N/BW in the EXE group ($p < 0.05$). Upon retesting at the 15 month time point both the DIS and EXE groups average maximum weight-normalized vertical force was ~7 N/BW. The jumping force data are summarized in Fig. 2.

Not surprisingly, the jumping performance of DIS animals was markedly poorer than EXE birds after a growth period marked by both general and localized muscle disuse. Nevertheless, the magnitude of peak vertical force in the DIS group was remarkably high, reaching nearly 6x body weight. This value is comparable to the peak forces reported previously from cage-reared guinea fowl [6]. This suggests that localized muscle paralysis during growth is compensated for, possibly either through growing new muscle, or by increased growth and use of use of synergists. It also suggests that the difference in force observed between groups at 6 months is due primarily to the availability of exercise as opposed to a BTX-A effect.

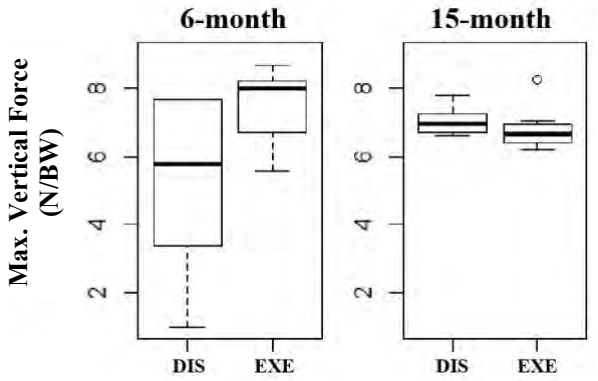

Figure 2. Box-and-whisker plots of max normalized vertical force at 6- (left) and 15-months (right).

To our knowledge, this is the first study to systematically assess whether movement impairment due to disuse during growth can be reversed. Our results suggest that maximal locomotor performance (jumping) can indeed be recovered after even severe locomotor and muscle disuse during growth. This finding has encouraging implications for exercise interventions for restoring function. How these findings correlate with morphological adaptations is currently being explored. The logical subsequent steps are to establish the exercise dose necessary to restore normal function and its timeframe, and if these findings relate generally across modes of movement and species.

EFFECTS OF ERRONOUS MOVEMENT PREDISPOSITION ON JUMP LANDING

Mitchell L. Stephenson and Jason C. Gillette

Iowa State University, Ames, IA, USA
email: mistephe@iastate.edu, web: kin.hs.iastate.edu

INTRODUCTION

Non-contact anterior cruciate ligament (ACL) injury research is commonly implemented with protocols that include a reactive component. This is included to better reflect sports experience, whereas an athlete alters their movement direction in response to an opponent. Experimentally, this is often simulated with a discrete visual (often LED) stimulus indicating the movement direction moments before the participant lands from a jump or plants their foot before a cut [1-2].

Limited past research has relied on video of an opposing athlete as alternative visual stimuli [1]. Deceptive movements of the recorded athlete may predispose participants to assuming an erroneous movement direction. This study seeks to determine whether an erroneous predisposition may alter jump landing in a way that may increase ACL injury risk when the participant corrects to the proper movement direction. To limit other confounding variables that may be associated with video stimuli, this research implements predisposition using discrete LED directional stimuli.

METHODS

Ten physically-active, right-foot dominant, uninjured females that commonly participate in soccer, basketball, volleyball, tennis, or hockey (20.8±1.5 years; 1.63±0.09 m tall; 61.9±6.7 kg) have volunteered for this ongoing study. Participants provided informed consent, executed a warm-up protocol, and performed practice trials.

Participants jumped forward 50% of their height from a 30cm tall block, landed bilaterally on two force platforms (2000 Hz, AMTI, Watertown, MA), and then quickly and fluidly jumped to the left or right 60° from anterior for maximum speed and distance [2]. The jump direction was indicated by one of two LEDs (left or right) mounted in front of the participant. These indicators were illuminated in one of five conditions: The anticipated (AN) condition illuminated the LED before the trial began. The reactive conditions illuminated the LED either immediately after they jumped from the 30cm block (RE1) or the instant they landed on the force platforms (RE2). The predisposition conditions illuminated the incorrect LED before the trial began, and then switched to the correct LED at takeoff from the 30cm block (PRE1) or at landing (PRE2). Anticipated and predisposition trials were indistinguishable at the beginning of the trial.

Participants performed at least three successful trials in each direction in each condition. They performed more AN conditions than PRE, such that assuming the initially-indicated direction was correct would result in fewer repeated trials. Participants were informed of this before the data collection started.

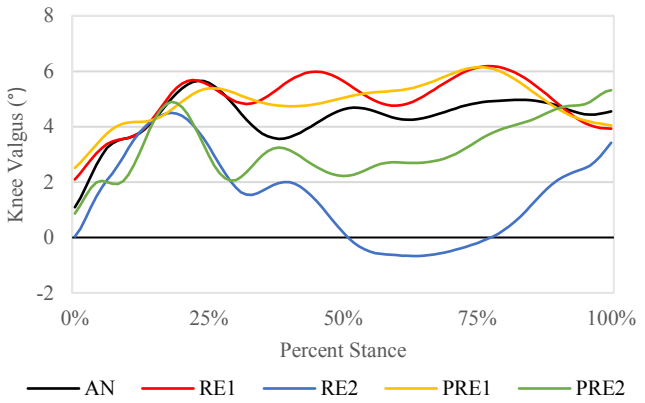

Figure 1: Ensemble mean knee valgus angle across percentage stance time for each condition while jumping left.

The jump direction and condition were computer-randomized to implement a double-blind design. Kinematics of 19 retroreflective markers placed on the right lower extremity, pelvis, and torso were recorded via 8 infrared cameras through Vicon Nexus 1.8.2 (200 Hz, Vicon Corp, Oxford, UK).

Peak knee valgus and flexion angles as well as the peak unilateral vertical ground reaction forces (VGRF) were extracted during the first 100ms of contact with the force platforms [3]. A repeated-measures ANOVA was performed to compare the effect of the condition on kinematics and landing VGRF for each jump direction.

RESULTS AND DISCUSSION

Significant main effects ($p < 0.01$) were identified in both movement directions for peak knee flexion angles and VGRF, but not peak knee valgus angles. Pairwise comparison results maintaining a false discovery rate of 0.05 are presented in Table 1.

Dependent variables were characteristically unique depending on jumping direction [2]. Left jumps demonstrated increased peak VGRF and decreased peak knee flexion angles in both the RE1 and PRE1 conditions compared to the AN, RE2, and PRE2 conditions. This may be interpreted as a stiffer, and possibly more dangerous [4], landing in the RE1 and PRE1 conditions.

Jumps to the right resulted in increased peak knee flexion angles in the RE1 and PRE1 conditions compared to the other conditions. Furthermore, the RE2 and PRE2 conditions demonstrated decreased peak flexion angles compared to the other conditions. Peak vertical ground reaction forces were highest in the RE2 and PRE2 conditions, and the PRE1 condition resulted in a smaller peak ground reaction force than the AN condition. The combination of increased VGRF and decreased knee flexion in the RE2 and PRE2 conditions again indicates a stiffer landing which may increase injury risk [4].

The RE1 condition did not significantly differ from PRE1, and RE2 did not differ from PRE2 in either jump direction for any reported variable. It appears that the effects of predisposition did not alter landing from the reactive conditions in the first 100ms of landing. However, Figure 1 does demonstrate frontal plane kinematic differences later in the landing phase. Qualitatively, researchers and participants noted increased difficulty in executing proper directional changes in the incorrectly predisposed conditions. Thankfully, these effects do not appear to affect the reported variables within the landing times expected to be consequential for ACL injury [3]. Participants reported after data collection that they did assume the initially-indicated direction was correct; we expect that it is unlikely that participants chose to ignore the stimuli until landing.

In conclusion, predisposing participants to an erroneous movement direction did not alter results within the first 100ms of landing, and therefore likely did not change ACL injury risk. It is possible that, in situations where erroneous predisposition is possible (such as deceptive opponents in sport), participants do not alter their pre-landing strategies in ways that may contribute to this lower extremity injury.

JOINT CONTRIBUTIONS TO TOTAL LOWER EXTREMITY POWER DURING A SINGLE-LEG HOP LANDING TASK AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

email: rachel.tatarski@osumc.edu

INTRODUCTION

The single-leg hop for distance (SLH) is often used to determine return-to-sport (RTS) readiness for patients recovering from anterior cruciate ligament reconstruction (ACLR) surgery. A limb-to-limb comparison of the hop distance with ≤5% asymmetry is considered clinically normal.[1] While hop distance symmetry is a valuable indicator of dynamic knee dysfunction, it does not capture abnormal mechanics that may confer injury risk. Sagittal plane knee extensor asymmetry during landing is a known predictor of second ACL injury even after ACLR.[2]

A deeper analysis into the force attenuation strategies during SLH landing after ACLR and patient-reported function may provide insight into compensations that are not necessarily apparent with hop symmetry. Thus, the purpose of this study was to compare the sagittal plane power absorption strategies between limbs during the landing phase of a SLH in individuals who have undergone ACLR and assess the relationships between joint contributions and patient-reported function. The hypotheses tested were 1) that the involved limb would demonstrate lower knee and higher hip power absorption during the SLH when compared to the uninvolved limb and 2) that knee contribution would be correlated with patient-reported function.

METHODS

Twenty individuals who had undergone ACLR gave written consent to participate in this study, which was approved by the university's IRB (Table 1). Participants had either completed physical therapy or were in the latest phases and were required to have full, pain-free knee range of motion, ≤1+ knee effusion on the effusion stroke test, and <30% hamstrings and quadriceps isokinetic strength deficits in order to perform the SLH. The symptoms, pain, and sports subscales of the Knee injury and Osteoarthritis Outcomes Score were used to assess patient-reported function (Table 1).[3]

Table 1: Participant demographics.

n	20 (9 males, 11 females)
Age (yrs)	20.6 ± 6.4
Height (cm)	172.3 ± 8.97
Mass (kg)	78.0 ± 16.8
Time since surgery (mon)	8.1 ± 3.6
KOOS – Sports	90.69 ± 11.13
KOOS – Pain	96.11 ± 4.97
KOOS – Symptoms	89.11 ± 7.81

Participants were fitted with 55 retro-reflective markers that were used to track body segments and define joint centers. Kinematics were captured at 240Hz with a 12-camera motion capture system (Motion Analysis Corp., CA) and ground reaction forces were captured at 1200Hz with an embedded force plate (Bertec, OH). Participants were instructed to begin the hop balanced on one foot, to hop as far forward as possible, and to land on the force plate with the same foot while maintaining balance. Hop distance was estimated during practice trials to ensure that the participant would land on the force plate.

The landing phase was defined as the first 0.5 seconds after initial contact (vertical ground reaction force >20N). Hop distance was calculated from the heel marker on the hopping foot. Limb symmetry index (LSI) was calculated as the percent of the involved limb to the uninvolved limb. Marker trajectory and force data were smoothed with a 6Hz and 50Hz low pass filter, respectively. Kinematic and kinetic data were imported into Visual 3D (v6 Pro., C-Motion Inc., MD) in which hip, knee, and ankle joint powers were calculated through inverse dynamics. The means of two successful trials on each limb were analyzed. Total limb negative power (TLP) was calculated as the sum of the hip, knee, and ankle negative joint powers. Hip, knee, and ankle

contributions at the time of the TLP peak were calculated as a percent of the TLP. Kinetic variables were normalized to body-weight*height.

The variables of interest were: hip, knee, and ankle joint contributions to TLP, peak TLP, and KOOS subscales. Paired t-tests were used to compare these variables on the involved and uninvolved limbs. Spearman's rho correlations were used to assess the relationship between KOOS subscales and knee contribution to the TLP. The alpha level was set to 0.05, *a priori*. Statistical analyses were carried out with Minitab (v17, PA).

RESULTS AND DISCUSSION

Participants hopped farther on the uninvolved limb (141.6 ± 23.2 cm) than the involved limb (149.3 ± 27.1 cm; p=0.02); however, the LSI was 95.0 ± 9.9%, which is considered within a normal range. Peak TLP was significantly greater on the uninvolved limb (p=0.001, Table 2). There were no significant differences between limbs for hip (p=0.334) or ankle (p=0.874) peak negative power; however, the peak power absorbed by the involved knee was significantly lower than the uninvolved knee (p=0.004; Table 2).

Table 2: Means and standard deviations for hip, knee, and ankle peak negative powers and the hip, knee, and ankle joint contributions to total lower extremity peak negative power for the involved and uninvolved limbs.

	Involved	Uninvolved
Hip Power	-5.87 ± 2.90	-6.39 ± 2.83
Knee Power	-7.39 ± 2.04*	-9.66 ± 0.87
Ankle Power	-2.22 ± 1.19	-2.16 ± 1.77
Peak Total Limb Power	-9.97 ± 2.85*	-12.33 ± 4.33

** denotes a significant difference, p < 0.05. Power is reported in W/kg*cm.*

Hip (p=0.089) and ankle (p=0.075) contributions to peak TLP absorption were not different between limbs (Figure 1). The knee contribution to TLP on the uninvolved side was significantly greater than on the involved side (p=0.028, Figure 1). In addition, the KOOS-Symptoms subscale was significantly related to the knee contribution to TLP (r=0.462, p=0.040), while the sports and pain subscales were not.

The data support the hypothesis that there would be a redistribution of power absorption away from the involved knee after ACLR.

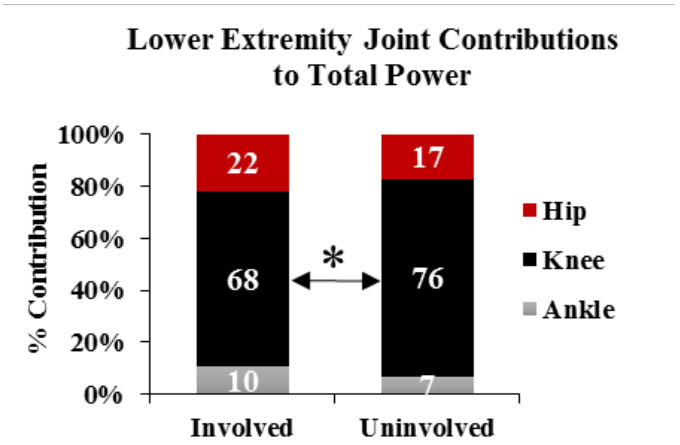

Figure 1: Hip, knee, and ankle contributions to total lower extremity negative power. Individual joint contributions were taken from the same frame as the peak for total joint power. (* indicates a significant difference between limbs, p < 0.05).

The reduction in knee contribution and peak power absorption on the involved knee indicates an "unloading" strategy and confirms power redistribution away from the involved knee.[4] Moreover, these data suggest a relationship between this redistribution landing strategy and function (symptoms).

Importantly, all participants had passed the clinical criteria to hop and LSI was well within normal limits, yet a different power absorption strategy on the involved limb remained, and was positively correlated with knee symptoms. Patient-reported function can be easily assessed by clinicians and should be considered when making RTS decisions.

CONCLUSIONS

Overall, the involved knee contributed significantly less to total limb power absorption which was significantly correlated to the KOOS-symptoms subscale score, despite clinically normal limb symmetry values in hop distance after ACLR.

INTRODUCTION

Linear methods of variability are concerned with the magnitude of variability and often consider deviations from a central mean as error. Utilization of nonlinear tools to examine variability allows for the exploration and measurement of the patterns of variability displayed by the system or the structure of the variability. This explores the deterministic properties of gait, or how previous iterations within the gait cycle influence subsequent and future iterations. (1) Nonlinear analysis of gait variability of the joint angle time series has not been investigated in developing children. Differences in the structure of variability of the joint angle time series of children at different points in development should be able to be identified using nonlinear tools of analysis. Not only will this shed light on the potential control mechanisms being used and the refinement of gait throughout development but will give a launching point for comparison of the natural trajectory of gait development to be used to help understand various types of pathological gait in children.

The purpose of this study was to assess the development of kinematic gait variability in children from ages 2-10 years old using nonlinear methods of analysis. We hypothesized that with age and walking experience, children will have increased stride-to-stride fluctuations in their gait.

METHODS

Our study involved 28 boys and girls split into four separate age groups. The age groups consisted of 2-3-year-old (n = 7), 4-5-year-old (n = 7), 6-7-year-old (n = 7), and 8-10-year-old (n = 7) (Table 3.1). Prior to participation in the study, parental informed consent and child assent was obtained as approved by the University's Institutional Review Board. Children were excluded from the study if they had any neurological disorders or musculoskeletal injuries that may affect gait.

Subjects were provided with a standard laboratory shoe (Nike Free 5.0). Retro-reflective markers were then placed on the subject at specific anatomical locations of the foot, shank, thigh and pelvis. Lower extremity marker locations were acquired for one three-minute walking trial at 100Hz using an 8-camera motion capture system. The walking trial consisted of at least 3-minutes of walking at self-selected comfortable walking speed while wearing the lab provided footwear. Data was left unfiltered to not affect or influence potential biological signals within the data. It has been shown that filtering the data can lead to altered nonlinear results.(2)

Joint angle time series in the sagittal plane of the ankle, knee and hip joints were computed using Visual 3D software (C-Motion Inc., Germantown, MD). Data processing and analysis were conducted using custom Matlab scripts (The Mathworks Inc, Natick, MA). Stride-to-stride fluctuations during the walking trials were evaluated using the largest Lyapunov Exponent (LyE). A one-way ANOVA with four factors (4 age groups) was performed to determine statistical significance for the dependent variable for the Ankle, Knee, and Hip joint angle time series respectively. The dependent variable included The Largest Lyapunov Exponent. When significant effects were determined, post-hoc comparisons were performed using the Tukey method.

RESULTS AND DISCUSSION

There were significant effects of age group for LyE of the ankle, knee, and hip joint time series $p < .05$. (Fig. 1) Post hoc comparison results for each joint among the age groups can be found in Table 1.
Nonlinear analysis of the joint angle time series

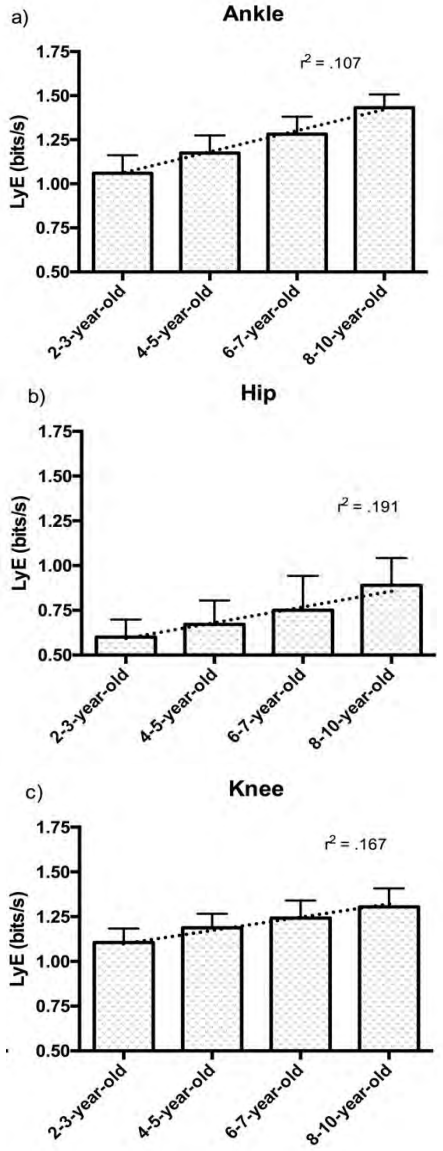

Figure 1: Bar charts showing the mean and standard deviation for Largest Lyapunov Exponent of the Ankle, Hip, and Knee joint time series. Data are reported for age group.

showed that the structure of gait variability in children is age dependent. There was an age effect on the LyE of the joint angle time series at the ankle, hip, and knee. All three joints showed an increase with age from youngest to oldest for the LyE. As children get older and gain more experience walking, their neuromuscular system and overall motor control are also maturing. The combination of maturation of the systems and gained experience leads to an overall better organization of movements. The increase in divergent patterns makes for a more robust movement system that is capable of dealing with small perturbations with little flaw. When we get older and become more experienced walkers, we can navigate our environment with ease. Small increases in rise or bumps in a path that could elicit falls in the youngest of walkers, are hardly noticed to the more adept, experienced walker.

CONCLUSIONS

Our results indicate that the nonlinear variability of children's gait increases as children age. The combination of a decrease in linear variability, or a refining and improved stability of gait, as well as an increase in nonlinear variability, or an increase in the complexity and quality of movement patterns, suggest an overall maturation of the neuromuscular system. Our results show that there is a refining of gait with age and motor maturation that is accompanied by an increase in complexity that speaks to the overall multifaceted organization of systems that is the maturation of gait.

INTRODUCTION

Selective dorsal rhizotomy (SDR) is a neurosurgical technique performed to reduce muscle spasticity and improve motor functions in children with cerebral palsy (CP) [1]. Combined with physiotherapy, SDR reduces pain, improves joint range of motion (ROM), and enhances gait performance. Even though improvement in patient mobility has been reported after SDR to last for many years, SDR has not prevented contracture formation [2]. To understand what is contributing to muscle contracture formation, it is necessary to assess the effects of SDR on ankle joint stiffness. We hypothesized that SDR (i) increases passive ankle ROM and (ii) decreases ankle joint quasi-stiffness.

METHODS

The Institutional Review Board of Mayo Clinic approved the study. 10 patients with CP (median age 6 years 2 months at the time of surgery) who had previously undergone SDR were included. Patients were studied 3 months (range 1 - 8 months) before (Pre-SDR) and 1 year 1 month (range 10 - 17 months) after (Post-SDR) surgery. The Gross Motor Functional Classification System (GMFCS) was used to classify the mobility of the patients. Ankle passive range of motion (ROM) was recorded with the knee angle at 0º (knee extension) and 90º (knee flexion).

3D gait analysis (Raptor-12HS, Motion Analysis Corp, Santa Rosa, CA), force plates (Model 9281B, Kistler Instrument Corp, Amherst, NY; Model BP400600, Advanced Mechanical Technology, Inc., Watertown, MA) and surface EMG (MA300, Motion Lab Sys, Inc., Baton Rouge, LA) were synchronized. The peak plantar flexion (PF) and peak dorsiflexion (DF) angles during walking were calculated for each participant. The phasic gastrocnemius activity was scored as follows: 0 = Phasic; 1 = Increased Phasic Activity; 2 = Continuous Low Level Activity; 3 = Continuous with Phasic Pattern; 4 = Continuous High Level Activity. Ankle joint quasi-stiffness [3] was calculated as the slope of the ankle moment vs ankle angle for the time interval from max DF to max PF during the gait cycle. Generalized estimating equations were used to evaluate changes in the ankle passive and dynamic characteristics pre- and post-SDR. Differences were considered significant if $p<0.05$.

RESULTS AND DISCUSSION

Pre-SDR GMFCS levels ranged from I to III. GMFCS levels of half of the children improved post-SDR.

Ankle joint passive ROM increased when measured with the knee flexed (Pre- and post-SDR median = 10º and 15º, interquartile range: 10º and 10º, respectively) ($p < 0.0001$) and knee extended ($p < 0.0001$) (Pre- and post-SDR median = 0º and 10º, interquartile range: 13.75º and 12.5º, respectively). This confirmed our first hypothesis.

After SDR, max PF during walking decreased ($p < 0.0001$) (Pre- and post-SDR median = -29.54º and -13.10º, interquartile range: 26.89º and 7.90º, respectively) and max DF increased ($p < 0.0001$) (Pre- and post-SDR median = 7.15º and 11.93º, interquartile range: 17.04º and 11.95º, respectively). This shift in ankle kinematics during walking indicates a reduction in equinus gait after SDR. Phasic gastrocnemius activity improved substantially post-SDR ($p < 0.0001$).

Ankle joint quasi-stiffness decreased ($p = 0.0017$) after SDR (Fig1A) (Pre- and post-SDR median = 0.056 Nm/kg/º and 0.051 Nm/kg/º, and interquartile

range: 0.031 Nm/kg/º and 0.019 Nm/kg/º, respectively). This confirmed our second hypothesis. Moreover, even though the total time of the gait cycle (Pre- and post-SDR median = 0.868 s and 0.935 s, and interquartile range: 1.308 s and 0.284 s, respectively) did not change (p = 0.99), the time interval from max DF to max PF (Pre- and post-SDR median = 0.125 s and 0.156 s, and interquartile range: 0.153 s and 0.253 s, respectively) increased significantly (p = 0.0068) after SDR (Fig 1B).

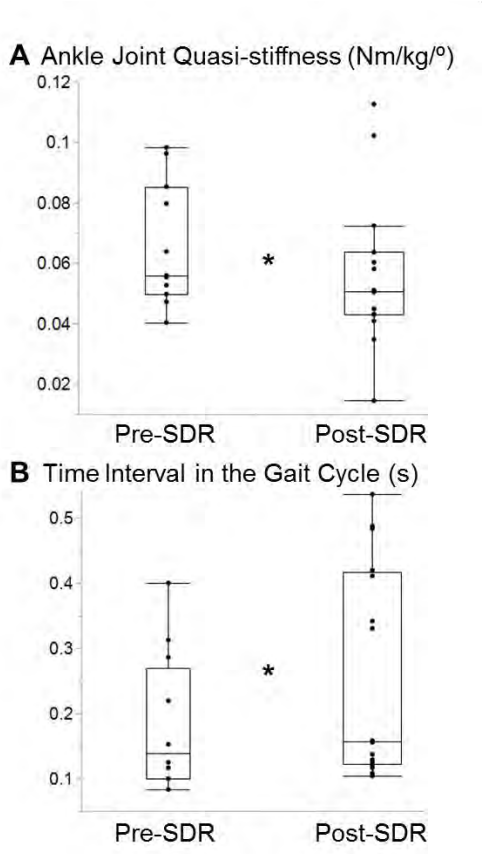

Figure 1: Box-and-whisker plot of **(A)** the ankle joint quasi-stiffness and **(B)** the time interval from max DF to max PF for Pre- and Post-SDR.
* indicates significant differences.

Decreased joint ROM and increased joint stiffness that characterize spastic CP are associated with changes in the material properties of contractile and non-contractile structures. Spastic contractions that cause muscle shortening are typically accepted as the main cause of muscle contracture formation. It has been reported that the active neural contribution of the plantar flexor muscles is a major source of higher ankle joint stiffness in CP [4]. In line with these works, our study demonstrates that SDR diminishes the neural source of spasticity and improves ankle joint quasi-stiffness. Therefore, the main reason of long term post-SDR contracture formation [2] is probably not be the active component. Previously, the increased passive tension that is unrelated to the stretch reflex was demonstrated for the spastic vastus lateralis [5]. Moreover, the extracellular matrix of biopsied hamstring muscles of children with spastic CP has been shown to be stiffer than age-matched controls [6]. Together with these previous data, our findings suggest that further research to understand muscle contractures should focus on mechanical alterations of non-contractile structures.

CONCLUSIONS

The present study shows that ankle joint characteristics during passive and dynamic conditions improve after SDR. Significant changes in ankle joint quasi-stiffness and in the time interval from max DF to max PF indicate better motor control together with other outcomes which reveal progress in dynamic joint parameters. Further research on muscle contracture following SDR is suggested to focus on mechanical alterations of intramuscular non-contractile structures as well as non-muscular tissues.

WALKING BALANCE ON A TREADMILL CHANGES DURING PREGNANCY

INTRODUCTION

An estimated 17%-39% of women fall during pregnancy, making falls a leading cause of accident-related injury during pregnancy [1]. There has been extensive research into standing balance changes during pregnancy. However, static balance measures may be inadequate for predicting dynamic balance change in a pregnant population [2]. In order to properly measure dynamic balance changes while walking, body center of mass (bCOM) location must be obtained.

We previously compared methods for determining the torso COM (tCOM) change and mass distribution changes throughout the body during pregnancy [3]. In this current study, we (1) tracked walking balance changes during pregnancy and (2) determined if the method for calculating bCOM significantly influences the balance measures.

METHODS

Fifteen pregnant women, ages 22 to 36 years at the start of testing, were tested in 4-week intervals from approximately 12 weeks gestation until delivery. Thirty-two anthropometric measurements were conducted for identifying volumes of 13 body segments. Fifty-four reflective markers were then attached for motion analysis.

Participants first performed a ten second standing static trial on a force plate. Participants then walked on a treadmill at a comfortable self-selected walking pace for a duration of sixty seconds. The final task required participants to lay supine on a backboard spanning two force plates for a duration of ten seconds.

A 10-camera motion capture system (Motion Analysis Corp.), recorded marker data at 100Hz. All motion capture data were filtered with a 6Hz low-pass Butterworth filter.

With assumed densities, 13 body segment masses and 12 COMs were identified [4]. We then compared the tCOM (13^{th} segment in our model) change through gestation using three methods: (A) through use of static force plate poses, (B) from Pavol anthropometry measurements [4], and (C) and combination using anterior and lateral locations from (A) and long axis location from (B). Whole-body center of mass (bCOM) was then calculated as the weighted sum of all segment COMs.

Strides were separated at right heel strike and balance measures averaged across strides. Control of balance was identified as the motion of the bCOM in three dimensions, and the bCOM angular motion relative to the ankle joint center. To measure the mechanical potential for fall, the minimum distances of the bCOM to the base of support edges were measured. Time of pregnancy (categorized by 4-week intervals) and model type (A. Force plate, B. Pavol, and C. Combined) were used as repeated-measure independent variables, and balance measures were used as depended variables in a generalized linear mixed model.

RESULTS AND DISCUSSION

We found that some balance control strategies started changing at the beginning of our study, indicating that they may have even started during the 1st trimester, prior to the start of our testing. Pregnant women started reducing their anterior-posterior motion (reduced AP angle changes) immediately during testing, corresponding with immediate and gradual reductions in preferred walking speed. This indicates previously noted changes in spatiotemporal gait measures between the second and third trimesters of pregnancy may

start even sooner, as a gradual reduction throughout gestation.

We found that step width starts to increase in the middle of the 2nd trimester (Table 1A). Correspondingly, the minimum distance between the center of gravity (COG) and lateral boarders of the stance foot start to increase (Table 1D). This change indicates a positive effect on balance, as it indicates that the bCOM is less likely to fall outside of the lateral edges of the base of support, reducing the need for corrective actions like body lean or crossover steps to avoid a lateral fall.

Going into the second trimester, pregnant participants had increased mediolateral bCOM angular motion (Table 1B) and liner motion (Table 1C). ML bCOM motion continued to increase through the third trimester even though step width decreased. Considering that we employed a treadmill for continuous gait, treadmill walking doesn't necessitate a decrease in step width of the average individual, but for pregnant women with increased abdominal volume, decreased step width may be employed on a treadmill to reduce the potential for waddling gait outside of the confined lateral boundary of a treadmill. Future studies should examine potential differences in treadmill vs. over-ground walking in a pregnant population. Accompanying this ML bCOM motion increase, the distance between COG and lateral base of support edge decreased. This combination of findings support a mechanism for waddling gait in the third trimester, and indicate balance control deficits from the beginning of the 3rd trimester on.

Unique to walking on a treadmill vs over-ground walking, there should be no AP excursion of the bCOM. We asked our participants to stay in the middle of the treadmill so that they would not risk falling of the back of the treadmill, but also not get to close to the front instrument panel and have markers blocked from camera view. AP excursion increased from the mid-2nd trimester on; another indication of decreased ability to control the bCOM motion as a result of pregnancy.

Our findings suggest that both sagittal plane measures and coronal plane measures related to bCOM position in the base of support can be effected by the method used to determine the torso center of mass location during pregnancy. The force plate method for determining torso COM results in the bCOM more anterior and centered laterally during walking.

CONCLUSIONS

Our results indicate significant changes in the control of balance during pregnancy. The likelihood of a fall in the lateral direction also increases. It is therefore important for women to be cautious when performing activities of daily living during pregnancy. The results of this study also indicate that some measures of balance are sensitive to the method used to identify torso COM. The results of this study will inform clinicians and patients about the temporal changes associated with pregnancy that increase the risk of falling and injury.

SIMCP: A SIMULATION PLATFORM TO PREDICT GAIT PERFORMANCE FOLLOWING ORTHOPEDIC INTERVENTIONS IN CHILDREN WITH CEREBRAL PALSY

INTRODUCTION

Three-dimensional gait analysis is typically used in the clinical decision-making process in children with cerebral palsy (CP). However, decision-making is complicated by the fact that the pathologic gait pattern results from the complex interaction between changes in musculoskeletal geometry, muscle weakness and impaired motor control. Since musculoskeletal modeling in combination with simulations of motion has the potential to non-invasively predict the effect of an intervention on gait performance, it might be a useful tool to establish a more data-informed decision on treatment selection compared to experimental gait analysis alone.

First, we present a simulation platform that will enable clinicians to compare the effect of different treatment modalities on gait performance in order to identify the treatment that has the highest potential to result in a closer-to-normal gait pattern, using a musculoskeletal model containing personalized musculoskeletal geometry and control, as well as pre-operative gait analysis data. Second, we present a case study in which the simulation platform was used to investigate if pre-intervention motion capture data in combination with a musculoskeletal model containing personalized musculoskeletal geometry and control could be used to predict post-operative gait performance in a child with CP.

METHODS

The simulation framework uses individualized musculoskeletal models as well as the joint kinematics from a typically developing (TD) child to calculate the ability of the patient to perform a typical gait pattern. We quantify the ability of the patient by the capability gap, which is the difference between the joint moments the model representing the CP child can produce, and the joint moments required for a TD gait pattern [1]. Bony geometries and muscle paths are personalized based on magnetic resonance imaging (MRI) [2]. The patient-specific lack of selective motor control is modeled based on muscle synergies computed from EMG measured during the pre-operative gait analysis. [3]. We assume that the intervention does not affect the number of synergies and the relative weighting of different muscles within a synergy. We developed a GUI to create the post-operative model by modifying the musculoskeletal geometry of the pre-operative model to mimic the effect of dedicated surgical interventions (e.g. extension osteotomy).

The pre- and post-operative model are subsequently used to compute the capability gap. To this aim, a synergy-constrained static optimization procedure is performed based on the patient's model while imposing joint kinematics and kinetics from a TD child. The reserve actuators indicate the gap between the required joint torques and the joint torque the muscles can produce, and therefore represent the capability gap according to our definition. The capability gap is therefore a measure of the inability of the patient to perform a typical gait pattern. By comparing the capability gap pre- and post-treatment, as well as between different treatment options, the effect of the surgery on the patient's capability to perform a normal gait pattern can be assessed.

This workflow was applied for a 10-year old female child with mild spastic triplegic CP (GMFCS II). The patient underwent a single-event multilevel surgery including bilateral psoas lengthening, rectus femoris transfer, tibia derotation, femur derotation and extension, and patella distalisation. Clinical pre-operative assessment of the patient showed a triple flexion gait pattern with increased femoral

anteversion and increased muscle tone in the bilateral hip flexors, hip adductors, rectus femoris, hamstrings, soleus and gastrocnemius.

During the pre- and post-surgery gait analysis (12 months post-surgery), marker trajectories, EMG (8muscles/leg) and ground reaction forces were measured. Pre- and post-surgery musculoskeletal models were created as described above, and were used to evaluate the patient's pre- and post-surgery capability gap, the latter with and without the corrective effect of the rectus femoris transfer.

The predicted capability gap was validated against the post-surgery gait analysis data. To this aim, we compared the pre- and post- surgery model-based capability gap (root mean square value) to the root mean square difference (RMSD) between measured TD kinetics, and the patient's pre- and post-surgery kinetics.

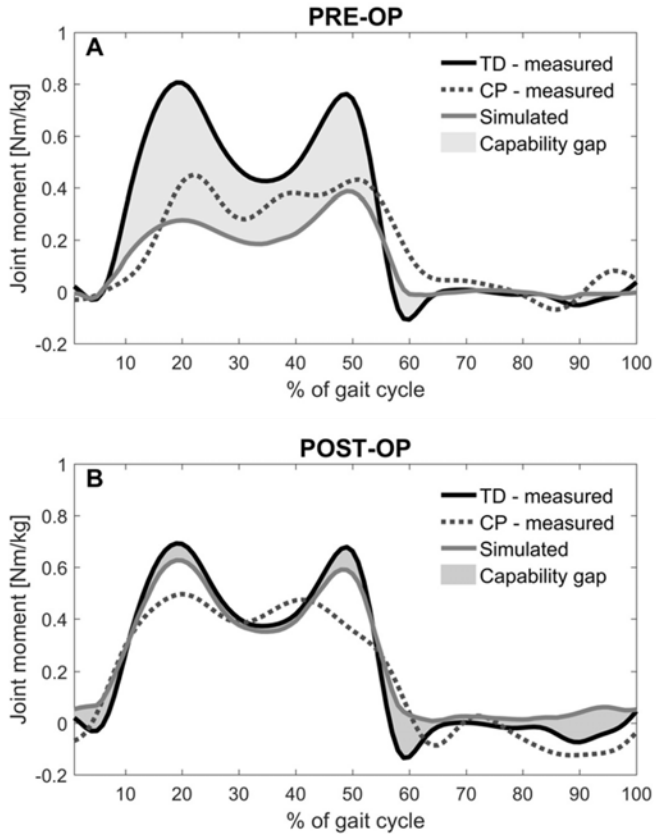

Figure 1. Experimental and model-based hip adduction joint moments and the capability gap pre- (A) and post-surgery (B).

RESULTS AND DISCUSSION

Post-operative joint kinetics during gait were more similar to TD gait kinetics than pre-operative gait kinetics. The post-surgery RMSD between patient and TD kinetics were smaller for six out of eight analyzed joints (average over all joints 0.28±0.18 Nm/kg and 0.17±0.10 Nm/kg for pre- and post-surgery, respectively). The pre- and post-surgery joint kinetics for the left hip adduction are shown in fig 1.

Our model-based simulations predicted a reduction of the root mean square capability gap post-surgery, indicating that the ability of the patient to produce normal gait kinetics increased. The RMS of the post-surgery capability gap was smaller for seven out of eight analyzed joints (average over all joints 0.14±0.06 Nm/kg and 0.10±0.03 Nm/kg for pre- and post-surgery, respectively), with the rectus femoris transfer further reducing the capability gap for hip and knee in the sagittal plane. The pre- and post-surgery capability gap for left hip adduction is shown in fig 1.

CONCLUSIONS

Our simulations predicted that the ability of the patient to produce healthy gait kinetics improved. This prediction is in accordance with the measured kinetics that was closer-to-normal after the intervention. At this stage, the simulation platform computes the theoretical capability and does not account for compensation strategies the patient adopts to overcome this capability gap. This might explain the difference between the capability gap and the RMSD between TD and CP kinetics. We are in the process of validating our framework by performing additional case studies. In addition, we will further improve model personalization by including changes in muscle-tendon properties and spasticity, and we are developing predictive simulations of movement kinematics. This first case study demonstrates the potential of our simulation platform to predict the effect of a surgical intervention on gait performance.

ASYMMETRICAL STANCE DURING CHILD CARRYING: IMPLICATIONS FOR BACK PAIN

[1]Kathryn L. Havens, [2]Alexandra Kahney, [2,3*]Erin M. Mannen
[1] Division of Biokinesiology and Physical Therapy, University of Southern California, Los Angeles, CA;
[2]University of Denver, Denver, CO; [3]University of Arkansas for Medical Sciences, Little Rock, AR
*Corresponding Author: emannen@uams.edu

INTRODUCTION

Low back pain (LBP) affects nearly 80% of Americans at some point in their lifetime [1]. During periods of prolonged standing, individuals with LBP exhibit differences in their posture. Specifically, individuals with LBP spend more time in symmetrical stance, rather than shifting their body weight to one leg or another [2]. These body weight shifts may be altered by load carrying. While research has explored the effects of military backpack load carrying on back pain, little is known about the effects of carrying a baby.

During infancy and early toddlerhood, babies must be carried by a care giver. Babies are often held and carried in arms, but babywearing, the practice of carrying an infant or young child on the caregiver's body in a carrier, is becoming more common as parents reap the benefits of close-proximity to their children while remaining "hands-free." While babywearing has been shown to have numerous emotional, physical, and physiological benefits for babies [3], little work has been done to analyze the impact of child-carrying methods on the biomechanics of a woman's body.

The purpose of this study is to 1) characterize asymmetrical stance during prolonged standing and 2) compare the effects of infant carrying on these mechanics.

METHODS

Ten female subjects (age: 27.4 ± 4.1 years; BMI: 21.5 ± 2.5 kg/m^2) with no ongoing musculoskeletal problems and no previous babywearing experience were enrolled in the IRB-approved study. Men, pregnant women, or those with a pregnancy within the past nine months were excluded. Participants underwent testing in the Human Dynamics Lab at the University of Denver.

Each subject completed fifteen-minute quiet standing tasks with each foot placed on a separate force plate (Bertec Corporation, Columbus, OH) for three conditions: **unloaded**, holding a 9-month old infant sized mannequin (Dietz, Freiburg, Germany) **in-arms**, and wearing a 9-month old infant sized mannequin in a self-fit baby carrier (**in-carrier**; Ergobaby, Inc., Los Angeles, CA) (Figure 1). Subjects were instructed to quietly stand for the fifteen-minute trials while keeping each foot on its respective force plate. Subjects rested between fatigue trials, and conditions were performed in a random order.

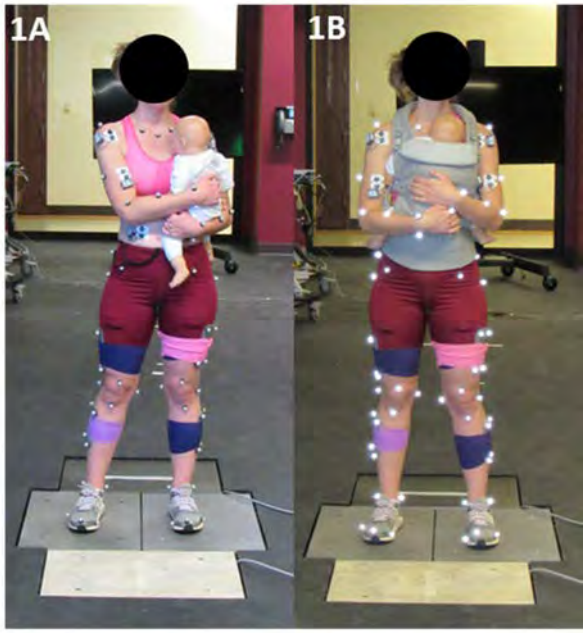

Figure 1: In-arms condition (1A) and in-carrier condition (1B).

Participants completed 100mm visual analog scales (VAS) to rank their pain and discomfort before and after the trials. Subjects were characterized as pain developers (PDs) if their VAS score increased by at least 10mm, and non-PDs if they had a <10mm increase during the unloaded condition.

Three-dimensional kinematics were collected using a 10-camera motion capture system (Vicon Motion Systems, Ltd., Oxford, UK), 250 Hz. Hip, trunk, and pelvis frontal plane angles were calculated (Visual3D, C-Motion, Inc., Rockville, MD, USA). Periods of asymmetrical stance were defined as time when at least 65% of the body weight was supported on one leg for at least one second, as determined by force plate recordings. Custom code (MathWorks, Natick, MA) was written to identify these periods and associated mechanics.

To characterize asymmetrical stance, descriptive statistics were used to demonstrate time in asymmetrical stance and number of body weight shifts. Peak hip, trunk and pelvis frontal plane angles were determined during periods of asymmetrical stance. These were compared to average angles during symmetrical stance using paired t-tests. To compare the effects of infant carrying, non-parametric Friedman tests were used to compare time in asymmetrical stance and number of body weight shifts, and kinematics during asymmetrical stance were compared using repeated measures ANOVA. Significance was set at $\alpha \leq 0.05$.

RESULTS AND DISCUSSION

Individuals spent about half of their time in asymmetrical stance. Wide variability between subjects in the total number of shifts and total time shifted was found. Hip angle, trunk lean and pelvic drop were all different between periods of asymmetrical stance compared to symmetrical stance. When subjects shift their weight onto one leg, they exhibited ipsilateral hip adduction, and contralateral trunk side-bending and pelvic drop ($p \leq 0.001$).

Significant differences between loading conditions were found for number of body weight shifts ($X2(2) = 7.467$, $p=0.024$) and total time in asymmetrical stance ($X2(2) = 10.903$, $p=0.004$) (Figure 2). When compared to the unloaded conditions, individuals spent more time in asymmetrical stance ($p=0.012$) during the in arms condition. Trends towards greater number of weight shifts were found in arms ($p=0.035$), and in carrier ($p=0.027$) compared to unloaded.

While individuals exhibited differences in kinematics during periods of weight shifting, no differences in hip, trunk or pelvis mechanics were found between loading conditions ($p>0.05$).

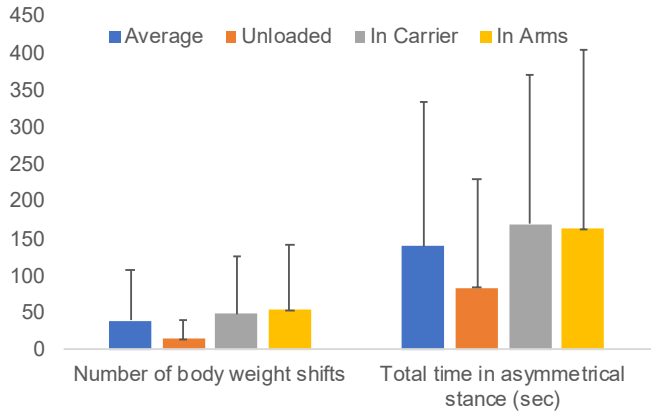

Figure 2: Weight shift characteristics

A preliminary analysis on 3/10 subjects who were characterized as PDs suggests that they significantly decreased both the number and time spent weight shifted. Additionally, the effect of the baby carrying method may be different for PDs v. non-PDs. This interesting finding warrants additional analysis.

CONCLUSIONS

Individuals shift their weight during prolonged standing and exhibit changes in their hip, trunk and pelvis posture. While holding a baby in arms and in carrier affects the shift time and duration, individuals use the same biomechanics under these varied loading conditions. However, individuals who develop pain during prolonged standing may benefit differently from carrying an infant in a carrier compared to those who do not develop pain.

LOWER EXTREMITY MUSCLE ACTIVITY OF HEALTHY INFANTS: IMPLICATIONS FOR HIP DYSPLASIA PATIENTS

[1*]Erin M. Mannen, [1]Akshay Krishnan, and [1]Brant C. Sachleben

[1]The University of Arkansas for Medical Sciences, Little Rock, AR, USA
*emannen@uams.edu

INTRODUCTION

Developmental dysplasia of the hip (DDH) refers to a group of disorders that can range from slight instability (Grades 1-3) to a severe dislocation (Grade 4) of the hip from the socket.[1] This condition occurs in 5.5 out of 1000 full-term babies within the first two days of life, and 10% of those patients continue to exhibit problems after 2 weeks of age.[2] In patients where DDH does not resolve on its own, infants are typically prescribed an orthopaedic brace or cast to aid in reducing the hip. In infants with DDH grades 1-3, the Pavlik Harness is the gold-standard of care and reduces hips with a 92% success rate.[3] Computational models have shown the positive impact of active adductor muscles on reducing DDH grades 1-3 when hips are placed in the optimal 90 degree flexion and 80 degree abduction position within the Pavlik Harness.[4]

Despite the success of the Pavlik Harness and the Rhino Cruiser, a similar orthopaedic brace, such restrictive devices are often uncomfortable for infants and problematic for parents to comply with as they require 24 hour/day usage for weeks to months. Babywearing, the act of carrying an infant in a device worn on a caregiver's body, often places infant hips in a flexed and abducted position (known as M positioning) that may be similar to the position provided by the orthopaedic devices. Furthermore, there is recent evidence showing that appropriate babywearing may prevent DDH.[5] However, no studies have evaluated the biomechanics of infant hips within these various devices.

The purpose of this study was to measure the lower-extremity muscle activity and hip positions of infants in common DDH devices compared to an inward-facing soft-structured baby carrier.

METHODS

Eight healthy full-term infants with no orthopaedic or neurological problems (5.0±1.5 months, 5 male) were enrolled in the IRB-approved study. Surface EMG (Delsys, Natick MA, USA) recorded muscle activity (1000 Hz) of bilateral gluteus medius, biceps femoris, quadriceps, and adductor muscle groups. Marker-based motion capture (Vicon, Oxford, UK) was used to track the lower extremity motion of the infants during four 30-second conditions: in a Pavlik harness, in a Rhino cruiser, held in an inward-facing soft-structured baby carrier (Boba, Inc., Boulder, CO, USA), and in a standard car seat. EMG data was rectified, filtered, and normalized to the Pavlik Harness condition via custom code (Matlab, Mathworks, Natick, MA, USA), and mean EMG signal and percent time that muscles were active at two standard deviations above the mean were calculated. Hip position data has not yet been analyzed, but hip flexion and hip abduction angles will be calculated for each condition. Paired t-tests were used to compare conditions to the Pavlik Harness condition ($p<0.05$).

RESULTS AND DISCUSSION

Lower limb muscle activity was *not* found to be significantly different in the Rhino cruiser or baby carrier (Boba) conditions when compared to the Pavlik harness, both in average signal (Figure 1) and in percent time above two standard deviations (Figure 2). Conversely, the car seat position resulted in approximately half of the mean muscle activity and five times less active time compared to the Pavlik harness condition.

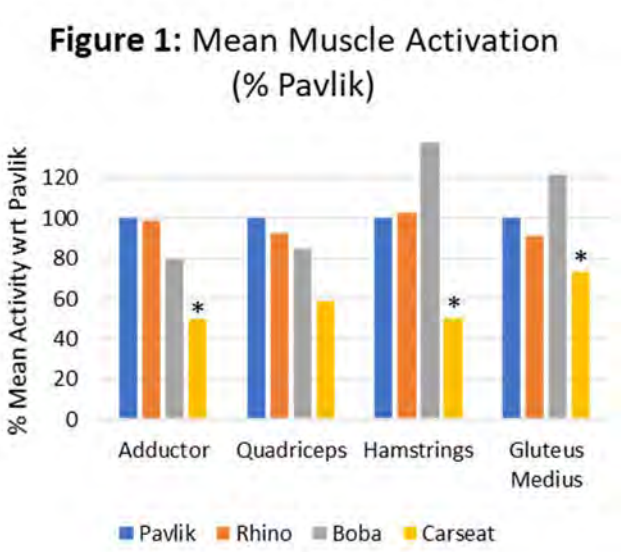

Figure 1: Mean muscle activity per condition as a percentage of mean muscle activity during the Pavlik harness condition. *p<0.05 v. Pavlik harness condition.

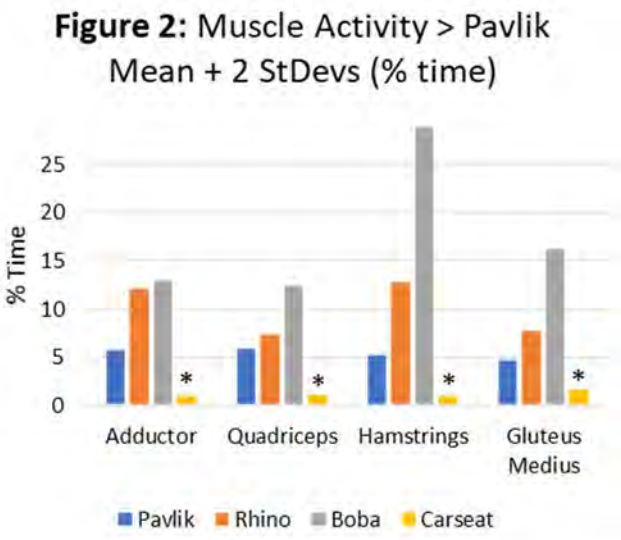

Figure 2: Percent time muscles were active above the mean + two standard deviations of the Pavlik harness condition. *p<0.05 v. Pavlik harness condition.

In agreement with previous computational models, the Pavlik harness and Rhino cruiser devices currently used to treat DDH in infants resulted in the highest levels of mean adductor muscle activity, supporting the use of the devices for reducing infant hips. The soft-structured infant baby carrier resulted in similar lower-extremity muscle activity for the infants in this healthy cohort, possibly indicating safe use in DDH populations. Conversely, the infants were significantly less active in the car seat, which may indicate that passive container-type of infant devices do not promote active lower-extremity muscles in healthy infants. However, hip positioning data for all conditions will be critical in assessing the appropriateness of use in healthy and DDH populations.

Limitations of the study include a small sample size, sometimes non-compliant subjects, and a data collection length of only 30 seconds per condition. Future work will include collection and analysis of 12 more subjects for both EMG and hip position during the various conditions. As parents continue to use infant devices, more research should be done on the musculoskeletal and biomechanical impact of infant positioning for both DDH and healthy infants.

CONCLUSIONS

Lower extremity muscle activity of healthy infants in a soft-structured baby carrier with M positioning of the hips was similar to the muscle activity of infants in orthopaedic devices used to treat patients with Developmental Dysplasia of the Hip. Furthermore, the car seat and other similar container-type of infant devices may not promote lower-extremity muscle activity.

RELATIONSHIP OF SEGMENTAL ENERGY FLOW AND ELBOW VALGUS LOAD DURING BASEBALL PITCHING

[1] Arnel Aguinaldo and [2] Rafael Escamilla

[1] Point Loma Nazarene University, San Diego, CA, USA
[2] California State University, Sacramento, CA, USA
email: aaguinal@pointloma.edu

INTRODUCTION

Elbow valgus load is considered to be a significant predictor of baseball pitching-related elbow injuries. Consequently, the relationship between multi-segment mechanics and elbow valgus load during baseball pitching has been well examined using statistical methods [1], forward dynamics [2], and most recently, induced acceleration analysis [3]. However, the mechanisms by which the flow of mechanical energy across moving body segments influence elbow valgus load during pitching remain unclear. Therefore, the purpose of this study was to examine the relationship of intersegmental power with elbow valgus load during pitching in adult baseball players. It was hypothesized that elbow valgus load would be most affected by segmental powers supplied by trunk and shoulder torques.

METHODS

A sample of 20 male baseball pitchers (age = 21.9 ± 3.7 years; height = 1.88 ± 0.06 m, mass = 89.5 ± 9.0 kg) were recruited from the professional (n=13) and collegiate (n=7) ranks and participated in this study after providing written informed consents approved by the university's Institutional Review Board. A set of 38 reflective markers (1.4 cm DIA) were placed on the skin overlying specific anatomical landmarks according to a 16-segment rigid-body model described by Aguinaldo and Chambers [1]. Each participant threw 15 fastballs off a bullpen mound while the global locations of the markers were captured with an outdoor 3D motion analysis system (Motion Analysis Corp., Santa Rosa, CA) at a sampling rate of 300 Hz. The joint kinematics and kinetics of each participant's throwing motion were estimated based on the rigid model defined by the marker locations and inertial properties for healthy adult males [1]. The mechanical power of the trunk, upper arm, and forearm segments were calculated as the time rate-of-change in kinetic energy delivered into or out of each segment by muscular and non-muscular components during pitching [3,4]. Each segmental power at any instant in time (i) was presumed to be equivalent to the sum of the powers (P_t) due to joint forces (F_j) and torques (T_j):

$$P_t(i) = \sum_{j=1}^{N} [T_j(i)\omega_j(i) + F_j(i)v_j(i)]$$

where N is the number of joints adjacent to a segment, ω_j is joint angular velocity about the segment's longitudinal axis (y) for the trunk and shoulder and medio-lateral axis for the elbow (x), and v_j is the linear velocity of the segment. Peak magnitudes of individual segment powers were extracted and entered into a stepwise regression analysis to determine the best linear model that predicts maximum elbow valgus (MEV) torque at a significance level of 0.05. As an index of pitching performance, ball speed was also evaluated to determine its relationship with each segmental power using linear regression.

RESULTS AND DISCUSSION

The mean ball speed and MEV torque were 36.9 ± 3.3 m/s (82.7 ± 7.5 mph) and 76.7 ± 27.6 Nm (Figure 1), respectively. The peak rotational powers of the trunk (3249 ± 1057 W), upper arm (-1407 ± 707 W), and forearm (-1740 ± 651 W) occurred sequentially prior to maximum external rotation (MER) of the throwing shoulder during baseball pitching (Figure 1). The timing and pattern in segmental power generation and absorption indicated that energy flows from the trunk to the arm segments. Moreover, the segmental power delivered by shoulder external rotation torque in the

arm cocking phase accounted for 54% of the variance in MEV torque ($r = .734$, $p < .001$) while ball speed was significantly related to the segmental power of the trunk ($r = .868$, $p < .001$).

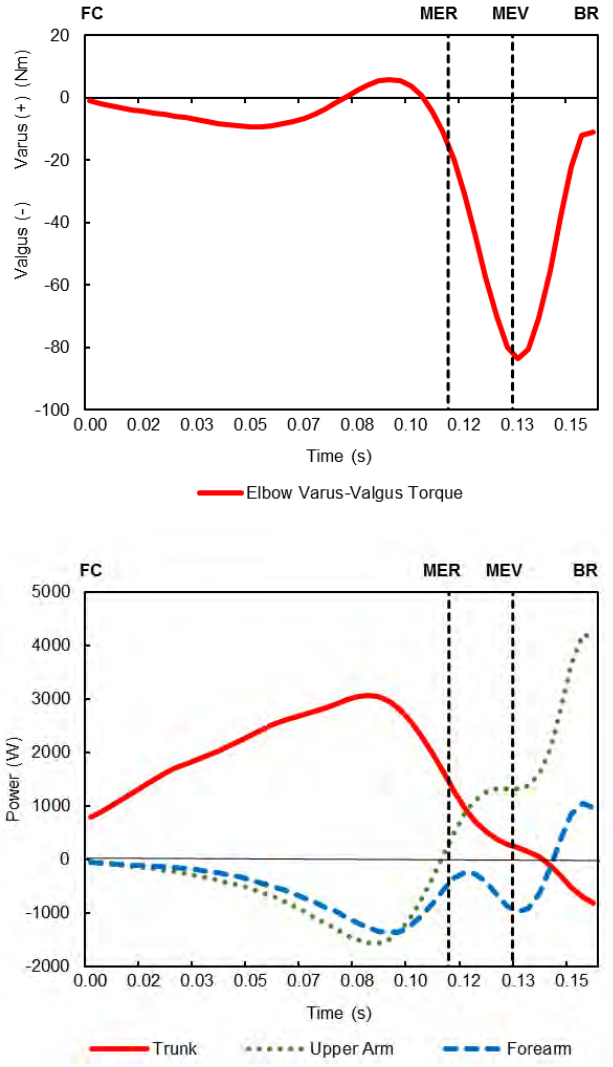

Figure 1: *Top:* Elbow varus (+) / valgus (-) torque during a baseball pitch; *Bottom:* Power histories of the trunk, upper arm, and forearm segments during a baseball pitch (FC = front-foot contact, MER = maximum external rotation, MEV = maximum elbow valgus torque, BR = ball release).

These findings suggest that the segmental energy flow that is associated with the lowest elbow valgus torques and the highest ball speeds represents the most efficient throwing mechanics. Subsequently, the loss of energy transferred from the trunk to the distal arm segments as a result of improper sequential body motion could lead to pitchers attempting to maintain optimal ball velocity by producing more internal torque at the throwing arm to compensate for this energy dissipation and thereby increasing their risk of a pitching-related injury at the elbow [1,3].

CONCLUSIONS

This segmental power analysis reinforces evidence previously presented by statistical methods [1] and induced acceleration analysis [3] that the rotational torque at the shoulder has the greatest effect on the development of elbow valgus load. The current findings support the notion that the transfer of segmental energy during baseball pitching generally follows a proximal-to-distal flow with power generated at the trunk by net muscular torques and absorbed at the upper arm and forearm. However, as this segmental power analysis is limited by the assumption that joint torques are produced by single-joint muscles [4], future research is needed to further decompose the energy transfer mechanisms by which moments from multi-joint muscles as well as from non-muscular components such as centrifugal, Coriolis, and velocity-induced forces influence valgus loading [2,3].

KINEMATIC TIMING DIFFERENCES IN THE BASEBALL SWING IN VARIOUS TRAINING DRILLS

INTRODUCTION

Baseball batting is one of the most difficult skills to develop in any sport and batters spend numerous hours refining the mechanics of their swing through repetition. These practice sessions are often performed alone or individually with a teammate or coach, and seldom involve hitting against a real pitcher. Perhaps the two most common training methodologies for the baseball swing are hitting a stationary ball placed on a tee and hitting a ball tossed from the side of home plate into the strike zone for a batter to hit forward, a drill commonly referred to as "soft toss". Other batting drill variations such as pop-up tees, various pitching machines, hitting balls of varying sizes and weights, and using bats of different barrel-widths and weights are frequently being introduced.

The kinetics and kinematics of the swing have been studied throughout the last 20 years, however most commonly only while batters hit a stationary ball on a tee [1, 2]. Welch et al. describe the separation of the biomechanics of the baseball swing into three phases: the lifting of the stride foot, the landing of the stride foot, and ball contact. While there have been several studies examining biomechanical parameters of swings at varying levels of competency [2] and others examining the effect of weighted bats [3], few studies have examined the effect of other batting drills on the kinetics and kinematics of the swing. **The purpose of this study was to evaluate kinematic and kinetic differences in the baseball swing between three common practice hitting drills.**

METHODS

Kinematic and kinetic data was collected for six male baseball batters (19.67 ± 1.37 years) in the Biomechanics Laboratory at East Carolina University. All participants had a history of playing competitive baseball at/after the age of 16. After providing informed consent, 58 reflective markers were applied to the participant. Glasses with six markers to track the position of the head were fitted to each participant, reflective markers were placed on the knob, midpoint, and end of the bat, and the ball was covered with reflective tape.

Participants were given time to warm-up prior to performing 5 practice hits and 10 collected hits in each of three commonly used practice batting drills: 1) a ball placed on a tee, raised to the height of the participant's mid-thigh, 2) soft-toss, and 3) a ball launched from a pop-up tee (Pop Toss Batting Tees) placed 0.85 m in front of home plate. Any trials in which participants swung and missed were discarded.

For each swing, the motion of the ball and reflective markers were measured by a ten-camera passive-marker motion capture system (360 Hz, Qualysis AB). Kinetic data was collected using two force platforms (1440 Hz, AMTI). Kinematic and GRF data were filtered using second-order low pass Butterworth digital filters with cut-off frequencies of 6 and 45 Hz, respectively, using Visual 3D software (C-Motion Inc.).

For each participant, the mean value for each biomechanical outcome variable was computed. Differences between mean values for each of the three batting conditions were analyzed using a paired t-test with a significance level of $p < 0.05$.

RESULTS AND DISCUSSION

Selected outcome variables are included in Table 1. The kinematics and timing of the swing appeared to

remain similar between batters hitting in the tee and soft-toss conditions, however batters demonstrated significant changes in the timing of their stride prior to swinging. Batters initiated their swing by lifting their stride foot closer to the time of ball contact in the pop-up tee condition compared to both the tee and soft-toss conditions ($p < 0.039$, $p < 0.036$). This change in stride initiation time led to a significantly shorter total stride time in pop-up tee compared to the tee and soft-toss conditions as well ($p < 0.024$, $p < 0.002$). Hitters also showed an altered timing of the sequence of the kinetic chain, reaching peak pelvic rotational velocity earlier compared to ball contact time in the pop-up tee condition compared to the soft-toss condition ($p < 0.011$).

The changes in stride timing were accompanied by a trend towards altered stride length and peak vertical ground reaction force produced by their rear leg during the stride. Batters demonstrated the longest stride length in the soft-toss condition compared to the tee and pop-up tee conditions and trended towards lower peak vertical ground reaction force in the pop-up tee condition compared to both the tee and soft-toss conditions.

CONCLUSIONS

Significant changes in the timing of baseball swing kinematics were seen in a pop-up tee hitting condition compared to a tee and soft-toss condition. The later initiation of the swing and shorter stride time may have led to a trend towards lower production of peak ground reaction force in the rear foot prior to ball contact.

It is unknown if the changes in swing mechanics seen while using the pop-up tee are either beneficial or detrimental as a training tool for baseball batters. While it may appear that hitting from a pop-up tee may have reduced hitting performance indicated by reduced peak vGRF, using a pop-up tee may in fact be more similar to facing a real pitcher, in which the batter's reaction time and the direction of travel of the ball are closest to that in the pop-up tee condition compared to hitting off of a tee or during soft-toss. Continued research is needed to evaluate the similarity of these three common baseball batting drills to in-game pitching.

INTRODUCTION

How does a youth athlete develop into a skilled adult athlete? This is a relevant question for a wide range of athletic activities, including baseball pitching. Previous research has quantified throwing mechanics for a sample of boys and girls, age 3 to 15 years, and showed component development levels, such as older children stepping forward with the contralateral leg and older children allowing the throwing arm to externally rotate at the side of the body instead of pushing the ball in front of the chest [1,2]. Additionally, there have been cross-sectional studies that have compared pitching biomechanics among various levels of competition [3,4]. Although these studies identified biomechanical differences among age groups, they did not show how or when specific changes occur within an individual. The ability to identify when these changes occur would allow athletes and coaches to use age-appropriate coaching techniques.

Thus, the purpose of this study was to examine biomechanical changes in baseball players during the first years of their pitching career. It was hypothesized that significant within-participant changes would be observed in pitching kinematics and kinetics as the pitchers grew older. Specifically, it was expected that joint forces, joint torques, and angular velocities would increase with age, while kinematics would change to be more similar to values of elite adult pitchers.

METHODS

Fifty-one youth baseball pitchers were recruited from the Birmingham community in early 2009 and 2010. Each pitcher came to the American Sports Medicine Institute (ASMI) biomechanics laboratory for initial testing during their first spring as a baseball pitcher. The pitcher was outfitted with 23 retro-reflective markers and was then instructed to warm-up. After conclusion of the warm-up, data for ten full-effort fastballs were collected. Each pitch was thrown from a pitching mound towards home plate located the league-appropriate distance away (typically 14.02 meters), while ball velocity was measured by a radar gun (Stalker Radar, USA). For all trials, three-dimensional motion data were tracked with a 12-camera automated motion analysis system sampling at 240 Hz (Raptor System, Motion Analysis Corp., USA).

Participants (and parents) were contacted each subsequent spring to return for biomechanical testing, and continued to be invited annually unless they were no longer pitching in organized baseball. After each biomechanical visit, no feedback was provided to the pitcher, his parents, or his coach about his pitching mechanics, per the study protocol.

Twenty kinematic and kinetic variables were calculated for each pitch as previously described [5]. Within-participant changes for each kinematic and kinetic parameter were tested with a mixed linear model with random effects. Least squares means for sequential ages were compared by use of Tukey's honestly significant difference test ($\alpha = 0.05$).

RESULTS AND DISCUSSION

Of the 51 pitchers enrolled, 35 participants were biomechanically tested a minimum of three years and were included in the analysis. For the 35 pitchers included into the analysis, 27 participants were 9 years old and 8 were 10 years old at the time of the initial testing. Due to the limited number of participants still pitching at the age of 16 years, the study was terminated at 15 years of age.

A significant increase in ball velocity was found each year when comparing to the previous. Significant kinematic differences with age were found for two of five velocity parameters as well as most (10/15) of the position parameters. Some of these are shown graphically in Figure 1. Several positional changes at the point of foot contact were noted with age, including stride length, lead foot position, and trunk separation. As a pitcher aged, they displayed less shoulder external rotation at foot contact but increased maximum shoulder external rotation during arm cocking.

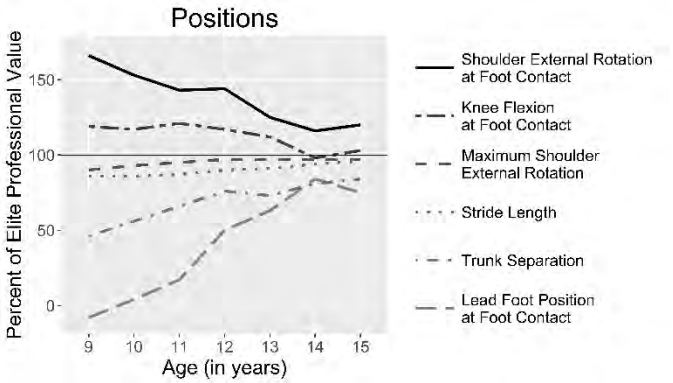

Figure 1: Some position parameters that had significant changes with age, with magnitudes expressed as percentage of mean value for elite professional pitchers.

All kinetic parameters increased significantly with age (Fig 2). Near the instant of maximum shoulder external rotation, shoulder internal rotation torque and elbow varus torque peaked to decelerate the arm cocking and initiate the arm's forward motion. Maximum shoulder horizontal adduction torque occurred as the arm cocked back and the upper trunk rotated to face the target. Near the instant of ball release, elbow flexion torque peaked to decelerate elbow extension. Maximum shoulder proximal force also occurred near this time to resist shoulder distraction.

As hypothesized, pitching kinematics and kinetics changed significantly during the first few years of pitching. The significant increases with age in all kinetic parameters were not surprising and were consistent with previous cross-sectional studies. Of particular note was the significant increase in normalized elbow varus torque from 13 to 14 years of age, and from 14 to 15 years, as varus torque is associated with tension (and tears) in the ulnar collateral ligament (UCL) which could explain the high rates of UCL injuries reported in baseball pitchers 15 years and older.

Figure 2: Significant kinetic changes with age, with magnitudes expressed as percentage of mean value for elite professional pitchers previously tested.

The most significant increases in kinematics occurred up until 12 or 13 years of age. The biggest changes appeared to be from 9 to 11 years of age for maximum shoulder external rotation, 10 to 11 years for trunk forward tilt, and 11 to 12 years for lead foot position and shoulder abduction.

CONCLUSIONS

Kinematic changes occur during the first few years of a youth pitcher's experience, particularly from ages 9 to 13 years. Forces and torques applied about the throwing shoulder and elbow increase with age, even when adjusted for height and weight, especially after 13 years of age which are likely attributed to strength changes after puberty. Improvements in kinematics and kinetics towards the magnitudes of professional pitchers were associated with increased ball velocity. Thus, prepubescent pitchers may work with their coaches to improve their motions, flexibility and arm paths. Once proper mechanics are developed, older adolescent pitchers can focus more on improving strength and power.

PLANARITY OF THE SWING IN NCAA DIVISION I SOFTBALL PLAYERS

[1] Travis Ficklin, [2] Robin Lund, [1]Sutherland Wyatt, [1]Connor Meyerhoeffer

[1] Dixie State University, Saint George, UT, USA
[2] University of Northern Iowa, Cedar Falls, IA, USA
email: travis.ficklin@dixie.edu

INTRODUCTION

Swing plane is often discussed by baseball and softball practitioners, particularly as it relates to optimizing the chance of success when taking pitch path into account [1]. To hit the ball, the path of the incoming pitch must intersect, even if briefly, with the plane of the swing. Much discussion is further had about just how much the pitch path is contained in the bat plane, and the ensuing disputes likely stem to some measure from misunderstandings about the geometry of the swing plane.

Previous work has described the planarity of the field hockey hit [2], and the planarity of the golf swing [3], but a similar description is still lacking for baseball and softball swings. Because of the importance of first being able to describe swing planarity before understanding its importance or relevance, the purpose of this study was to develop a method of describing the planarity of swings made by NCAA Division-I softball players.

METHODS

Home run swings (n=27) made by NCAA Division-I players in games were captured by two video cameras recording at 100 Hz. Landmark data for the body, the tip and knob of the bat, and the ball were manually digitized in each camera view. A 3D calibration object and the Direct Linear Transformation method were used to reconstruct landmark locations in three dimensions, with a global frame of reference in which Y was the direction from home plate toward the pitcher, Z was vertically upward, and X was the cross product of the Y and Z directions. The location data were analyzed from the onset of the swing until contact was made. Onset was defined as the frame in which the bat tip began its final arc toward contact.

The locations of the bat tip during the swing (onset to contact) were resampled in equidistant sections of arc length toward contact, and then fitted with a plane using a least-squares fit in three dimensions. The plane was defined by its normal, expressed as a unit vector perpendicular to the plane.

The perpendicular distance from the plane to the bat tip in each frame was calculated (d_{PLANE}). This was done by projecting the location of the bat tip onto the normal of the plane. Because the normal was calculated using the least-squares fit, a projection onto this normal of zero was deemed to be exactly in the plane. The time-series data representing this projection were then normalized with respect to $d_{PLANE,}$ of the bat tip for the frame at impact. Mean d_{PLANE} and its standard deviations for the bat tip in and out of plane for each swing were calculated for each trial. Additionally, the normal direction defining the plane was compared to the direction of a vector defining the trunk to determine its alignment with the batter's body (θ_{TILT}) at contact.

RESULTS AND DISCUSSION

The descriptive statistics for the planarity of each swing can be found in Table 1. The visual representation of d_{PLANE} for the swings is depicted in Figure 1.

It is evident visually, that the bat tip proceeds from being above the average tilted swing plane to being in it when the values are normalized to distance from the plane at contact. The pattern seems to be bi-phasic. At about 50% of the swing duration, the bat tip becomes more in-the-plane every frame until contact.

The swing itself seems to be very planar. The average d_{PLANE} for the swings was 0.0038 +/- 0.0009 m as swings progressed, and the standard deviations in this value per swing were 0.0021 +/- 0.0005 m. The plane was tilted from the trunk of the batter with a

θ_{TILT} at contact of 28.4 +/- 13.9 degrees from the direction of the normal defining the plane.

The tight-fitting planarity of the swing may be best explained by the definition of swing onset in this study. Because the swing only contained the time during which the bat tip was in its final arc toward contact, it is reasonable that the plane was so well-defined and that the bat tip was so close to the plane during the swing. Defining swing time in other ways may change this result. More, because this sample included only successful swings, it cannot reveal whether there is more variability to d_{PLANE} in unsuccessful ones, and therefore whether such variability is problematic.

The tilt of the swing plane, θ_{TILT}, away from the trunk axis may be interesting to practitioners as they describe swing plane in terms of the body reference frame. However, other body references were not considered in this study, such as arm axes, leg axes, or other body references that practitioners may use as teaching cues. The current sample, however, demonstrates that the swing plane is not strictly formed about the trunk as contact is approached.

CONCLUSIONS

A method to describe the plane if the softball swing has been presented. The results of this study suggest that the plane of the softball swing is increasingly tightly followed as the bat follows its path to contact. This study only utilized the bat tip to define the plane, and it remains unknown if other definitions of the plane would yield similar results. Future studies should include a more heterogeneous sample of swings. Also, this method needs to be employed with baseball swings before it is known whether planarity is similar for them. Lastly, these variables must be investigated for predictive power in swing success, as well as explored for body movements that produce them.

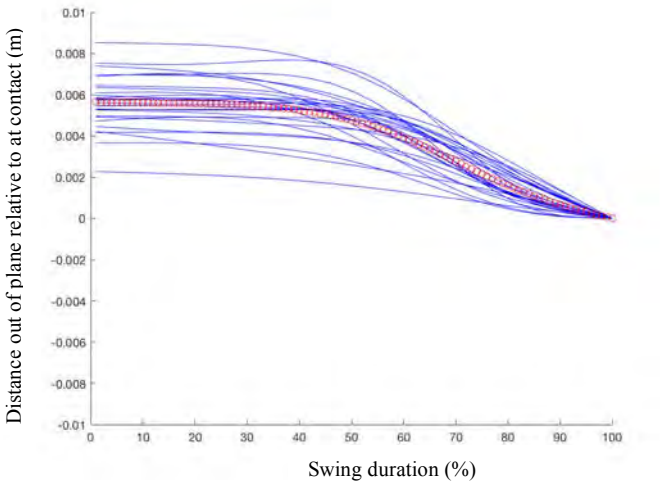

Figure 1. Time-series d_{PLANE} data normalized to swing time (100%) and compared to the value at contact. The swing proceeds from the bat tip being slightly out of plane early on to on-plane as contact is approached. The red circles represent average values for all swings during the swing duration.

INTRODUCTION

It has been attempted to categorize baseball and softball swings based on generic movements such as a "push" pattern [1]. Players who adopt the push pattern use their arms to move the bat forward as the trunk is rotating during the swing.

This swing pattern is not considered to be an elite pattern for several reasons. First, the path of the barrel is downward as it moves towards the pitch and does not match the path of the pitch. In order to match the pitch path, the barrel should be moving slightly upward [2]. Second, because the barrel does not enter the path of the pitch until later in the swing, contact must be made further forward which means the hitter has less decision time to visually evaluate the quality of the pitch. Finally, this pattern will result in less acceleration of the bat during the initial moments of the swing [1].

Currently, there is no systematic way to quantify whether a swing exhibits the push pattern. The purpose of this study was to develop a method of quantifying "push" and to investigate the relationship of time spent in the push pattern during the swing to swing kinematics in Division-I softball players.

METHODS

In-game home run swings (n=27) were analyzed in 3D using the Direct Linear Transformation method. Video data were manually digitized from two cameras recoding at 100 Hz. Landmark location data for the body, the tip and knob of the bat, and the ball were reconstructed in three dimensions, with a global frame of reference in which Y was the direction from home plate toward the pitcher, and Z was vertically upward. The X direction was the cross product of the Y and Z directions. The location data were reconstructed from 0.25 s before contact until contact was made.

Several kinematic variables for this period were calculated: v_{BAT}, t_{SWING}, a_{BAT}, a_1 and a_2, where v_{BAT} was the speed of the bat tip at impact, t_{SWING} was the time from swing onset to contact (onset was determined as the initial start of the bat tip on its final arc toward contact), a_{BAT} was the average bat acceleration obtained by dividing v_{BAT} by t_{SWING}, and a_1 and a_2 were similarly calculated accelerations for the first and second halves of t_{SWING}, respectively.

Then, "push" (P) was quantified. First, for each frame, a vector from the rear shoulder to the front shoulder was formulated. Then, the location of the mid-grip by the hands on the bat was projected onto this vector. P was then expressed as a proportion of the distance of this projection from rear to front shoulder. A push value P of 0.00 would mean the hands were directly in front of the rear shoulder as the trunk rotated during swing. Positive values represent the hands moving forward with respect to the shoulder vector as the trunk rotated. All P values were then expressed with respect to the initial value for the onset of the swing. Last, t_P was then calculated as the percentage of t_{SWING} during which P was positive (i.e., pushing was occurring).

Pearson product-moment correlations were then calculated between t_P and the swing kinematic variables (v_{BAT}, t_{SWING}, a_{BAT}, a_1, and a_2). The level of significance was set at $p < 0.05$ for all inferential tests.

RESULTS AND DISCUSSION

Visual representation of P for all swings can be found in Figure 1. The correlation matrix can be found in Table 1.

A similar pattern was observed when P was plotted against time for all swings (Figure 1). The hands had a tendency to move back and then forward from the

initial position as contact was approached. Some of the swings featured hands that tended to stay behind the rear shoulder as the torso rotated during the swing whereas others moved forward sooner and spent more time in front of the rear shoulder which indicated the push pattern.

Significant positive relationships were observed between t_P and several of the swing kinematic variables. These relationships indicate that swings with more t_P tended to have greater v_{BAT} and a_{BAT}. This was unexpected because the push pattern is considered to a negative characteristic associated with the swing. It is possible that the homogeneity of a data set made up from only homeruns could explain this result. Each swing could be considered high quality based on the outcome and so adding swings with less favorable outcomes may change the nature of these relationships. A second reason to explain these unexpected results could be related to the nature of the bats used in softball compared to baseball. The moment of inertia is located much closer to the knob in a softball bat and they are significantly lighter than baseball bats making them easier to accelerate [3].

The significant relationship between t_P and a_2 (and the lack of a relationship between t_P and a_1) supports the theory that the push pattern swing makes it more difficult to accelerate the bat during the beginning of the swing.

CONCLUSIONS

A novel method of quantifying the extent to which a swing displays the push pattern was presented. Unexpectedly, as swings displayed more of this characteristic, certain beneficial swing kinematics increased. Future research should evaluate the effects of the push pattern in the sport of baseball. Additionally, a more heterogeneous sample of softball swings should be studied.

DXA-DRIVEN INVERSE DYNAMICS OF PITCHING ARM KINETICS IN YOUTH BASEBALL PLAYERS

Jay A. Sterner, Sofia R. Sanchez Porush, Scott K. Reaves, Scott J. Hazelwood, and Stephen M. Klisch

California Polytechnic State University: San Luis Obispo, CA, USA
email: sklisch@calpoly.edu

INTRODUCTION

Baseball pitching arm injuries in young athletes have steadily increased in recent years [1]. Ulnar collateral ligament (UCL) reconstructive (Tommy John) surgery rates in 15-19 year olds increased 9% per year from 2007 to 2011 [2]. Motion analysis studies of youth pitchers are aimed at developing a better understanding of, and identifying preventative strategies for, pitching-related injuries [3]. However, previous studies assumed body segment masses scaled from total body weight for the inertial properties in the equations of rigid body dynamics. Since the arm segments reach high accelerations during pitching, we hypothesized that DXA (dual energy X-ray absorptiometry)-driven inverse dynamics (ID) will predict different pitching arm kinetics than standard ID with scaled masses. The aims were to: 1) conduct DXA scans and motion analysis experiments of youth baseball pitchers and 2) compare elbow and shoulder kinetics calculated using scaled and subject-specific DXA masses for the pitching arms.

METHODS

All protocols were approved by Cal Poly's Human Subjects Committee. DXA scans and motion analysis studies were conducted with youth baseball pitchers (n=13) (aged 10.9 ± 0.4 years, height 148.0 ± 7.5 cm, weight 40.8 ± 8.6 kg). DXA scans were conducted using a Lunar iDXA scanner (GE Healthcare, WI, USA). The pitching experiment (Fig. 1) used a 9-camera motion analysis system with Cortex and PitchTrak software (Motion Analysis Corp., CA, USA). Following a 10-minute warming up exercise protocol, 48 markers were placed on anatomical landmarks based on the PitchTrak marker set. The pitcher then threw 10 pitches that were recorded in Cortex. The upper arm, forearm, and hand mass ratios used in PitchTrak were altered to: 1) standard scaled values [4] and 2) subject-specific values calculated from DXA total body and body segment masses.

Fig. 1: Youth pitcher with retroreflective markers.

PitchTrak analyses were used to obtain maximum values for shoulder compressive force (SCF), shoulder internal rotation torque (SIRT), elbow compressive force (ECF), and elbow varus torque (EVT). Scaled ID and DXA-driven ID predictions of each kinetic value were compared using paired t-tests ($p<0.05$). Also, percent differences between kinetic values were calculated in a subject-specific manner to report a range of "errors" when using standard scaled masses.

RESULTS AND DISCUSSION

Table 1: Mass ratio (%) of pitching arm segments used in PitchTrak (mean ± 1 S.D.)

	Scaled	**DXA**
Hand with ball	0.98± 0.08	1.03±0.11
Forearm	1.62± 0.00	1.50±0.10
Upper Arm	2.71± 0.00	3.33±0.30

The scaled and subject-specific DXA mass ratios were different for the hand with ball ($p<0.05$), forearm ($p<0.001$), and upper arm ($p<0.00001$) (Table 1).

The predictions of pitching arm kinetics using scaled and DXA masses were different for SCF ($p<0.05$), but not for SIRT ($p=0.097$), ECF ($p=0.37$), or EVT ($p=0.31$) (Fig. 1). The percent difference between calculated kinetics using scaled and DXA masses, in a subject-specific manner, ranged from -1.6 to 28.0% for SCF, -4 to 30% for SIRT, -6 to 30% for ECF, and -35 to 40% for EVT, with positive percentages indicating a larger value for DXA masses.

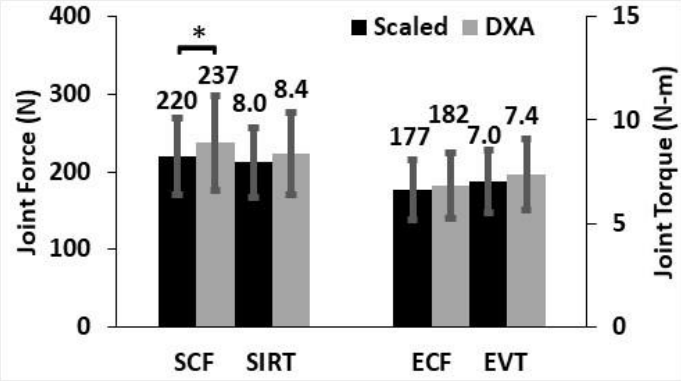

Fig. 1: Maximum compressive forces and torques for shoulder (left) and elbow (right) with scaled and DXA pitching arm segment masses. Means ± 1 S.D. shown. * = significant difference ($p\leq0.05$).

Interestingly, using the subject-specific DXA masses had a greater effect on calculated shoulder kinetics than calculated elbow kinetics. In contrast to elbow kinetic values, shoulder kinetic values depend additionally on upper arm mass, and upper arm masses exhibited the largest difference between scaled and DXA values. Although significant differences were only found for 1 of the 4 kinetic values, subject-specific differences were occasionally very high; thus, DXA driven ID is more desirable when the aim is to obtain accurate kinetic values for a single subject as opposed to a group of subjects. For example, our results suggest that ID analyses with scaled masses could be underestimating SIRT and EVT by 30 to 40% for youth baseball pitchers. One limitation of the study was that the size of the lab only allowed the pitchers to throw 30 feet instead of the entire regulation distance.

CONCLUSIONS

The major findings of this study were that 1) scaled and DXA-driven ID predictions of SCF values were significantly different for youth baseball pitchers and 2) subject specific errors in pitching arm kinetic values were as high as 40%.

These findings suggest future studies aimed at quantifying the effects of subject specific masses on adult pitchers. Adult pitchers have both larger masses and arm accelerations than youth pitchers, so differences between standard and DXA-driven ID may be even greater than those reported here. Thus, future studies should continue to quantify the effects of subject specific masses on adult pitching arm kinetics.

Although not described above, EMG muscle activation data was collected and will be used in ongoing studies to obtain muscle forces, joint contact forces, and loads carried by soft tissues, including those that are frequently injured (e.g. the elbow UCL).

MASS ADDED TO A RUNNING-SPECIFIC LEG PROSTHESIS INCREASES METABOLIC POWER DURING RUNNING

INTRODUCTION

Individuals with a unilateral transtibial amputation (TTA) are able to run with the use of a running-specific prosthesis (RSP). An RSP is comprised of carbon fiber, lacks an anatomical 'ankle' joint, and is lighter than a biological foot and partial shank. RSPs are attached in series to the residual limb of the affected leg (AL). During running, metabolic power increases by approximately 1% for every 100g added bilaterally to the feet of individuals without an amputation (P_{NA}) [1], but it is unknown how mass added to an RSP influences metabolic power or vertical ground reaction (vGRF) force symmetry between the AL and unaffected leg (UL) in individuals with TTAs.

The purpose of this study was to investigate the metabolic and biomechanical effects of mass added unilaterally to an RSP and bilaterally to the legs of individuals with a TTA during running. We hypothesized that when mass is added to the RSP or bilaterally to the legs, metabolic power will increase proportionally during running. We also hypothesized that peak and stance average vGRF would be more symmetric between legs when mass is added to the RSP compared with no added mass.

METHODS

We measured the metabolic rates and ground reaction forces (1000 Hz) of three subjects (1F) with a unilateral TTA (mean ± SD: 36.7 ± 3.8 years, 64.1 ± 4.5 kg, 1.72 ± 0.05 m). Subjects used their own RSP, reported no musculoskeletal injuries within the past 6 months, and had at least 1 year of experience using an RSP. This study was approved by the University of Colorado Boulder IRB and all subjects provided informed consent prior to participation.

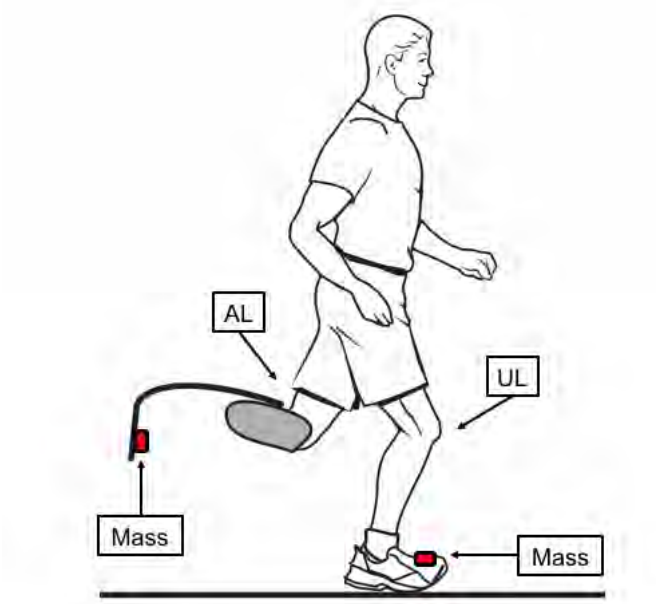

Figure 1: Added mass locations on subject's affected leg (AL) and unaffected leg (UL).

Subjects ran on a force-measuring treadmill (Treadmetrix, Park City, UT) at 2.5 m/s with randomized conditions of 0g, 100g, and 300g added unilaterally to their RSP or bilaterally to the legs. Each trial was 5 minutes long with 5 minutes rest between trials. We adhered mass 10 cm from the distal end of the RSP on the dorsal surface for the AL and 10 cm from the distal end of the foot on the laces of the shoe for the UL (Fig. 1). We measured rates of oxygen consumption and carbon dioxide production via indirect calorimetry (ParvoMedics TrueOne 2400, Sandy, UT), calculated average metabolic power from the final 2 minutes of each trial using a standard equation (Brockway, 1987), and normalized gross metabolic power to body mass including the RSP.

We used the symmetry index (SI) to determine peak and stance average vGRF symmetry between the AL

and UL [2,3]. Perfect symmetry between legs equals 0%.

$$SI = \left| \frac{(UL - AL)}{0.5(UL + AL)} \right| * 100$$

We constructed linear mixed effects models (α = 0.05) to determine the effect of added mass on metabolic power during running, peak vGRF SI, and stance average vGRF SI.

RESULTS AND DISCUSSION

For every 100 g of mass added to the RSP, gross metabolic power increased by 0.27 W/kg (p = 0.0040). For every 100g of mass added bilaterally to the legs (200g total), gross metabolic power increased by 0.32 W/kg (p=0.0047).

Adding mass to the legs had no effect on stance average vGRF SI (p = 0.2660) or peak vGRF SI (p = 0.0970). Additionally, there was no effect of whether the mass was added unilaterally to the RSP or to both legs on stance average or peak vGRF SI (p = 0.7001, p = 0.4969).

The data support our first hypothesis (Fig. 2). For every 100g of mass added to the RSP, metabolic power increased by 2.2% during running. We found that for every 100g of mass added bilaterally to the legs of people with a TTA, metabolic power increased by 2.6% during running. Previous studies have shown that adding 100g to both shoes of P_{NA} increases gross metabolic power by approximately 1% during running at 3.35 m/s [1] and our results suggest that mass added to both legs of individuals with unilateral TTAs has a 2.6 times greater effect than adding mass to both shoes of P_{NA} during running at 2.5 m/s.

Our data do not support our second hypothesis. Added mass to the RSP did not change peak vGRF SI or stance average vGRF SI. Future research is planned to increase the subject sample size.

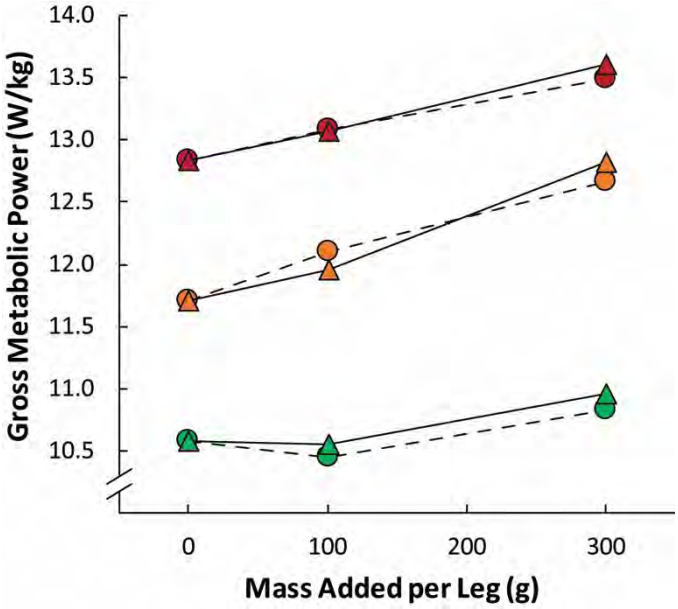

Figure 2: Subject-specific gross metabolic power of running with mass added unilaterally (*circles and dashed lines*) and bilaterally (*triangles and solid lines*).

CONCLUSIONS

Generally, decreasing the metabolic cost of distance running improves performance [4]. Our findings suggest adding mass to the legs of individuals with TTAs increases metabolic power during running. Thus, individuals with TTAs should not add mass to their RSP in an effort to improve distance running performance.

INCREASING PUSH-OFF ENERGY FROM A PROSTHETIC FOOT MAY NOT REDUCE ENERGY LOSSES IN THE CONTALATERAL LEG DURING GAIT

Audra Davidson, Eston Walden, and Young-Hui Chang

Georgia Institute of Technology, Atlanta, GA, USA
email: yh.chang@ap.gatech.edu

INTRODUCTION

Patients with unilateral lower extremity limb loss are roughly 17 times more likely to develop knee osteoarthritis in their sound limb [1]. This elevated risk of knee osteoarthritis development is often tied to the increased loading of the sound limb that occurs in patients with unilateral limb loss [2]. Increased sound limb loading is strongly linked to the loss of plantarflexor musculature and subsequent reduction in push-off power in the affected limb [2, 3]. Dynamic walking principles predict that decreased power produced by the trailing (affected) limb during push-off should increase negative work done on the leading (sound) limb during heel strike, potentially resulting in overloading of the sound limb [3].

Powered ankle prostheses attempt to solve this problem by increasing the magnitude of a prosthetic ankle's push-off power, as increasing push-off is suggested to reduce sound limb loading [1, 3]. Thus far, these devices have been unsuccessful in restoring loading symmetry [4]. We reasoned that adjusting the timing of prosthesis power delivery could also modulate mechanical work done by the affected (trailing) limb. Notably, this could potentially reduce negative work done on the sound (leading) limb without increasing prosthesis power demands [5].

Our goal was to characterize the effects of adjusting the timing settings of a commercially available powered prosthesis to investigate its influence on ankle power delivery and, ultimately, on the negative work experienced by the leading (sound) limb in patients with unilateral limb loss during treadmill walking. We hypothesized that: 1) push-off power would increase as timing of power delivery occurs earlier in the gait cycle; and, 2) negative work of the intact leading limb would vary inversely with propulsive work performed by the amputated trailing limb.

METHODS

Five males with unilateral traumatic transtibial amputation (mean age 41±17.0yrs, mass 79.0±8.0kg, height 1.84±0.08m) gave informed consent prior to participating in this IRB-approved study.

Subjects were fitted with an emPOWER robotic ankle prosthesis (Ottobock, Bedford, MA) by a certified clinician. After a warm up, each subject walked on a treadmill at 1.1 m/s for 3 minutes for each of 7 randomized trials for a given timing condition (baseline, 3 late and 3 early). We used default tuning parameters suggested by the vendor as the baseline setting. Timing of ankle power delivery was adjusted using a wireless control interface (Ottobock, Bedford, MA). Kinetics data were obtained via force plates (AMTI, Watertown, MA) instrumented into a custom, dual-belt treadmill [5]. We collected lower body kinematics using an 8-camera motion capture system (Vicon, Centennial, CO; Visual 3D, C-Motion, Germantown, MD).

Prosthesis push-off timing was defined as the percent of the gait cycle when peak power was reached. Lower limb power output was calculated via Unified Deformable (UD) model analysis [7]. Energy delivered by the prosthesis during push-off was calculated by integrating the last positive region of the ankle power curve. Sound limb collisional work was calculated by integrating the first negative region of the COM work rate curve [8]. Pearson's correlations were used to determine the relationship between prosthesis timing and power with sound limb collisional work.

RESULTS AND DISCUSSION

No relationship was found between the device's timing settings and the measured timing of peak power delivery from the device ($R=-0.08$, $p=0.66$). The timing settings were significantly correlated

with prosthesis push-off work, however, with earlier timing conditions producing more power (R=-0.73, $p<0.001$). Neither timing condition nor calculated push-off timing were correlated with negative work on the lead leg ($p\geq0.197$). This suggests that altering the timing of power delivery via standard device tuning methods does not significantly alter push-off timing of the emPOWER prosthesis, but does influence positive prosthesis work produced by the device.

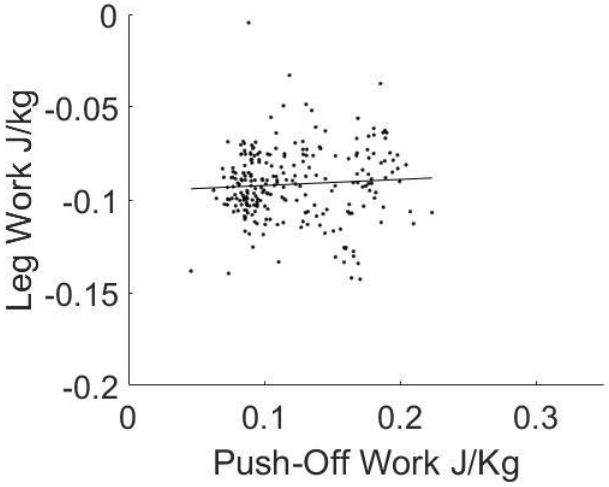

Figure 1: Relationship between prosthesis push-off work (J/Kg) and sound limb collisional work (J/Kg) across five male patients with unilateral limb loss.

Increasing push-off work to approximate or exceed physiological levels did not reduce loading on the sound limb. We saw no overall correlation between push-off work and sound limb collisional work across subjects (Fig. 1, R=0.29, p=0.31). These findings are consistent with previous studies, demonstrating that increasing ankle prosthesis power levels do not reduce sound limb collisional work or restore loading symmetry [4, 9].

This suggests that the positive work provided by the prosthesis was dissipated before reaching the COM, as positive prosthesis work was not correlated with sound limb collisional work. This could be due to power damping caused by the limb/socket interface, or altered joint control strategies when using a powered prosthesis. Only a short accommodation time with the device was provided to subjects for this study. Longer training times may help to promote full utilization of the delivered mechanical power. Each subject responded differently to increases in power, suggesting that personalized tuning and training may also be necessary.

CONCLUSIONS

The amount of push-off power rather than timing of power delivery is altered with standard suggested tuning methods of the emPower powered ankle prosthesis. Increasing the prosthesis push-off power does not immediately reduce sound limb collisional work. Due to possible damping and altered control strategies, a longer tuning and adaptation period with more extensive, personalized training may be required to alter sound limb collisional work.

INTRODUCTION

Over half of community living persons with lower-limb loss fall every year [1]. However, the factors that underlie this high fall prevalence have not been sufficiently explored. Our previous research suggests that *a priori* information of a lateral perturbation during walking influences the proactive mechanisms employed by below-knee prosthesis users (BKPUs) to resist this disturbance [2]. Specifically, providing information on the timing of a perturbation known to be directed towards the impaired limb encourages an increase in the margin-of-stability (MoS) on the impaired side just prior to the perturbation instance. The consequences of this control strategy on response dynamics have not yet been explored. The purpose of this study was to follow up our previous analysis to assess the effects of *a priori* information (direction, timing) of a lateral perturbation on response dynamics of BKPUs. We hypothesized that aligned with this BKPU proactive strategy when perturbation direction and timing were known, there would be a decrease in displacement of the body center-of-mass (BCoM) compared to when timing is unknown due to efforts to resist disturbance. We also hypothesize that due to a loss of an active ankle joint and critical forms of proprioception [3, 4], BKPUs' BCoM excursion would be greater on the impaired side with no difference in non-impaired controls.

METHODS

Six BKPUs (48±8yrs, 70±11kg, 1.7±0.1m) using their customary prostheses and 13 non-impaired controls (29±11yrs, 65±10kg, 1.7±0.1m) participated in the study. Subjects received lateral perturbations during a series of treadmill walking trials. *A priori* knowledge of the perturbation direction was provided, but timing was either not provided or provided through both visual and audio cues [2]. For this analysis, we examined four conditions of iterations of perturbation direction (impaired/non-dominant, sound/dominant) and timing (unknown, known). Subjects walked at their self-selected speed for all trials while perturbations of 12% bodyweight over 400 ms were generated by motorized cables attached to a waist harness [2]. Positions of markers on the pelvis were recorded at 100 Hz (Qualisys, Göteborg, Sweden), and used to define the BCoM position. BCoM displacement was estimated by subtracting the BCoM position at the start of the perturbation from the position at the end of the exposure, and averaged across trials for each condition. A mixed three-way ANOVA (α=0.05) tested the main and interaction effects of perturbation direction, perturbation timing, and group.

RESULTS AND DISCUSSION

A plot of representative BCoM trajectories with respect to time for the conditions of unknown time and when perturbations were directed towards either limb are displayed in Figure 1.

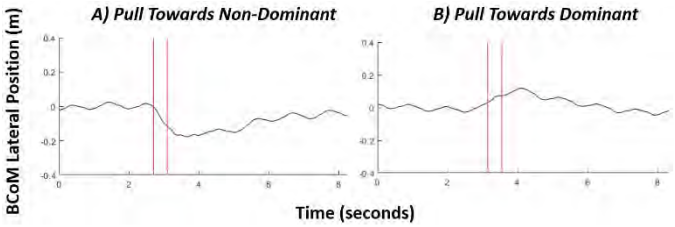

Figure 1: BCoM trajectories for one subject pulled towards the A) non-dominant and B) dominant limb. Vertical red lines=start and stop of perturbation. Positive to negative values indicate right direction.

The main effect of direction was significant (p=0.023), with BCoM displacement greater when perturbed toward the impaired/non-dominant limb

than the sound/dominant limb (Fig 2). No other main or interaction effects were significant ($p \geq 0.194$).

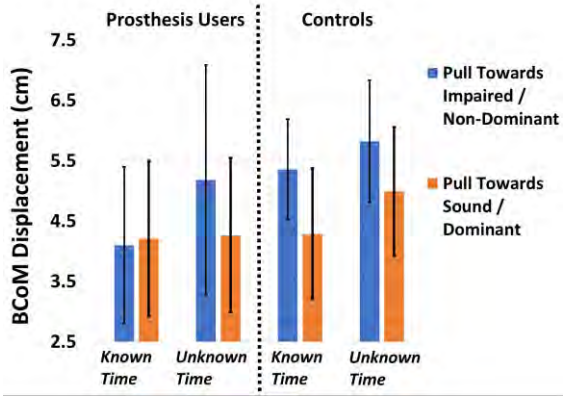

Figure 2: Average BCoM displacement separated by timing, direction, and group. Error bars=95% CI.

The results suggest that across both groups a larger lateral displacement of the BCoM is experienced when a perturbation is directed towards the control non-dominant limb and the BKPU impaired limb. The expectation that this increased BCoM displacement would be observed only in BKPUs was not supported as no interaction or group effects were significant. Additionally, both groups appear to experience similar displacements in BCoM during the perturbation exposure.

This finding may suggest that despite the unique unilateral lower limb impairment experienced by BKPUs, both BKPUs and non-impaired controls experience a bias in reactive control that favors the sound/dominant limb. However, given this impairment in BKPUs, the observed increase in MoS on the impaired limb side when timing of an expected perturbation is known [2] is reasonable to accommodate for this increase in BCoM displacement. Our previous results suggest that preceding MoS is not increased when timing is unknown to avoid prolonged exposure to elevated stability costs [2], although this strategy would likely benefit overall locomotor stability.

The results of this study suggest that across subjects BCoM displacement is not significantly affected by *a priori* knowledge of perturbation timing. Specifically, although this knowledge encourages an increase in MoS on the BKPU impaired limb side prior to the perturbation [2], there is no reduction in BCoM displacement. This finding did not support our hypothesis, as it was expected that BKPUs would employ a control strategy to minimize BCoM excursion and further enhance the distance between the base-of-support and extrapolated center-of-mass. Consequently, it may be that both controls and BKPUs do not employ control strategies that specifically minimize BCoM displacement following a lateral perturbation of this magnitude. Given our previous results [2], while BKPUs may partially rely on proactive strategies to enhance locomotor stability, non-impaired controls likely depend on reactive strategies. Subsequent analyses will focus on *a priori* knowledge effects on lateral BCoM velocity which may serve as an alternative means to maximize locomotor stability [2]. Additionally, the global maximum of BCoM displacement and time to reverse BCoM trajectory after perturbation will also be analyzed.

CONCLUSIONS

Non-impaired controls and unilateral BKPUs experience similar BCoM displacement when subjected to a lateral perturbation of 12% bodyweight. These displacements are not affected by *a priori* knowledge of timing, but both groups experience greater displacement with perturbations directed toward the impaired/non-dominant limb.

Comparison of Modular and Rigid Socket Systems for Lower Limb Amputees: A Preliminary Study

[1] Corey Pew, [2]Shane R. Wurdeman and [1]Richard R. Neptune

[1] Department of Mechanical Engineering, University of Texas, Austin, TX
[2] Department of Clinical & Scientific Affairs, Hanger Clinic, Austin, TX
email: Corey.Pew@utexas.edu, web: www.me.utexas.edu/~neptune/

INTRODUCTION

Lower limb amputees often express dissatisfaction with the fit of their prosthesis [1]. Prosthesis fit has been identified as a vital characteristic when evaluating a patient's prosthesis and often determines whether an individual will use their prosthesis effectively [2]. The fit of the socket system can also significantly affect amputee mobility, comfort, activity level, residual limb skin health, vocational success and safety [1–4].

The prosthetic socket plays a critical role in coupling the prosthesis to the residual limb. The current standard-of-care consists of a static exoskeleton socket secured to the residual limb through an elastomeric liner in combination with a mechanical locking pin or an element of negative pressure [5]. The residual limb, however, is dynamically changing shape and volume throughout the course of the day [6]. The impedance mismatch between the static, rigid socket and the dynamic, soft residual limb leads to the socket fit varying from ideal to poor throughout the day. The result of a poorly fitting socket is pain and discomfort that can limit the amputee's comfort and mobility.

Modular socket systems have recently become available that attempt to improve the coupling of the prosthesis to the user by providing components that can be manually adjusted. This allows the user to fine-tune the fit between the socket and limb as conditions vary throughout the day and over longer periods. This preliminary investigation sought to determine if one such modular system, the Hanger ComfortFlex Adapt system (Hanger Inc., Austin, TX), could provide improvements to user comfort, satisfaction, quality of life and mobility as compared to the standard-of-care (**Figure 1**).

Figure 1: Comparison of socket systems. A: Standard-of-care rigid exoskeleton socket, B: Hanger ComfortFlex Adapt modular socket.

METHODS

Utilizing a preliminary review of records provided by Hanger Clinic, we investigated differences between an adjustable, modular socket design (ComfortFlex Adapt) and the rigid, static sockets in above-knee prosthesis users using: 1) the Socket Comfort Score (SCS), 2) the Prosthesis Evaluation Questionnaire Well-Being subsection (PEQ-WB) modified to use a 10-point ordinal scale, and 3) the Prosthetic Limb Users Survey of Mobility (PLUS-M). This preliminary data utilized only the Well-Being subsection of the complete PEQ. The PEQ-WB consists of a satisfaction with amputation (PEQ-Sat) and a quality of life (PEQ-QoL) question. We were able to obtain data for 8 individuals with the modular socket (age: 46.1 ± 13.9 yrs., height: 176.9 ± 8.0 cm, mass: 85.5 ± 17.8 kg), which we then compared with 11 individuals using a conventional rigid socket (age: 49.3 ± 11.4 yrs., height: 172.7 ± 9.0 cm, mass: 87.7 ± 24.5 kg). Individuals with the rigid

socket were extracted from a large clinical outcomes database using an algorithm based on similar age, height, and mass. Groups were compared using independent t-tests to calculate associated p-values.

RESULTS AND DISCUSSION

When comparing results between the two socket types from the five scales, individuals with the modular socket reported increased socket comfort (SCS) (p=0.005), satisfaction (PEQ-Sat) (p=0.182), quality of life (PEQ-QoL) (p=0.141), overall well-being (PEQ-WB) (p=0.152), and mobility (p=0.003) (**Figure 2**).

These preliminary results highlight the potential differences that can exist between an adjustable, modular socket and a rigid, static socket design. While these initial results indicate that a modular socket has the potential to improve outcomes of comfort and mobility for lower limb amputees, more subjects are needed to increase our statistical power and determine if these outcomes can be generalized to the lower limb amputee population.

CONCLUSIONS

Modular socket systems may provide improvements to amputee comfort and mobility as compared to the standard-of-care rigid sockets. A future, in-depth study with a larger patient group is being designed to determine how modular sockets might benefit lower limb amputees. A study of socket systems could then be used to help guide clinical practice to determine when and how modular socket systems should be used with the lower limb amputee population.

INTRODUCTION

Mechanically-active ankle-foot prostheses for individuals with transtibial amputation (TTA) can produce mechanical power commensurate with the biological ankle during the push-off phase of gait [1]. Mechanical ankle power production can reduce metabolic energy expenditure [2,3] and increase prosthetic ankle range of motion compared to passive prostheses [1]. However, not all studies demonstrate a reduction in metabolic cost [4] and the range of whole-body angular momentum (*H*) can remain elevated compared to non-amputees [5].

These inconsistent findings may be due to active prostheses providing increased push-off power during terminal stance, but functioning similarly to passive prostheses during early stance [1]. Thus, the effects of an active prosthesis on whole-body coordination of balance may not be adequately captured by analyses such as range of *H*. A method for testing for statistically significant changes throughout the gait cycle, such as Statistical Parametric Mapping (SPM), is needed [6]. We used SPM to analyze segment contributions to frontal-plane *H* during uphill and downhill walking with passive and active prostheses.

METHODS

We evaluated data from 10 individuals with TTA (1F/9M, mean±SD: 30±5 years, 1.83±0.10 m, 96±7 kg) and 10 non-amputees (2F/8M, 24±5 years, 1.80±0.09 m, 91±10 kg). All individuals with TTA were Medicare Functional Classification Level K4. Trials were performed with the participants' clinically-prescribed passive prosthesis and the BiOM H2 Power Ankle (BiOM, Inc.). Participants acclimated to the BiOM over 43.4±18.1 days. Participants walked on a 16-foot ramp at slopes of 0°, ±5°, and ±10° at a fixed speed. Whole-body kinematics were tracked using 57 reflective markers (120 Hz, Motion Analysis Corp). Thirteen-segment full body models were created for each person using Visual3D (C-Motion, Inc.), with segment masses computed as a percentage of total body mass. The passive prosthesis shank mass was reduced by 30% and moved 30% more proximally. The BiOM was modeled with the same inertial properties as a biological shank and foot. We computed segment contributions to *H* as

$$\vec{H}_i = (\vec{r}_i - \vec{r}_{body}) \times m_i(\vec{v}_i - \vec{v}_{body}) + I_i\vec{\omega}_i$$

where $\vec{r}_i$, $\vec{v}_i$ and $\vec{\omega}_i$ are the position, velocity, and angular velocity of the i^{th} segment, $\vec{r}_{body}$ and $\vec{v}_{body}$ are the position and velocity of the whole-body COM, and m_i and I_i are the mass and inertia matrix of the i^{th} segment. H_i was normalized by body height, mass, and average horizontal walking velocity and expressed as a percentage of left or prosthetic limb gait cycle (gc).

Contributions of each arm, leg and the trunk to *H* were compared using spm1d [6] in MATLAB (The Mathworks, Inc.). A generalized linear model was created with ramp angle and group (non-amputee, passive, active) as fixed effects, and a random intercept for each subject. Using the SPM equivalent of ANOVA, we tested for significant fixed effects at each time step (α=0.05). Post hoc pairwise comparisons (α=0.0005 after Bonferroni correction) were performed during intervals in which significant main or interaction effects were found.

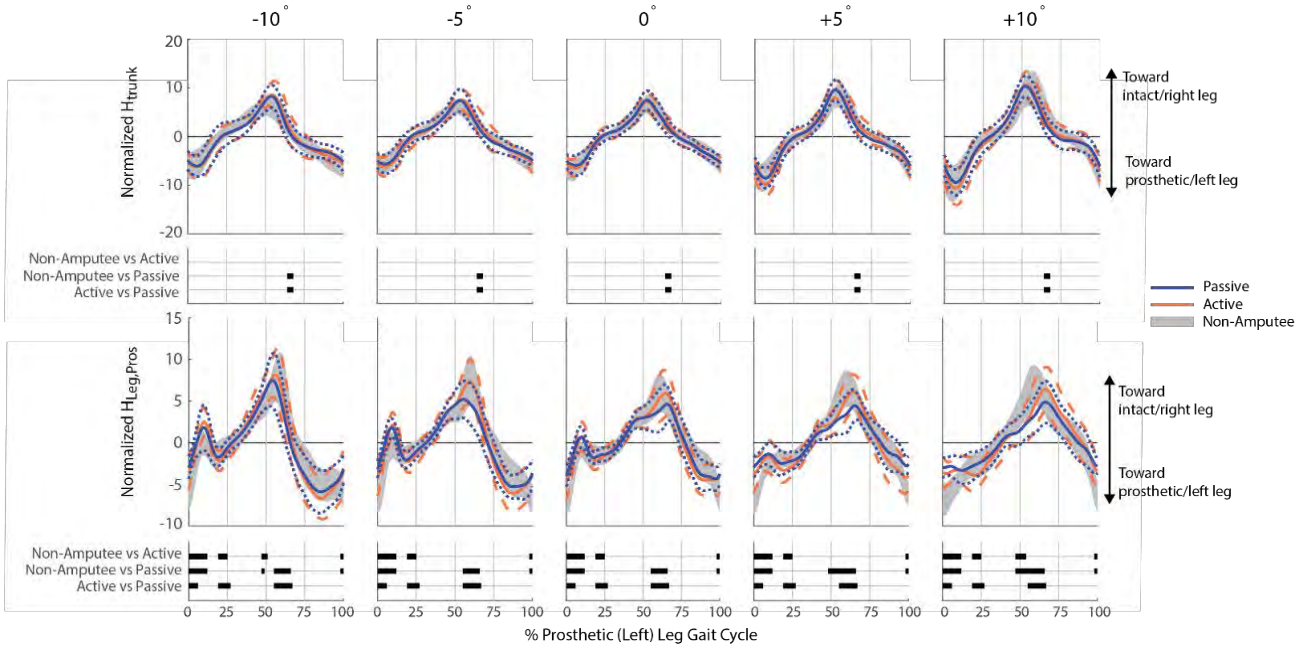

Figure 1: Mean (solid lines) ±1SD (dashed lines) normalized H_{trunk} and $H_{Leg,Pros}$. Mean±1SD non-amputee values are in shaded gray. Bars below each figure indicate significant differences between groups.

RESULTS AND DISCUSSION

There were significant differences in H_{trunk} just after toe-off (63-68% gc) on all slopes for the passive prosthesis compared to the other conditions, but not between the active prosthesis and non-amputees (Fig. 1). H_{trunk} was more positive when using the active compared to passive prosthesis, indicating greater angular momentum toward the intact leg at prosthetic leg toe-off (~63-68% gc). Similar differences were observed in $H_{leg,pros}$ at slopes of 0° and ±5° (Fig. 1), suggesting that ankle joint power contributes additional frontal-plane H_{trunk} and $H_{leg,pros}$ toward the intact leg.

Furthermore, the lack of differences between the active prosthesis and non-amputees suggests that the active prosthesis improves coordination of dynamic balance at toe-off. This finding is consistent with other studies demonstrating increased ankle push-off power [1,7] and trailing leg mechanical work [2,3] when using active compared to passive prosthetic ankles. Our findings also support simulations showing that the ankle plantarflexors contribute to frontal-plane H toward the contralateral leg in late stance [8]. We expand on these simulation results by identifying that ankle power generation primarily affects the ipsilateral leg and trunk, and has little effect on the intact leg.

Our analysis also indicated that both active and passive prostheses contributed a significantly lower magnitude of $H_{leg,pros}$ compared to non-amputees in early stance. This result is likely because active prostheses effectively function like passive prostheses during this portion of the gait cycle.

In conclusion, while the power produced by active prosthetic ankles during late stance appears to restore normative balance regulation at toe-off, the benefits of these devices are likely limited by user adaptation and/or device functionality during early stance.

MEDIAL-LATERAL GAIT STABILITY IN PEOPLE WITH TRANSTIBIAL AMPUTATION ACROSS WALKING SPEEDS

Ryan D. Wedge, Andrew K. LaPrè, Frank C. Sup, and Brian R. Umberger
University of Massachusetts, Amherst, MA, USA
email: umberger@kin.umass.edu, web: www.umass.edu/locomotion, www.ecs.umass.edu/mie/mrrl

INTRODUCTION

People with lower limb amputation have a greater incidence of falling compared with people without amputation [1]. They are unable to produce as much force on the prosthetic side to recover from perturbations [2] and may adapt different strategies compared with the intact side to decrease the risk of falling. People with lower limb amputation demonstrate inter-limb asymmetries, such as a shorter step length on the intact side compared with the prosthetic side, which may be a functional adaptation to increase stability. Understanding the adaptations people with amputation make will enhance rehabilitation and prosthesis interventions and ultimately help decrease the risk of falling.

Gait stability in people with a unilateral transtibial amputation has been shown to vary between limbs. When using a global (i.e., center of mass) measure, such as margin of stability (MoS), there is greater stability on the intact side in the backwards (BW) direction [3,4] and greater stability on the prosthetic side in the medial-lateral (ML) direction [3]. The same trend for BW MoS remains across a range of speeds [4] but it is unknown how ML MoS varies beyond preferred speed.

When determining MoS, how the base of support (BOS) is defined can alter the magnitude of the MoS. The BOS was originally defined based on the center of pressure (COP) [5], though more recently investigators have used ankle markers to define the BOS [3]. Alternatively, the limits of the BOS could be defined using markers on the foot rather than on the ankle but the effects on ML MoS are unknown.

Gait stability across speeds is of interest because of the multiple speeds people use when walking, and may help quantify the capacity to avoid a fall at different speeds. How the base of support is defined when using markers is also important because it could the affect the magnitude of MoS and the conclusions of the study. The purpose of this study was to evaluate ML MoS across walking speeds using three different methods for defining BOS.

METHODS

Data were collected for seven subjects (2 females; mass: 74.3 ± 15.0 kg; height: 1.78 ± 0.09 m) with a unilateral transtibial amputation. All subjects were rated at a K3 or K4 level and used a standard pylon and a split toe flex-foot.

Minimum ML MoS during stance phase was calculated based on the extrapolated position of the center of mass (CoM) relative to the lateral margin of the base of support, which was defined three different ways based on markers on the lateral ankle (LANK), the lateral heel (LHL), and the fifth metatarsal (FMET). Kinematic data were captured using a high-speed motion capture system as subjects walked overground at three speeds: preferred (1.27 ± 0.04 m s^{-1}) and ±20% preferred (1.05 ± 0.04 m s^{-1} and 1.55 ± 0.07 m s^{-1}). CoM ML position was estimated from markers on the right and left anterior and posterior superior iliac spines, and then numerically differentiated to determine CoM velocity (vCOM).

Minimum ML MoS was determined during stance phase for both limbs (prosthetic and intact) for three trials at each of the three speeds. Dependent variables were tested for differences using 2 (limb) x 3 (speed) MANOVAs followed by post-hoc tests using the false discovery rate procedure with significance set at $\alpha = 0.05$.

RESULTS AND DISCUSSION

The magnitude of the minimum ML MoS was greater for the prosthetic side compared with the intact side across speeds for all three BOS definitions (Figure 1), with a significant main effect of limb. There were no significant speed effects or interactions. There were significant pairwise

differences between limbs at preferred (p=0.033) and fast (p=0.002) speeds for the FMET BOS definition, and all pairwise differences between limbs across speeds and BOS definitions had large effect sizes, except for LANK at the slow speed, which had a medium effect size (Figure 1).

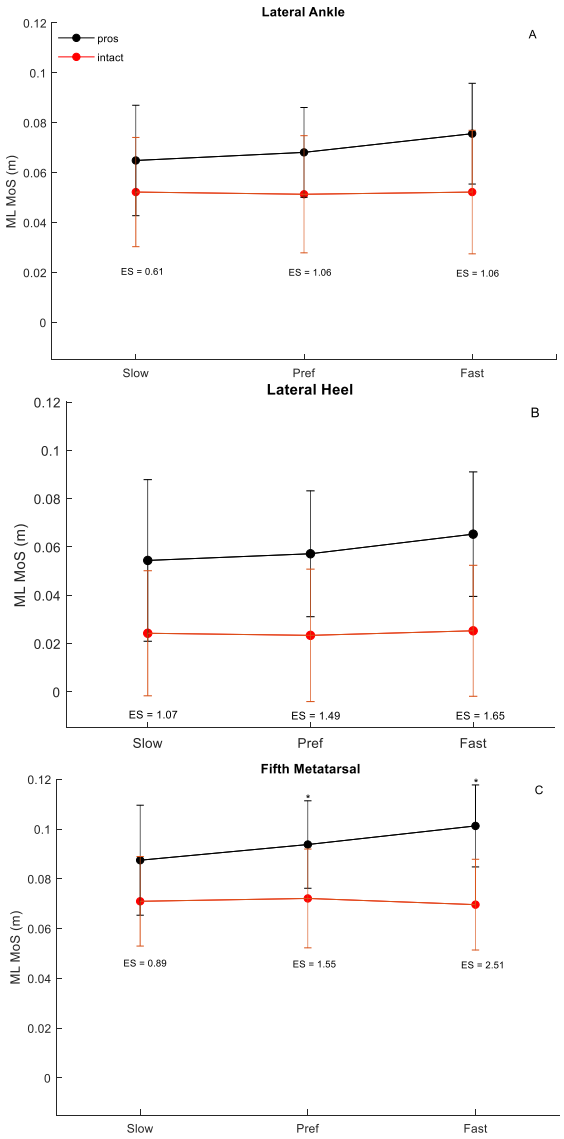

Figure 1: Minimum ML MoS during stance calculated using the LANK (A), the LHL (B), and the FMET (C) as the BOS for both limbs across speeds. The * symbol denotes a significant difference between limbs and ES = effect size.

The greater ML MoS on the prosthetic side compared with the intact side is consistent with previous findings [3] at the preferred speed, and was found to remain consistent across speeds (Figure 1). The lack of speed dependence for ML MoS differed from our previous finding that BW MoS at heel strike significantly increases with speed [4]. The greater ML MoS during stance on the prosthetic side may be a strategy to provide a greater margin of safety when the body is supported on the prosthetic limb, which is not able to produce as much force compared with the intact side [2].

The different methods for defining BOS using markers on the ankle and foot lead to similar general conclusions about the ML MoS across speeds. The main effects of limb and generally large effects sizes were consistent across methods. The BOS based on the FMET marker may have the advantage of greater sensitivity as it also identified statistically significant pairwise differences. Future work is needed to determine how the results obtained with different markers compare with the COP when defining the lateral BOS.

CONCLUSIONS

People with unilateral transtibial amputation demonstrate different stability patterns between limbs and in different directions. Rather than the increase in BW MoS previously observed with speed, ML MoS was maintained across speeds and was greater for the prosthetic limb. Taken together, these results may represent adaptations people with lower limb amputation make in response to a greater risk of falling in the mediolateral direction when the body is supported on the prosthetic limb, regardless of walking speed.

POSTURAL INFLUENCES ON REGIONAL SUPRASPINATUS AND INFRASPINATUS ACTIVATION IN ISOMETRIC ARM ELEVATION EFFORTS

INTRODUCTION

Rotator cuff muscles stabilize the glenohumeral joint against humeral head translations and the suprapinatus (SUP) and infraspinatus (INF) can particularly contribute during arm elevation. Several EMG studies have quantified the activation of SUP and INF during different exercises and postures. In clinical settings, elevation posture is usually defined by thoraco-humeral elevation angle and elevation plane (sagittal, coronal, scapular). The activation patterns of SUP and INF in different elevation postures have scarcely been compared and very few studies considered the effect of elevation planes [1]and elevation angles[2] on muscle activation.

In addition, most EMG studies considered SUP and INF as a single muscle unit while anatomical studies suggested that there are two neuro-anatomically distinct regions within SUP (anterior, posterior) and three regions within INF (superior, middle, inferior) muscles. Only Kim et al. [3] reported the activation of both anterior and posterior SUP during some exercises and no EMG study evaluated the activation of the three regions of INF.

The aim of this study was to quantify the activation of different SUP and INF regions during resisted isometric arm elevations in different arm postures in order to explore the effect of elevation angle and elevation plane on muscle activation pattern.

METHODS

31 right-handed healthy individuals including 16 females (21.8 ± 1.6 years) and 15 males (23.2 ± 3.4years) participated in this study. EMG signals from anterior and posterior SUP were detected using indwelling electrodes as described by Soo Kim et al. [3]. Intramuscular electrodes were also placed into the superior, middle and inferior regions of infraspinatus muscles through a protocol validated in the local university. The data were collected using a Noraxon system with 3000Hz sampling rate.

The participants performed 18 isometric exertions against a robotic device that provided stationary resistance after completing 11 MVC exertions. The test postures included abduction, scaption and flexion at 30°, 90° and 150°of arm elevation in two load conditions: Maximal Voluntary Force (MVF) and 50% MVF. The force was exerted against a tri-axial force transducer, and sampled at 1500Hz before conversion to a digital signal using a Labview program. The participants could observe their %MVF on screen. Each trial lasted 6 sec and repeated once with 1-2 min rest between trials.

The raw EMG data were bandpass filtered, full wave rectified and linear enveloped using a low pass filter (fc = 2Hz). For each muscle, the maximum value across all MVC and MVF trials was extracted to represent the maximum voluntary excitation (MVE). All EMG data were presented as %MVE. The mean activation values were assessed using two-way repeated measure ANOVAs, with two independent variables: plane and angle of elevation, and their interaction effect.

RESULTS AND DISCUSSION

Supraspinatus (Figure 1): Changes in arm posture did not influence activation of the posterior region. This may indicate that the posterior region has mostly a stabilizing role. However, the effects of plane and angle were statistically significant for anterior SUP. At 50%MVF load condition, the activation of anterior SUP was in average 40.7%MVE and 38.9%MVE in scaption and abduction respectively, which were significantly higher than flexion (35.4%MVE). While applying

maximal force, the activation of anterior SUP was significantly lower in 30° of flexion (40.2%MVE) than abduction (53.2%MVE) and scaption (48.6%MVE). This indicates that anterior SUP contributes more prominently in lower regions of arm abduction.

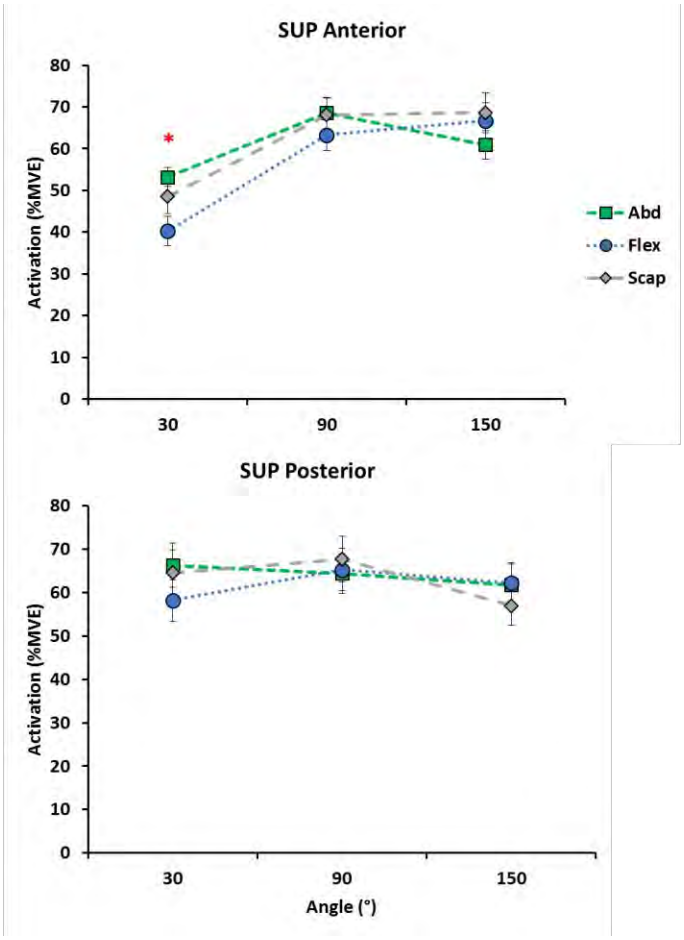

Figure 1: Activation of anterior and posterior regions of supraspinatus in different postures (maximal force), * = significant interaction ($p<0.05$)

Infraspinatus: The activation of superior INF was not affected by arm posture at low elevation angles (30°). However, in 90° of elevation, this region was more active during flexion. Likewise, the activation of middle INF was higher in flexion, irrespective to the elevation angles (Figure 2). This indicates that the superior and middle regions of INF are more involved in arm flexion. Irrespective to the plane of elevation, the inferior infraspinatus had higher activation in 90° (62%MVE) and 150° (58.6%MVE) of elevation than 30° (47.9%MVE) by applying maximal force.

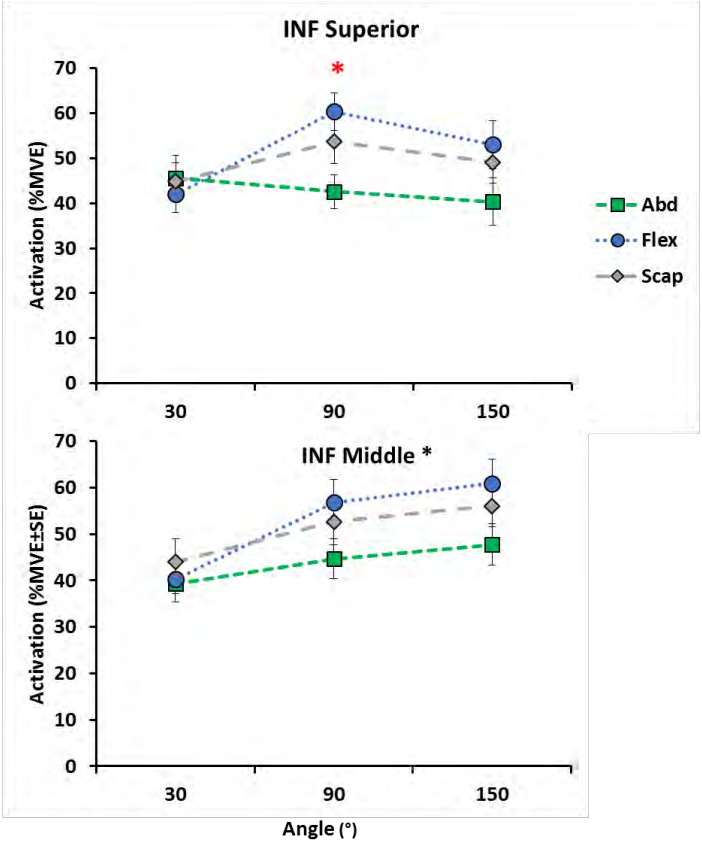

Figure 2: Activation of two infraspinatus regions in different postures (maximal force). *= significant interaction, *=Significant main effect ($p <0.05$)

CONCLUSIONS

Apart from posterior SUP, the contribution of the other regions of SUP and INF to arm elevation are influenced by plane and angle of elevation. The results of this study can help to identify the postures in which different regions of SUP and INF experience higher demand or exertion, and transfers directly to the development and modification of assessment and rehabilitation paradigms.

SHOULDER KINEMATICS AND SUPRASPINATUS PROXIMITY DURING LEVEL AND SIMULATED RAMP PROPULSION

Beth A. Cloud, Stefan Madansingh, Emma Fortune, Melissa M. Morrow, and Kristin D. Zhao

Mayo Clinic, Rochester, MN, USA
email: cloud.beth@mayo.edu

INTRODUCTION

Individuals with spinal cord injury (SCI) report shoulder pain at rates up to 70% [1]. Imaging studies demonstrate that individuals with SCI have evidence of overuse shoulder pathology as early as 3.5 years after SCI [2]. Among the pathologies observed are rotator cuff tendinopathies and tears.

Certain scapular and humeral motions are suggested to be associated with subacromial impingement (SAI). In SAI rotator cuff tendons are impinged be between the humerus and scapula which can lead to tendon damage. Both level and ramp propulsion are characterized by scapular and humeral motions that have been associated with SAI [3].

The purpose of this study was to determine if shoulder kinematics and proximity of the supraspinatus insertion relative to scapular landmarks differ between level and simulated ramp propulsion.

METHODS

Individuals with SCI who use a manual wheelchair (MWC) as their primary mode of mobility were recruited to participate in this IRB approved study. Participants propelled on a custom set of rollers in two conditions (1) level and (2) simulated ramp (ramp). The ramp condition was simulated by raising support under the casters to create a 1:12 inclination (standard per the Americans with Disabilities Act (ADA) guidelines).

Unilateral shoulder kinematics were measured at 120 Hz with an electromagnetic system (Liberty, Polhemus). Thorax, scapula, and humerus local coordinate systems were defined using International Society of Biomechanics (ISB) standard landmarks [4]. Kinematics were quantified for the scapulathoracic (ST) joint, glenohumeral (GH) joint, and thorax relative to global (THOR). ST kinematics were quantified with the ISB standard rotation sequence (YX'Z"). GH kinematics were quantified with an alternative sequence (XZ'Y", [5]). THOR kinematics were quantified with a ZX'Y" sequence. Kinematic values were determined at 0, 25, 50, 75, and 100% of push and recovery propulsion phases.

Supraspinatus proximity relative to the coracoacromial (CA) arch (comprised of acromion, CA ligament, and coracoid) was determined by animating CT bone-models with GH kinematic data. The supraspinatus insertion site and inferior CA arch were defined as surface meshes. The minimum distance between the two surface meshes (supraspinatus proximity) was calculated by custom Matlab (Mathworks Ltd) code. The percentage of impingement time (%Supra) was quantified as the percentage of each phase that the supraspinatus insertion was within 5mm of the CA arch (Figure 1). Cadaver studies indicate the supraspinatus is about 5mm thick [6], therefore a space smaller than 5mm would suggest tendon impingement.

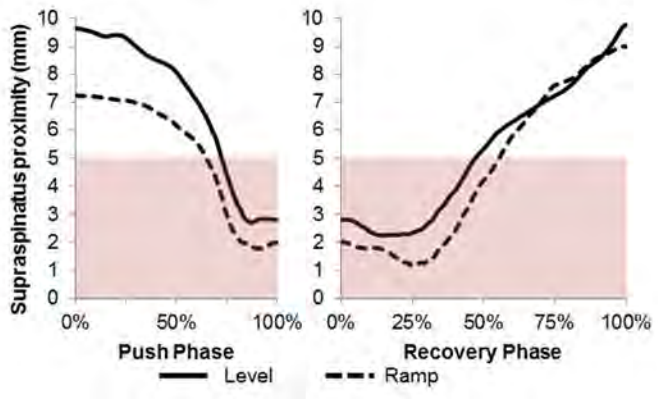

Figure 1: Supraspinatus time series for a sample participant. Push phase was ~40% of the total cycle. Pink shaded area denotes proximity <5mm

Five cycles from level and ramp propulsion were used for analysis. Analyses were performed within

each phase (push and recovery). %Supra was compared between the level and ramp conditions with a Wilcoxon signed-rank test. A series of linear mixed models for repeated measures were used to compare all GH and ST kinematics as well as THOR flexion between conditions and events.

RESULTS AND DISCUSSION

Ten individuals participated (age: 37±13yr, 9 male, SCI range: C5-T6, time since SCI: 10±11yr).

%Supra was significantly higher ($p<0.05$) in the ramp condition during recovery but not push (median difference (IQR): 9.1% (-0.7, 29.8); 5.5% (-5.3, 15.4), respectively; Figure 2). There was a main effect of event for all kinematics evaluated (as expected due to nature of the task). There was a main effect of condition in all 3 GH rotations, ST internal/external rotation, ST upward/downward rotation, and THOR flexion/extension in both push and recovery phases ($p<0.05$, Table 1). Condition-event interactions were seen in GH internal/external rotation in both phases and GH abduction during recovery ($p<0.05$).

Participants tended to be relatively more abducted, horizontally adducted, and externally rotated at the GH joint in the ramp condition. The difference in GH internal/external rotation was more pronounced at the end of push and beginning of recovery and in GH abduction at the beginning of recovery. Participants tended to be relatively more internally and upwardly rotated at the ST joint and use more thorax flexion during ramp propulsion.

CONCLUSIONS

GH, ST, and THOR kinematics differ by propulsion condition. The differences in each GH rotation are each small in magnitude but together have an effect on the impingement of the supraspinatus during propulsion, as evidenced by the %Supra changes.

The differences seen at the ST joint and thorax are likely repositioning the GH joint relative to the push rim and necessitating a change in GH kinematics. Work is ongoing to determine if the differences seen in the propulsion conditions can be leveraged to change an individual's percentage of time in impingement within a particular condition (i.e., training to propel with less ST internal rotation).

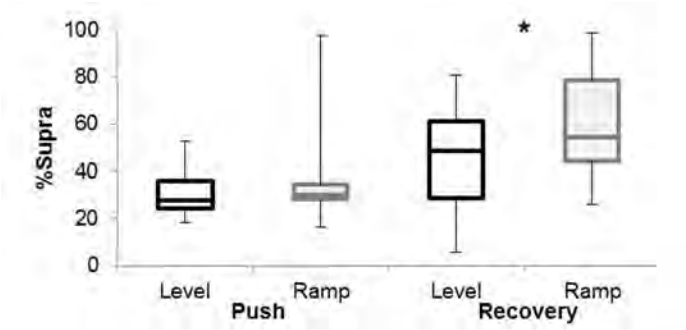

Figure 2: %Supra by condition and phase. Box plots show median, IQR, and min to max (error bars).

ANTERIOR AND POSTERIOR SUPRASPINATUS ACTIVATION AFFECTED BY PLANE OF ELEVATION AND PHASE OF MOTION USING INDWELLING ELECTROMYOGRAPHY

Alan C. Cudlip and Clark R. Dickerson

University of Waterloo, Waterloo, ON, CANADA

INTRODUCTION

The rotator cuff includes four muscles, and the supraspinatus is the most common site for injury initiation within this muscle group. The supraspinatus has a complex morphology, consisting of anterior and posterior regions, attaching to different sections of the supraspinatus tendon [1]. Recent research has determined that these two regions have divergent distributions of fiber types, and these regions may have different mechanical functions that are influenced by arm posture [2, 3].

Differences in activation patterns between the two regions of supraspinatus are minimally described. Previous research investigated both regions in static arm postures with a single hand load [3]. Accurate representation of differences in regional activations can elucidate recruitment strategies with increased resolution. This study quantified activation patterns of the anterior and posterior regions of the supraspinatus through different humeral ranges of motion and manual force intensities.

METHODS

15 participants [26 ± 3.7 years; 1.71 ± 0.05m height; 78.2 ± 13.1 kg body weight] completed 42 arm elevation tasks with 2 factors: plane of elevation (0/15/30/40/60/75/90°) and 3 intensities (unloaded/ 20%/40% of maximal elevation strength), each completed twice using a fixed cadence (Figure 1). Each trial consisted of one arm elevation and lowering, with 2 seconds to complete each phase of movement. Indwelling electromyography was recorded from anterior and posterior supraspinatus regions and a surface electrode over supraspinatus at 3000Hz (Noraxon Telemyo 2400 T G2), linear enveloped and normalized to muscle-specific maximal outputs. Motion capture was collected for the torso and right upper extremity using an 8 camera VICON MX20 system (VICON, Oxford, UK) at 50Hz. Kinematic analysis consisted of data filtering, marker reconstruction and local joint coordinate system reconstruction and shoulder angles were determined using ISB standards [4]. Activation levels at elevation angles were extracted in 5° increments from 5-135° for both ascending and descending motions. Multiple 2 way repeated measures ANOVAs using 4 factors (muscle region, plane of elevation, elevation angle, intensity) with each 2-way interaction examined activity changes.

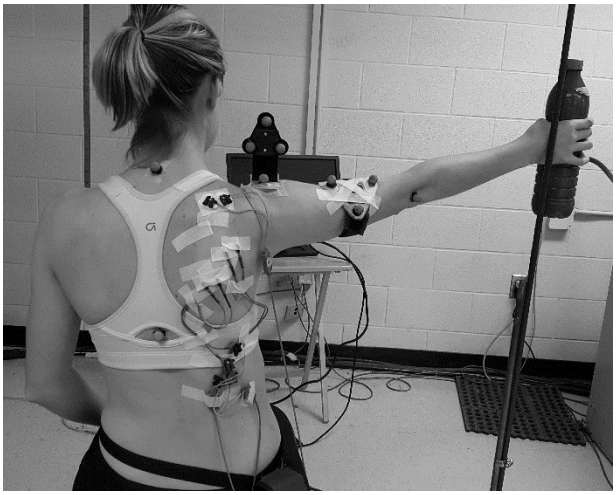

Figure 1. Arm elevation was completed at 3 hand force intensities in 7 planes of elevation.

RESULTS AND DISCUSSION

Elevation angle*Muscle region interactions were present for all EMG signals ($p<0.01$, Figure 2). All peak activations occurred during the ascending phase of motion, while posterior supraspinatus had a more consistent level of activation throughout arm elevation and depression, with standard deviations in activation that were ~50% smaller than the anterior region between 30-135° of elevation. Previous research has indicated similar persistent activation of posterior supraspinatus throughout the range of motion [3], though activation differences between these regions were smaller than previously reported.

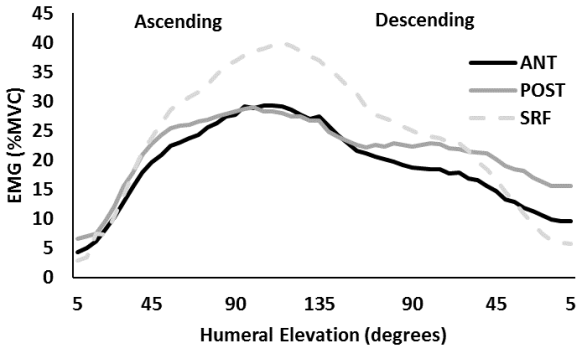

Figure 2. Elevation Angle*Muscle region effected existed ($p<0.01$), with higher elevation angles typically increasing activation.

An interaction between elevation angle and plane of elevation was present, with peak activation occurring between 90-115° in each plane, and increasing activation occurring in more sagittal planes of elevation ($p<0.01$, Figure 3). Differences between planes of elevation at the same angle ranged from 2.9 %MVC at 5° elevation to 14.3 %MVC at 55° elevation. Comparing the sagittal plane to more coronal planes of elevation consistently decreased activation at the same elevation angle, with some exceptions. The supraspinatus likely has a greater mechanical advantage in the coronal plane due to changes in 3D glenohumeral joint configurations and increasing moment arms in these postures [5].

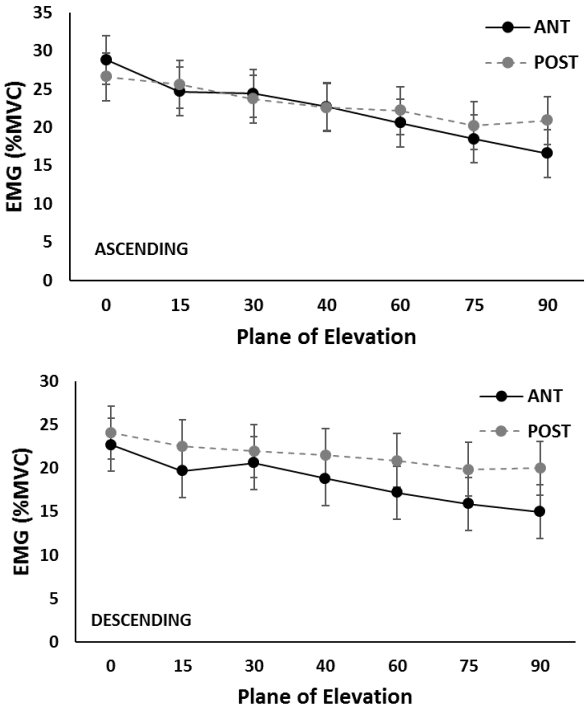

Figure 3. Plane of elevation*Muscle interactions lowered activation in more sagittal planes, and relative activations between anterior and posterior supraspinatus altered within movement phases.

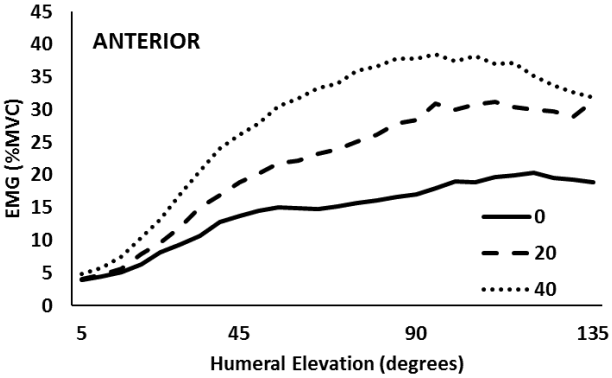

Figure 4. Angle*Load interactions ($p<0.01$) indicated greater muscle activation with increasing abduction angle and load (0/20%/40%).

Load and elevation angle interactions indicated higher elevation angles and loads increased activity by >40 %MVC ($p<0.01$, Figure 4). Muscle region and plane of elevation interactions increased activity in the anterior region in sagittal movements ($p<0.01$).

CONCLUSIONS

This research provides novel anatomical insights into supraspinatus activation across an extended shoulder range of motion. The findings from this study indicate that the supraspinatus has a complex activation pattern, and is heavily modulated by arm posture and phase of motion. Future research examining *in vivo* or *in vitro* responses of supraspinatus will need to examine the entire shoulder range of motion, as specific muscular responses are strongly influenced by posture and type of motion.

CUMULATIVE SHOULDER IMPINGEMENT DURING FREE-LIVING MANUAL WHEELCHAIR PROPULSION

Emma Fortune, Beth Cloud, Stefan Madansingh, Meegan Van Straaten, Dennis Murphree, Kristin Zhao, Melissa Morrow

Mayo Clinic, Rochester, MN, USA
email: Fortune.Emma@mayo.edu

INTRODUCTION

The shoulder is the most common musculoskeletal pain site for manual wheelchair (MWC) users [1]. Shoulder pain can limit function and quality of life, and is often caused by rotator cuff tears and tendinopathies resulting from impingement of the supraspinatus tendon within the subacromial space [2]. Overuse is thought to be a major causal factor [3]. However, little is known regarding cumulative impingement exposure.

Wearable sensors have been used to identify WC propulsion [4]. A method using upper arm IMUs to objectively quantify MWC users' daily propulsion activity combined with estimations of shoulder impingement exposure could further the understanding of the link between MWC propulsion and shoulder impingement. This study presents data demonstrating the use of lab-based tendon impingement estimations with field-based propulsion detection to estimate cumulative supraspinatus impingement in MWC users.

METHODS

For this IRB-approved study, four MWC users with spinal cord injuries (SCIs) (29±6 yrs, injury levels T4-T6, 1 F) performed multiple MWC-related activity trials including propulsion on a ramp on rollers for 15 cycles and on level rollers for two minutes. Tri-axial acceleration data were collected from upper arm Opal IMUs (APDM Inc, USA; 128 Hz) while video data (60 Hz) and humeral and scapular kinematics (using electromagnetic sensors (Liberty, Polhemus; 120 Hz)) were collected.

Activity and peak detection algorithms were applied to the acceleration data [5] in MATLAB (Mathworks, USA). Activity cycles were identified as the acceleration data between consecutive peaks. A neural network model, with inputs of activity cycle acceleration features, was developed and validated from lab data (by video comparison) to identify propulsion activity. The supraspinatus proximity to the acromion (SPA) was calculated by determining the minimum distances between the supraspinatus tendon insertion site and the underside of the acromion using a generic reconstructed bone surface model (Fig 1). Each task's supraspinatus impingement % time was determined (Fig 2) by quantifying the % of time when the SPA was less than 5 mm [6].

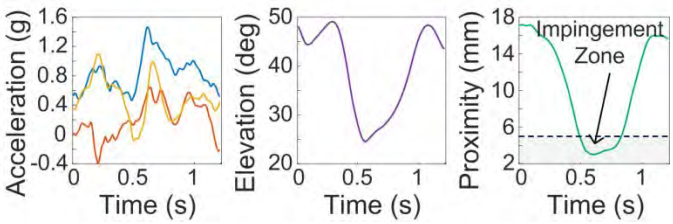

Figure 1: Right arm tri-axial acceleration, humerothoracic elevation and supraspinatus proximity to the acromion (SPA) for one propulsion cycle from a sample lab trial from subject 2.

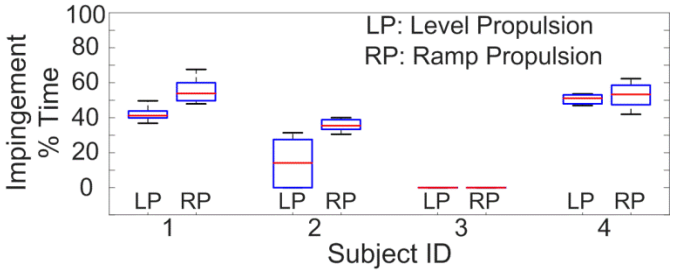

Figure 2: Supraspinatus impingement % time calculated for lab-based propulsion. Boxplots represent % time ranges across each subject's trials.

Subjects wore the IMUs for 1 to 3 days in their natural environment and propulsion time was estimated (Fig 3). Each subject's supraspinatus impingement % time during propulsion was estimated by multiplying their field-based propulsion time by their lab-based propulsion impingement % time. As the IMU algorithm cannot

yet separate level from ramp propulsion, cumulative impingement % times were calculated assuming (1) all level propulsion and (2) all ramp propulsion.

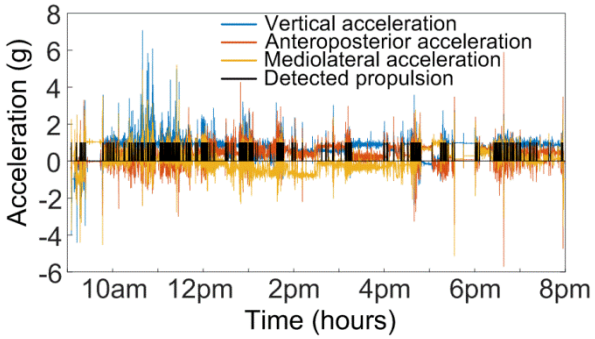

Figure 3: Right arm acceleration during a sample day for subject 2 with detected propulsion periods.

RESULTS AND DISCUSSION

The lab-derived elevation angles and associated SPA values were similar to previous reports [7]. Subjects' estimated daily propulsion time (39-88 mins), propulsion cycles (1956-4282) and associated supraspinatus impingement time (0-48 mins) are presented in Table 1. Previous WC studies have reported less than one hour of average daily wheeling time [8], which is similar to our observations. To place the impingement % time in context, in a rat shoulder overuse model, supraspinatus tendon pathology was observed in rats after 4 weeks of performing 1 hour of overuse activity for 5 days/week resulting in 7500 strides/day [9]. Based on our preliminary data, after ~60 days, MWC users would reach an equivalent number of propulsion cycles and impingement % time as in the rat study. These preliminary results highlight the potential of significant cumulative damage over multiple months of MWC use.

CONCLUSIONS

These preliminary results illustrate the potential of this method to estimate shoulder injury risk time in the field. Further, these results suggest that there is significant cumulative time spent in supraspinatus impingement from propulsion alone, and the inclusion of additional activities involving elevation and loading will further compound impingement time.

INTRODUCTION

Upper limb function is critical for performing activities of daily living (ADL) and maintaining independence [1]. Natural, three-dimensional (3D) upper limb movement requires coordination of multiple degrees of freedom (DOF). Unconstrained movement enables DOF redundancy, allowing tasks to be completed by adoption of several different postures [2]. Understanding the ways in which healthy adults control upper limb DOF during performance of ADLs will enable future exploration of the mechanisms underlying movement control deficits in other groups, like older adults or those with a musculoskeletal injury. The goal of this study is to identify normative upper limb control strategies used by healthy adults during ADL performance.

METHODS

Fourteen ostensibly healthy, right hand dominant young adults (7M/7F, mean age 21.7±2.2yrs) were studied. Participants performed 7 ADL tasks selected to represent a variety of daily tasks and arm postures within the upper limb workspace. Tasks included: forward reach with an empty soda can, upward reach with an empty soda can to a shelf at two heights (shoulder height, eye level), empty cup to mouth, hair comb, turning a book page, pledge (right hand to left side of chest), and tooth brushing. Three trials of each task were performed and averaged. Movement of 12 passive reflective markers placed on anatomical locations on the upper limb and torso were tracked at 200Hz with 8 Kestrel motion capture cameras (Motion Analysis Corp., Santa Rosa, CA). Data was post-processed and filtered using a 6Hz low-pass 2nd order Butterworth filter using Cortex (Motion Analysis Corp., Santa Rosa, CA) software. A custom Matlab (The MathWorks, Natick, MA) program was used to calculate the kinematics and kinetics for 7 DOF (shoulder flexion/extension, abduction/adduction, internal/external rotation, elbow flexion/extension, forearm pronation/supination, wrist flexion/extension, radial/ulnar deviation) using previously reported methods [3]. Kinetics at the shoulder, elbow, and wrist were decomposed into contributions from muscle torque (MT), interaction torque (IT), gravitational torque (GT), and net torque (NT) bounded by Eq. 1.

$$NT = MT + GT + IT \quad (1)$$

The role of active control and passive factors (gravity, inter-segmental dynamics) was explored at each joint by computing the contribution of MT to NT. A two-dimensional (2D) representation of each joint's 3D torque was calculated by computing the scalar projection of MT, IT, and GT vectors upon the NT vector [2]. It was hypothesized that a leading pattern [4] would be observed across ADLs, whereby the shoulder rotates actively while the elbow rotates passively, or the elbow rotates actively while the shoulder rotates passively.

RESULTS AND DISCUSSION

Assessment of torque contributions to NT demonstrated distinct phases of shoulder and elbow control (Fig.1). Each phase is demarcated by the transition of either shoulder or elbow MT projection on NT from positive contribution (positive value) or zero contribution (negative value signifying that MT opposes NT). For example, with the hair comb task, MT contributes to NT both at the shoulder and elbow in phase 1 (cf. orange line, Fig.1A,B). During phase 2, the shoulder leads the movement actively while the elbow moves passively with MT opposing elbow movement. Both joints move passively in phase 3 (MT projection on NT is negative at both joints), and the elbow is rotated actively while the shoulder is rotated passively in phase 4.

This analysis identified three patterns of shoulder

and elbow coordination that were present in all tasks, except tooth brushing, despite the variety of movements and postures tested, supporting our hypothesis. These patterns included: 1) active shoulder rotation, passive elbow rotation; 2) passive shoulder rotation, active elbow rotation; and 3) passive shoulder rotation, passive elbow rotation. In addition, some tasks included a phase of active rotation of both the shoulder and elbow at the beginning (e.g. Fig. 1) or end of the movement, or both. These phases served to overcome gravity at the beginning of the movement or compensate for gravity at the end of the movement when the limb had to be stopped. Assessments at the wrist suggest that MT mainly compensates for passive torque to adjust wrist motion according to task requirements.

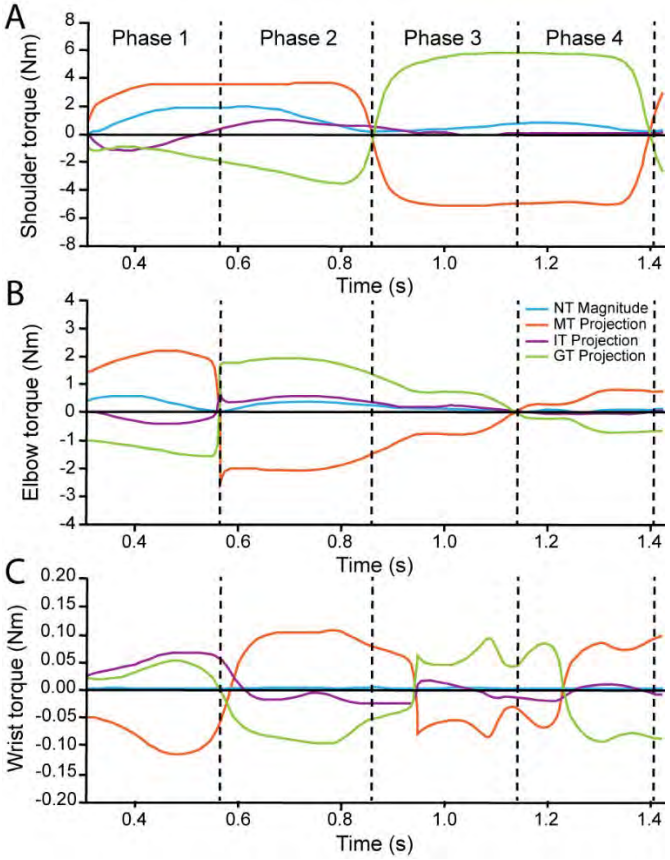

Figure 1: Torque projections at shoulder (A), elbow (B), and wrist (C) joints for hair comb task. MT (orange), IT (purple), and GT (green) vectors have been projected onto the NT vector; NT magnitude is shown in blue.

Identification of 3 shoulder-elbow control patterns, whereby at least one joint rotated passively, represent joint control primitives that direct performance of upper limb movements that are habitual. A lower prevalence of these joint control primitives was observed in ADL tasks that were less habitual, like tooth brushing; during tooth brushing, participants were asked to brush in a medial-lateral direction, which may conflict with typical tooth brushing movements used by the participant. The presence of identified control primitives suggests that the central nervous system prioritizes minimization of neural effort for joint coordination in order to reserve neural resources for other, higher-level cognitive tasks [4].

CONCLUSIONS

This study expands assessment of control mechanisms of upper limb tasks to include ADLs in 3D. Previous research of planar, line drawing tasks has identified that one joint typically leads the movement, while remaining upper limb joints follow largely passively [4]. Results have identified that despite the diversity of joint postures required across ADL tasks, 3 joint control primitives emerged for performance of unconstrained 3D tasks, supporting the leading joint theory previously proposed for planar tasks [2]. These findings suggest that healthy young adults adopt more simplified movement control strategies that rotate a single joint actively, which initiates movement at the trailing joints through mechanical coupling with IT and GT contributions. This suggests that the central nervous system prioritizes resources to other cognitive tasks during the performance of well-learned tasks, like ADLs. Ongoing work seeks to examine how identified joint control strategies change in the context of aging or musculoskeletal injury.

INTRODUCTION

Conventional electromyography (EMG) evaluation of supraspinatus and infraspinatus often relies on a single paired intramuscular electrode in each muscle, which assumes a singular mechanical function. However, studies have defined two architecturally distinct regions in the supraspinatus (anterior and posterior) [1] and three regions in the infraspinatus (superior, middle, and inferior) [2]; each region is also innervated by a distinct nerve branch of the suprascapular nerve [3]. EMG analysis of these muscle regions is emerging; however, a set of test exertions that generates maximal activations in all muscular regions is undefined. The purpose of this study was to quantify the activation of two anatomically distinct regions within the supraspinatus (anterior, posterior) and infraspinatus (superior and middle) during different MVIC exertions and identify optimal combinations of tests for normalizing these EMG data.

METHODS

31 right-handed healthy individuals (15 M, 16 F, age=22.5±2.5 y) participated. Information from the four regions of the infraspinatus and supraspinatus were obtained by fine wire electrodes. Participants performed 15 MVIC tests in a randomly assigned order against manual resistance. The MVIC tests selected were those recommended for normalizing shoulder EMG, or slight variations of these postures [5,6]. Each MVIC test was performed once for 5 seconds (s) and 2 minutes of rest separated tests to minimize muscle fatigue. Raw EMG signals were collected at 3000Hz.

The raw EMG data were digitally bandpass filtered using a 2nd order Butterworth filter (10-1000Hz). Then, all signals were full wave rectified and linear enveloped using a low pass filter (fc = 2Hz). The peak activation of each muscle during each MVIC trial was normalized to the maximum value across all MVIC trials (%MVIC). For each muscle, the MVICs for which activation of >90%MVIC occurred were identified. An optimal set of MVIC combinations, defined as those which elicited >90% MVIC activation in the muscles of interest in >90% of the population, were defined. These sets were identified for regions of the infraspinatus and supraspinatus muscles as well as both combined.

RESULTS AND DISCUSSION

Rotator cuff muscle activation exhibited large variability across MVICs and no single test achieved maximal activation of both regions of either the supraspinatus or infraspinatus. The highest, and lowest mean activations obtained during the MVICs ranged from 70-79% MVIC and 42-47% MVIC respectively (Figure 1). A total of 5-8 MVICs were needed to obtain >90% activation in 90% of the participant population for individual muscular regions. The criterion can be met for all 4 regions studied using a set of 10 MVICs (Table 1).

The results coincide with previous studies, indicating that a combination of MVICs are required to normalize EMG data from either a single muscle or a group of shoulder muscles across a population [4,5]. Although these studies investigated 1-3 rotator cuff muscles, none evaluated the regional activation. The current results both reiterate the importance of selecting MVICs based on the muscle(s) of interest and show that consideration of the specific muscular regions of interest is required.

High mean activity observed in both regions of the infraspinatus and supraspinatus muscles is consistent with the stabilizing role of the rotator cuff muscles

(Figure 1). In contrast to prime movers, the rotator cuff muscles are active across the large range of motion at the shoulder. The data from this study add to this construct, demonstrating that although anatomically distinct from one another, the regions of the supraspinatus and infraspinatus muscles likely share a stabilizing role at the GH joint as high levels of activation were observed across several MVICs performed in various postures.

The most important contribution is establishment of a basis for continued EMG research of the distinct regions of these muscles by outlining reliable MVIC test combinations to normalize intramuscular EMG data. Identifying the codependence or independence of muscular activation and control requires deliberate comparison of EMG from the various regions. This will help to precisely identify the overall and regional functions and contributions of these complex muscles, including providing clarification regarding proposed rotator cuff pathology pathways.

CONCLUSIONS

Robust normalization of EMG data for individual regions of the supraspinatus and infraspinatus muscles requires 5-8 MVIC exertions to generate >90% activation across 90% of the test population. Proposed combinations can reduce inter-participant variability in generating maximal activation for the several muscle partitions. To generate optimal MVIC data across all regions, a combination of 10 MVICs is required.

SENSITIVITY OF HIP LOADING TO PERIACETABULAR OSTEOTOMY REORIENTATION

[1]Brecca M. M. Gaffney and [1]Michael D. Harris
[1]Program in Physical Therapy, Washington University School of Medicine, St. Louis, MO, USA
email: brecca.gaffney@wustl.edu

INTRODUCTION

Developmental dysplasia of the hip (DDH) is characterized by abnormal acetabular and femoral geometries, which provide insufficient coverage and stabilization of the hip joint [1]. As a result, the mechanical loading and stress on the articular cartilage within the hip is altered, which can damage the cartilage and labrum [2]. Due to the altered hip loading mechanics, DDH is a major etiological factor of hip osteoarthritis (OA) development, which increases the risk of OA by 4.3 fold [3].

Periacetabular osteotomy (PAO) is the most common surgical treatment in the U.S. for DDH, and involves reorienting the acetabulum to provide more complete coverage of the femoral head [4]. Although PAO effectively improves short-term pain and function [4], long-term reports indicate that 71% of PAO hips progress to advanced hip OA or arthroplasty [5]. One potential explanation for the long-term inefficacy of PAO is the limited understanding of the effect of PAO on joint mechanics. Specifically, the influence of the individual degrees of freedom of PAO reorientation on hip mechanics remains unknown. Probabilistic analyses provide the most comprehensive approach for assessing the effect of input variability on biomechanical calculations [6]. Accordingly, the objective of this investigation was to determine the sensitivity of hip joint mechanics to PAO reorientation within a probabilistic framework.

METHODS

One female patient with diagnosed DDH scheduled for PAO (age: 32 years; BMI: 22.3 kg/m^2; lateral center edge angle (LCEA): -4.1°; acetabular inclination: 33.6°) participated by walking on an instrumented treadmill at a self-selected speed (1.42 m/s) while whole-body kinematics and ground reaction forces were recorded (100 Hz and 2000 Hz sampling frequencies, respectively). A subject-specific musculoskeletal model was created by scaling a model scaled to body segment dimensions and mass that included female pelvis geometry [7] and detailed hip and knee musculature [7, 8] The model was modified to include four degrees of freedom at the hip socket to simulate PAO reorientation (Fig. 1). A residual reduction algorithm was performed to improve dynamic consistency between measured external forces and the forces produced by the model by making minor perturbations to the torso center of mass and model kinematics.

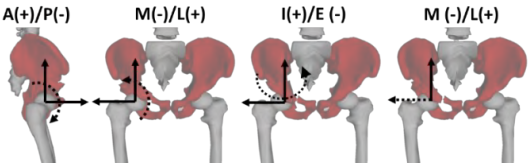

Figure 1. PAO was simulated within the musculoskeletal model by adding four degrees of freedom to the acetabulum: anteroposterior (AP) rotation, mediolateral (ML) rotation, internal/external (IE) rotation, and ML translation. Dashed line indicates positive direction for each DOF.

The sensitivity of hip joint reaction force (JRF) to PAO reorientation was assessed using a Monte Carlo (MC) simulation with 2,000 iterations. Within each MC iteration, each degree of freedom was randomly perturbed relative to the hip joint center within bounds specified within the model: AP rotation [-30° to 30°]; ML rotation [-20° to 30°]; IE rotation [-20° to 30°]; ML translation [-3 mm to 3 mm]. Hip mechanics (muscle forces and joint reaction forces) were determined within each MC iteration using static optimization and joint reaction analysis. The range of hip mechanics were estimated using 0.5 and 99.5% confidence bounds (99% probability the value lies between the bounds). The timing of peak hip resultant JRF during early stance (JRF1: ~14% gait cycle) and late stance (JRF2: ~47% gait cycle) were determined. Sensitivity factors between peak hip mechanics in each direction at JRF1 and JRF2 and each degree of freedom of PAO reorientation were calculated using correlation factors.

RESULTS AND DISCUSSION

Confidence Bounds: Acetabular orientation had a larger influence on hip JRF in the superoinferior (SI)

and AP directions than the ML direction during both the stance (0-61% gait cycle) and swing period (62-100% gait cycle), as indicated by the differences in bound sizes (Fig. 2). As an example, the maximum bound size of the SI hip JRF was 506.4 N (79.1% BW) and the maximum bound size of ML hip JRF was 216.5 N (33.8% BW).

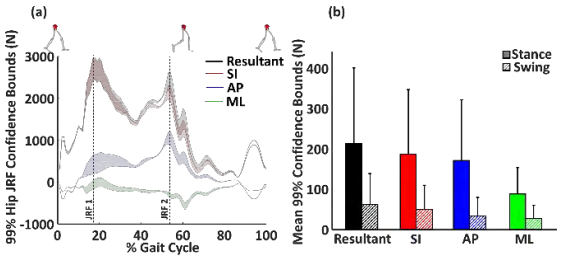

Figure 2. (a) Ensemble average and (b) mean ± 1SD of 99% hip JRF confidence bounds.

Sensitivity Factors: During early stance (JRF1), hip JRF was moderately ($0.5 \leq r \leq 0.75$) sensitive to socket ML and IE rotation (Fig. 3). Specifically, these results indicate that as the lateral rotation of the socket is increased, the magnitude of the resultant hip JRF during early stance is decreased ($r = -0.64$). This finding is of particular interest given DDH is most commonly diagnosed using the lateral coverage of the femoral head (LCEA), making this degree of correction one of the most common in PAO. During late stance (JRF2), the hip JRF was strongly ($r \geq 0.75$) sensitive to AP socket rotation (Fig. 3). Specifically, in late stance when the hip is in extension, the hip joint reaction force in the anterior direction is increased as the orientation of the socket becomes more anteriorly rotated. As the anterior rotation of the socket is increased, the length and moment arm of the rectus femoris is decreased, thus reducing the active force generating capabilities of this muscle, which is associated with an increase in anterior joint reaction force [9]. As a result, the optimization criterion increased recruitment in hip surrounding hip flexors (psoas and iliacus) in order to restore muscle balance within the hip joint. Conversely, because degenerative changes are often observed in the anterosuperior acetabulum prior to surgery, patients with DDH adopt pain avoidance movement compensations to shift joint loading away from this region. The increase in JRF following anterior socket reorientation may indicate that the hip joint is more suitable to support loading patterns more consistent with healthy normal patterns (i.e. normal hip extension).

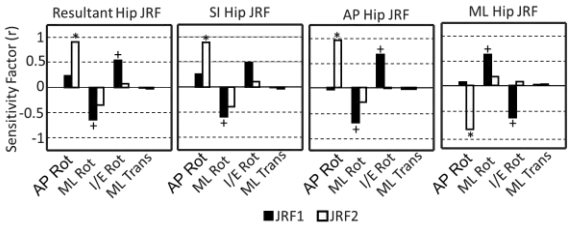

Figure 3. Sensitivity factors correlated between peak hip JRF (JRF1 and JRF2) and acetabular orientation. * Indicates strong correlation ($r \geq 0.75$) and + indicates moderate correlation ($0.5 \leq r \leq 0.75$). Sensitivity factors were calculated with a level of significance of $p \leq 0.05$ and considered statistically significant of the 95% confidence interval did not cross zero.

CONCLUSIONS

A musculoskeletal modeling analysis of the impact of simulated PAO on hip joint reaction force identified the AP alignment of the socket to have the greatest impact on the magnitude and direction of hip JRFs throughout the entire stance period. Furthermore, lateralization of the socket orientation was associated with a decrease in hip JRF. Socket position has a direct effect on muscle moment arms and lines of action because it alters their position relative to the hip joint center. Understanding the sensitivity of the hip joint reaction force to specific alignment can be used to help facilitate optimal alignment of the acetabulum to reduce or shift the hip JRF in patients with DDH. Future work will implement input distributions based on the degree of PAO orientation, and their associated change on hip joint center location, taken from post-operative radiographs.

INTRODUCTION

Walking speed has been determined to be an excellent predictor of physical performance and function in older adults [1]. Walking speed in healthy control subjects has been strongly correlated with most kinematic and kinetic variables including range of motion (ROM), joint angles, ground reaction forces and joint moments [2]. In older adults, certain walking speed cut-offs have been determined in order to be able to determine patient safety with various ambulatory tasks. In order to be able to be considered a safe community ambulator, patients need to achieve a walking speed of 0.8 m/s [3], while those who are able to walk at 0.9 m/s or greater are able to safely complete housework independently [4]. Finally, patients who are able to walk at 1.1m/s are able to successfully and safely carry groceries and complete light yard work [5], while being able to walk at 1.3m/s or faster is an indication of patients being able to cross the street safely [3].

Total ankle arthroplasty (TAA) is a surgical option for the treatment of end-stage ankle osteoarthritis (A-OA). A-OA has been associated with limitations in gait mechanics and walking speed and previous work has indicated that following TAA walking mechanics and walking speed are not returned to the level of age matched controls [6]. Therefore, the purpose of this study was to determine whether TAA patients are able to achieve walking speed benchmarks by one year post-TAA as well as determining what biomechanical measures are correlated with walking speed and finally determining gait mechanics cut-offs that predict the ability for TAA patients to achieve a 0.9m/s walking speed post-TAA.

METHODS

A prospective, pretest/posttest mixed model cohort study was completed during which 197 patients were assessed prior to surgery as well as 1 year following surgery (**Table 1**). Patients were included in this study if they had unilateral A-OA, were able to walk without the use of an assistive device. All patients provided informed written consent prior to participation in this study.

Table 1: Patient Demographics

	Male (n=90, 45.7%)	Female (n=107.54.3%)
Age at Surgery	63.13 ± 8.85	61.73 ± 9.94
Height (m)	1.78 ± 0.7	1.64 ± 0.6
Weight Pre (kg)	90.94 ± 14.96	81.03 ± 18.93
Weight 1yr (kg)	90.78 ± 15.37	81.07 ± 18.67
Surgical Side	R: 40, 44.4% L: 50, 55.6%	R: 58, 54.2% L: 49, 45.8%

Each patient then completed a standard gait assessment with a modified Helen-Hayes marker set using an 8 camera motion analysis system (120Hz) (Motion Analysis Corporation, Santa Rosa, CA) and 4 embedded force plates (1200Hz) (AMTI, Watertown, MA) [6]. Seven barefoot walking trials were collected at a self-selected walking speed with a focus on the surgical limb. Visual 3D (C-Motion, Bethesda, MD) was used to calculate joint kinematics and kinetics. Matlab (Mathworks, Natick, MA) was then used to identify variables of interest including: ankle ROM (A-ROM), peak plantar flexion (PF) moment (Nm/kg), peak plantarflexion (PPF) angle, peak PF power (W/kg), peak weight acceptance (WA-vGRF) and peak propulsive vertical ground reaction forces (P-vGRF).

Correlations between the biomechanical variables of interest and walking speed at 1 year post-TAA was completed using the statistical package R ($p<0.05$ considered significant). Finally, ROC curves were generated to determine the biomechanical outcomes 1 year post-TAA that predict the ability to achieve a 0.9m/s walking speed. Variables with an area under the curve (AUC) >0.8 are considered to have good to excellent prognostic value for the outcome, in this cases a walking speed of 0.9 m/s.

RESULTS AND DISCUSSION

Of the 197 patients, 91.8% achieved a walking speed of at least 0.8 m/s, 85.3% were able to walk at 0.9m/s or greater, 65.0% walked at 1.1 m/s or greater, while only 24.4% achieved a walking speed of 1.3 m/s. Many of the biomechanical variables were correlated 1 year following TAA, however, most of these variables were weakly correlated with the exception of the peak PF moment and the propulsive vGRF. Following TAA, A-ROM was correlated with PPF, and peak PF power, while peak PF moment was correlated with peak PF power, WA-vGRF and P-vGRF. Finally, peak PF power was correlated with WA-vGRF and propulsive vGRF, while, the WA-vGRF and the P-vGRF were also weakly correlated. All variables of interest, except for A-ROM, were weakly correlated with walking speed at 1 year post-TAA (**Table 2)**.

ROC curves were generated for each biomechanical variable to determine cutoff values that needed to be achieved in order to achieve a post-TAA walking speed of 0.9 m/s (**Figure 1)**. The area under the curve (AUC) was used to determine excellent, good, fair and poor ability to predict who could achieve a walking speed of 0.9m/s. The peak PF moment and WA-vGRF demonstrate good AUC results, while the P-vGRF and peak PF power have fair results (**Table 2)**.

The results of this study indicate that following TAA, less than 32% of patients are able to achieve a walking speed of 1.27±0.2 m/s during over ground ambulation, the average walking speed for age matched healthy older adults [7].

In addition, the associations between walking speed and gait mechanics that have been typical in healthy controls do not appear to apply when examining TAA patients, therefore, we cannot assume that changes in specific mechanics will drive changes in walking speed as we are looking to develop post-TAA interventions. For example, A-ROM has been associated with walking speed in healthy control subjects [2], while there is no correlation between these two measures in TAA patients. These patients use varying compensatory patterns to control pain and deal with limited joint motion. This variability could account for some of the challenges in finding measures with good sensitivity and specificity to predict post-TAA walking speed. Therefore, additional measures such as symmetry and proximal joint mechanics should be investigated.

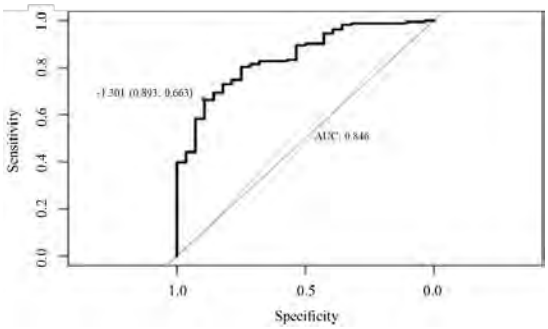

Figure 1: Sample ROC curve results for peak PF moment with a good AUC.

CONCLUSIONS

Associations between walking speed and gait mechanics are affected by pathology and therefore when developing intervention strategies in these populations we cannot assume that changing specific mechanics will change walking speed based on the associations that are present in healthy control subjects.

HOW DOES INTERNAL-EXTERNAL ROTATION OF THE FEMORAL COMPONENT IN TKA CHANGE PATELLOFEMORAL BIOMECHANICS DURING STAIR ASCENT?

[1] Joshua D. Roth, [1] Colin R. Smith, and [1] Darryl G. Thelen

INTRODUCTION

Up to 25% of patients are not satisfied after mechanically aligned (MA) total knee arthroplasty (TKA). One of the common sources of dissatisfaction is post-operative pain[1]. For example, the incidence of anterior knee pain is approximately 8%[2]. While anterior knee pain is a multifactorial problem, internal-external (I-E) rotation of the femoral component is an important intraoperative factor due to its effect on the trochlear groove location and resulting patellofemoral mechanics. Anterior knee pain may arise when an abnormally placed groove alters patellofemoral (PF) motion, giving rise to elevated ligament tension (e.g. the medial, mPFL, and lateral, lPFL, patellofemoral ligaments, also known as medial and lateral retinaculum) and/or elevated PF contact forces.

Accordingly, the objective was to determine how sensitive the tension in the mPFL and lPFL and PF contact forces are to I-E malrotation of the femoral component during stair ascent, which is an activity that often exacerbates anterior knee pain.

METHODS

TKA was virtually performed on a validated, multibody model of the knee[3]. This model included 6 degree-of-freedom tibiofemoral and patellofemoral joints, elastic foundation contact, and bundles of nonlinear spring elements to represent the ligaments. Components were aligned to restore the native joint lines (i.e., kinematically aligned) in the reference rotation because it most closely restored the native anatomy. To account for different alignment targets and possible surgical errors, the I-E malrotation of the femoral component was randomly varied from the reference alignment, which was parallel to the posterior femoral joint line, based on a uniform distribution between ±16°[4] (Figure 1). To account for variability in the soft tissue properties between patients, the stiffness and resting length of the soft tissue restraints of the knee were also randomly varied[5] (Figure 1). This knee model was incorporated into a lower extremity musculoskeletal model with 35 muscles spanning the hip, knee and ankle[6].

Using a high throughput computing grid, a total of 1000 probabilistic simulations of stair ascent were performed with variable I-E malrotation of the femoral component and variable soft tissue

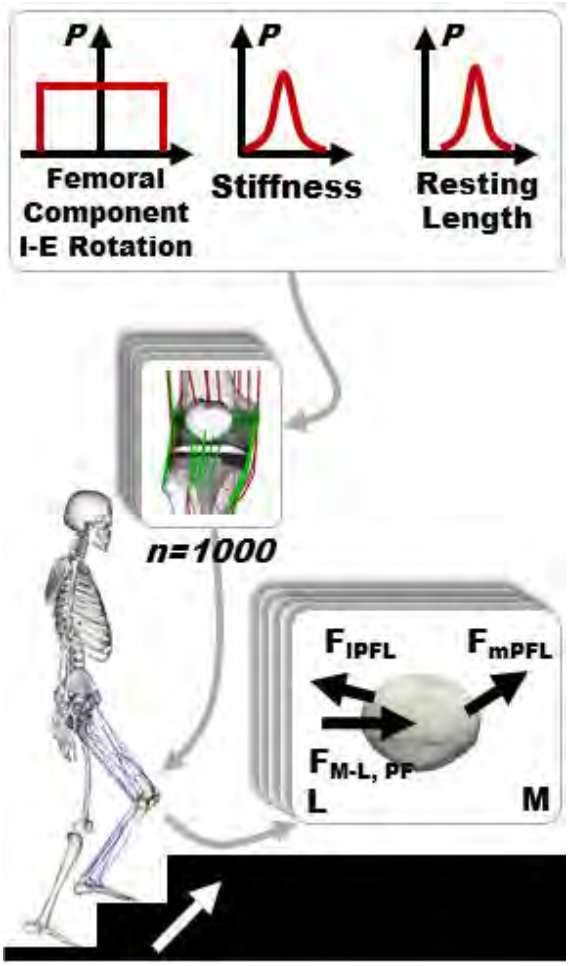

Figure 1. Schematic provides overview about how internal-external (I-E) malrotation of the femoral component along with ligament properties were varied to study the effect of I-E malrotation of the femoral component on patellofemoral biomechanics.

properties. The Concurrent Optimization of Muscle Activations and Kinematics (COMAK) simulation routine was used to calculate the muscle forces and internal knee mechanics needed to generate measured whole body dynamics and ground reactions at each frame of /motion[5].

At peak patellar contact during stance (25% stance, knee flexion = 45°), linear regression was used to assess the sensitivity of (1) the tension in the mPFL and lPFL and (2) the medial-lateral (M-L) component of the patellar contact force to I-E malrotation of the femoral component. Because the mPFL and lPFL became slack over some range of the I-E malrotations of the femoral component, the regressions were performed over the range where the structure was engaged.

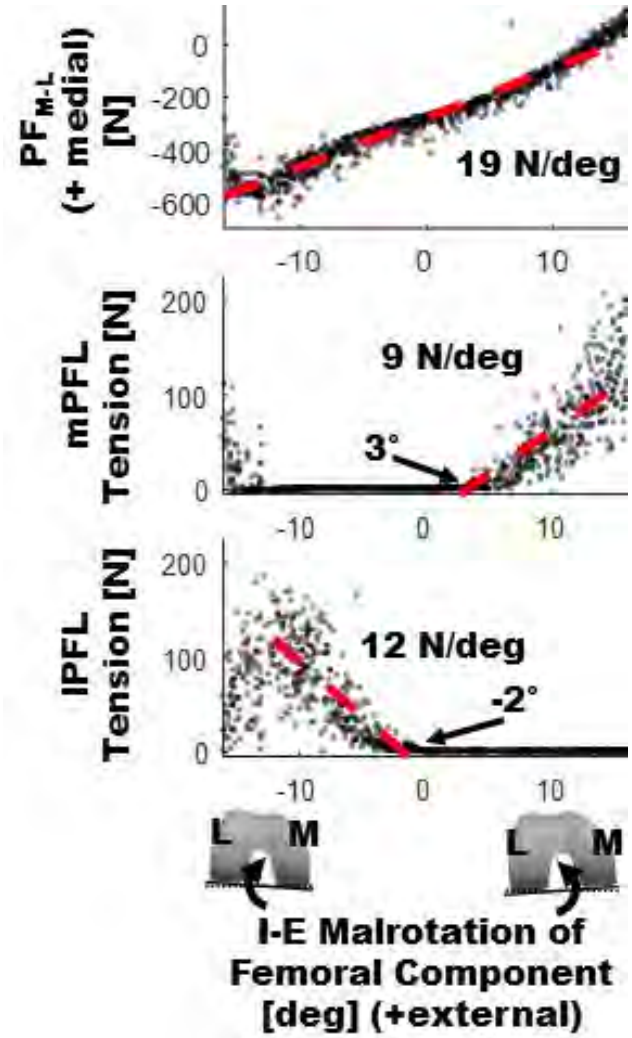

Figure 2. Scatter plots show the sensitivities of the M-L component of the PF contact force (PF_{M-L}), mPFL tension, and lPFL tension to the FC I-E malrotation.

RESULTS AND DISCUSSION

Tension in the mPFL and lPFL and the M-L component of the PF contact force were all highly sensitive to I-E malrotation of the femoral component. External malrotation decreased the M-L component of the PF contact force (19 N/deg, r^2 = 0.8), but engaged the mPFL starting at 3° of external malrotation (9 N/deg, r^2 = 0.7). Internal malrotation both increased the M-L component of the PF contact force and engaged the lPFL starting at 2° of internal malrotation (12 N/deg, r^2 = 0.7). Beyond 12° of internal malrotation, lateral subluxation of the patella began to occur, which is reflected by a drop in the lPFL tension and an increase in mPFL tension.

A major strength of the proposed computational approach is the ability to determine a tolerance for I-E rotation of the FC that results in tolerable tissue loads. These findings indicate that I-E rotations closer to the native posterior femoral joint line might reduce the risk of elevated tensions in the mPFL and lPFL and elevated PF contact forces. Our future work will incorporate variables such as femoral component design, patellar component thickness, and q-angle into our analyses.

CONCLUSIONS

We found high sensitivities of PF biomechanical metrics to I-E malrotations of the femoral component, which is important given that the rotational variability we considered reflects the ranges observed surgically. Moving forward, our probabilistic framework holds promise to determine causal links between I-E rotation of the femoral component and post-operative anterior knee pain to complement clinical observational studies.

BIOMECHANICAL EVALUATION OF MINIMALLY INVASIVE STABILIZATIONS OF PELVIS WITH ACETABULAR LESION

INTRODUCTION

Osteolytic metastatic lesions frequently occur around the acetabulum in cancer patients and can cause structural weakening of the pelvis, leading to pathologic fractures. Acetabular reconstruction through minimally invasive percutaneous techniques has demonstrated clinically efficacy, allowing most patients to achieve full weight-bearing status [1, 2]. Biomechanically, little is known of the effectiveness of these procedures in restoring stability and strength to the pelvic segment during load-bearing activities. The purpose of this study was to evaluate the biomechanical behaviors of three distinct methods of percutaneous acetabular stabilization in the setting of lytic metastatic disease.

METHODS

A customized composite hemipelvis model based on an actual patient's CT-scans was created for this study (Pacific Research Laboratories, Vashon, WA). The model contained a 13 ml defect in the medial and superior acetabulum partially involving the medial and superior acetabular walls consistent with a Harrington type III [3]. Ten identical models were assigned to four study groups: 1) cementoplasty (n=2), 2) percutaneous screws fixation (n=2), 3) cement-augmented percutaneous screws fixation (n=2), and 4) untreated control (n=4). With the aid of a soft tissue torso surrogate, models were stabilized using minimally invasive, fluoroscopically guided percutaneous techniques [1]. For group 1, a cement cannula was advanced into the lesion from a posterior superior iliac spine (PSIS) access site. For group 2, an 8.0x155 mm cannulated, partially threaded ischial screw (Stryker, Asnis III) was placed from an ischial access superiorly through the posterior column and a second 8.0x150 mm posterior-anterior (PA) screw was placed from a PSIS access anteriorly, through the lesion, to the anterior inferior iliac spine (AIIS), bridging the anterior and posterior columns. For group 3, identical screws were placed, with cement injected into the lesion through the PA screw prior to advancing it into the AIIS (Fig.1).

Figure 1: CT-images showing screws trajectories.

Compressive load-to-failure tests were conducted on a servo hydraulic loading frame (MTS Landmark 370, MTS Systems, Eden Prairies, MN). Dental cement was used to pot the iliac wing in a configuration that mimics single-leg support of the mid-stance phase of a gait with 15-degree flexion and 10-degree adduction of the hip. Lateral shift of 5cm was added to the loading point to simulate the lateral displacement of the pelvis as the center of gravity moves closers to the stance leg. A fourth-generation composite femur (proximal half) with good fit to the acetabular socket of the hemipelvis was used to deliver the load to the acetabulum (Fig.2).

Load-to-failure tests were carried out in a series of displacement-controlled ramp loading and unloading runs with incremental displacement, until a failure was observed. Based on pilot tests, displacement steps of 3mm, 7mm, and if needed 10mm were selected. The loading rate was kept at a quasi-static rate of 0.1mm/sec. The axial force and displacement data were measured using MTS built-in loadcell and LVDT sensor and recorded at 100Hz. Yield force, maximum axial deformation, and fixation stiffness

were obtained from the load-displacement plot. Linear regression analysis and Dunnett's test were used to assess the effects of stabilization procedure in comparison to the non-treated controls ($p<0.05$).

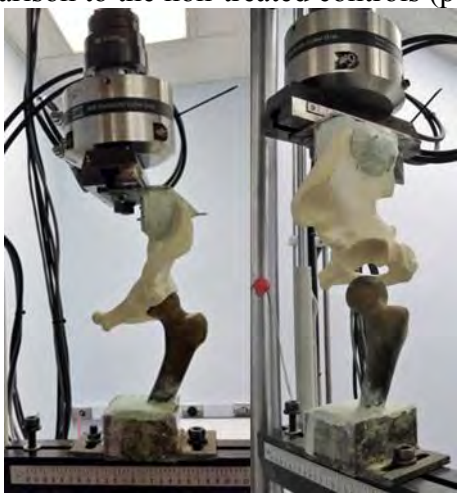

Figure 2: Testing setup.

RESULTS

The ultimate strength of cementoplasty group was the highest, at 4022±1032N, and was 46% higher than the non-treated control ($p=0.048$). Augmented screws fixation was a close second, at 3778±125N, and 37% higher than the control ($p=0.10$). Screws only group was at the same level as the control. Similar pattern was observed with yield strength (Fig.3). All three treatments improved axial stiffness of the hemipelvis, with the highest stiffness from augmented screws fixation, at 1061±123N/mm and was 45% stiffer than the control ($p=0.055$). The improvement in stiffness over the non-treated control was 24% in cementoplasty and 15% in screws fixation ($p>0.10$).

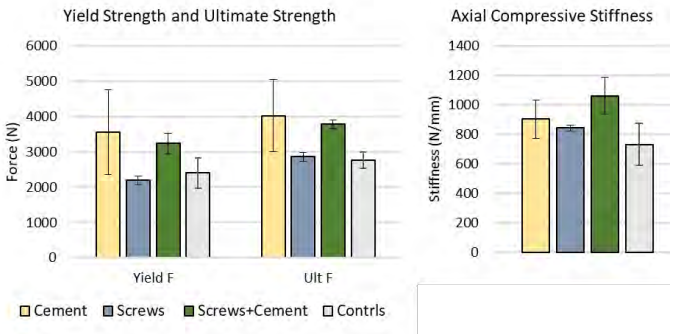

Figure 3: The mean (sd) strengths and stiffness of the three treatment groups and non-treated control.

When visually examining post-test acetabular fracture patterns, it was noted that fractures were initiated at the acetabular dome near the site of lesion and propagated anteriorly to split the acetabular rim. A slight difference was that multiple crack lines formed near the lesion in the non-treated controls, causing partial collapse through the lesion. While in the treated groups, especially ones with cementing, a single crack line ran through center of the dome. However, protrusion of the femoral head was not observed in any of the specimens.

DISCUSSION

Augmented screws fixation demonstrated the highest stability under single-leg weight bearing condition and the least deformation at failure point compared to the other fixation methods. Both cementoplasty and augmented screw fixation were able to restore the axial strength of the hemipelvis to withstand forces up to 5-times of average bodyweight. Screw fixation without cement augmentation showed improvement in stability but not in strength. Findings from the study suggest that percutaneous cement injection improves weight bearing strength by effectively filling the bone defect to prevent collapse of the acetabular wall, while greater segmental stabilization of the pelvis is achieved with screw fixation of the anterior and posterior columns of the acetabulum.

This study was the first to use a customized composite model for biomechanical comparison of percutaneous pelvic stabilization techniques for lytic acetabular metastases. While the loading scenario was simple and quasistatic and sample sizes are limited, consistency in mechanical behaviors was demonstrated, suggesting a reasonable model to evaluate more complex stabilization techniques.

IS KNEE BIOMECHANICS DIFFERENT DURING UPHILL WALKING OF DIFFERENT SLOPES BETWEEN OLDER ADULTS WITH AND WITHOUT TOTAL KNEE REPLACEMENT?

[1]Chen Wen, [2]Harolds E. Cates, [1]Songning Zhang
[1]Biomechanics/Sport Medicine Lab, The University of Tennessee, Knoxville, TN, USA
[2]Tennessee Orthopedic Clinics, Knoxville, TN, USA

INTRODUCTION

Uphill walking is an inevitable part of daily living and causes higher knee joint loading compared to level walking [1]. Previous gait analyses during uphill walking have only focused on young healthy populations [2,3]. Currently, no studies have explored knee kinematics and kinetics for uphill walking in total knee replacement (TKR) patients. Furthermore, uphill walking has been integrated into rehabilitation protocols after TKR surgery [4]; therefore, a comprehensive biomechanical analysis of its benefit for this population is warranted. The purpose of this study was to compare knee biomechanics of the replaced limb to the non-replaced limb of TKR patients and healthy controls during walking on level ground and inclined surfaces of 5°, 10° and 15°. The information from such a study may help physical therapists creating appropriate rehabilitation protocols and optimizing total knee prosthesis designs.

METHODS

Twenty-five TKR patients were recruited from a local orthopedic clinic (68.8 ± 4.9 years, 1.70 ± 0.11m, 83.2 ±15.6 kg, 22.1 ± 11.72 months since surgery). The inclusion criteria for TKR patients were having a unilateral total knee replacement (conducted by a single surgeon) between 6 months and 60 months and between the ages of 50 and 75 years. Potential participants were excluded if they had any additional lower extremity joint replacements, any additional diagnosed osteoarthritis (OA) of the hip or ankle, severe OA at the contralateral knee of TKR, BMI greater than 38, or neurological diseases. Ten older adults between the ages of 50 and 75 years without any lower extremity pathology participated in the study as healthy controls (69.1 ± 4.5 years, 1.74 ± 0.12 m, 75.0 ± 23 kg).

Three dimensional (3D) kinematic data were collected using a 12-camera motion capture system (240 Hz, Vicon). A customized instrumented ramp system consists of a walkway that is 1 m wide and 3 m long and with two separate walking surfaces/structures bolted on to two force platforms (1200 Hz, AMTI). The inclined angle of ramp surfaces can be adjusted to 5°, 10° and 15°. Gait speeds were monitored by two sets of photocells and two electronic timers (Lafayette Instrument Inc.), placed 3 meters apart for level walking, and 1.5 meters apart at shoulder height for ramp walking. Visual 3D (C-Motion) was used to compute 3D kinematics and kinetics. Kinematic and GRF data were smoothed at a cutoff frequency of 8 Hz using a fourth-order zero-lag Butterworth low-pass filter. All joint moments were computed as internal moments.

A 2 x 2 x 4 (limb: replaced, non-replaced limb x group: TKR and healthy controls x incline slope: 0°, 5°, 10° and 15°) mixed model ANOVA was used to examine the interactions and main effects of selected dependent variables ($p<0.05$, SPSS 24.0). When the ANOVA showed a significant three-way interaction, two-way ANOVAs were followed. When two-way ANOVAs showed significant interaction or main effect, post-hoc comparisons with Bonferroni adjustments were used to detect differences between limbs and slopes.

RESULTS AND DISCUSSION

There were no differences of age, height, and mass between TKR and healthy groups. TKR patients had greater BMI than healthy controls ($p=0.014$). Participants walked significantly faster on level ground than on 5°, 10° and 15° ramp, respectively ($p<0.002$). No differences of speed in all slope conditions were found between TKR and healthy groups.

A significant limb×slope×group interaction was detected in knee extension range of motion (ROM) ($p=0.01$, Table 1). In follow-ups, a significant limb×slope interaction was found for TKR patients

(p=0.015) and a significant slope×group interaction for replaced limb (p=0.019). Post hoc comparisons showed that non-replaced knees had greater extension ROM than replaced knees in 10° uphill walking (p=0.049). Knee extension ROM increased significantly as the incline angle increased in both TKR replaced and non-replaced limbs and both limbs of healthy controls (p<0.002 for all comparisons). Both TKR replaced and non-replaced limbs had smaller knee extension ROM than their respective matched limbs of healthy controls in all uphill conditions (p<0.016).

Significant limb×slope interaction (p=0.006), group (p=0.019) and limb (0.008) main effects were found for peak knee extension moment (KEM, Table 1). In replaced limbs, the peak KEM was greater in 15° compared to level and 5° uphill walking (p<0.012) and was greater in 10° compared to 5° uphill walking (p=0.002). In TKR non-replaced limbs, the moment was greater in 15° uphill compared to level walking, 5°, and 10° uphill walking respectively (p<0.009 for all comparisons). The moment was also greater in 10° compared to level and 5° uphill walking, respectively (p<0.001 for all comparisons). It was also smaller in replaced limbs compared to non-replaced limbs in 10° (p=0.002) and 15° (p<0.001) uphill walking. TKR patients had lower peak KEM than healthy controls (p<0.021). A significant slope main effect was observed for peak loading-response knee abduction moment (KAbM, p=0.009, Table 1). The peak loading-response KAbM was greater in level walking compared to 10° (p=0.013) and 15° (p=0.003) uphill walking.

The results from this study demonstrated that TKR patient had lower knee extension ROM and peak KEM than healthy controls during uphill walking. In addition, knee extension ROM increased significantly as the incline angle increased. The peak KEM was greater in uphill walking compared level uphill walking. The peak loading-response KAbM was greater in level walking compared to uphill walking. Uphill walking may have the potential to become a safe rehabilitation exercise for unilateral TKR patients. But it should be avoided walking on a 10° or steeper slope in rehabilitation exercises.

A CROSS RECURRENCE QUANTIFICATION ANALYSIS OF HIP MUSCLE EMG COUPLING DURING STEP-DOWNS

John H. Hollman, Nicholas J. Beise, Michelle L. Fischer and Taylor L. Stecklein

Mayo Clinic College of Medicine and Science, Rochester, MN, USA
email: hollman.john@mayo.edu

INTRODUCTION

Neuromuscular control, operationally defined as the non-consciously regulated recruitment of muscles in preparatory anticipation of or reactionary response to joint movements or loading conditions for the purpose of maintaining functional joint stability [1], may be assessed in part with electromyography (EMG). Impaired neuromuscular control of hip muscles may contribute to movement coordination deficits of the lower extremity.

We reported previously that gluteus maximus (GMax) recruitment and hip extensor strength modulate transverse plane hip and frontal plane knee kinematics during a jump-landing task [2]. Similar EMG findings are corroborated by others [3]. We propose that examining coupled GMax and gluteus medius (GMed) recruitment may provide a greater understanding of the extent to which hip neuromuscular control influences lower extremity kinematics than merely examining muscle strength or EMG recruitment magnitudes.

We examined coupled GMax/GMed recruitment using cross recurrence quantification analyses and their contribution to variability in frontal plane hip kinematics during single-limb step-downs.

METHODS

30 healthy adults (20 women and 10 men, mean age 23.5 ± 1.5 years, mean BMI 24.3 ± 3.1 kg/m^2) participated. Isometric hip extensor strength was measured with a handheld dynamometer. Hip and knee kinematics during 20 step-downs from a 19-cm step were acquired at 100 Hz with a Vicon MX system. We used the Plug-in-Gait marker system to model lower extremity segments and Nexus software to quantify pelvis and lower extremity kinematics. Marker trajectories were filtered with a Woltring quintic spline filter (20-mm mean square error). GMax and GMed EMG signals were captured at 1000 Hz with bipolar surface electrodes and a Bagnoli-16 amplifier. Signals were band-pass filtered between 20 and 450 Hz with a fourth-order Butterworth filter and processed through a root-mean-square (RMS) algorithm with 100 msec time constants and sliding windows with 90% overlap.

To examine GMax/GMed recruitment coupling, we used cross recurrence quantification analyses (cRQA) described by Webber & Zbilut [4]. Briefly, cRQA examines characteristics of two time series embedded in a reconstructed phase space containing sufficient dimensions to define the system's state. According to Takens [5], that phase space may be reconstructed with time delayed copies of the series. We used a time delay of 60 samples based on average mutual information functions, 3 embedding dimensions based on global false nearest neighbors analyses, and a radius at 20% of a SD.

We examined the following measures:

- Determinism (DET): proportion of recurrent points that fall on diagonal lines of 2 or more points in a cross recurrence plot; represents the predictability of coupling between two signals.
- Divergence (DIV): estimates rates at which coupled trajectories in the phase space diverge; an indication of chaos in coupled signals.
- Shannon entropy (ENT): probability the length of diagonal recurrence lines will be repeated in the cross recurrence plot; estimates variety of patterns in which two signals are coupled.

Multiple regression ($\alpha = .05$) and partial correlation coefficients were used to examine relationships between variability in frontal plane hip data (SD of peak hip adduction angles) and (1) isometric hip extension strength, (2) mean GMax and GMed recruitment, normalized to maximal voluntary

isometric contraction (% MVICs) and (3) DET, DIV and ENT in coupled GMax/GMed recruitment patterns.

RESULTS AND DISCUSSION

Participants performed the task with 52.9 ± 10.1° of hip flexion, 18.3 ± 5.9° hip adduction, 72.2 ± 7.2° knee flexion and 5.2 ± 13.0° knee valgus. Mean GMax and GMed recruitment was 15.4 ± 9.9 and 18.1 ± 11.6% MVIC, respectively. The coupled GMax/GMed recruitment patterns were 74.4 ± 9.9% deterministic with a divergence exponent of .05 ± .03 and a Shannon entropy of 2.11 ± .51 bits/bin (see Fig. 1 for representative example).

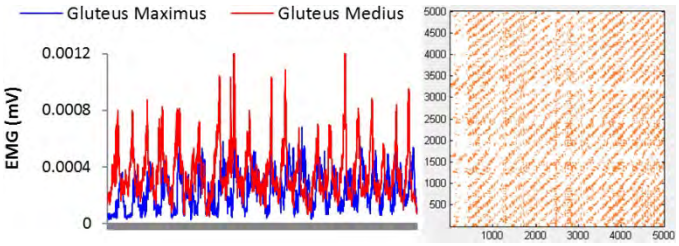

Figure 1: GMax and GMed EMG signals, with cross recurrence plot.

The multiple regression model accounted for 39.4% of the variance in peak hip adduction SDs during the step-downs (cumulative R^2 = .394, p = .044). Per Fig. 2, variance in hip adduction correlated with ENT (r = .554, p = .011) and DET in coupled GMax/GMed recruitment (r = -.487, p = .029). Variance in adduction SDs was not significantly correlated with hip extensor strength, mean GMax recruitment or mean GMed recruitment (partial r = .148, .351 & .019; p = .534, .130 & .937, respectively).

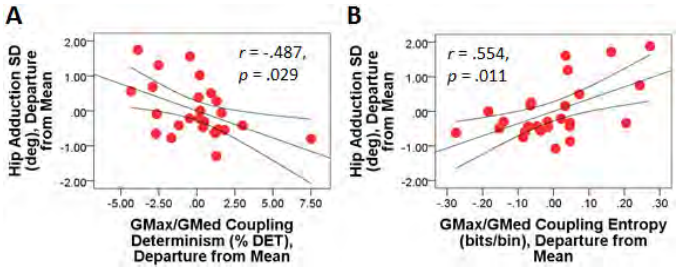

Figure 2: Partial correlation between hip adduction variability and GMax/GMed coupling determinism (A) and entropy (B).

Hip extensor strength, GMax recruitment and GMed recruitment suppressed the zero-order correlations between variability in peak hip adduction angles and entropy and determinism in the coupled GMax and GMed recruitment patterns. When strength and recruitment magnitudes were controlled, however, those relationships increased. Participants with greater variability in peak hip adduction performed the step-downs with greater entropy and lesser determinism in coupled GMax/GMed recruitment. Lesser predictability (decreased DET) and greater irregularity in the variety of patterns in which GMax and GMed recruitment patterns are coupled (greater ENT) may give rise to greater variation in frontal plane hip motions and may have implications for neuromuscular control mechanisms that contribute to movement coordination deficits.

CONCLUSIONS

Variability in peak hip adduction during single-limb step-downs correlated more strongly with determinism and entropy in coupled GMax and GMed recruitment patterns than with participants' hip extensor strength or their magnitudes of muscle recruitment. Examining coupled GMax and GMed recruitment patterns through cross recurrence quantification may provide a greater understanding of the extent to which neuromuscular control of hip muscles modulates lower extremity kinematics than merely examining muscle strength or EMG recruitment magnitudes.

INTRODUCTION

Obesity is a well-documented risk factor for knee osteoarthritis (OA) [1]. Among obese individuals, knee pain is prevalent. How the knee pain, in addition to existing obesity, contributes to the cartilage contact characteristics, such as cartilage contact deformation and cartilage contact area of the knee will provide insight into the pathomechanics of knee OA and may help us determine potential modifiable factors targeting the obese individuals with or without knee pain. In this study, we aimed to investigate the articular cartilage contact deformation in obese individuals with and without knee pain.

METHODS

Eighteen obese individuals knee pain on most days (15 females, 3 males; age: 42.4±9.4yrs; body mass index (BMI): 39.5±2.5 kg/m^2; pain level (0-100): 63.8±17.4) and seven obese individuals without knee pain (6 females, 1 male; age: 40.1±9.8yrs; BMI 37.1±2.1 kg/m^2) were recruited for this study. This study protocol was approved by the Institutional Review Board at Boston University. Each subject provided written informed consent.

One knee from each subject was selected for MR scan using a 3-Tesla machine (Philips, Achieva, Eindhoven, The Netherlands). The imaging protocol was a Proton Density-Weighted (PDW), Spectral Attenuated Inversion Recovery (SPAIR) sequence with a slice thickness of 1mm and image resolution of 512x512. For an individual with knee pain, the knee with more pain was scanned; for an individual without knee pain, the knee was chosen randomly. The MR images were reviewed and manually segmented to construct the 3-dimensional (3D) subject-specific bone and cartilage surface models for each subject.

Each subjects walked on a treadmill at 1.5 mph (0.67 m/s), and the MR-scanned knee was imaged by a dual fluoroscopic imaging system (Philips, BV Pulsera, Eindhoven, The Netherlands) at 30 Hz with 8ms pulse width. The knee position was processed through a 2-Dimensional to 3D registration procedure. The femoral and tibial cartilage models were mapped to the corresponding bone models at each knee position for cartilage contact analysis. The cartilage contact was represented by the overlapped surfaces of the tibial and femoral cartilage models. In this fashion, we were able to calculate cartilage contact deformation, cartilage contact area (mm^2), and thickness at the contact location [2]. Cartilage deformation was calculated by the amount of penetration of the cartilage surface models divided by the thickness of cartilage models at the same location (mm/mm) [2]. Cartilage thickness (mm) was calculated in the regions of contact.

Independent t tests were used to test the difference in the contact deformation, contact area, and cartilage thickness at contact locations between the obese groups with and without knee pain using MATLAB 2014b (MathWorks, Natick, MA). The analyses for medial and lateral compartments were performed separately. All tests were considered statistically significant when the p-value was less than 0.05.

RESULTS AND DISCUSSION

The cartilage deformation in both medial and lateral compartments was about 0.3 mm/mm (~30%) during the stance phase of the gait cycle. There was no significant difference between obese individuals

with and obese individuals without knee pain **(Fig 1A, 1B).**

In the cartilage thickness analysis, there was no significant difference between the two groups, suggesting that during the stance phase of the gait cycle the loading was consistently transmitting through the regions with similar thickness on both tibial and femoral cartilage **(Fig 1C-1F)**.

In terms of contact area, the two groups with obesity had similar contact area in both medial and lateral compartment at heel strike **(Fig 1G, 1H)**. Thereafter, the obese group without knee pain showed a tendency to increase the contact area and maintain the increase until the end of the stance phase when compared with the obese group with knee pain. This suggests that obese individuals without knee pain may distribute the joint load better than those with knee pain.

CONCLUSIONS

Obese individuals with knee pain had less cartilage contact area during the stance phase of the gait cycle than obese individuals without knee pain, but were not different in terms of the cartilage contact deformation or the thickness at contact location. These contact characteristics explain partly why some obese individuals experience knee pain while others do not..

INTRODUCTION

Knee Osteoarthritis (KOA) is a painful and debilitating disease associated with mechanical loading in the medial compartment of the knee joint [1]. Unloader braces, a prevalent conservative treatment option for KOA, apply a brace abduction moment (BAM) to reduce the knee adduction moment (KAM) which is associated with medial compartment knee loading. While benefits of knee braces have been demonstrated in multiple studies, their efficacy is potentially limited by tolerable BAM magnitude, and/or brace discomfort leading to poor patient compliance [2]. Considering that the BAM is intended to reduce knee load during a small portion of the total time a brace is worn (stance phase), and that larger BAMs cause user discomfort leading to poor compliance, modulating the BAM so that it is present only during stance may improve comfort and compliance. With the advent of wearable lower limb exoskeletons, and robotic orthoses, it follows that an active robotic unloader brace may better control the KAM and improve patient comfort and brace use. The purpose of this study was to design and develop an offboard controlled robotic unloader knee brace and to measure the range of BAMs it can produce during steady state walking. Development of such a brace will provide a tool for exploring the effects of active knee joint unloading on KOA to inform the investigation of novel treatment methods.

METHODS

Active Brace System Design

The system is conceptualized as a three-point bending brace actuated via an offboard actuation system through a Bowden cable. An unloading mechanism was designed and fit to a modified off-the-shelf (OTS) brace (Fig. 1). The offboard actuation system, comprised of a motor, controller, gearing stage, and chassis, was designed to meet the performance criteria required for modulating knee brace load through a range of 0 to 10 Nm during the gait cycle (GC). The brace was instrumented with a load cell located at the brace condyle pad to directly measure the force transmitted through the brace to the user and to calculate the BAM.

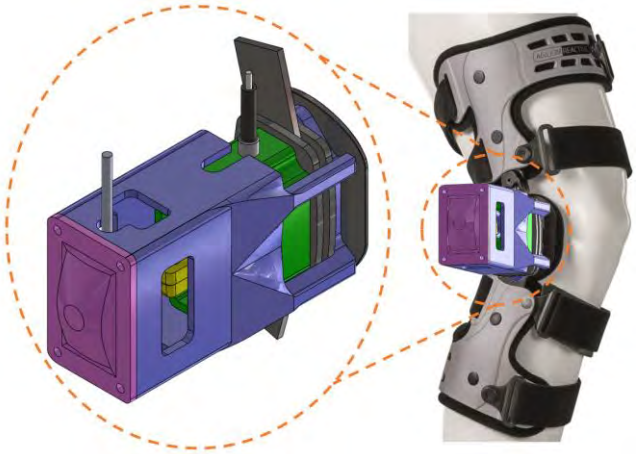

Figure 1: Mechanical design of active knee brace. The knee condyle pad is driven medially to produce a frontal plane KAM that is measured with a load cell in series with the condyle pad.

Human Subject Testing

One male subject diagnosed with medial knee osteoarthritis was recruited for this IRB approved study at the VA Puget Sound Health Care System. Following informed consent, the subject was fitted with the active brace and underwent walking trials. While wearing the active brace, the subject walked at self-selected speed on a split-belt instrumented treadmill under four active BAM conditions: (1) minimum, (2) low, (3) medium, and (4) high. For the fifth (5) condition, the active brace was decoupled from the offboard system and set to operate like a commercially available OTS brace. A constant electrical current command (manual input of Fig. 2) was sent to the motor during walking trials in conditions (1-4). For the minimum condition, the input was tuned to the lowest current level that yielded a non-zero load at the brace. Low, medium, and high levels were scaled from the minimum level, and selected to encompass the abduction moment range of commercially available passive braces.

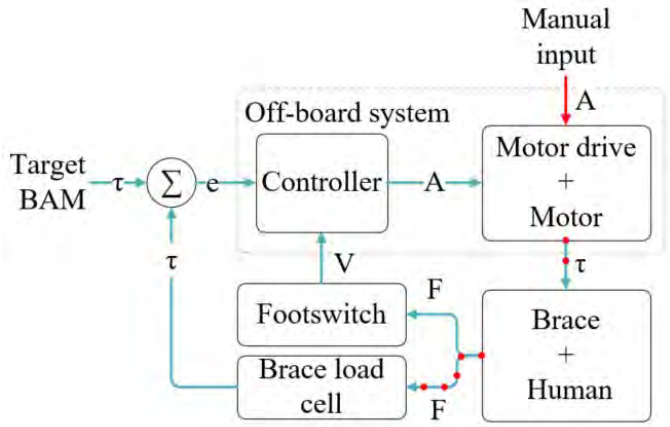

Figure 2: Open-loop and closed-loop brace control schemes, where V=volts, e=error, A=amps, τ=torque, F = force. The open-loop scheme (red, red/blue lines) was used in this experiment.

Condition (5), the passive mode, is representative of the current standard in bracing, where the unloading mechanism was fixed, and the brace tuned to a static position using the native OTS functionality of the brace. The brace force was adjusted to approximate the magnitude of the medium active condition (condition 3). Ground reaction force and brace load cell data were collected at 1200 Hz and filtered using a 4th-order low-pass Butterworth filter with 60 and 40 Hz cutoff frequencies, respectively. BAM was calculated from load cell measurements and brace geometry with the following equation:

$$BAM = F_m(L_{ls} - \frac{L_{ls}^2}{L_b})$$

where F_m is the force measured at the load cell, L_b the brace length, and L_{ls} the length from the lower strap to the condyle pad.

RESULTS AND DISCUSSION

Minimum, low, medium high, and passive conditions resulted in mean ± 1 standard deviation BAMs of 0.004±0.001, 0.028±0.002, 0.048±0.005, 0.073±0.006, and 0.047±0.002 Nm/kg, where means are calculated for first to second peak GRF, 20-50% of GC (Fig. 3). The minimum condition exhibited desirable mechanical transparency, maintaining a near zero BAM. The results indicate that a range of current inputs yielded a proportional range of BAM output. Although current input commands were constant within conditions, the BAM magnitude notably fluctuated over the GC. Bowden cable friction, frontal plane knee kinematics, and muscle contraction (soft tissue compliance under the straps) are likely factors that contributed to the shape of the BAM across the GC. A closed loop control scheme (Fig. 2) will subsequently be implemented for real-time intra step BAM control.

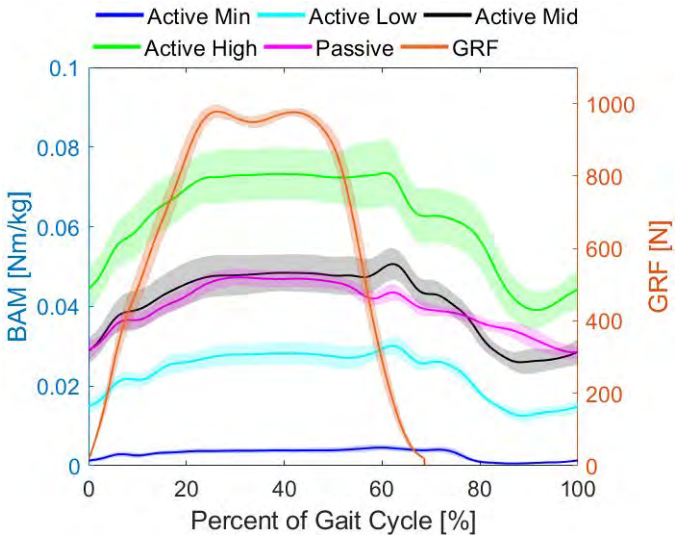

Figure 3: Average ± one standard deviation BAM and vertical GRF for the five study conditions.

In previous studies, mean BAMs of 0.065 Nm/kg for first peak GRF, 0.064 Nm/kg for second peak GRF [3], and 0.04 Nm/kg for first to second peak GRF [4] have been reported for OTS braces. The active brace system therefore achieved BAM magnitudes comparable to commercially available braces.

CONCLUSIONS

The realized active brace varied BAM on a KOA subject proportional to a range of inputs transmitted by an offboard actuation system. The system therefore exhibited desirable performance for a closed-loop active brace capable of exploring the effects of BAM modulation for KOA.

EFFECTS OF DYSPLASTIC PELVIS MORPHOLOGY ON HIP MUSCLE LINES OF ACTION, MOMENT ARM LENGTHS, AND CONTRIBUTIONS TO JOINT REACTION FORCES

Ke Song, Brecca M. M. Gaffney, Cecilia Pascual-Garrido, and Michael D. Harris

Washington University School of Medicine, St. Louis, MO, USA
Email: harrismi@wustl.edu

INTRODUCTION

Developmental dysplasia of the hip (DDH) is characterized by abnormal pelvic morphology, including a shallow acetabulum, insufficient femoral coverage, and lateralized hip joint center (HJC) [1]. Such deformities result in altered hip intra-articular loading, which leads to damage in the labrum and articular cartilage, and increases the risk of early development of hip osteoarthritis [1].

In addition to bony deformity, hip joint loading is also affected by the force and torque generation of muscles spanning the hip. Specifically, joint reaction forces (JRF) are dependent upon muscle lines of action (LoA) and the corresponding moment arm lengths (MAL) [2]. However, the effects of abnormal pelvis morphology on these parameters in patients with DDH remains unknown. Because muscle paths and forces are difficult to measure *in vivo*, musculoskeletal models can be used to analyze their biomechanical roles in hips with deformity. Our objective was to quantify the effects of dysplastic pelvis morphology on hip muscle LoAs, MALs, and force contributions to JRFs during gait. We hypothesized that compared to healthy hip, a dysplastic hip with more lateral HJCs would have smaller abductor MALs, more medially-directed LoAs, higher medial muscle forces and hip JRFs.

METHODS

First, a musculoskeletal model was created with pelvis morphology of a representative healthy young adult. Specifically, 3D pelvis geometry, HJC locations and hip muscle paths were derived from CT images of a healthy subject [3], who had no previous lower extremity pathology or injury, and had pelvis radiographic measures in normal ranges (**Table 1; Fig. 1A**). An established OpenSim model with 23 degrees of freedom (DoF) and 96 muscle-tendon units (simtk.org/projects/hip_muscles) was modified by incorporating the subject-specific pelvis geometry, HJCs and muscle paths. Kinematic and force data from barefoot gait for this healthy subject were used to calculate muscle forces and JRFs during a gait cycle via inverse kinematics, residual reduction analysis and static optimization, as documented [3].

Table 1: Demographics & hip geometric characteristics.

	Age /Sex	BMI	LCEA	AI	ACEA	HJC (cm)		
						AP	SI	ML
Healthy	28/M	24.3	31.7°	4.8°	32.5°	-6.1	-6.8	8.8
DDH	23/M	26.2	-2.7°	35.9°	-2.5°	-6.1	-7.2	9.7

LCEA = lateral center-edge angle; AI = acetabular inclination; ACEA = anterior center-edge angle. HJC are from pelvis origin to right hip (affected side of DDH; matched side of healthy).

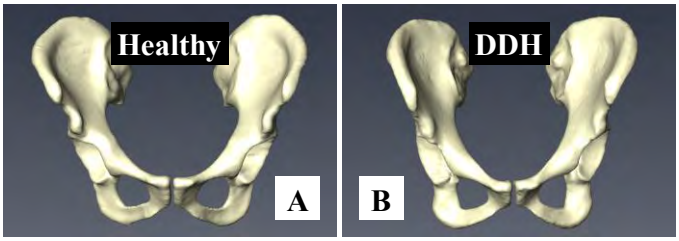

Figure 1: Pelvis geometry of (**A**) a representative healthy young adult and (**B**) a patient with DDH, characterized by a shallow, upwardly sloped acetabulum (high AI) and poor antero-lateral femoral coverage (low LCEA and ACEA).

Next, a representative DDH model was created using 3D geometry from a patient with DDH [3] (**Table 1; Fig. 1B**). Pelvis geometry and HJC locations of the healthy subject were substituted for the DDH pelvis; muscle paths, optical fiber lengths, and tendon slack lengths were then updated accordingly. To directly assess the effects of DDH pelvis morphology on LoA, MAL, muscle force and JRF, model inertial properties were maintained from the healthy model, and analyses were re-run with experimental kinematic and force data from the healthy subject.

Effective muscle LoAs were computed with wrapped paths taken into account [4]. LoA was expressed as a unit vector in antero-posterior (AP), supero-inferior (SI), medio-lateral (ML) components of the pelvis frame, which represented a muscle's potential to

contribute force in these directions (directional contribution) [2]. Muscle forces were then resolved by each LoA component. Lastly, muscle MALs in each hip DoF were computed using a generalized force method [5]. MALs, directional contributions, and estimated forces of iliopsoas, rectus femoris, tensor fascie latae, and gluteal muscles were compared between healthy and DDH models.

RESULTS

Results from the 3 muscle-tendon units that contributed more than 10% of hip JRF peak (Jp) are reported: anterior fibers of gluteus medius (GMedAnt), rectus femoris (RF), and iliacus (IL).

Hip muscle MALs in DDH differed from healthy mainly in hip flexion and adduction (**Fig. 2**). Flexion MAL of RF and abduction MAL of GMedAnt both decreased. Additionally, both RF and IL switched from abduction to adduction roles during stance.

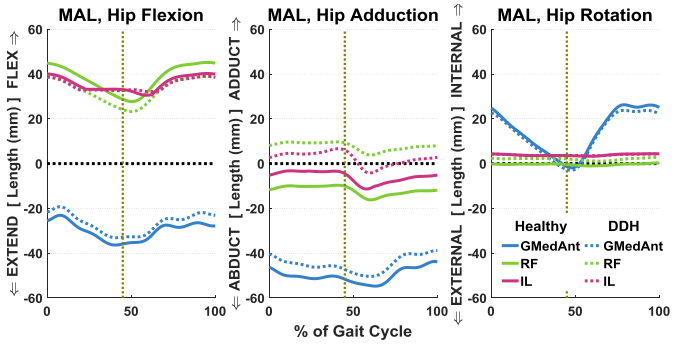

Figure 2: MALs for hip flexion, adduction, and rotation. Vertical band = time of Jp (JRF peak).

Muscle directional contributions in DDH differed from healthy primarily for IL and GMedAnt, with little changes for RF (**Fig. 3**). Most notably, both GMedAnt (0.05 to 0.20 at Jp) & IL (0.03 to 0.09 at Jp) became more medially directed.

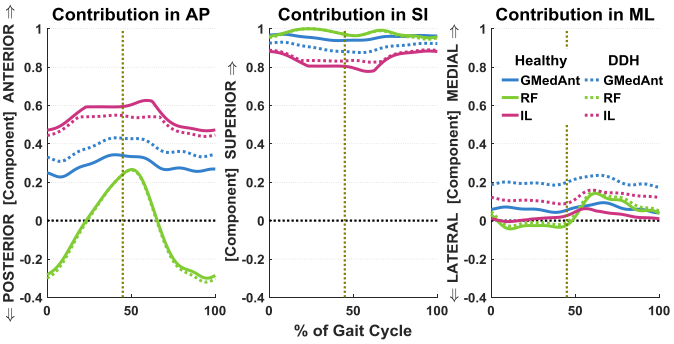

Figure 3: Hip muscle force directional contributions. Vertical band = time of Jp (JRF peak).

All muscle force components in DDH increased (**Fig. 4**). In particular, medial IL and GMedAnt forces raised by 308% and 535% respectively at time of Jp. Correspondingly, hip JRF and its components also increased (by 43% in resultant, 183% medially at Jp).

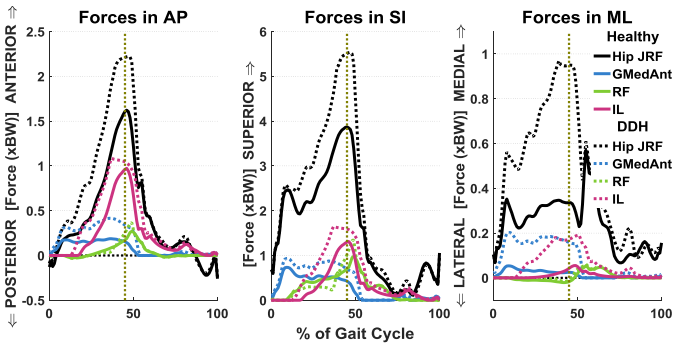

Figure 4: Hip muscle forces and JRFs. Vertical band = time of Jp (JRF peak). Note different vertical scales.

DISCUSSION AND CONCLUSIONS

DDH pelvis morphology had considerable effects on muscle LoAs, MALs, and force contributions to JRFs during gait. Reduced flexion MALs demanded higher force from hip flexors (e.g. by 45% at Jp for RF), which also switched to adduction MALs in the frontal plane due to a lateralized HJC. Consequently, the flexors could tend to abnormally adduct the hip during stance, while the abducting MAL of GMedAnt decreased simultaneously. Both required the hip-stabilizing abductor force to be also higher. As a result, increased forces from both hip flexors and abductors raised hip JRFs in multiple directions. Additionally, lateralized HJC caused muscles with shorter LoAs (e.g. GMedAnt and IL) to direct and contribute force more medially. This could further increase ML hip muscle forces and JRF, which supports our hypothesis and a recent DDH study [3]. To conclude, dysplastic pelvis morphology altered hip muscles' directional force contributions and ability to generate torques, which corresponded to higher hip JRFs on the acetabulum. Despite limited by 1-on-1 comparison, these representative findings provide insights to pathomechanics of DDH and may inform interventions aimed at establishing a normal hip biomechanical environment.

IMPACT OF EXERCISE-INDUCED PAIN ON TIBIOFEMORAL CONTACT FORCES IN KNEE OA

[1] Ethan Steiner and [1, 2] Katherine A Boyer

[1] University of Massachusetts Amherst, Amherst, MA, USA
[2] University of Massachusetts Medical School. Worcester, MA, USA
Email: esteiner@umass.edu

INTRODUCTION

Knee osteoarthritis (OA) is a chronic degenerative condition marked by pain and stiffness that can fluctuate widely over time, often as a result of weight bearing activity [1]. Pain fluctuations brought on by weight bearing activity have been associated with inferior physical performance and increased risk of falling [2]. As this exercise-induced pain represents a significant component of the overall pain experienced by individuals with OA, there is a need to understand the associated biomechanical response to determine the potential consequences on physical function and knee joint health.

One of the challenges of quantifying the relationship between gait mechanics and pain in OA is that gait mechanics may be a stimulus for pain and/or change as a result of the motor system's response to pain. Prior work has found an association between the knee adduction moment and overall symptom severity [3], suggesting greater joint loading results in more severe symptoms. However, it's also possible that greater structural changes from tissue degeneration in those with more severe disease leads to greater loading. Therefore, to probe the relationship between pain and gait mechanics in knee OA, the aim of this study was to examine the effects of pain induced by multiple bouts of treadmill walking on the joint moments and forces in patients with symptomatic knee OA.

METHODS

Six adults with mild-to-moderate physician diagnosed symptomatic knee OA were included in this analysis. Inclusion criteria were ages 50-75 years, BMI < 35 kg/m^2, good general health, ability to walk unaided, and have no history of cardiovascular or neurological disorders. Participants completed an IRB approved informed consent document prior to starting the study.

Treadmill protocol: Participants completed two separate 20 minute treadmill walks at: 1) preferred walking speed; and 2) faster than preferred speed. In between, participants rested for 40 minutes. The protocol was designed to simulate walking that occurs during daily living with a rest time to minimize fatigue. Perceived knee pain was evaluated on an 11 point numerical pain rating scale at the start and end of the treadmill protocol with a change in pain level ≥ 1 considered to be clinically significant.

Data Collection: Overground walking mechanics were quantified before and after the treadmill protocol. Participants completed 3 overground walking trials over a 25m walkway at a preferred pace, while kinematic and kinetic data was collected. Electromyography (EMG) was collected during the treadmill protocol for the rectus femoris, vastus lateralis, vastus medialis, biceps femoris, and semitendinosus.

Data Processing: A custom MATLAB program was used to calculate external knee joint moments via inverse dynamics for each trial. OpenSim was then used to estimate tibiofemoral force [5]. A musculoskeletal model consisting of 23 degrees of freedom and 92 muscles [6] was scaled to a static trial for each participant. The three walking trials before and after the treadmill protocol were processed using inverse kinematics. Next, a residual reduction algorithm was performed to ensure dynamic consistency between model kinematics and ground reaction forces. Static optimization was then performed for each trial to estimate muscle forces. Following static optimization, OpenSim's JointReaction analysis tool was used to estimate tibiofemoral compressive forces. Experimental EMG was compared visually to estimated muscle activation produced by OpenSim to improve confidence in the simulation results. Paired t-test were used to assess the changes in peak knee joint moments and forces pre and post exercise ($p \leq 0.05$).

RESULTS AND DISCUSSION

All participants experienced clinically significant increases in knee pain (2.33 ±0.33). There were significant increases in the peak external knee flexion moment ($p = 0.025$) but no differences in 1st or 2nd peak knee adduction moments following the treadmill protocol (Figure 1). The external knee flexion moment has been considered as a surrogate measure for the total joint forces [7], thus suggesting an increase in the joint forces in early stance. However, analysis of the musculoskeletal modelling results indicated that there was no significant change in the 1st peak tibiofemoral joint force but there was significant increase in the 2nd peak force ($p = 0.016$) following the treadmill protocol (Figure 2).

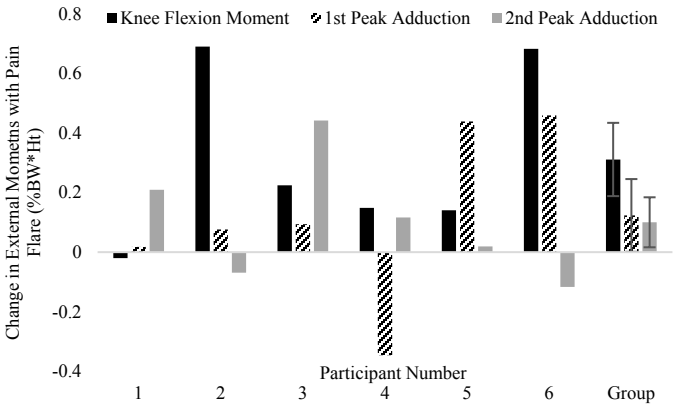

Figure 1: Change in external knee joint moments in response to the treadmill protocol for each participant as well as mean and SE for the group.

Both the lack of a consistent compensatory gait adaption to offload the knee joint in early stance and the increase in joint forces in late stance, with the increase in pain response, are surprising. Experimental knee pain studies have consistently shown a reduction in both knee flexion and adduction moments with the onset of pain [8]. There is also evidence to suggest more severe OA patients develop a compensatory gait strategy to offload the 2nd peak knee contact force, compared to less severe patients, as a way to lessen knee force duration at high loading [4]. The unexpected response in the participants may suggest an inability to successfully adapt to increases in pain following serial bouts of activity due to factors such as reduced proprioception, movement control or as a result of muscle fatigue. Numerous prospective studies have supported a causal relationship between knee joint kinetics and the rate of structural progression, suggesting there may be an increased risk for disease progression following serial bouts of moderate activity.

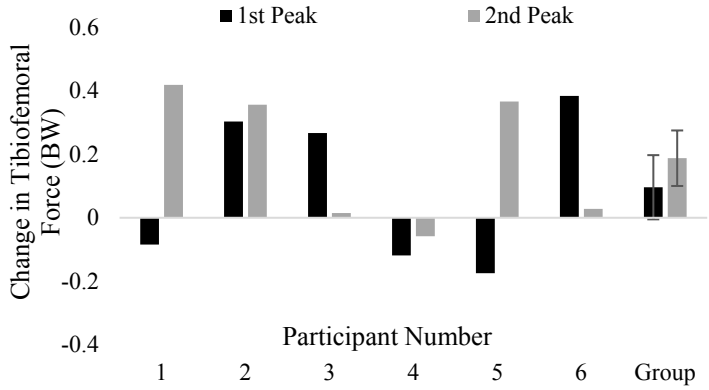

Figure 2: Changes in the 1st and 2nd peak tibiofemoral contact force following the treadmill protocol for each participant as well as mean and SE for the group.

CONCLUSIONS

The increases in knee flexion moment and tibiofemoral forces following the treadmill walks suggest that most participants did not develop a compensatory strategy to offload knee forces in response to the exacerbation of pain. Understanding the factors contributing to the lack of biomechanical pain response may provide insight for new rehabilitation targets.

INTRODUCTION

Weakness of the hip abductor muscles is thought to contribute to lower extremity musculoskeletal problems, including patellofemoral pain and non-arthritic hip pain. In particular, weakness of the posterior portion of the gluteus medius (GlutMed), which has an extension and an external rotation moment arm, and dominance of the tensor fasciae latae (TFL), which has a flexion and internal rotation moment arm, have been implicated for the faulty movement pattern of hip adduction and internal rotation during weight-bearing. Therefore, it is common to prescribe sidelying hip abduction with the hip in external rotation to strengthen the GlutMed to address this fault. However, based on a few electromyography studies [1-3], it seems that external rotation promotes TFL activation while internal rotation promotes GlutMed activation. One potential explanation for this counter-intuitive finding is that the hip external rotation results in a hip flexion muscle moment during this exercise while the hip internal rotation results in a hip extension moment.

Thus, the purpose of this study was to evaluate the hip moments and muscle activity during sidelying hip abduction with three different hip rotation positions: internal, neutral, and external.

METHODS

Ten healthy adults (5 males, 5 females, 20.4±0.7yrs, 1.7±0.1m, 64.6±8.0kg) provided written informed consent and participated in the study.

A surface electromyography (EMG) system (Delsys Inc.) was used to obtain muscle activity. Electrodes were placed over the muscle bellies of the gluteus maximus (GlutMax), posterior portion of the GlutMed, middle portion of the GlutMed, and TFL on the participant's dominant side. Maximum voluntary isometric contractions (MVICs) were measured using standardized manual muscle testing techniques [4].

Kinematic data of the pelvis and lower limb were collected using a 10-camera motion capture system (VICON®). Markers were place bilaterally on the participant's pelvis, and unilaterally on the participant's dominant lower limb [5]. Participants were in sidelying on a treatment table, and instructed to raise their leg up to a bar positioned at approximately 30° of hip abduction. Participants completed five trials of sidelying hip abduction under three hip rotation conditions: internal, neutral, and external. For each condition, participants were instructed in the desired hip rotation and given verbal cues to maintain that position throughout the movement. Participants were also instructed to maintain the same position of the pelvis for each condition and given verbal feedback if the pelvis position was visibly different.

EMG and kinematic and kinetic data were analyzed using Visual3D. Raw EMG signals were band-pass filtered between 10 Hz and 390 Hz using a 4^{th} order Butterworth filter with zero phase lag. Filtered EMG signals were processed using root-mean squared (RMS) smoothing with a moving window of 100 msec. Average RMS activation was normalized using MVICs and extracted for two phases of movement: ascent (start of movement to peak hip abduction) and descent (peak hip abduction to end of movement). Participant-based mean activation, hip angles, pelvic segment angles, and hip moments of the five trials for each condition were exported for further analysis.

Repeated measures ANOVA was used to compare the mean muscle activation, kinematics, and kinetics within subjects for the three hip rotation positions. When the ANOVA was significant, additional pairwise comparisons were performed.

RESULTS AND DISCUSSION

Muscle activation, hip and pelvis kinematics, and hip kinetics (Table 1) were affected by the hip rotation position during sidelying hip abduction.

Muscle Activation: Individuals had different mean gluteal muscle activity for the three positions. For the GlutMax, the activity during ascent and descent in the external rotation condition was greater than activity in either the neutral ($P \leq .02$) or the internal rotation condition ($P \leq .03$). For the posterior GlutMed, activity during ascent and descent in the neutral condition was less than in the external rotation ($P \leq .03$) or internal rotation condition ($P \leq .02$). For the middle GlutMed, during the ascent phase, activity was greater in the internal rotation condition than in either the external rotation ($P = .03$) or the neutral condition ($P < .001$). During the descent phase, the middle GlutMed activity during the internal rotation condition was higher than the neutral condition ($P = .01$). There were no differences in TFL activity during the ascent or descent phases ($P \geq .65$) among the three conditions.

Kinematics: The mean hip rotation angle was different among the three conditions (Table 1, $P < .001$). As expected, the hip was in the most external rotation during the external rotation condition and the least in the internal rotation condition. The peak hip abduction angle was slightly different among the three conditions ($P = .01$). The mean hip flexion angle was not different among the conditions ($P = .11$). The mean pelvic position in the transverse plane (forward / backward rotation) was different among the three positions ($P < .001$). The pelvis in the internal rotation condition was in more forward rotation (toward prone) than in the neutral or external rotation conditions.

Kinetics: The mean hip moment in the sagittal plane was different among the conditions ($P < .001$). In the internal rotation condition, there was a hip flexion muscle moment, while the moment was in the direction of extension for both the neutral and external rotation conditions. The mean hip abduction and rotation moments were not different among the conditions ($P \geq .27$).

CONCLUSIONS

These preliminary findings suggest that hip rotation position during the sidelying hip abduction exercise affects the hip moment in the sagittal plane and may help explain previously reported differences in muscle activity. The position of the pelvis in the transverse plane likely contributes to the differences in hip moments. Based on these findings, it may be appropriate to perform sidelying hip abduction with the hip in neutral rotation and the pelvis rotated forward when the goal of the exercise is to elicit GlutMed activity in a more functional position.

INTRODUCTION

Electromyograms (EMG) are commonly used to estimate movement intent for control of human-machine interfaces (HMIs), such as prosthetic limbs. Emergent algorithms that aim to restore more life-like control can estimate simultaneous and independent movements across multiple joints [e.g. 1]. These algorithms typically require that each EMG is associated with only one primary biomechanical function (e.g. wrist extension). Recording such EMG is challenging in some HMI applications. For instance, EMG is susceptible to crosstalk when muscles are close to one another and overlapping (as in the proximal forearm of people with transradial amputation) and when it is recorded using surface electrodes (currently the only clinically-approved method for recording EMG for prosthesis control) [2]. Limb posture changes may also shift the location of surface electrodes relative to the underlying muscles and reduce the functional specificity of EMG [3]. We previously developed an EMG-driven, musculoskeletal model-based control algorithm that estimates simultaneous wrist and hand movements [4]. Using our algorithm, we conducted two studies to preliminarily evaluate the consistency of subjects' performance of a real-time control task across different limb postures and the extent to which performance could be improved with EMG processing and recording methods expected to provide more function-specific EMG.

METHODS

Musculoskeletal Model-Based Controller. Our 2-degree-of-freedom (wrist and metacarpophalangeal (MCP) flexion/extension) model with four virtual muscles [4] was implemented for real-time EMG-driven control in MATLAB, as previously described [5]. Briefly, EMG were recorded from four forearm muscles that primarily contribute to wrist and/or MCP movement. EMG data were smoothed and normalized by EMG collected during maximum voluntary contractions (EMG-MVC) to estimate muscle activation state (0 = inactive, 1 = maximally active). Activations were applied to the virtual muscles during a forward dynamics simulation to estimate joint kinematics for real-time control of a 2-segment planar virtual hand on a video monitor.

Real-Time Virtual Control Task. In each trial, subjects attempted to move the virtual hand to each of four different target hand postures (Fig.1A) in a randomized order. For each target, subjects were first required to move both joints of the virtual hand to within 8° of a resting (relaxed) posture for 0.25 consecutive seconds, then to within 5° of the target posture for 0.5 consecutive seconds. We computed three task performance measures: task duration (**TD**), normalized path length (**NPL**, path length divided by minimum path length, in joint angle space), and number of overshoots (**NO**, overshoot= virtual hand moved in then out of target range).

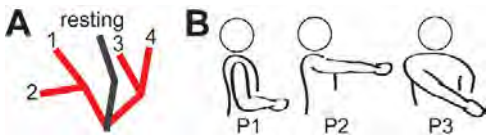

Figure 1: (A) Hand posture targets. (B) Static upper limb postures in which virtual task was performed.

Study 1: EMG processing (normalization) method: Seven able-bodied subjects (6 male, ages 21-32 years) gave their informed consent to participate. In each of 4 blocks of trials (12 trials per block), 4 trials were performed in each of 3 static upper limb postures in a randomized order: neutral arm with elbow at 90° flexion (P1), forward reach (P2), and contralateral reach (P3) (Fig.1B). Subjects assumed a neutral (F1) and pronated (F2) forearm posture in blocks 1/3 and 2/4, respectively. EMG were recorded using surface electrodes (sEMG). In blocks 1/2, EMG were normalized by EMG-MVC recorded in P1F1 (p1MVC); in blocks 3/4, EMG

were normalized by EMG-MVC recorded in the tested posture (psMVC). We performed a 3-way ANOVA to determine the effect of factors "upper limb posture", "forearm posture", and "EMG normalization method" on task performance.

Study 2: EMG recording method: Four able-bodied subjects from Study 1 (3 male, ages 21-25 years) and one transradial amputee (female, age 23) gave their informed consent to participate. In two sessions, EMG were recorded using either sEMG or fine-wire intramuscular electrodes (iEMG). iEMG were placed with ultrasound guidance in approximately the same muscles from which sEMG were recorded. For each electrode type, subjects performed 4 virtual task trials in each of 2 forearm postures (F1 and F2) in a randomized order. The amputee, unable to pronate the residual forearm, only performed trials in F1. We compared task performance between sEMG and iEMG trials using a Generalized Linear Mixed Model.

RESULTS AND DISCUSSION

Study 1. TD (p=.005) and NPL (p=0.019) were statistically significantly worse (i.e. higher) in F2 than in F1; all other differences were not statistically significant (p>0.05). Notably, normalizing by psMVC, which was expected to improve the accuracy of computed muscle activation states, did not significantly improve task performance compared to trials in which EMG was only normalized by p1MVC (Fig.2). Analysis of EMG (not shown) indicated that subjects adapted their contraction effort to overcome differences in EMG magnitude across postures.

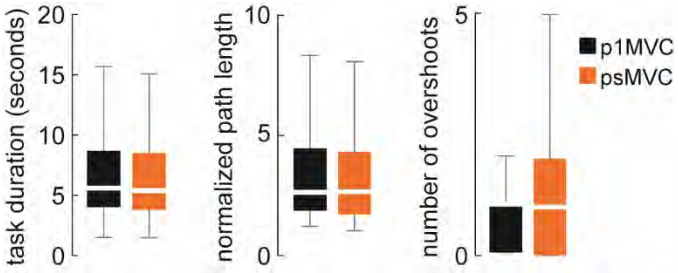

Figure 2: Box plot comparison of task performance measures between the two EMG-normalization conditions for able-bodied subjects (Study 1).

Study 2. There was a trend of more consistent, but not better, values of NPL with iEMG than sEMG (Fig.3). However, there was no statistically significant effect of electrode type or forearm posture (p>0.05). Qualitatively, for the subject with transradial amputation, all three task performance measures were worse with iEMG than sEMG.

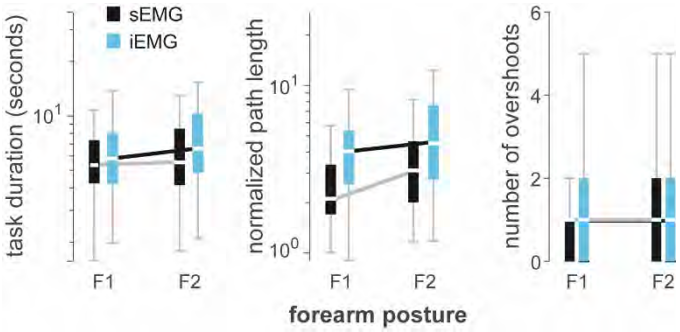

Figure 3: Box plot comparison of task performance measures between electrode type and between forearm postures for able-bodied subjects (Study 2).

CONCLUSIONS

Our results suggest that sEMG and normalizing EMG to MVC from only one posture may be sufficient for providing reliable control of 2 degrees of freedom. This was surprising since both normalizing EMG by psMVC and iEMG recording were expected to provide better function-specific EMG and, thus, enable better real-time control performance. Some limitations of our study were the small sample size (only 1 amputee) and that testing conditions differed from those of real-world tasks (no physical prosthesis/socket, virtual tasks performed in static postures). Some subjects also verbally reported that iEMG felt unusual and/or uncomfortable, which may have confounded the effect of iEMG signal quality on task performance. Our results motivate future work to further evaluate our algorithm's potential to enable more natural control of prosthetic hands and other EMG-driven HMIs.

Mapping Together Thumb Kinetic and Kinematic Function

Joshua P. Drost, Tamara Reid Bush

INTRODUCTION

Hands are used for daily interactions with multiple devices ranging from keyboards to food. When hand function is reduced, it is critical that we understand how much function was lost and where it was lost to insure the best possible treatment. Currently, loss in hand function is determined using subjective methods such as surveys, pain scales and radiological exams; *objective* methods to quantify changes in hand function are critically needed [1, 2]. A hand model that includes complete *force and motion* abilities of an individual will allow comparisons of the changes in hand function and improved rehabilitation and treatment strategies.

Previously, the authors modeled changes in the motion abilities of the hand [3]. This model included the full range of motions of the fingers. However, the movement of the thumb and the forces it can generate have not yet been studied and mapped together. The thumb is critical for understanding the hand.

Thus, the goal of this work was to develop a protocol to measure the kinematic and kinetic abilities of the thumb and map them together.

METHODS

Seven participants (three female and four male, average age 22.6 years, SD 2.1 years) without any reported injury or arthritis were included in this study. Movement was measured using a seven-camera motion capture system and force was measured using a six-axis load cell with a custom interface device.

Full range of motion of the thumb was determined using three motions. 1) Full extension of the thumb to full flexion of the metacarpalphalange (MCP) and interphalangeal (IP) joint (Figure 1a). 2) Radial abduction of the carpometacarpal (CMC) joint and opposition to pinky MCP joint (Figure 1b). 3) Radial adduction of the carpometacarpal (CMC) joint and opposition to pinky MCP joint.

Maximum forces were measured in two directions in each of eight positions (Figure 1c-1d). The positions were based on varying rotation of the palm and abduction of the thumb. The palm was tested at four angles relative to the ground: 0°, 30°, 60° and 90°. At each rotation, the thumb was tested in two positions: full adduction (touching the palm) and maximal

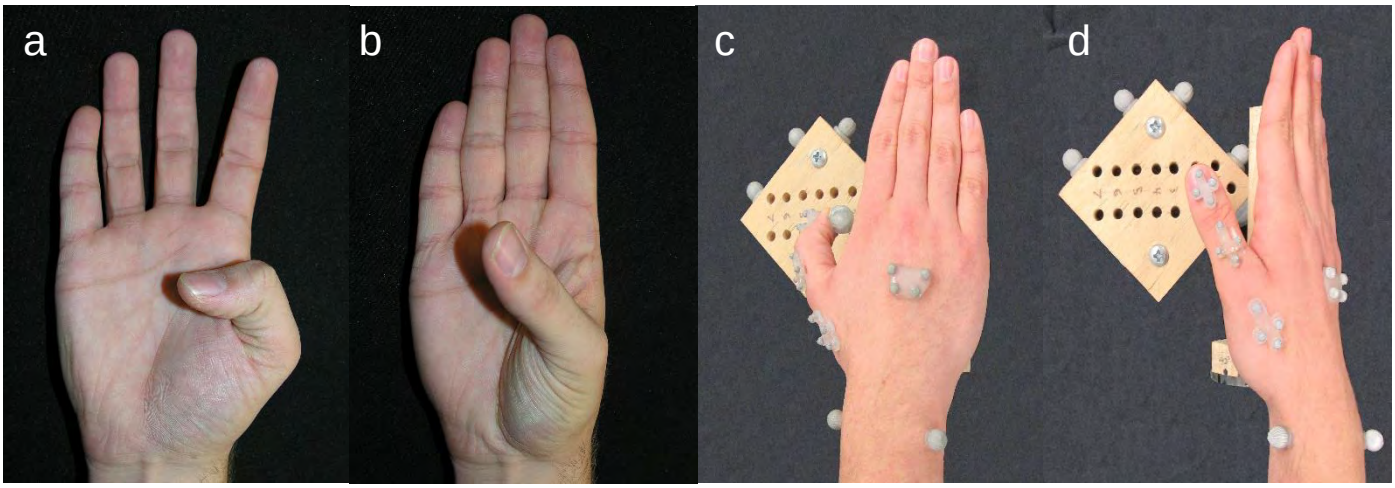

Figure 1: Testing procedure. Range of motion was measured through a) full flexion of the MCP and IP joints of the thumb and b) full ranges of opposition. Force capabilities were measured at multiple positions and directions; shown are palm at c) 0° (horizontal) and force directed medially d) and palm at 60° with respect to horizontal with force directed towards ground.

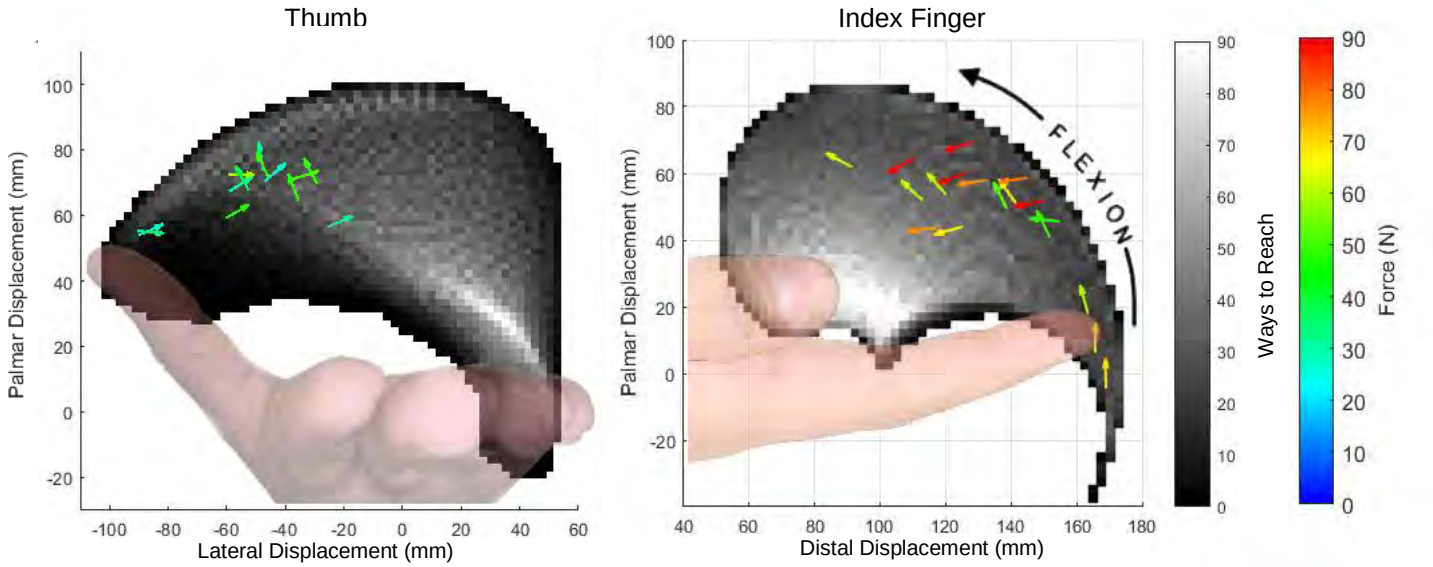

Figure 2: Finger function maps for the thumb and index finger. Greyscale background describes number of ways to reach each point. Colored arrows describe the force actions measured. The transparent hands show the orientation of the hand.

abduction of the thumb. At each position the participant was asked to apply maximal force towards the ground and then towards the hand.

After collection, the data were analyzed in three steps: determining the range of motion, the force data, and mapping the forces to the range of motion. The kinematic abilities of the thumb were determined by finding the full range of motion of each joint: the IP and MCP joints were treated as hinge joints and permitted to move in flexion/extension; the CMC was treated as a saddle joint and was measured using radial abduction (thumbs up motion) and palmar abduction (gripping motion). The thumb posture during each possible angle combination was identified and the full range of motion computed. Force data were analyzed in terms of the 1) fingertip posture (x, y, z coordinate) 2) the direction of the force applied, and 3) force magnitude. The force data were mapped to the range of motion by determining the rotation matrix between the coordinate systems of the load cell and motion capture system and computationally aligning both the motion and force data to the same coordinate system, relative to the CMC joint of the thumb.

RESULTS AND DISCUSSION

Figure 2 displays the motion and force abilities of the thumb and index finger. Due to the 3D nature of the thumb movement and to the complexities of presenting the data in 3D, the thumb motion and forces have been projected onto a 2D plane for visualization. The range of motion is described by the grayscale background, with the scale representing number of joint angle combinations that can be used to reach each point on the grid. The forces are represented as colored arrows, with the color indicating force magnitudes. As can been seen in Figure 2, the current methodology is able to measure forces over half the range of motion. Future work will include an additional protocol to measure the forces during full opposition to the fifth MCP joint.

There is a need for an objective method for diagnosing loss of hand function. This work provides a significant step in moving towards a full model of hand function by addressing the complicated movement pattern of the thumb. Future work will combine the thumb and fingers to understand interactions and investigate how function of the thumb changes due to hand osteoarthritis.

INTRODUCTION

Stroke affects about 600,000 people annually in the United States [1], resulting in significant functional impairment of those affected. While both upper and lower extremity functions are compromised, the recovery of upper extremity appears to be more limited [2]. Restoration of the hand function should be prioritized due to its functional importance, and its recovery is well correlated to the overall recovery of the overall upper extremity function. Typically repetitive movements of the hand (in a functional context) are prescribed for patients, instead of strength training, since resisted activities may increase flexor spasticity, interfering with a proper coordination of the hand muscles. Recent studies, however, suggest that resisted strength training may be beneficial for improving function post-stroke.

While the effectiveness of strength training has been demonstrated mostly in gait training, its benefit in upper-extremity (hand) function remains unclear [4]. Most manual tasks require complex spatiotemporal coordination of many muscles, thus focusing on proper muscle coordination during movements could be more beneficial. However, as extensor weakness is commonly observed post-stroke, strength training (of weakened finger extensor) could be helpful. As these two trainings typically involve different task types (static force exertion vs. movement) and muscle contraction types (isometric vs. concentric), different patterns of motor adaptation to assistance (provided during task) may also emerge.

In this study, therefore, we aim to examine the effects of task characteristics (force production vs. multi-joint movement) on the motor adaptation to assistance in healthy subjects. Here, we focused on the between-task difference in the muscle activation patterns and their adaptation to assistance.

METHODS

Twenty-four healthy subjects (age: 21 – 43 yrs) participated in the experiments, in which two different types of assisted finger extension task were performed (Exp 1. vs. Exp. 2).

Exp. 1: Twelve subjects (5 males) performed static finger extension tasks by producing a submaximal dorsal fingertip force against a load cell. Subjects wore an exotendon device, a modified version of a biomimetic device (BiomHED) [3] (Fig. 1). An exotendon that mimics the anatomy of the extensor digitorum communis (EDC) tendon were actuated by an electric motor (A-max 16, Maxon AG, Switzerland) to provide targeted assistance to the EDC muscle. Subjects first produced the dorsally-directed fingertip force (40% of their maximal voluntary force) with no assistance (10 trials), then with the targeted EDC assistance provided by BiomHED (10 trials).

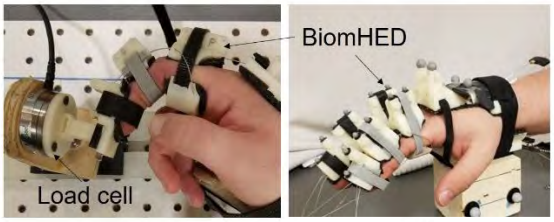

Figure 1. Experimental setup: (a) movement

Exp. 2: Another group of twelve subjects (8 males) performed 'timed' finger extension movements, which consisted of a preparation (2-sec), opening movement (3-sec), and sustaining of the open hand position (3-sec). A custom graphical user interface (LabView, National Instruments, Austin, TX) provided visual cues regarding the timing of different phases in the form of sliding bar with marks. Similar to Exp. 1, the task was performed without assistance (10 trials) first, then with assistance (10 trials).

Recording: Three pairs of disposable, self-adhesive silver/silver chloride surface electrodes (Noraxon, Scottsdale, AZ, USA) were used for surface EMG recordings from an intrinsic hand muscle (first dorsal interosseous; FDI), and two extrinsic muscles (EDC and flexor digitorum superficialis; FDS). EMG signals were inspected while subjects performed several finger/wrist motions related to the target muscles, and the location was adjusted if crosstalk was detected. The EMG signals were sampled at 1000 Hz and band-pass filtered (5Hz - 400Hz).

RESULTS AND DISCUSSION

Two distinct types of muscle coordination pattern were found to be employed for the two tasks. The activation level of the extrinsic extensor muscle (EDC) was not significantly different, while the activation level of the extrinsic flexor (FDS) and intrinsic (FDI) muscles were significantly smaller during movement (Task 2) than static task (Task 1) ($p < 0.04$ for FDS and FDI; see Fig. 2a). The observed between-task difference in the two muscles is likely due to their different primary roles during finger tasks (FDI: directional control of fingertip force; FDS: stability of multi-link system; [4]).

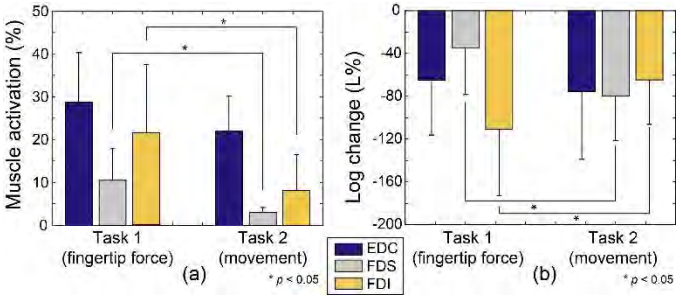

Figure 2. Between-task difference in (a) muscle activation level; (b) relative change in activation level

More importantly, the effects of targeted assistance of the extrinsic extensor muscle (EDC) were different between the two types of tasks (Fig. 2b). Under the targeted EDC assistance, the degree of reduction in the EDC activation were similar between the two tasks. However, the degree of FDS reduction was greater during movement ($p = 0.02$), while a significantly greater decrease in the FDI activation was observed during isometric task ($p = 0.05$; Fig. 2b).

The between-task difference in the motor adaptation to assistance was signified in the coordination of the muscle pairs (i.e., cocontraction ratios), as they showed contrasting patterns: under assistance, the CCR values of EDC-FDS and FDI-FDS pairs decreased during force production, but increased during movements. Contrastingly, EDC-FDI CCR increased during isometric task, but decreased during movement. The FDI-FDS CCR showed the largest between-task difference ($p < 0.001$). Overall, a greater degree of change was observed in Task 1.

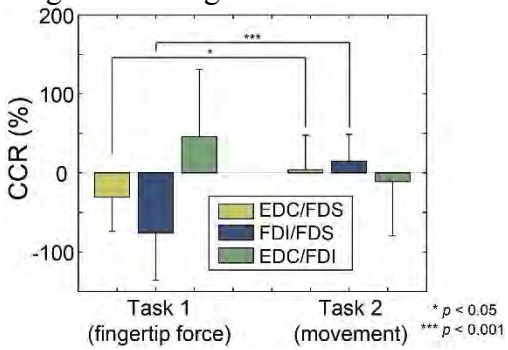

Figure 3. Between-task difference in cocontraction ratio

The results of this study suggest that the type of task should be carefully determined based on specific impairment characteristics of individuals and corresponding training goal (e.g., strengthening extrinsic extensor muscles vs. intrinsic muscles). While the targeted muscle assistance did not cause any substantial change in the muscle coordination (Fig. 2b) during movements, the assistance decoupled (and reduced) the activation of the intrinsic muscle during isometric force production, thus more suitable for those with extensor weakness. Assisted movement training may be desirable for those with severe intrinsic impairment, as the task does not require its activation much. We will test the same experimental protocol with stroke patients to examine whether they exhibit similar between-task difference in their motor adaptation patterns.

INTRODUCTION

In 1987, O'Neill et al. reported a patient with multiple sclerosis (MS) who experienced rapid reversible deterioration in gait and increase in degree of pyramidal weakness of the lower limbs with neck flexion; this phenomenon was so prominent that affected patients had to hyperextend their necks in order to walk. [1] This manifestation was named McArdle's sign (McS) after M.J. McArdle who recognized this sign. [1] This sign has since been largely overlooked and the mechanism of is poorly understood. McS may have potential diagnostic value, especially in challenging cases of myelopathy, and possibly even therapeutic implications as an indicator of mechanically-induced conduction block, and thereby a reflection of the presence of spinal cord demyelination.

The aim of this study was to quantify neuromotor activation via decomposed electromyography (dEMG) of patients chosen because they had detectable finger extension weakness, a sensitive and easily testable muscle group; patients enrolled were classified by diagnosis: MS, other myelopathies and peripheral neuropathies. Additionally, 17 healthy controls were tested. We hypothesized that neuromotor activation as measured by dEMG would predict clinically diagnosed weakness.

METHODS

Informed consent was obtained from all study participants (n=48; 21M:27F, age 49.0±13.1). McS is detectable in muscle groups sensitive to upper motor neuron lesions. We specifically evaluated finger extensor strength (extensor digitorum) since it is both a sensitive and convenient indicator of McS. Clinical McS was rated by a clinician with head in extension and flexion positions. McS is graded 0-3 (0=Not detectable; 1=Barely detectable; 2=Moderate; 3=Prominent). A dEMG electrode (Delsys; Natick, MA) placed on the belly of the extensor digitorum measured surface EMG as each patient extended their four fingers isometrically. A 40 second rest interval was utilized in between individual contractions to allow for proper recovery of muscle force. Three 'baseline trials' with the neck in neutral position were obtained to determine subject maximal voluntary isometric contraction (MVIC). Afterward, three successive trials (with rest periods) were then performed in each neck position (head/neck in randomized order of flexion, neutral, or extension position) at 25% MVIC. Neck position was recorded by two gyroscopic sensors affixed to a headband (**Fig. 1**). EMG data was post-processed with Delsys dEMG Analysis software.

Figure 1. McArdle Biomechanical Test Setup. Subject's arm is secured in the device. Torque cell (blue arrow) measures torque as subject pushes on padded black bar. Two gyroscopes in headband measure neck flexion/extension (yellow arrow).

ANOVA and receiver operator curves (ROC) were performed in JMP 13 (SAS Institute Inc., Cary, NC). dEMG variables included in the model were: number of firings, recruitment, derecruitment, and average firing rate. A p-value <0.05 was considered statistically significant.

RESULTS AND DISCUSSION

Characteristic findings of dEMG were a decrease in function for Grade 1 McS, a recovery for Grade 2, and then a further loss of function for Grade 3 (**Fig. 2A**). Consequently, the ROC of dEMG as a predictor for McS demonstrates 'good' diagnostic accuracy for McS Grade 3, 'fail' for Grade 2, 'fair' for Grade 1, and 'poor' for Grade 0 (χ^2=1028.53; p<0.0001; **Fig. 2B**). For Grade 3, dEMG was 0.81 sensitive and 0.82 specific (χ^2=609.75; p<0.0001) for clinical McS.

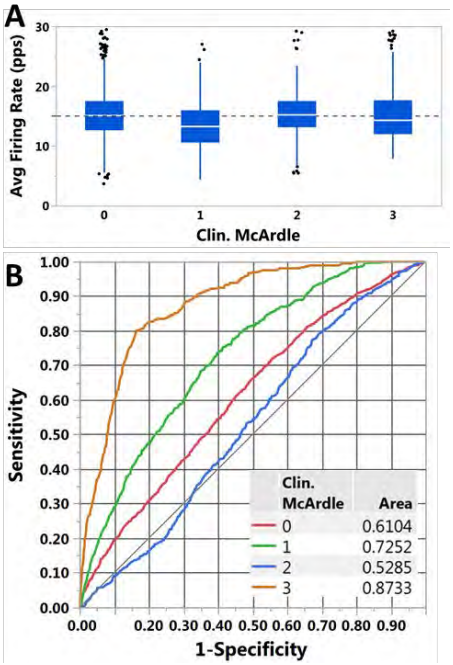

Figure 2. dEMG characteristics of clinical McS and ROC curve of dEMG as a predictor of clinical McS. Respective area under the curve (AUC) is provided for each McS grade.

Specifically evaluating the differences of neck position, there was excellent diagnostic effects of dEMG in neutral position for McS Grade 3 (χ^2=426.87; p<0.0001). With neck flexion, there was improved clinical diagnostic accuracy (χ^2=523.27; p<0.0001; **Fig. 3**); 'excellent' for McS Grade 3, 'poor' for Grade 2, 'fair' for Grade 1, and 'poor' for Grade 0. Neck extension was the least diagnostic of the three neck positions (χ^2=296.67; p<0.0001).

When divided by neck position and sex, females demonstrated improved diagnostic prediction of clinical McS than males for Grade 3. However, these criteria reverse for Grade 1 and 2. With all neck positions, females demonstrated 'excellent' diagnostic accuracy for McS Grade 3 (**Table 1**).

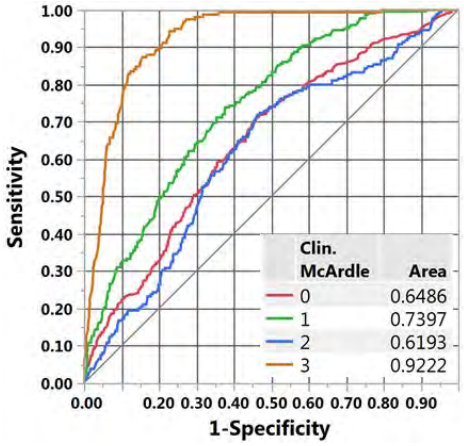

Figure 3. ROC curve of dEMG with subjects in neck flexion as a predictor of clinical McS. Respective area under the curve (AUC) is provided for each McS grade.

CONCLUSIONS

This data demonstrates that neuromotor activation as measured by dEMG is both sensitive and specific to clinically observed muscle 'weakness,' especially with neck flexion as observed with McS. This is an important objective measure that coincides with subjective clinical interpretation and could prove useful for confirming or predicting diagnosis of MS. Future work should determine specificity and sensitivity of dEMG to MS vs other peripheral neuropathies or myelopathies.

INTRODUCTION

Neuromuscular disorders such as stroke and spinal cord injuries can lead to severe movement disability and compromise the ability to perform activities of daily living. Physical rehabilitation involving repetitive movement task execution is a primary method to re-train and recover neuromuscular functionality. Virtual reality (VR) environments have been previously utilized to facilitate greater cognitive engagement with unique, colorful displays and task gamification [1]. In this study, we investigate employing a VR environment to systematically vary operation of a visualized virtual hand prosthesis [2] to alter sense of agency. Cognitive agency is the perception that one is the true author of one's actions [3]. We hypothesize that with greater agency, individuals will improve functional movement performance. In turn, such findings may provide a foundation to design VR-based paradigms that identify agency and correlate it to operational conditions which accelerate rehabilitation.

In this study, we investigate the potential role of agency in reach to precision pinch grasp. Precision pinch involves dexterous manipulation of small objects and greater cognitive attention. In VR, the virtual hand prosthesis moves with that of a subject's real hand. But visualized operation of the virtual hand is systematically modified to potentially alter sense of agency. Operational parameters include speed, addition of random noise, and a condition for automated task completion once initiated. These parameters are chosen to consider common operational issues for assistive devices often tuned by a clinical-level engineer.

METHODS

A. Subjects

Ten volunteers (8 male, 2 female, 21 ± 3 years in age) have participated according to protocols approved by the local Institutional Review Board. Subjects were screened to be able-bodied, right-hand dominant, and to have no previous injury or surgery to the upper extremities, no cited neuromuscular disease, and correctable-to-normal vision.

B. Motion capture system

Hand movements were tracked using retro-reflective motion capture of marker clusters placed on the index finger, thumb, and wrist using nine infrared cameras (*Prime17, OptiTrack, Natural Point, Inc.,* Corvallis, OR). Motion capture data were sampled at 120Hz with *Motive* (*Natural Point, Inc*.) and then streamed over a broadcast ethernet network to a remote computer running *MATLAB 2017a* (*Mathworks, Inc.*, Natick, MA).

C. Virtual reality environment

The physics engine displaying the hand prosthesis was *MuJoCo* (*Multi-joint dynamics with Contact, Roboti LLC*, Redmond, WA). Using *MATLAB*-compatible API code, streaming motion data were used to drive motions of the virtual hand in real-time.

D. Protocol

Each subject participated in a single, two-hour experiment session. After donning marker clusters on the motion hand, each subject would wear a VR headset (*BestFace 3D VR, Nibiru OS, Japan*) to visualize the *MuJoCo* display. A single trial involved moving the motion hand from a calibrated starting position, while observing the virtual hand move towards a target sphere (**Figure 1**). Each subject was asked to take the most efficient (shortest path-length) trajectory. To complete the 'action' for the trial, the target had to be contacted by the virtual hand thumb and index finger to undergo a color change (green to black). The subject was made aware of a sound (short beep) as a sensory 'consequence' of the 'action' at a variable time-interval (0 to 1 sec) following contact. To indicate intentional binding between action and consequence as a measure of agency [3], the subject

would estimate the time-interval. It was inferred that with greater agency one would perceive a compressed (shorter) time-interval [4].

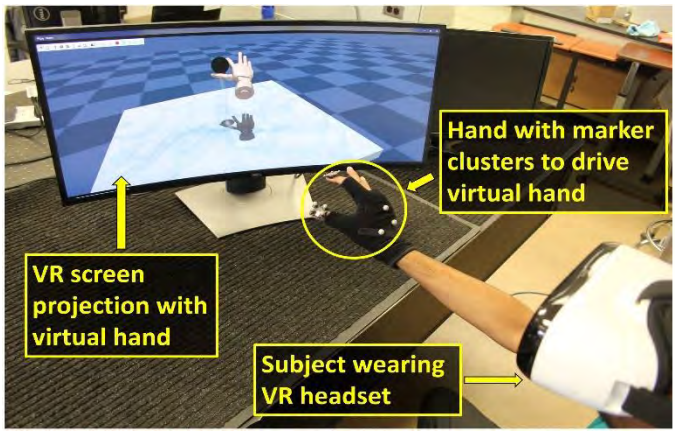

Figure 1: Subject reaching and pinching through to ensure virtual hand contacts sphere target.

Twenty trials were done for each of six virtual hand operation conditions. The conditions were: (1) 'normal' (control) - VR hand motion matched that of subject's real hand, (2) 'slow' - VR hand moved 50% slower than real hand, (3) 'fast' - VR hand moved 50% faster than real hand, (4) 'noisy' - VR hand had added random noise, up to 10% the expected total path-length, (5) 'auto' - VR hand was gradually under greater preset control in approaching the target instead of subject control, (6) '1-phase grasp' - no reaching (transport phase) as hand initially placed near target prior to contact.

RESULTS AND DISCUSSION

All conditions showed significant changes in agency relative to 'normal', except 'noisy' (**Table 1**). 'One-phase' had the greatest increase in agency, strongly implicating the role of transport in attenuating agency for grasp contact. 'Slow' and 'auto' had the greatest decreases in agency, suggesting a sense of control loss when operation lags or is automated. Desirable performance was taken as lower variability in path length. Performance was significantly lower for 'fast' and 'auto' but higher for 'slow'. Performance and agency appear correlated with automation, but not by variations in speed. Moderate visual noise appears tolerable in having had no apparent effect on performance or agency. This study serves as an able-body concept protocol whereby visualized motions are altered and mis-matched against intact proprioception and no haptic feedback.

The next phase of this research will build upon the principles identified in this study that relate agency, performance, and operation condition. We expect this versatile platform can be used to develop "customized" control systems for hand grasp assistive devices or rehabilitation paradigms for specific pathology groups. We seek to optimize controller operation not only for better performance but to leverage agency for accelerating functional gains. Applications of this platform may include the development of better hand neuroprostheses [5] following spinal cord injury, sensorimotor prostheses following upper-limb amputation [6], and exoskeleton-assisted stroke rehabilitation [7].

INCREASE IN MEDIAN NERVE LONGITUDINAL MOBILITY BY TRANSVERSE WRIST COMPRESSION IN PATIENTS WITH CARPAL TUNNEL SYNDROME

INTRODUCTION

The carpal tunnel in the wrist is formed by the dorsal interconnected carpal bones and the volar transverse carpal ligament. Median nerve, one of the tunnel contents, is vulnerable to entrapment in the space-limited tunnel leading to compression neuropathy called carpal tunnel syndrome (CTS). It has been shown that patients with CTS have restricted median nerve excursion in the transverse direction at the distal [1] and proximal [2] level of the carpal tunnel, and in the longitudinal direction [3,4]. Nerve gliding exercises were developed for the purpose of increasing the mobility of the median nerve as treatment for CTS [5]. Recent studies support that the carpal tunnel space can be augmented by narrowing the carpal arch width [6-9]. Furthermore, it has been shown that applying radioulnar wrist compression (RWC) decreases median nerve flattening in patients with CTS [9]. The augmented carpal tunnel space might induce less flattening of median nerve thus leading to increase in median nerve mobility. However, the implications of RWC on median nerve mobility in CTS patients have not been examined. Therefore, the purpose of this study was to investigate the effects of RWC on the median nerve longitudinal mobility in the carpal tunnel in patients with CTS. It was hypothesized that the longitudinal median nerve mobility would be enhanced in CTS patients under RWC.

METHODS

Eleven (n=11) patients diagnosed with CTS (51.5±16.3 years; 7 female, 4 male; 8 right hands, 3 left hands) participated in this study. The subjects were recruited based on a history of paresthesia, pain, aching, tingling, dull, weakness, clumsiness and/or numbness in the median-innervated hand territory for at least three months, at least one positive physical examination of Tinel's sign, Phalen's test or carpal compression test, and a mean CTS Severity Score greater than 1.5 [10]. All subjects provided written informed consent for the study approved by the Institutional Review Board. Each patient lay supine on a testing bed with the arm abducted and hand supinated, while the wrist fit in a custom-made RWC system. The thumb was fixed in 45° extension and the proximal/distal interphalangeal joints of the four fingers were fixed in anatomical neutral position (Figure 1), but the metacarpophalangeal joints are free to move.

Figure 1. Experimental setup of in vivo ultrasound imaging

The RWC system applied transverse compressive forces of 0, 10 and 20 N across the distal carpal tunnel level for 3 minutes and then high-frequency (17 MHz) dynamic ultrasound images with 0.062 mm resolution captured the longitudinal median nerve within the carpal tunnel during finger flexion/extension. Each force condition was repeated three times in a randomized order. A 3-minute rest was provided between consecutive trials. Angular finger motion at the metacarpophalangeal joints were recorded by an electrogoniometer which was synchronized to ultrasound image capture. Cyclic finger flexion/extension was conducted between neutral (0°) and 90° flexion at a pace of 0.3 Hz. Longitudinal median nerve displacement was analyzed by a custom LabVIEW program using speckle cross-correlation algorithm [11]. The program defined regions of interest (ROIs) (6.2×1.8 mm) at a 0.62 mm increment along the midline of the median nerve ranging from proximal to distal boundaries of the tunnel. Each ROI frame by frame

corresponding to individual finger flexion angles. Median nerve displacement in the carpal tunnel was calculated as the mean value of individual displacements of all ROIs. Least-squares linear regression was performed for median nerve displacement as a function of finger flexion angle. The slope of the linear equation was used to quantify the mobility of the nerve. One-way Friedman repeated measures ANOVAs were performed to examine the effect of force magnitude (0, 10, and 20N) on the median nerve mobility. Post-hoc Tukey's tests were used for pairwise comparisons and p-value less than 0.05 was considered statistically significant.

RESULTS

R-square values of the linear regression on the median nerve displacements in the carpal tunnel as a function of finger flexion from all subjects were 0.9 ± 0.01. Median nerve mobility was significantly affected by the RWC levels ($p<0.05$, Figure 2). Pairwise comparisons showed that the median nerve mobility under 10N RWC (0.0053 ± 0.0022 mm/degree) was significantly greater than the no compression condition (0N) (0.0034 ± 0.0015 mm/degree, $p<0.05$). However, the median nerve mobility did not differ between 0N and 20N conditions ($p=0.23$) nor between 10N and 20N conditions ($p=0.47$).

DISCUSSION

This study revealed that compression applied to the wrist in the radioulnar direction could enhance the median nerve longitudinal mobility in CTS patients. Previous studies have demonstrated that CAW can be narrowed with increasing carpal arch area [6, 7], and that this narrowing can be achieved in vivo [8, 9]. The increase in median nerve mobility of CTS patients from wrist compression in the current study might due to the increase of carpal arch area and decompression of median nerve. Surprisingly, 20N wrist compression didn't increase the median nerve mobility as 10N wrist compression did. The increase of transverse wrist compression did not necessarily increase the median nerve longitudinal mobility. The excessive compression could increase more carpal tunnel area but might hinder the median nerve mobility. Median nerve mobility might be dependant on multiple surrounding biomechanical factors. Moderate wrist compression may provide relief of nerve compression in patients and restore the median nerve mobility with CTS. One limitation of this study was that tracking of the median nerve might be inaccurate due to the same tracked nerve region moving out of the image plane. Experimental and image processing methods can be improved to accurately track nerve motion with dynamic imaging in 3D.

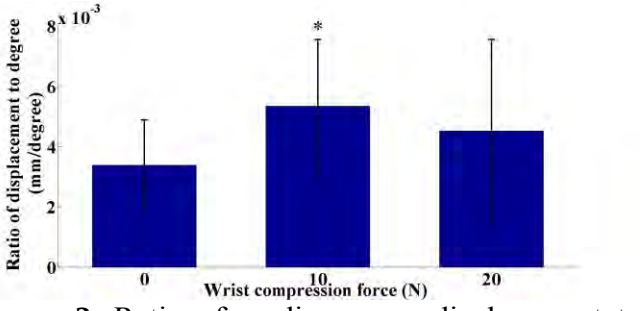

Figure 2. Ratio of median nerve displacement to the finger flexion degree (median nerve mobility) under the force magnitudes of 0, 10, and 20N. (* $P<0.05$).

INTRODUCTION

The structure of biological tissue has been shown to affect its function. In the case of plantar soft tissue, the unique structure of the fat chambers is hypothesized to play a vital role in force dissipation and energy absorption during walking. [1,2] Prior work used dissection and histological methods to define the structure of typical healthy plantar soft tissue. [1,2] However, there are inherent limitations to histological morphological analysis.

Typically, manual morphological analysis is time-intensive, prohibiting comprehensive analysis of a large-scale study. Recent advances in computer vision have enabled rapid automated tissue identification. Using texture-based tissue classification methods could be an efficient and accurate way to obtain comprehensive morphological information in large-scale structure-function investigations.

METHODS

Kather's open-source texture-based multiclass classification framework originally developed for preliminary histopathological prostate cancer diagnosis [3] was expanded to include 14 texture-based feature detectors, 5 feature set reduction strategies, and 9 classification algorithms (Table 1).

Plantar soft tissue specimens were obtained from nine fresh cadaveric feet (age range: 61-79 years) and prepared for histological analysis using standard methods for modified Hart's stain for elastin. Large, whole-slide images of resolution 2.43 um/px were obtained using a Nikon Eclipse i80. 3500 smaller single-tissue training images were extracted from a subset of images obtained. The training images were comprised of five unequal groups of single tissue classes (adipose n=885, dermis n=540, epidermis n=361, muscle n=464, sepate n=522) and background (n=727) for six total classes. Feature detection algorithms were applied to these training images to reduce each image into vectors of textural information. These vectors stored the unique textural features of each tissue for identification and of the six tissue and background classes in the whole-slide images.

Following feature identification, feature set reduction strategies were employed to reduce the number of features applied to the classification to only those features most relevant to each texture; this decreases the likelihood of overfitting the classification model. Reduced feature sets were used to train classifiers, and the trained classifiers were then tested on the training data using 10-fold cross validation. Classifier accuracy was assessed using the multiclass Matthews Correlation Coefficient (MCC) to account for both false positive and false negative error across all six classes. After training, the best classifiers were identified using the multiclass MCC score. These classifiers were applied tile-wise to the whole-slide images in order to segment the whole-slide images into tissue sections. Segmented images were compared to ground-truth whole-slide images which were manually segmented by a trained histologist.

RESULTS AND DISCUSSION

The three best MCC scores achieved for classification of the training images were obtained using sequential backward selection-reduced RGB color space histogram features with radial basis SVM (MCC=0.96), f-IOCLBP all features with linear SVM (MCC=0.958), and stepwise multilinear regression-reduced f-IOCLBP features and radial basis SVM (MCC=0.957) (see Table 1 for

abbreviations). These accuracy measures are expected to be larger than those of a new data set given the reuse of training and testing data. In the more difficult task of whole-slide image segmentation, preliminary results indicate that the f-IOCLBP algorithm with all 342 features and linear SVM classification yielded the highest accuracy of 80.21% (Figure 1). This segmentation accuracy may be improved by changing the size of tiles used in tile-wise comparison, combining feature sets, or further feature reduction to alleviate overfitting errors.

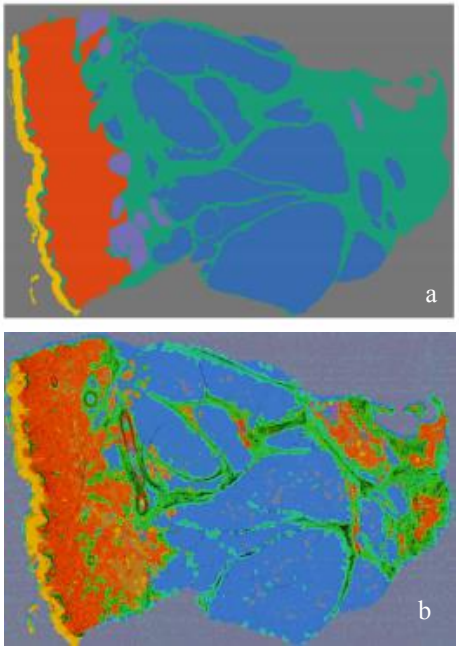

Figure 1: a. Manually-segmented ground-truth b. Classification segmentation of the same whole-slide image with all 342 f-IOCLBP features and linear SVM classification.

CONCLUSIONS

Many machine learning methods developed for cancer histopathology are applicable to issues in biomechanics. Rapid quantification of tissue morphology can enable large-scale study of structure-function relationships when coupled with classic *in vitro* mechanical testing. Additionally, the comprehensive study of entire histomorphological specimens without sacrificing information through statistical sampling could provide insight into the bias introduced using sampling methods or regional microscopic morphological variation within tissues. This texture-based classifier is a promising first step toward rapid morphological analysis. Optimized tile size, more tissue classes, and better feature reduction strategies should be investigated to improve the segmentation accuracy of this framework.

INTRODUCTION

An objective understanding of human foot and ankle function can drive innovations and development of 'bio-inspired' wearable devices, such as prostheses, and exoskeletons. Specifically, knowledge regarding how mechanical force and work are produced within the biological foot-ankle structures can help determine what type of materials (e.g., elastic or viscous) or components (e.g., battery-powered actuators) are required to engineer biomimetic devices. A recent study of human walking found that the biological foot-ankle structures (when accounting for contributions from all anatomical subsections) produce near equal magnitudes of negative and positive work [1]. In other words, the biological foot-ankle structures are mechanically similar to an elastic unpowered device that can store and return energy. This knowledge may facilitate the optimization of unpowered devices that are inexpensive, yet highly functional.

For future designing or customization of wearable foot-ankle devices, a generalized technique to synthesize mechanics of structures distal to the shank is warranted, such as quantifying the total force, displacement, and work. For example, displacement of the center-of-pressure relative to the shank during stance in normal walking has been used to quantify the 'net deformation' of the foot-ankle system [2]. Such information has yielded novel approaches for prescribing prosthetic foot-ankle components that attempts to preserve a natural 'roll-over shape' [2]. Yet, to prescribe elastic devices that can store and return mechanical energy, a comprehensive knowledge regarding the force, displacement, and work of the biological foot-ankle system is needed.

The purpose of this study was two folds. First, we aimed to quantify the total force, displacement, power, and work of all structures distal to the shank in normal walking. Second, we tested the hypothesis that subject's body height and mass are strong predictors for the individual variability of force, displacement and work. This knowledge would facilitate creation of a simple data-driven model that could predict idealized force, displacement and work profiles (distal to the shank) that may be used to customize unpowered wearable foot-ankle devices, such as prostheses and exoskeletons.

METHODS

Eleven healthy subjects (6 females, 5 males, ages 24.2 ± 2.9 yrs, height 1.72 ± 0.08m, and body mass 75.3 ± 21.8 kg) participated in a fully-instrumented gait analysis. Prior to data collection, subjects were instrumented with a 6 degrees-of-freedom marker-set [3] to estimate the motions of the lower extremity during walking. The subjects walked barefoot at four walking velocities: 0.4, 0.6, 0.8 and 1.0 statures/s. The data from one walking velocity (0.8 statures/s) was included in this abstract. Data was processed and analyzed using Visual3D software (C-Motion Inc., Germantown, MD). A second-order dual-pass low-pass Butterworth filter (6Hz for kinematic data and 25Hz for kinetic data) was applied to the raw data.

To quantify force and displacement relative to the shank during stance, we transformed the ground reaction force and center-of-pressure (COP) data from the laboratory coordinate system to the shank's coordinate system (SCS), respectively [2]. To quantify mechanical power due to all structures distal to the shank, we used a unified deformable segment analysis [4]. To quantify mechanical work, we integrated power over time.

Multiple regression analyses were performed to determine if body height and weight were related to measures of force, displacement and work. Specifically, we analyzed the peak force in the anterior-posterior (A-P) and superior-inferior (S-I) axes of the SCS, as well as the total displacement along the A-P and S-I axes. We also examined the positive and negative mechanical work.

RESULTS AND DISCUSSION

During the first ~75% of stance, the structures distal to the shank (i.e., foot-ankle) produced negative power, whereas during the last ~25% of stance, the structures produced positive power (Figure 1a). These structures produced slightly greater magnitude of negative work (-16.18 ± 8.05 J) than positive (13.14 ± 4.57 J), resulting in slight net negative work (-3.05 ± 5.63 J) (Figure 1b). Body height and body mass accounted for 66.1% of the variance in positive work ($p=0.013$) and 85.5% of the variance in negative work ($p<0.001$). Body mass significantly predicted positive work ($\beta=.789$, $p=0.014$) and negative work ($\beta=-.877$, $p=0.001$). However, body height was not significantly correlated to either.

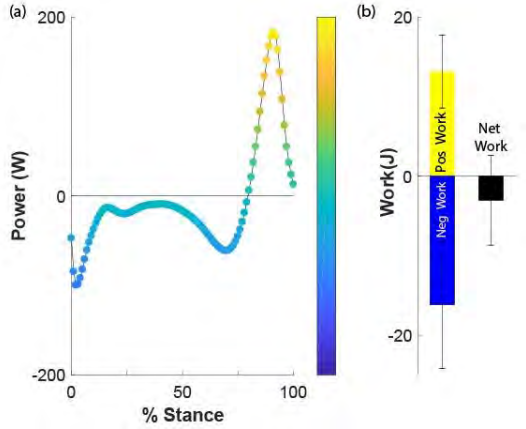

Figure 1. Average mechanical power (a) and work (b) distal to the shank during stance phase (N=11). The colors correspond to the intensity of the power. The magnitude of negative work (blue) is slightly greater than positive work (yellow), resulting in slight net negative work (black).

The COP in the SCS primarily displaced in the anterior direction during stance (Figure 2). The COP displaced in the superior direction in the presence of a superior-directed force through most of stance, which is analogous to a spring being compressed longitudinally (i.e., foot-ankle structures performing negative work) (Figure 2). During terminal stance, the COP displaced in the inferior direction in the presence of a superior-directed force, which is analogous to a spring recoiling after being compressed (i.e., foot-ankle structures performing positive work). Body height and body mass did not significantly account for the variance in displacement along the A-P and S-I axes. Body height and body mass explained 67.9% of the variance in the peak force along the A-P axis ($p=0.011$) and 99% of the variance in the peak force in the S-I axis ($p<0.001$). Body mass significantly predicted peak force in the A-P axis ($\beta=-.584$, $p=0.046$) and peak force in the S-I axis ($\beta=.986$, $p<0.001$), however body height was not significant.

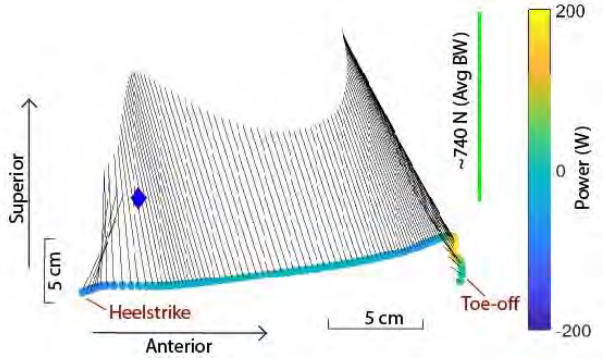

Figure 2: Displacement, force and power distal to the shank during stance phase. The colored circles indicate displacement of the COP in the shank coordinate system (SCS), and the colors of the circles represent power intensity at each point in stance. Black lines represent the ground reaction force in the SCS, in which the length of the vector denotes the magnitude of the force. Blue diamond represents the location of the ankle joint center in the SCS.

CONCLUSIONS

The force, displacement, and work characteristics of distal-to-shank structures in normal walking are largely predicted by body mass. These findings can inform the design and customization of unpowered foot-ankle devices (prostheses, exoskeletons) that can emulate biological functions during walking.

ANKLE KINEMATICS VARY WITH THE NUMBER OF SEGMENTS IN MULTI-SEGMENT FOOT MODELS

[1]Hoon Kim, [1]Marwan Aljohani, [1]William I. Wolf, and [1]Kristof Kipp

[1] Marquette University, WI, USA
email: hoon.kim@marquette.edu

INTRODUCTION

The biomechanical analysis of human movements depends on the use of appropriate musculoskeletal models. One important issue with respect to modeling the foot-ankle complex concerns the number of segments within the musculoskeletal model. For example, multi-segment foot models (MFM) produce results that are more realistic foot-ankle movements than single-segment foot models [1]. While MFM appears to be more appropriate, the number of foot segments and the definitions of segments differ greatly between models. The purpose of this study was to compare ankle joint kinematics derived from MFM with different number of segments (2-segment MFM (2MFM) vs. 5-segment MFM (5MFM)).

METHODS

Four male collegiate track and field athletes (22±0 years old, 1.85±0.05m, 79.8±5.0kg) participated in this study. All athletes signed an informed consent form, which was approved by the University's Institutional Review Board.

Fifty-one reflective markers (with at least 3 markers per segment) were attached to bony landmarks of all participants. The three-dimensional positions of the markers were recorded with a motion capture system (Vicon 612, Vicon, Los Angeles, CA, USA) at 100 Hz. Ground reaction forces were recorded from two force plates (OR6-6, AMTI, Watertown, MA, USA) at 1000 Hz. Kinematic data were filtered with a 4th order low-pass Butterworth filter at a cutoff frequency of 12 Hz.

Athletes performed vertical hopping tasks at three different frequencies (2.0 Hz, 2.2 Hz, and 2.4 Hz). After being familiarized with the tasks, subjects hopped at each frequency for approximately 10 seconds. The ground reaction force data were used to detect the stance phase during the hopping tasks. Five hops from each hopping tasks were selected for analysis.

Two MFMs (2MFM and 5MFM) were scaled to each athlete [1]. The 5MFM consists of five segments in the foot (talus, calcaneus, midfoot, forefoot, and toes). For the 2MFM, the articulations between calcaneus, midfoot, forefoot, and toes were locked such that only the talus and foot segments remained. Three-dimensional ankle joint kinematics were calculated using inverse kinematics (IK) procedures in OpenSim [2].

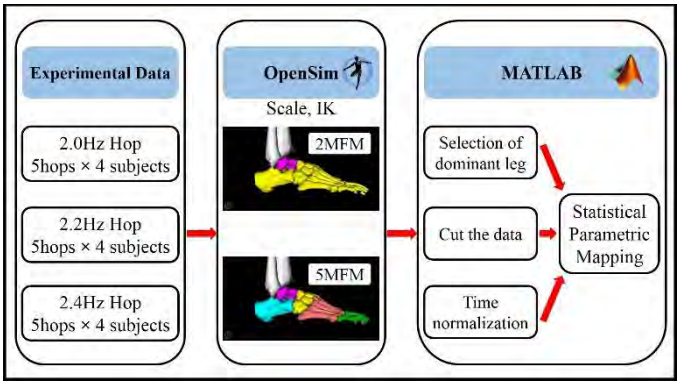

Figure 1: Workflow chart

Stance-phase ankle joint kinematics of the 2MFM and 5MFM in the frontal and sagittal plane were time-normalized and compared with Statistical Parametric Mapping (SPM) [3].

RESULTS AND DISCUSSION

The SPM analysis indicated significant effects between the 2MFM and 5MFM ankle kinematics in the sagittal and frontal plane for all hopping frequencies. Given that the effects were similar for all three hopping frequencies, only data from the 2.0 Hz will be discussed.

In the sagittal plane, the SPM analysis indicated significant differences in kinematics across almost the entire stance phase; identically smooth random time-series data would produce a cluster of this

breadth with a probability of $p = 0.001$ (Figure 2). In the frontal plane, the SPM analysis indicated significant differences in kinematics at the beginning and end of the stance phase; identically smooth random time-series data would produce clusters of this breadth with a probability between $p = 0.046$ and $p = 0.025$, respectively (Figure 2).

Model-based differences in dorsi-/plantar flexion at the talocrural joint occurred across most of ground contact, whereas differences in inversion/eversion at the subtalar joint occurred during the early phase and end phase of ground contact. However, the kinematic patterns at the talocrural joint are similar to each other. In contrast, the motions at the subtalar joint differed such that with the 2MFM there was more inversion during early and end phase and less inversion during the middle phase of hopping. Difference in frontal plane kinematics may have important clinical implications because excessive subtalar joint motion is purported risk factor for lateral ankle sprains.

Modeling the ankle-foot complex with an appropriate number of segments therefore seems to be important issue when researchers investigate kinematic characteristics associated with injury prevention and rehabilitation.

INTRODUCTION

Each year there are 100,000 new cases of tibiotalar osteoarthritis (OA) in the United States [1]. Tibiotalar OA is characterized by pain, difficulty walking, and a poor quality of life [1, 2]. Surgery, including tibiotalar arthrodesis and total ankle replacement, is the only reliable treatment option for end-stage tibiotalar OA [3]. Tibiotalar arthrodesis, which involves fusing the tibia and talus, is most commonly performed. This procedure alleviates pain, but nearly 50% of patients are unable to return to their desired activities due to complete restriction of the tibiotalar joint [4]. Eliminating tibiotalar motion may also contribute to secondary OA at the adjacent joints in the hindfoot, especially the subtalar joint [5]. Measurements of subtalar kinematics after tibiotalar arthrodesis would improve our understanding of the biomechanical effects of this surgery, and could identify the pathogenesis of OA at this joint.

The objective of this study was to quantify in-vivo, dynamic subtalar motion using dual-fluoroscopy (DF), which is a radiostereometric technique that accurately measures in-vivo bone motion without the use of markers adhered to the skin. We hypothesized that the subtalar joint of the arthrodesis limb would demonstrate increased motion relative to that of the contralateral, asymptomatic, non-surgical ankle.

METHODS

In this IRB-approved (University of Utah #65620) preliminary study, four asymptomatic patients who previously underwent unilateral tibiotalar arthrodesis were studied (2 men, 2 women; 53.8 ± 9.5 yrs; BMI 26.9 ± 3.2 kg/m^2, 2 right, 2 left). The mean time from surgery to testing was 4.0 ± 2.1 years. Plain film radiographs were collected prospectively to screen participants for subtalar deformities or degeneration on the arthrodesis limb and for OA and/or deformities on their contralateral limb. No subjects were excluded based on these criteria.

A validated high-speed DF system was used to measure subtalar kinematics [6]. All participants completed one trial of overground barefoot walking at a self-selected speed. A computed tomography (CT) scan of each patient was acquired (SOMATOM Definition AS; Siemens Medical Solutions) from mid-tibia through metatarsals at a 0.6 mm slice thickness. For each patient, the fused tibia/talus and calcaneus were segmented on the surgical side and the tibia, talus, and calcaneus were segmented on the contralateral side (Amira 6.0; Visage Imaging). Markerless tracking [7] was used to quantify in-vivo motion of the subtalar joint on the surgical and contralateral side. Subtalar joint angles were calculated using landmark based coordinate system definitions [8] and the Grood and Suntay method [9].

Given the small sample, the mean 95% confidence intervals (CIs) of the joint angles were plotted to visualize group profiles. Separate paired t-tests assessed subtalar joint angle differences between the arthrodesis and contralateral limbs. Comparisons were made between total ranges of motion (ROM) during stance and for the joint angle magnitude and direction at three separate time points (i.e., loading response, mid-stance, terminal stance) corresponding to 15%, 50%, and 85% of normalized stance.

RESULTS AND DISCUSSION

Arthrodesis and contralateral subtalar joint angles did not consistently differ when visualizing their 95% CI joint angle profiles during the entire stance phase (Figure 1). However, over the entire activity, the arthrodesis subtalar joint 5.5º (4.3º, 6.8º) exhibited significantly less inversion/eversion ROM ($p = 0.01$) than the contralateral limb 7.8º (6.7º, 8.8º) with a trend towards inversion. When analyzed at the discrete time points, significant differences were found in one instance. Specifically, during the

loading response, the arthrodesis subtalar plantarflexion angles were significantly greater than those of the contralateral limb (p=0.03). Clinically, the increased plantarflexion occurring at loading response indicates hypermobility. The hypermobility may be compensating for the fixed tibiotalar joint, which no longer allows for this typical motion as the limb transitions to weight-bearing.

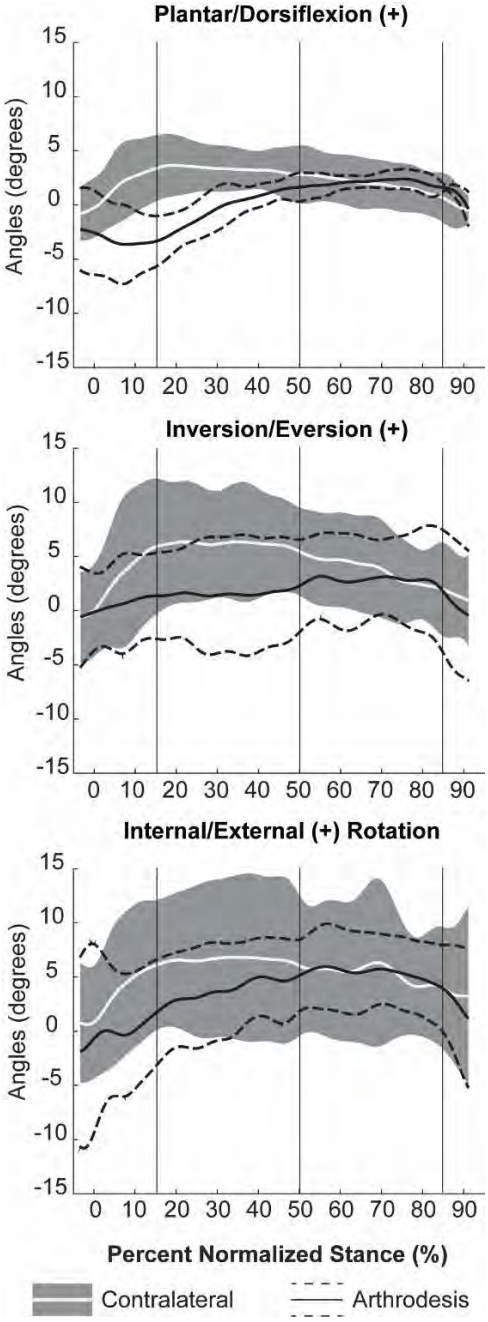

Figure 1: Mean (± 95% CI) subtalar joint angles for the surgically-altered limb (black) compared to the non-surgical contralateral limb (gray). Data are plotted per normalized percent stance. Vertical lines correspond to discrete time points that were analyzed.

Considering the small sample size, a post-hoc power analysis was conducted. For comparisons of Inv/Ev ROM and loading response plantarflexion, calculated power was 86% for Inv/Ev and 99.9% for loading response results. However, we recognize that our population size is a statistical limitation and are currently analyzing 6 additional asymptomatic tibiotalar arthrodesis subjects.

CONCLUSIONS

To our knowledge, this is the first study to investigate subtalar kinematics following arthrodesis using DF. We found altered subtalar joint angles in the arthrodesis limb, providing evidence that compensatory motion may induce OA in joints adjacent to the fusion site. Although only a preliminary study, our results are encouraging and warrant further investigation using a larger sample size. In the future, we intend to study patients undergoing arthrodesis pre- and post-surgical intervention to understand to what extent compensatory movements exist pre-operatively during the onset of OA. Clinically, patients may already demonstrate stiffness of their subtalar joint secondary to post-traumatic injuries which would not be addressed by fusing the tibiotalar joint. Ultimately, these data may provide the information necessary to develop novel treatment strategies aimed at alleviating pain and improving function.

INFLUENCE OF LIFETIME RUNNING EXPOSURES ON ANKLE KINETICS AND PLANTARFLEXOR MORPHOLOGY

[1]Ramzi M. Majaj, [1]Douglas W. Powell, [1]Max R. Paquette

email: rmmajaj@memphis.edu, website: http://www.memphis.edu/shs/research/mal.php

INTRODUCTION

Aging is associated with reductions in walking (1) and running (2) speeds. Older runners run with reduced preferred (2) and maximal (3) running speed accompanied by a reduction in step length (2,3) which may be the result of lower magnitudes propulsive forces and ankle kinetics observed with aging (2). Running experience (4), volume and intensity (5) may contribute to the preservation of ankle kinetics as runners age. Further, running training also appears to influence morphological properties of plantarflexors with age (6). However, the influence of lifetime running exposure on ankle kinetics during running and, morphological properties of plantarflexors is not well understood.

Considering the importance of training stimuli on endurance performance and muscle function in older adults, the purpose of this study was to examine the influence of lifetime running exposure on ankle kinetics during running, and medial gastrocnemius (MG) morphological properties in older runners. We hypothesized that older runners with higher lifetime running exposure would run with larger peak ankle moment and positive power compared to runners with low lifetime running exposure. We also expected that runners with high lifetime running exposure would have larger pennation angle, shorter fascicle length, and greater fascicle stiffness of the MG compared to runners with lower lifetime running exposure.

METHODS

Runners over 50 years of age with different lifetime running exposure participated in the study. Participants were grouped in low (LRE; 8834±3823 miles; n=12; 59±8 yrs) or high (HRE; 45984±14967 miles; n=9; 62±7 yrs) lifetime running exposure (Table 1). Lifetime training exposure was defined as the product of number of lifetime running years, average weekly lifetime running mileage, and average number of weeks running per year. During a single testing session, participants performed five successful over-ground running trials at 2.7m/s (±5%) while kinematic (240Hz Qualisys, Sweden) and ground reaction force (GRF) (1200Hz, AMTI, USA) data were collected simultaneously using Qualisys, Track Manager software. Using kinematic and GRF data, net joint moments were calculated using Newtonian inverse dynamics (Visual3D, C-Motion), and joint powers were calculated as the dot product of joint moment and angular velocity. The average peak joint moments and positive powers of the five trials was used in statistical analyses.

Following the running trials, right MG morphological characteristics were assessed using a linear array ultrasound transducer (L12-4MHz Philips, Lumify; USA), positioned along the longitudinal axis of MG at ~50% of muscle length, and secured using a custom-designed plastic mold. Ultrasound images where taken in both rested and dynamic conditions. During these measurements, participants were secured to a custom-built table with a strain gauge (Model MLP-1k, Transducer Techniques, Temecula, CA) in line with a chain and a custom foot pedal used to target plantarflexor tensile forces. Participants were in a prone position with the ankle joint angle at 90 degrees. The plantarflexor tensile forces corresponded to 25%, 50%, 75%, and 100% of previously reported forces of plantarflexors during running (7). MG imaging and analysis were conducted by the same sonographer using free online software (ImageJ, NIH). Pennation angle (θ) was measured as the angle of insertion of muscle fascicle into the deep aponeurosis. Fascicle length (FL) was then computed for rested and dynamic images using a previously reported equation (8). Stiffness was computed as the slope of tensile forces applied on strain gauge, and changes in FL between rested and dynamic

conditions (ΔL). Independent sample t-tests ($p \leq 0.05$) (SPSS 24.0, IBM) and Cohen's *d* effect sizes were used to compare all dependent variables.

RESULTS AND DISCUSSION

Our results reveal no differences in step length, ankle plantarflexors and knee extensor torques and positive powers, and hip flexion torque between older runners of different lifetime running exposure ($p>0.05$) (Table 2). Runners with HRE ran with greater concentric hip power compared to runners with LRE ($p=0.020$; $d=1.16$). These results are consistent with previous literature showing that individuals with higher overall capacity produce more hip power during walking (9). These results demonstrate that although middle-aged runners run with similar positive joint powers as young runners when weekly mileage is similar between groups (5), more lifetime running exposure does not appear to improve ankle joint kinetics within an older runner population.

Table 2: Peak lower limb joint torques and positive powers (mean±SD).

	LRE	HRE
Propulsive Force (BW)	0.21±0.03	0.21±0.04
Ankle Torque ($Nm \cdot kg^{-1}$)	-2.2±0.2	-2.3±0.4
Ankle Power ($Nm \cdot kg^{-1}$)	6.8±0.8	7.2±2.0
Knee Torque ($Nm \cdot kg^{-1}$)	1.98±0.35	1.91±0.50
Knee Power ($W \cdot kg^{-1}$)	3.03±0.84	3.11±0.98
Hip Torque ($Nm \cdot kg^{-1}$)	0.67±0.11	0.70±0.18
Hip Power ($W \cdot kg^{-1}$) *	2.19±1.31	3.14±1.0

Notes: *: $p<0.05$ with moderate Cohen's *d* effect size.

MG imaging revealed that pennation angles under rested and all dynamic tensile forces were smaller for the HRE group compared to runners with LRE ($p<0.05$; $d=0.96$-1.04), with no differences in MG stiffness ($p>0.05$; $d=0.01$) (Table 3). Runners tend to have larger MG pennation under resting conditions compared to non-active individuals (4) but contradicting literature reports no differences in MG pennation angle between older adults with different training exposures (10). Conflicting evidence may be the result of the cross-sectional nature of these studies and it is evidence that longitudinal studies are still needed to understand the influence of lifetime training exposures on morphological properties of muscles.

Table 3: Fascial length (FL) change between rested and dynamic conditions, tensile forces (TF), and stiffness for MG (mean±SD).

	LRE	HRE
25% ΔL (mm)	7.18±2.85	5.24±2.38
50% ΔL (mm)	9.42±3.10	8.92±3.38
75% ΔL (mm)	11.31±3.28	10.60±2.76
100% ΔL (mm)	13.86±4.70	11.46±3.00
TF 25% (N)	148.2±21.8	137.1±19.3
TF 50% (N)	264.0±44.0	234.4±38.4
TF 75% (N)	378.9±67.6	332.5±50.1
TF 100% (N)	495.6±89.7	434.1±66.9
Stiffness ($N \cdot mm^{-1}$)	39.5±18.8	39.8±22.7

CONCLUSIONS

Lifetime running exposure in older runners does not appear to influence ankle and knee kinetics but runners with HRE appear to run with greater hip concentric power compared to those with LRE. In addition, lifetime running exposure does not appear to influence mechanical properties of MG despite differences in pennation angles. However, this study was cross-sectional and longitudinal cohorts are necessary to truly understand how lifetime running exposure may influence joint kinetics during gait, and muscle morphology in older runners. Finally, we are currently studying the influence of lifetime running exposure on gait biomechanics and plantarflexor morphology in older adults to better understand the impact of running on walking function with aging.

ROBOTIC APPROACH TO CHARACTERIZE ALTERED ANKLE MECHANICS AFFECTED BY STROKE AND MULTIPLE SCLEROSIS

INTRODUCTION

Neurological disorders, such as stroke and multiple sclerosis (MS), are one of the leading causes of adult disability around the world. These disorders often impact lower limb function such as postural balance and locomotion. While mounting evidence suggests that the human ankle joint plays one of the most important roles in lower limb function at the interface between the neuromuscular system and the physical world [1], little is known about how neurological disorders alter ankle mechanics and how this alteration impacts the overall quality of patients' lower limb function. This is mainly due to the lack of appropriate characterization technology. In this study, we proposed a robotic approach to characterize ankle mechanics during upright standing, ran a pilot study with stroke and MS subjects, and evaluated its reliability.

METHODS

Two chronic stroke survivors (age: 54-60, weight: 60-65 kg) and two relapsing and remitting MS patients (age: 49-50, weight: 63-81 kg) participated in this pilot study. All subjects were affected on their right leg. In addition, three healthy subjects (age: 23-31, weight: 56-71 kg) were recruited to serve as a reference. This study was approved by the Institutional Review Board of Arizona State University and all experiments were performed after informed consent of the subjects.

We utilized a novel multi-axis robotic platform to quantify stiffness and damping components of the ankle mechanics during upright standing in 2 degree-of-freedom (DOF) of the ankle, specifically, dorsiflexion-plantarflexion (DP) and inversion-eversion (IE) [2] (Fig. 1).

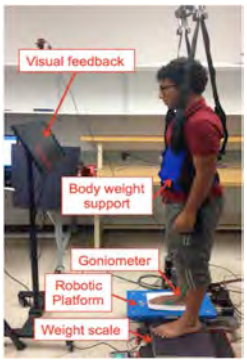

Figure 1 The experimental setup.

Each subject was instructed to stand upright with the right foot (affected side) on the robotic platform and the left foot on the weight scale, which was used to ensure equal weight distribution between legs. A dual-axis goniometer was attached to the subject's ankle to measure ankle angles in 2 DOFs. To encourage the subject to maintain the same upright posture, visual feedback was used, which displayed real-time center-of-pressure location in 2 DOFs as well as weight distribution between legs.

Once the subject maintained upright posture, ramp perturbations (amplitude: 3°, speed: 40°/s) were applied to the ankle in one of the 4 directions in random order: dorsiflexion, plantarflexion, inversion, and eversion. Ten repeated trials were completed for each perturbation direction.

Ankle stiffness and damping parameters in each DOF were quantified by fitting a 2nd order model (consisting of ankle stiffness, ankle damping, and foot inertia) to the measured kinematics and torques at the ankle. Reliability of quantification was evaluated by calculating the percentage variance accounted for (%VAF) between the measured ankle torques and estimated ankle torques from the best-fit 2nd order model.

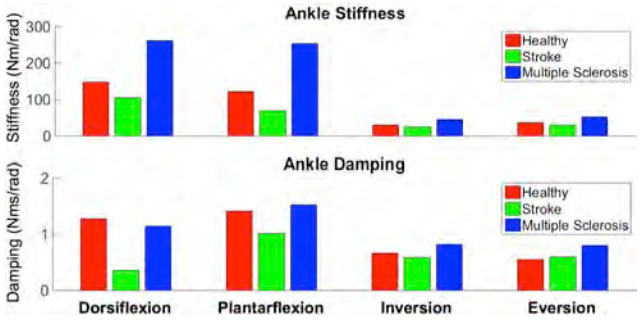

Figure 2: Comparison of ankle stiffness (A) and damping (B) of healthy, Stroke and MS subjects.

RESULTS AND DISCUSSION

In all stroke and MS subjects, the reliability for the characterization of ankle mechanics, i.e., %VAF, was higher than 98% in both DOF of the ankle and in any perturbation directions. This high reliability with a 2nd order model demonstrated that even altered ankle mechanics in stroke and MS patients could be accurately quantified by ankle stiffness and ankle damping parameters as in healthy subjects.

Ankle stiffness and damping in DP (DP stiffness and damping) of both stroke subjects were lower than those of healthy subjects (Fig. 2). In particular, DP stiffness of the first stroke subject was 2~3 times lower than the healthy human stiffness (Table I). Lower DP stiffness and damping could explain the prevalence of drop foot in stroke survivors.

Ankle stiffness in IE (IE stiffness) of both stroke subjects was lower than that of healthy subjects. However, the difference in IE stiffness between groups (stroke vs. healthy) was much smaller than DP stiffness. Ankle damping in IE (IE damping) was comparable to that of healthy subjects (Table I).

Contrary to the results in stroke subjects, DP stiffness of both MS subjects was higher than that of healthy subjects. In average, DP stiffness of MS subjects was about 2 times higher than the healthy human stiffness. This result may be due to higher spasticity and/or altered passive muscle properties in MS patients. DP damping of MS subjects was comparable to that of healthy subjects (Table I).

Both MS subjects exhibited higher IE stiffness and damping than those of healthy subjects. However, the difference in IE stiffness between groups was much smaller than DP stiffness (Table I).

CONCULSIONS

This study demonstrated that the proposed robotic approach based on a multi-axis robotic platform could be reliably used for the quantification of altered ankle mechanics in 2 DOFs in stroke and MS patients, evidenced by the high reliability measure in all experimental conditions.

This study also confirmed that altered ankle mechanics during upright standing are highly dependent on the type of neurological disorder. In addition, according to the results of this pilot study, both stroke and MS have higher impact on the alteration of ankle mechanics along DP in the sagittal plane than IE in the frontal plane.

Findings in this study support the need for individual characterization of altered ankle mechanics in order to deliver optimal patient-specific rehabilitation services. For example, the MS subjects in this study would need stretching exercises to increase joint flexibility, while the stroke subjects would need strengthening exercises to reduce weakness at the ankle joint.

REM sleep without atonia affects steady-state gait in early Parkinson's disease

Sommer Amundsen Huffmaster[1], Matthew Petrucci[1], Maria Linn[1], Michael Howell[1], Paul Tuite[1], Colum MacKinnon[1]

[1]Department of Neurology, University of Minnesota, MN, USA 55455
email: cmackinn@umn.edu, web: http://www.neurology.umn.edu/mackinnon_lab.html

INTRODUCTION

Advancing Parkinson's disease (PD) is associated with the emergence of postural instability and gait disturbances. These symptoms tend to occur earlier and be more severe in people that have PD and rapid eye movement (REM) sleep behavior disorder (RBD) [1]. RBD is a parasomnia characterized by dream enactment and elevated muscle activity during REM sleep (termed REM sleep without atonia, RSWA). People with RBD have a high probability of developing Parkinson's disease (PD) or a related neurodegenerative disorder [2,3], suggesting a link between the loss of REM sleep atonia and the neural system that controls gait and posture.

People with RBD and no diagnosis of neurodegenerative disease (e.g., PD) show abnormalities during steady-state gait. However, the variables affected were confined to those in the temporal domain including decreased velocity, cadence, and increased variability in double support and swing time [4]. For this reason, we tested the hypothesis that people with early PD who express RSWA would show significant changes in temporal measures of steady-state gait compared to those with PD without RSWA and matched controls.

METHODS

Thirty-three individuals with PD were tested (22 with RSWA+, age 65.1 ± 6.6, 11 females; 13 without RSWA-, age 62.5 ± 7.8, 7 females) along with 18 matched control subjects (age 60.8 ± 7.4, 12 females). Categorization of having abnormal levels of RSWA was based on the results of an overnight sleep test and assessment of REM sleep EMG activity from the polysomnographic recordings. PD subject's gait was tested after overnight withdrawal from Parkinson's disease medications. Steady-state gait was tested using a GaitRite walkway (CIR Systems, Inc, Franklin, NJ). Subjects were instructed to walk continuously at their comfortable walking pace around an oval course that included the GaiteRite walkway. A minimum of 35 full steps on the walkway were collected in each subject to ensure reliability [5]. Standard spatial and temporal gait characteristics were computed. Right and left leg variables were reassigned as being either more- (MA) or less-affected (LA) by Parkinson's disease (determined by summing their laterality scores from the Unified Parkinson's Disease Rating Scale). General linear model univariate ANOVAs were used to test for differences between groups (threshold for significance at $p < 0.05$).

RESULTS AND DISCUSSION

Significant main effects were observed for many of the temporal features of steady-state gait (Table 1). For follow-up comparisons of the PD-RSWA+ group to controls, gait speed ($p = 0.017$), and normalized speed (leg length/s; $p = 0.024$) were significantly slower while double-support time (MA: $p = 0.044$, LA: $p = 0.031$) and percent of gait cycle spent in double-support (MA: $p = 0.040$, LA: $p = 0.024$) were significantly longer. Similar effects were observed in lateralized variables. Percentage of the gait cycle spent in stance ($p = 0.004$) and swing ($p = 0.004$) with the LA leg were increased, and decreased, respectively, and the percentage of the cycle in single support of the MA leg was increased ($p = 0.004$) in the PD-RSWA+ group compared to controls. MA stride ($p = 0.038$) time variability was also significantly larger in the PD-RWSA+ group than controls. It is noteworthy that few differences in the temporal characteristics of gait were observed between the control and the PD-RSWA- groups, with the exception of LA stance time variability ($p = 0.003$). The only variables that showed significant differences between PD groups were LA stance ($p = 0.035$) and MA stride time variability ($p = 0.038$). Interestingly, PD-RSWA- had less variability compared to controls and PD-RSWA+. There were

no significant main effects of group across any of the spatial parameters of gait ($p > 0.05$).

CONCLUSIONS

Many of the timing variables associated with steady-state over-ground gait were different in the PD-RSWA+ group relative to matched controls subjects. In contrast, spatial variables were not significantly different across groups. Few differences were seen between those with PD-RSWA- and control subjects.

Our findings are consistent with the report that people with RBD, but no diagnosis of PD (although potentially in a prodromal stage of neurodegenerative disease), show significant changes in many temporal, but not spatial, gait variables [4]. This suggests that early pathophysiological changes in the brainstem circuitry controlling the regulation of muscle tone during REM sleep is associated with alterations in the timing of the locomotor cycle. Thus, simple temporal measures of gait may provide a biomarker of early or prodromal neurodegenerative process leading to postural instability and gait dysfunction. Individuals with these changes should be targeted for early exercise interventions to prevent or slow the evolution of gait impairment and perhaps slow disease progression.

INTRODUCTION

Rotator cuff repair (RCR) surgery has a high rate of failure, with 25-94% re-tearing reported [1,2]. Failure is thought to be due to excessive strain on the surgical repair construct before proper healing has occurred, possibly through over activation of the rotator cuff muscles [3]. Persistent postoperative stiffness has been shown as a complication of RCR, with rates ranging up to or greater than 10% [4]. It is critical to engage the shoulder in passive range of motion exercises to avoid adhesions in the immobilized joint, while care is taken not to activate the muscles of the shoulder to avoid re-tearing of the surgical construct. The purpose of this study was to assess the activation of the shoulder muscles during passive exercises used in physical therapy immediately following RCR surgery using fine wire and surface electromyography (EMG).

METHODS

Approval was obtained from the Medical College of Wisconsin Institutional Review Board prior to beginning the study, and all subjects signed informed consent. 14 subjects, 8 females (24.9 ± 4.5 years) and 6 males (27.8 ± 3.1 years) were included in the study. Subjects were screened to determine eligibility. Exclusion criteria included: any history of shoulder injury, surgery, instability or pain, knowledge of rehabilitation exercises, as well as over the age of 50. The dominant hand shoulder was used for all subjects. All electrodes were applied by a board certified Physical Medicine and Rehabilitation physician. Four fine wire (fwEMG) electrodes were inserted into the supraspinatus (SUPR), infraspinatus (INFR), teres minor (TEMI) and subscapularis (SUBS) muscles, along with six surface (sEMG) electrodes placed on the biceps (BICE), posterior deltoid (PODE), lateral deltoid (LADE), anterior deltoid (ANDE), upper trapezius (UPTR) and the middle trapezius (MITR) following methods previously described [5,6].

EMG data were collected at 2000 Hz using a Delsys Trigno Wireless EMG system (Natick, MA) running EMGWorks 4.3.1 software. After EMG placement, maximum voluntary isometric contractions (MVIC) were recorded for each muscle. Using a Biodex System 3 to position the arm in the correct position, the subject was instructed to perform three maximal isometric contractions of each muscle for three second intervals, with ten seconds of rest between contractions. The peak amplitude during the three trials was defined as 100%.

Subjects were instructed by a licensed physical therapist in the proper technique of the following tasks: 1. Seated external rotation with a cane; 2. Standing towel slide into flexion; 3. Codman's pendulums; 4. Swiss ball rolls into flexion; 5. Seated towel slides into flexion; 6. Standing forward bows into flexion; 7. Seated pulleys into flexion; 8. Seated pulleys into scaption; 9. Seated pulleys into abduction; 10. Continuous Passive Motion (CPM) machine level 1 (30 to 50° abduction (ABD), 0 to 10° external rotation (ER)); 11. CPM level 2 (30 to 95° ABD, 0 to 25° ER); 12. CPM level 3 (30 to 140° ABD, 0 to 40° ER); 13. Donning a brace; 14. Doffing a brace; 15. Donning a brace with assistance; 16. Doffing a brace with assistance. Subjects practiced each task to the satisfaction of the therapist, and then EMG activity was recorded for all muscles during 3 repetitions of each task. The mean EMG activity values were calculated for each muscle for the entire duration of each task. All EMG data, including MVIC trials, were processed using a root-mean-square algorithm with a 0.625 second moving window. Muscle activation was normalized as %MVIC for each muscle for all tasks.

Two-sided Wilcoxon signed rank tests were applied using SAS version 9.4 (Cary, NC) and R 3.4 (www.r-project.org) statistical software to compare the %MVIC with 15%, which is considered a safe level of effort [5]. Exercises were classified into clinical groups by their statistical significance and the magnitude of their medians (Table 1).

Table 1: Safety score p-values

1	**Definitely Safe**: p-value < 0.001, median < 5%
2	**Safe**: p-value < 0.01, median < 10%
3	**Potentially Safe**: p-value < 0.05, median < 15%
4	**Borderline LOW**: p-value > 0.05, median < 10%
5	**Borderline**: p-value > 0.05, median between 10-20%
6	**Borderline HIGH**: p-value > 0.05, median > 20%
7	**Potentially Dangerous**: p-value <0.05, median> 15%
8	**Dangerous**: p-value < 0.01, median > 20%

RESULTS AND DISCUSSION

One hundred and sixty study outcomes were analyzed and categorized into a safety score (Table 2). The safety score aimed to attribute a level of risk associated with the corresponding exercise in terms of the level of muscle activation as measured by EMG. The average safety score for the fwEMG and sEMG were calculated, along with the overall score for each exercise. Three tasks (standing towel slides into flexion, standing forward bows into flexion, and donning a brace with assistance) showed a mean %MVIC greater than 15% and reached the peak safety score in the subscapularis muscle. No other muscles were over the 15% cutoff level for any task. Tasks such as exercises going into flexion (Ex 2, 4, 6), pulleys (Ex 7, 8, 9), and donning a brace (Ex13) show greater EMG activity, while the CPM machine at levels 1 and 2 (Ex 10, 11) showed the lowest EMG activity for the rotator cuff muscles. The main limitation of the current study was using subjects devoid of shoulder pathology. The activity of the shoulder muscles in healthy subjects may not be representative of the activity of individuals with a repaired rotator cuff muscle.

Overall, the goal of this study was to determine shoulder muscle activation during routinely prescribed rehabilitation tasks, to better inform clinicians on prescribing early post-operatively exercises. The bulk of the tasks demonstrated activation levels below the 15% cutoff. Though the supraspinatus, infraspinatus, and teres minor EMG activity was generally low, higher activity was observed in the subscapularis. Therefore, caution should be used when administering exercises to individuals with tears involving the subscapularis.

WALKING BIOMECHANICS IN INDIVIDUALS WITH KNEE OSTEOARTHRITIS AFTER QUADRICEPS STRENGTHING

INTRODUCTION

Altered knee sagittal plane kinetics during walking are associated with worse pain outcomes in individuals with knee osteoarthritis (KOA) [1]. It is hypothesized that knee sagittal plane kinetics are influenced, in part, by quadriceps weakness [2]. Therefore, it is plausible that improving quadriceps strength may alter gait biomechanics. The primary purpose was to determine the association between baseline quadriceps strength and walking gait biomechanics linked to KOA onset and progression. The secondary purpose was to determine if individuals who increased quadriceps strength following 4-weeks of physical therapy (responders) demonstrated changes in gait biomechanics compared to individuals who did not increase quadriceps strength (non-responders).

METHODS

Physical Therapy for Knee Osteoarthritis
53 individuals with radiographic and symptomatic KOA (Kellgren-Lawrence grade 2-4, 47% female, 62.3±7.1 years, BMI = 28.5±3.9 kg/m^2) were enrolled in 10 sessions of supervised, progressive lower extremity strengthening directed by a licensed physical therapist over a 28-day period.

Quadriceps Strength
Maximum isometric quadriceps strength was measured on the involved limb (with bilateral KOA, the involved limb was defined as the more symptomatic limb) using a dynamometer at baseline and following the 4-week physical therapy protocol. 3-5 maximal strength practice trials were conducted to determine a target torque threshold. Then 2 maximal effort trials were conducted where participants were instructed to straighten their knee as fast as possible to reach or surpass the target torque threshold. Quadriceps strength was defined as peak torque and normalized to body mass (Nm/kg). The minimal detectable change (MDC) of quadriceps strength was calculated using the standard error of measurement and intraclass correlation coefficient from the baseline quadriceps strength measurements [3]. Individuals who increased quadriceps strength by ≥0.31 Nm/kg were classified as strength responders; those who did not increase by this amount were classified as non-responders for the secondary analysis.

Walking Gait Biomechanics
Participants were outfitted with retroreflective markers and walked at a self-selected comfortable speed down a 6m walkway that contained 2 staggered, embedded Bertec force plates and a 10-camera three-dimensional motion capture system (Vicon Nexus). 5 trials were collected where the participant walked at a pace within 5% of the average speed determined during previous practice trials. Vertical ground reaction force (vGRF), knee flexion angle, and internal knee extension moment were time-normalized to percent of stance phase (heel-strike to toe-off) using linear interpolation techniques. Moments were normalized to the product of body weight (BW) and height (m), and vGRF was normalized to BW. Peak vGRF, knee flexion displacement, peak knee flexion angle, and peak internal knee extension moment (a larger negative value = greater moment) were identified during the first 50% of the stance phase. Ensemble average waveforms were created by averaging the waveforms of each trial for each participant.

Statistical Analysis
For the primary aim, linear regression analyses were conducted to determine associations between baseline quadriceps strength and biomechanical variables after accounting for walking speed as a

covariate (ΔR^2). For the secondary aim, one-way ANCOVAs were conducted (percent change in walking speed from baseline to 4-weeks as the covariate) to determine differences between each biomechanical variable following 4-weeks of physical therapy between strength responders and non-responders. Next, ensemble average waveforms with 95% confidence intervals (CI) were plotted throughout the stance phase for responders and non-responders, and time points where 95% CI did not overlap were considered statistically different.

RESULTS

There were no differences in demographics between responders (n=21) and non-responders (n=32). Greater peak vGRF (R = 0.37 ΔR^2 = 0.08, p=0.02), peak knee flexion angle (R = 0.24, ΔR^2 = 0.12, p=0.01), and peak internal knee extension moment (R = 0.12, ΔR^2 = 0.08, p=0.04) all significantly associated with greater quadriceps strength after accounting for walking speed at baseline while knee flexion displacement (R = 0.11, ΔR^2 = 0.06, p=0.07) did not. Between strength responders and non-responders, there were no significant differences in the percent change of any biomechanical variable from baseline to 4-weeks (p-values ranged from 0.31 to 0.52). Visual examination of ensemble average waveforms with 95% confidence intervals between responders and non-responders showed no significant differences in any portion of the stance phase for any biomechanical variable (Figure 1).

DISCUSSION

Greater quadriceps strength associated with greater biomechanical variables at baseline; yet there were no differences in walking gait biomechanics between responders and non-responders to the strength intervention at either time point. Quadriceps strengthening may not be a mechanism directly responsible for an acute change in walking gait biomechanics in individuals with KOA. Future studies should consider directly targeting gait biomechanics with specific interventions to optimize gait in individuals with KOA, as quadriceps strengthening alone may not sufficiently influence adaptations in gait biomechanics.

DEVELOPMENT OF AN INTERVENTION-FOCUSED METRIC OF GAIT BALANCE

[1,2] Jesse C. Dean

[1] Ralph H. Johnson VAMC, Charleston, SC, USA
[2] Medical University of South Carolina, Charleston, SC, USA
email: deaje@musc.edu

INTRODUCTION

Many clinical populations, including chronic stroke survivors, exhibit deficits in gait balance. Such deficits can limit gait function due to an increased fall-risk and an increased fear of falling. The high prevalence of this problem has motivated the development of numerous metrics to quantify gait balance [1-2].

Several of these metrics have shown promise for identifying individuals with an increased fall-risk or fear of falling. However, few metrics provide clear justification for a specific intervention, and thus are of limited usefulness to clinicians. In contrast, an ideal gait balance metric would be one in which the identified deficit suggests the appropriate treatment.

For example, a metric quantifying muscle weakness could clearly be used to justify a strengthening intervention. A metric quantifying maximal aerobic capacity could be used to justify a cardiovascular-focused intervention. Conversely, a potential link between fall-risk and increased step width [1] would be unlikely to justify training a narrow step gait.

We propose that a metric quantifying the relationship between pelvis motion and foot placement [3] has the potential to serve as a gait balance metric with a direct link to treatment. Supporting this proposal, healthy controls actively adjust step width based on mediolateral pelvis motion. A failure to do so has been linked to post-stroke balance deficits [4].

The purpose of this study was to determine whether our metric of post-stroke gait balance is both valid and adaptable in response to targeted treatment. First, we validated this metric against measures of direct clinical interest. Second, we determined whether this metric can be experimentally manipulated. A promising balance metric would pass both tests.

METHODS

The gait metric of interest quantifies the mechanics-dependent step-by-step adjustments in step width [3]. Briefly, in healthy controls, the mediolateral pelvis displacement relative to the stance foot at the start of a step predicts step width (Fig. 1). We quantify the strength of this relationship by calculating the partial correlation between these two measures (ρ_{disp}), accounting for mediolateral pelvis velocity. The face validity of this metric is supported by the long accepted link between step width modulation and mediolateral gait stability [5].

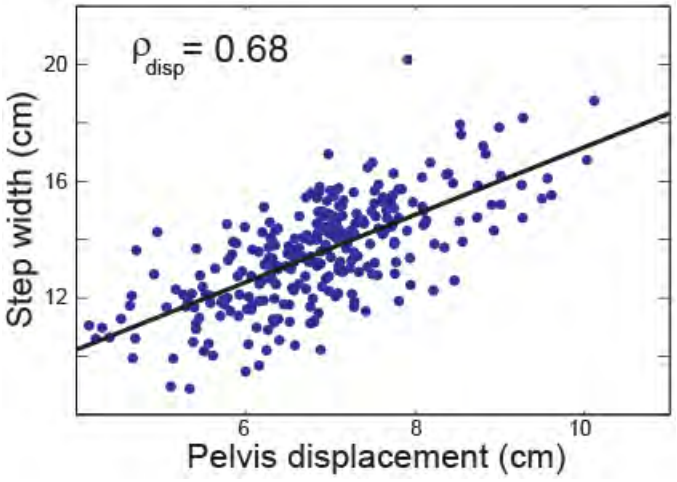

Figure 1. Relationship between pelvis displacement and step width. Each dot represents a single step.

The first component of this study involved 46 chronic stroke survivors (20 F / 26 M; 58 ± 14 yrs) able to independently walk at ≥0.2m/s. Participants provided informed consent using an IRB-approved form. We quantified ρ_{disp} using marker data collected from 3-minutes of treadmill walking at self-selected speed. We measured Functional Gait Assessment score (FGA; a common clinical test of gait balance) and self-selected overground walking speed (a common measure of general gait function). Finally, we recorded whether participants had fallen in the prior year, or had a self-reported fear of falling.

To test the criterion validity of our metric, we correlated ρ_{disp} with FGA score and overground speed. We also used receiver operator characteristic analysis to determine whether ρ_{disp} predicts individuals with a history or fear of falling.

The second component involved a subset of previous participants (n=18; 14 F / 4 M; 67 ± 10 yrs). Participants first walked normally on a treadmill at self-selected speed for 3-minutes. They then walked for 6-minutes while interfaced with a novel force-field, detailed previously [6]. The force-field applied mediolateral forces to the legs to influence step width on a step-by-step basis [7]. For the first 5-minutes, the force-field either *Assisted* balance (n=9) or *Perturbed* balance (n=9) by pushing step width either toward or away from mechanically-appropriate locations, respectively. For the final minute of walking, the force-field simply got out of the way.

We quantified the change in ρ_{disp} relative to baseline during *Assisted* and *Perturbed* modes (direct effects), as well as in the final minute of walking (after effects). We used paired t-tests to determine whether any of these changes reached significance ($p<0.05$).

RESULTS AND DISCUSSION

ρ_{disp} was positively correlated with both FGA score ($r=0.54$) and overground speed ($r=0.55$). ρ_{disp} was also related to an individual's likelihood of having a history or fear of falling, quantified with an area under the curve (AUC) value of 0.72. Following a suggested rule of thumb [8], all of these relationships would be classified as having a large effect size. Interestingly, the AUC value derived from ρ_{disp} exceeded the matching calculated values from FGA score (0.55) or overground speed (0.58). Our metric thus appears to be at least as valuable as common clinical measures for predicting negative consequences of poor gait balance in this population.

Participants appeared to increase ρ_{disp} while step width was *Assisted* by the force-field (Fig. 2), but this change did not reach the level of significance ($p=0.09$). When the assistance ceased, participants simply returned to their baseline ρ_{disp} level. In contrast, ρ_{disp} was significantly ($p<0.001$) reduced when step width was *Perturbed* (Fig. 2), followed by a significant ($p=0.04$) increase in ρ_{disp} for the next minute of walking. These results demonstrate that our metric of gait balance can be experimentally manipulated using methods focused on the step-by-step adjustment of step width.

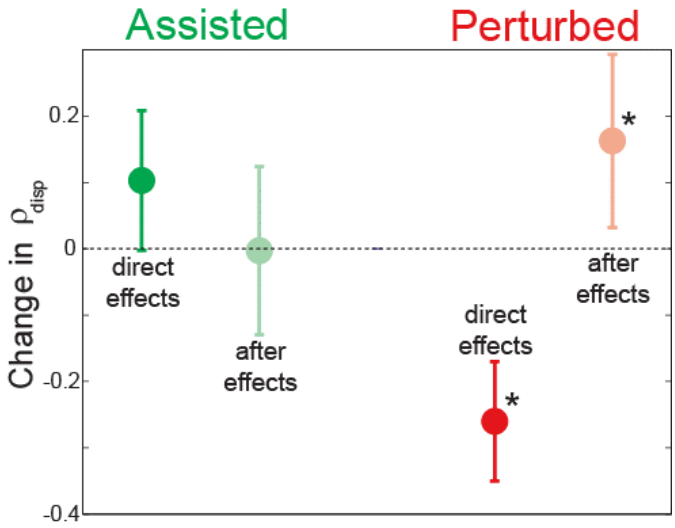

Figure 2. Direct effects and after-effects of walking with the force-field in *Assisted* and *Perturbed* modes.

CONCLUSIONS

Our proposed metric of gait balance (ρ_{disp}) focuses on one specific aspect of a stable walking pattern – the ability to appropriately adjust step width based on the mechanical state of the body. Despite this narrow focus, our results demonstrate that ρ_{disp} meets our dual goals of: 1) validity in comparison to measures of clinical interest; and 2) the potential to be experimentally manipulated. This combination of results has motivated an ongoing intervention (NCT02964039) to test whether repeated exposure to our force-field can improve post-stroke gait balance.

INTERNAL REPRESENTATION OF EXTERNAL PATIENT DYNAMICS DURING LOCOMOTOR REHABILITATION

[1] Sarah E. Goodman and [1,2,3] Christopher J. Hasson

[1] Departments of Bioengineering, [2] Physical Therapy, Movement and Rehabilitation Sciences, and [3] Biology
Neuromotor Systems Laboratory; Northeastern University, Boston MA [email: c.hasson@northeastern.edu]

INTRODUCTION

Locomotor impairments significantly reduce the quality of life and are typically addressed with locomotor rehabilitation. A key aspect of this therapy is that it involves simultaneous co-adaptation and learning: therapists must learn a patient's unique locomotor dynamics to apply forces effectively and elicit desired changes; patients must adapt to therapist force inputs to modify locomotor patterns in the way prescribed by the therapist. The current lack of understanding about this dynamic interaction may to some extent explain why a high percentage of patients retain locomotor impairments after rehabilitation [1].

In this work, we focus on the problem least explored: how do therapists learn patient locomotor dynamics? This is unknown in part due to the challenge of conducting controlled locomotor rehabilitation studies, as it can be difficult to quantify therapist adaptation if the patient is adapting in parallel.

Prior research using reaching tasks has shown that when faced with novel dynamics, e.g., artificial force fields, humans develop internal models of the field dynamics [e.g., ref. 2]. Here, we extrapolate this idea to investigate whether therapists develop internal models of *locomotor dynamics*, which constitutes a more dynamically complex model compared to standard velocity-dependent force fields.

In this work, we present a new paradigm that uses an interactive locomotor simulator to circumvent co-adaptation confounds and investigate how humans learn to modify a patient's locomotor dynamics. In this approach, subjects use a manipulandum (GeoMagic Touch; 3D Systems) to interact with a locomoting virtual patient (VP), which is given an instantaneous stroke. The stroke is rendered as an end-point impedance [3] that pulls the subject's hand into a typical stroke locomotor pattern, as would happen if subjects were holding onto the ankles of real stroke survivors. In this scenario, subjects must learn how to apply the correct forces to the VP's leg to restore healthy locomotor kinematics. Internal model formation is probed using a classic force-field approach with a locomotor twist: pathological locomotor dynamics are used as the force-field. The hypothesis is that humans adapt to novel external locomotor dynamics by developing internal models of the dynamics.

METHODS

The VP was modeled as a planar linked two-segment system representing the thigh and shank (foot omitted). Rigid body impedance contributions, i.e., gravity, Coriolis, and inertial forces, were based on manipulandum deviations from a reference locomotor pattern derived from pre-existing post-stroke locomotor kinematics [4] scaled down by 96.5%. Neuromuscular impedance contributions were represented by variable-stiffness rotational spring-dampers at the knee and hip joints, which modeled the spring-like behavior of muscle and geometric effects. The treadmill ground reaction forces were modeled using spring-dampers.

Healthy subjects practiced training the VP using the manipulandum under four conditions:

C1: Moving the VP's ankle to follow a healthy locomotor trajectory (80 steps).

C2: Adapting to a sudden stroke induced in the VP by applying forces to restore a healthy VP locomotor pattern (80 steps x 5 blocks).

C3: Adapting to the sudden elimination of the VP's stroke (40 steps).

C4: Adapting to a change in the VP's shank mass (40 steps).

In all conditions, the VP continuously walked in place as if on a treadmill. Intentionally, in the stroke condition (C2) the VP always tried to assume the same impaired locomotor pattern, i.e., it did not adapt. To probe internal model formation in C1 and C2 force channels [5] were applied during 8 randomly-selected 8 steps (out of 80). For these, the

stroke dynamics (if present) were turned off for one step and stiff springs applied orthogonal forces to keep the VP in a channel that followed the healthy kinematic trajectory. C3 probed after-effects by suddenly removing the VP's stroke (40 steps), and C4 tested generalization by changing a model parameter; shank mass increased by 50% (40 steps).

RESULTS AND DISCUSSION

Preliminary results are described here. When the VP was given a stroke the manipulandum generated forces that pulled the subject's hand (and VP's leg) towards the nominal stroke locomotor trajectory (Fig. 1; magenta line). With practice, subjects adapted by applying forces to counter this impedance (Fig. 1; red vectors), making the VP's leg follow the healthy trajectory (Fig 1; green line).

To probe adaptation, random force channels were imposed during the stroke practice condition (C2). During these trials, subjects exerted forces against the channel throughout almost the entire locomotor cycle, from mid-stance to heel-strike (Fig. 1; middle row; blue vectors). The presence of these forces reflect, in part, a subject's forward motor plan – at least during the first part of swing before significant feedback-driven modifications were possible.

A caveat in this force-channel interpretation is that a portion of the forces exerted during the force channels were due to subjects' inability to make the VP perfectly follow the healthy locomotor trajectory *without* the stroke dynamics imposed, especially during the rapid leg-swing. Therefore, the forces subjects exerted against the force channel during the healthy condition (C1) were subtracted from the stroke force-channel responses (C2; Fig. 1; middle row), which gives a clearer picture of a subject's adaptation to the *stroke* locomotor dynamics alone (Fig. 1; bottom row).

A significant aftereffect was observed after the stroke dynamics were switched off (C3), i.e., subjects made kinematic errors in the opposite direction. Subjects also showed generalization, as the kinematic errors with the parameter switch were smaller than during initial adaptation.

CONCLUSIONS

Together, the distinct patterns of forces that subjects exerted during the force channel trials, the presence of after-effects, and the generalization of performance lend support to the hypothesis that humans develop internal models of external patient locomotor dynamics. If these results hold for additional subjects, it will provide a theoretical foundation for future studies to explore ways of enhancing therapist effectiveness, such as speeding up and improving the accuracy of therapist internal models, and improving robotic gait rehabilitation control algorithms.

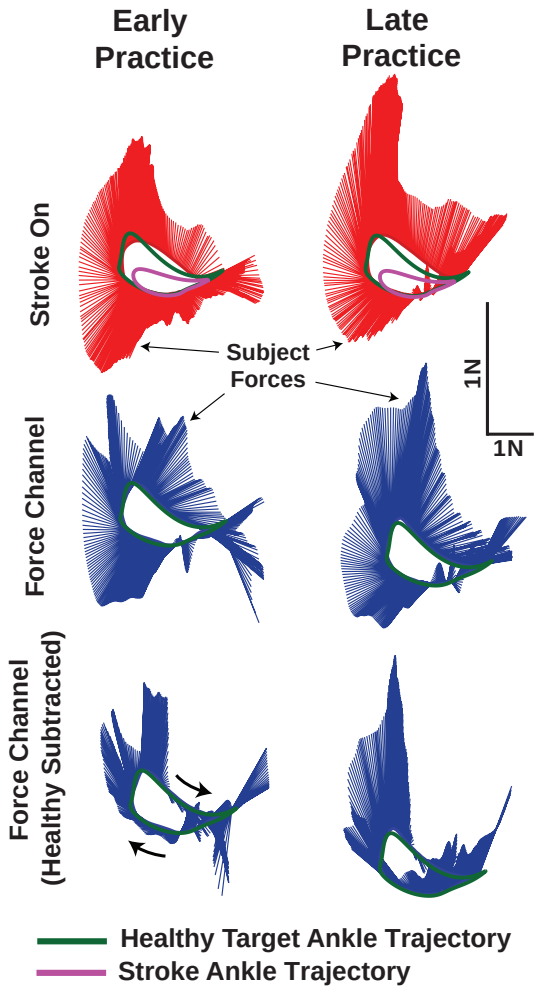

Figure 1. Exemplar kinematics and kinetics (applied forces) of subject adaptation to imposition of a stroke in the locomotor dynamics of a virtual patient. Adaptation to the stroke dynamics is shown in red, force-channel responses are shown in blue (see text for more details). Note scale is stretched vertically.

RELATIONSHIP BETWEEN NUMBER OF PHYSICAL THERAPY VISITS AND GAIT-RELATED OUTCOMES IN PATIENTS WITH BELOW-KNEE AMPUTATION

[1]Julianne Stewart, [1,2]Michael Marks, [1]Trevor Kingsbury, [1]Marilynn Wyatt

INTRODUCTION

The military healthcare system uses a well-structured, interdisciplinary approach to caring for service men and women who undergo amputation [1]. Patients who receive care at Naval Medical Center San Diego (NMCSD) have access to physical therapy (PT) five days per week once in the post-acute rehabilitation phase but use this resource to varying extents. Access to PT is far greater in the military healthcare setting than in the civilian healthcare system in the US, regardless of patient engagement with this resource [2].

As a part of the continuum of care for patients with amputation, instrumented gait analysis is available to help inform clinical decision-making and practice in physical therapy and prosthetic care. Patients have the option to undergo regular gait analysis throughout their rehabilitation at NMCSD beginning with a baseline (BL) gait study when deemed safe by a treating physical therapist to ambulate using a prosthesis without an assistive device. Each patient's BL gait study is then used to gauge the impact of further interventions and the patient's recovery during rehabilitation.

It is hypothesized that increased post-acute PT attendance in a group of patients with transtibial amputation, in the time frame between amputation and a gait study approximately six months (6mo) following the BL study, will lead to larger improvements in gait-related outcomes. Specifically, it is hypothesized that there will be a positive correlation between number of PT visits and percentage change in gait velocity, unaffected leg step length (SL), and affected leg stance time (StT). Additionally, it is hypothesized that there will be a negative correlation between number of PT visits and percentage change in affected leg SL, unaffected leg StT, and peak lateral trunk lean.

METHODS

A retrospective analysis of the NMCSD Gait Lab patient registry (IRB protocol #NMCSD.2014.0026) was performed and patients were selected for inclusion if they had a unilateral transtibial amputation between April 2012 and July 2017 and underwent both a BL and 6mo gait study in the NMCSD Gait Laboratory. Eight male patients were identified that fit these inclusion criteria. The patient group was aged 28.9±6.3 years. The number of post-acute physical therapy visits each patient attended was collected using the same patient registry.

During each gait study, retroreflective markers were applied to each patient's full body. Half of the included patients were markered using a modified Helen Hayes configuration throughout the duration of their care while the remaining patients were markered using a Six Degrees of Freedom (6DoF) configuration due to a change in lab procedures.

Three dimensional gait analysis was performed with a system of 12 Eagle motion capture cameras (Motion Analysis Corp., Santa Rosa, CA) and four force plates embedded into the laboratory floor (AMTI, Watertown, MA, USA). Data were collected using Cortex (Motion Analysis Corp., Santa Rosa, CA) and processed with Visual 3D (C-Motion Inc., Germantown, MD, USA) after a 4th order Butterworth filter was applied with a cutoff frequency of 6 Hz and 50 Hz for kinematic and kinetic data respectively.

Statistical analysis was performed using Excel (Microsoft, Redmond, WA, USA) and a Pearson's product-moment coefficient was calculated to

examine for correlation between number of physical therapy visits and each gait-related variable. Regression was performed for each variable.

RESULTS AND DISCUSSION

The only variable that was found to have a negative correlation with number of PT visits was affected leg step length (R = -0.83, R^2=0.68, p=0.01, Figure 1). Contrary to the authors' hypothesis, no variables were found to have a significant positive correlation with number of PT visits. However, several variables showed a trend toward correlation with number of PT visits. See Table 1 for details.

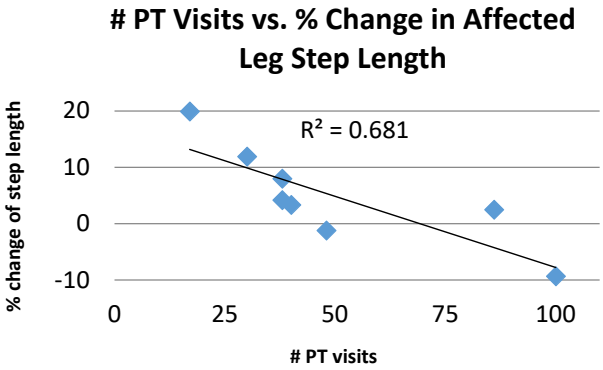

Figure 1: Scatterplot with number of PT visits on the horizontal axis and percentage change in affected leg step length from BL study to 6mo study on the vertical axis (trendline and R^2 value displayed).

The desired direction of change for affected leg step length can be patient-specific. A decrease may be the desired outcome for amputees who demonstrate large asymmetries in step length between affected and unaffected legs. However, affected and unaffected step length may both increase with increases in gait velocity, as demonstrated by the majority of positive changes in Figure 1.

Several caveats should be discussed when interpreting these results. The small sample size available for this analysis limits the ability to draw strong conclusions regarding the correlation between amount of physical therapy and gait-related outcomes. It should also be noted that many of these patients exhibited gait parameters within or very near the normal range for able-bodied individuals at the time of their BL studies and had engaged in 16.9±9.0 PT visits since final closure of amputation which might contribute to their excellent gait quality. Finally, two patients engaged in twice the amount of physical therapy visits of many of the other patients in this sample which may represent either difficult courses of care or very high levels of motivation. These two potential explanations would likely impact gait quality in very different ways and may skew the findings.

CONCLUSIONS

Understanding the relationship between amount of physical therapy after amputation and rehabilitation outcomes is crucial in order to optimize the function of patients and to ensure efficient use of resources. In addition to the finding of a negative correlation between number of PT visits and affected step length, trends between PT visits and multiple other variables should encourage further study of this relationship.

INTRODUCTION

Low back pain (LBP) is a common musculoskeletal impairment among persons with lower limb amputation (LLA), capable of substantially reducing longer-term quality of life [1]. During activities of daily living, such as walking, altered trunk-pelvic motion with (vs. without) LLA impose greater mechanical loads on spinal tissues, and thus have been suggested as a risk factor for the development of LBP [2]. Moreover, in the presence of LBP, further alterations in trunk-pelvic motion have been identified [3-5], yet the effects of these altered motions with LBP on spinal loads remain unclear. The purpose of this study was to evaluate the influences of LBP on trunk-pelvic motion and spinal loads among persons with LLA. We hypothesized that there are differences in trunk-pelvic motions that are associated with larger spinal loads between persons with LLA with and without LBP, supporting a pathway wherein repeated exposure to abnormal spine mechanics can adversely affect spine health.

METHODS

Eighteen persons with LLA – 8 with LBP ("LLA-P") and 10 without LBP ("LLA-NP") – and 10 uninjured controls ("CTR"; without LBP) participated (Table 1). The LLA-P group reported chronic LBP (n=7; every day or nearly every day in the most recent 6 months, n=1; at least half of days in the most recent 6 months) [6]. Mean (standard deviation) pain in the past seven days = 3.8 (1.3). Participants walked overground across a 15m walkway at 1.3 m/s, with speed enforced by auditory feedback. An 18-camera motion capture system (Qualisys, Göteborg, Sweden) tracked (120Hz) trunk and pelvis kinematics via 10 reflective markers. Marker trajectories were low-pass filtered (Butterworth, 6Hz).

Table 1. Mean (SD) participant demographics.

	LLA-P	LLA-NP	CTR
Age (yr)	35.1 (8.7)	36.4 (6.8)	29.7 (8.9)
Stature (cm)	177.5 (8.0)	179.3 (5.9)	176.0 (6.3)
Mass (kg)	86.8 (11.5)	91.6 (14.6)	73.2 (13.4)
Time (yr)	5.2 (2.6)	10.5 (3.1)	N/A

Tri-planar (global) trunk and pelvis angles, and pelvis center of mass position were calculated in Visual3D (C-motion, Germantown, MD, USA), time-normalized to stride, and subsequently input to a non-linear finite element model of the spine [8]. A heuristic optimization procedure, controlled via MATLAB (Mathworks, Natick, MA, USA), estimated trunk muscle forces and spinal loads by minimizing the sum of squared muscle stress (i.e., the cost function) across 56 muscles. Individual muscle forces were summed across local (i.e., connecting individual lumbar vertebrae to the pelvis) and global muscles (i.e., connecting the thorax/rib cage to the pelvis). Spinal loads were compiled from the intervertebral level at which maximum spinal loads occurred (i.e., L5/S1). Peak spinal loads and muscle forces were determined and normalized to body mass. Trunk ranges of motion (ROM) were also determined. Separate one-way repeated-measure ANOVAs assessed the effect of group (LLA-P, LLA-NP, CTR) on all outcomes (P<0.05). Bonferroni-corrected t-tests (P<0.0167) assessed pairwise differences when main effects were observed.

RESULTS AND DISCUSSION

Main effects were observed in frontal (P=0.003) and transverse (P<0.001) plane trunk ROM (Table

1). In the frontal plane, trunk ROM were larger in LLA-P (P=0.001) and LLA-NP (P=0.011) vs. CTR. In the transverse plane, trunk ROM were larger in LLA-P versus both LLA-NP (P=0.015) and CTR (P<0.001), but were similar between LLA-NP versus CTR (P=0.022). No main effects were observed in peak spinal loads (P>0.078) or global muscle forces (P=0.076; Table 1). However, peak local muscle forces differed between groups (P=0.017); local muscle forces were larger in CTR vs. both LLA-P (P=0.012) and LLA-NP (P=0.016).

Despite larger trunk ROM in both the frontal and transverse planes, a lack of differences in spinal loads among LLA-P and LLA-NP vs. CTR are contrary to both our hypotheses (LLA-P ≠ LLA-NP) and prior work [LLA-NP > CTR; 8]. Nevertheless, larger transverse motions with vs. without LBP are consistent with prior work in persons with (transfemoral) LLA [4]. Interestingly, all persons in the LLA-P group had transtibial LLA while those in the LLA-NP group comprised a combination of both transtibial (n=7) and transfemoral (n=3) LLA. In the absence of LBP, alterations in the characteristics of trunk-pelvic motion are typically larger in persons with transfemoral vs. transtibial LLA [2]. It is therefore possible that presence of chronic LBP has concurrently increased trunk-pelvic motions in a group that is otherwise more similar to uninjured CTR. Also, while we identified group differences in local muscle forces, further consideration may be warranted for the model/optimization assumptions regarding muscle recruitment strategies with vs. without LBP [9]. Of note, despite categorization of chronic LBP, participants in the LLA-P group at the time of testing reported mean (standard deviation) numerical pain scores of 2.2 (1.3).

In summary, although prior work has identified larger spinal loads in persons with vs. without LLA, the current results do not necessarily support the notion that larger spinal loads during walking influence the persistence of LBP. It is however possible that individuals in the LLA-P group experienced larger spinal loads at some point prior to developing LBP and, thus, future work is needed to longitudinally characterize the temporal relationships in these outcomes with time since LLA to better elucidate the causal relationships.

EMG ANALYSIS OF AN UPPER BODY EXOSKELETON DURING AUTOMOTIVE ASSEMBLY

Jason C. Gillette and Mitchell L. Stephenson

Iowa State University, Ames, IA, USA
email: gillette@iastate.edu

INTRODUCTION

Shoulder injuries in the workplace result in the longest recovery time of any body part: 23 median days missed [1]. Common causes of shoulder pain include bursitis, tendinitis, impingement, instability, and arthritis [2]. Repetitive overhead postures are widely thought to increase the risk of shoulder injury. Threshold limit values (TLV) for upper limb fatigue have been developed that relate maximum voluntary contraction (MVC) to duty cycle [3]. Using this equation, a 39.5% MVC should not be exceeded with a 10% duty cycle, and a 16.5% MVC should not be exceeded with a 50% duty cycle.

When worksite modifications are impractical or impossible, robotic or passive assistive devices may be utilized in an attempt to prevent shoulder injuries. The Levitate Airframe is a passive exoskeleton designed to support arm weight during overhead shoulder postures. Previous testing with workers at John Deere indicated promising reductions of deltoid muscle activity when using this exoskeleton [4]. The purpose of this study was to assess this exoskeleton during overhead automotive assembly at Toyota Canada. Our hypothesis was that deltoid muscle activity would be reduced with the exoskeleton.

METHODS

Eleven experienced male workers (age 35±7 yr) volunteered for this study. Data were collected for ten overhead automotive assembly tasks. One participant performed three job tasks, five participants performed two job tasks, and five participants performed one job task. Eight job tasks were performed by two participants, and two job tasks were performed by one participant (18 comparisons). Approximately 12 minutes of data were collected per job task, with nine job tasks having ten repetitions (automotives completed), and one job task having three repetitions (multiple stations). Data for each job task were collected with and without use of the exoskeleton.

IRB-approved informed consent was obtained from all participants. Data were collected using a Delsys Trigno wireless electromyography (EMG) system at a sampling frequency of 1926 Hz using Delsys EMGworks software. EMG sensors were placed on eight muscles: right and left anterior deltoid, biceps brachii, superior trapezius, and lumbar erector spinae. Maximum voluntary isometric contractions (MVIC) were performed in the following postures: shoulder abduction empty can, seated elbow flexion, and prone spinal extension. EMG data were analyzed using custom written code in Matlab.

EMG signals were inspected to remove any non-physiological artifacts. The EMG data were bandpass filtered with a 4^{th}-order zero-lag Butterworth filter from 20-450 Hz and then rectified. Next, the EMG data were low-pass filtered at 10 Hz to create a linear envelope. A moving window was used to determine the maximum one second of sustained EMG amplitudes for the MVICs. The job task EMG amplitudes were divided into consecutive one second intervals. The highest 10% and 50% of EMG amplitudes were determined as a measure of 10% and 50% duty cycles.

Maximum 10% and 50% EMG amplitudes were normalized by the maximum one second MVICs (%MVIC). EMG amplitudes presented here are for the dominant arm anterior deltoid, biceps brachii, and trapezius muscles. The right and left side erector spinae muscle results were averaged. Paired t-tests were used to compare EMG amplitudes between conditions (with and without the exoskeleton) in all job tasks, with significance indicated at $p < 0.03$ (adjusted for 18 comparisons with 11 participants). Maximum 50% deltoid amplitudes are presented for individual job tasks (Figure 1) to explore if some tasks benefited differently from exoskeleton usage.

RESULTS AND DISCUSSION

Maximum 10% EMG amplitudes were significantly reduced for the deltoid (p=0.02), biceps brachii (p=0.01), and erector spinae (p=0.01) when wearing the exoskeleton (Table 1). There was not a significant change in trapezius EMG amplitudes (p=0.35). The deltoid demonstrated the greatest magnitude of EMG amplitude change: a 6.5% MVIC reduction with the exoskeleton. Deltoid EMG standard deviations exceeded the 39.5% TLV without the exoskeleton but fell below this level with the exoskeleton. Trapezius EMG standard deviations exceeded the 39.5% TLV both without and with the exoskeleton.

Maximum 50% EMG amplitudes were significantly reduced for the deltoid (p<0.01), biceps brachii (p<0.01), and erector spinae (p=0.03) when wearing the exoskeleton (Table 1). There was not a significant change in trapezius EMG amplitudes (p=0.61). The deltoid showed the greatest magnitude of EMG amplitude change: a 4.4% MVIC reduction with the exoskeleton. Deltoid EMG average exceeded the 16.5% TLV without the exoskeleton, but the average and standard deviation fell below this level with the exoskeleton. Trapezius EMG averages exceeded the 16.5% TLV both without and with the exoskeleton.

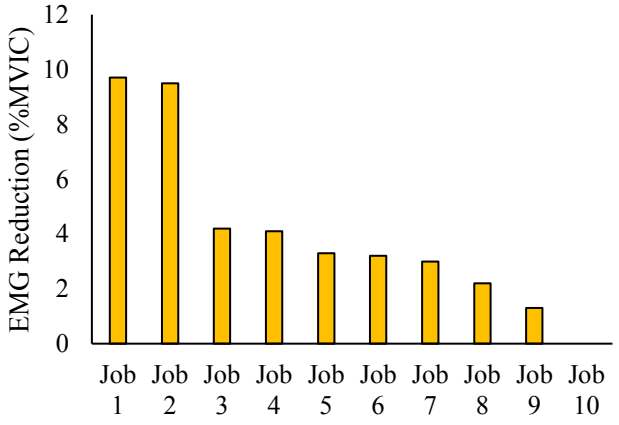

Figure 1: Reduction in maximum 50% EMG amplitudes for the deltoid as a function of job task.

Our hypothesis was supported by the significant reduction in deltoid EMG amplitudes when wearing the exoskeleton. Thus, the exoskeleton appeared to support the primary deltoid functions of shoulder flexion and abduction. Reductions in biceps brachii EMG may be due to exoskeleton stabilization of the shoulder to indirectly support elbow flexion. The unexpected reductions in erector spinae EMG may be explained by the exoskeleton reducing anterior lean and promoting a more upright posture. Effects on the trapezius were mixed, with possible benefits of shoulder abduction support mixed with possible shoulder strap restriction of scapular elevation.

We suggest assessing specific job tasks to determine potential benefits of assistive devices. The Levitate Airframe is most likely to benefit repetitive overhead movements that challenge the deltoid. When considering the different job tasks, there were tasks where the exoskeleton was more beneficial than others (Figure 1). We suggest that it is important to consider EMG amplitudes and standard deviations relative to TLVs as an indicator of fatigue and injury risk. In addition, analyzing maximum 10% and 50% EMG amplitudes may be useful for assessing risks associated with low vs. high repetition tasks.

SKILL TRAINING VERSUS STRENGTH AND FLEXIBILITY EXERCISE IN PEOPLE WITH CHRONIC LOW BACK PAIN: EFFECTS ON KINEMATICS

[1] Quenten L. Hooker, [1] Kristen Roles, [1] Linda R. Van Dillen

[1] Washington University School of Medicine, St. Louis, MO, USA
Email : quenten.hooker@wustl.edu, vandillenl@wustl.edu

INTRODUCTION

An estimated 60-80% of all adults have experienced low back pain (LBP), and up to 75% of people with LBP fail to recover fully within one year [1, 2]. As LBP persists, people often have limitations in physical function [1]. Therefore, for many people LBP is a long-term function limiting condition.

The Kinesiopathologic Model (KPM) provides a theoretical framework for understanding the development or persistent course of LBP [3]. Specifically, the KPM suggests LBP may be a result of the repeated use of direction-specific movement patterns in the lumbar spine with functional activity performance [3]. For example, it has been documented that people with chronic LBP show repeated use of a movement pattern of early lumbar excursion during performance of functional activities [3,4]. The goal of treatment, therefore, would be to change the direction-specific movement pattern and introduce variability of movement across functional activities, in order to transfer tissue demands away from a sensitized and painful lumbar region.

Exercise is one of the primary non-surgical approaches for treating chronic LBP [5]. However, there is a lack of support for the benefits of one type of exercise over another [5]. Individualized movement training (i.e. skill training), utilizes patient specific instruction during functional activity performance to aid in the acquisition of new motor skills. Given skill training is individualized, it is likely that skill training is more effective at changing direction-specific movement patterns compared to general exercise (i.e. strength and flexibility).

The purpose of this study was to investigate the effects of skill training on early sagittal plane hip and lumbar spine excursion during a functional activity test of picking up an object (PUO). It was hypothesized that skill training would elicit *1)* greater changes in early hip and lumbar spine excursion and *2)* greater variability in hip and lumbar spine movement after treatment compared to strength and flexibility exercise.

METHODS

154 people (60 male, 94 female, 42.7 ± 11.7 years, 1.7 ± 0.1 meters, 73.8 ± 13.3 kg, 32.7 ± 9.8 mODI) with chronic non-specific LBP were included in a single-blind, prospective, randomized, controlled clinical trial. After completion of pre-treatment movement testing, participants were randomized to 1 of 2 treatment conditions: skill training or strength and flexibility exercise. Both conditions received 6, 1-hour treatment sessions (once/week for 6 weeks). Participants in the skill training condition received individualized training to modify pain-provoking, stereotypic patterns of movement used during functional activities. Participants in the strength and flexibility condition were prescribed general progressive, resistive trunk exercise (e.g. trunk curl ups) and trunk and limb flexibility exercise (e.g. hamstring stretching).

At baseline and immediately after the treatment phase, participants completed a functional activity test of picking up an object (PUO). 3-dimensional marker co-ordinate data were collected using 8 cameras (Vicon Motion Systems, LTD, Denver, CO) at 120 Hz. Joint kinematics for the hip and lumbar spine were calculated in Visual 3D (C-Motion Inc., Germantown, MD). Biomechanical variables of interest included early (1st half of the decent for a PUO task) sagittal plane hip and lumbar spine excursion.

Independent samples t-tests were used to determine if there were differences in hip or lumbar spine excursion between conditions at pre and post-

treatment data collection. Dependent samples t-tests were used to determine if there were changes in hip or lumbar spine excursion from pre to post-treatment for both conditions. Pearson product-moment correlations were used to examine the relationship of A) early lumbar excursion for pre and post-treatment and B) early hip excursion for pre and post-treatment for each treatment condition.

RESULTS AND DISCUSSION

Mean Values. Similar amounts of early hip and lumbar excursion were observed between treatment conditions at baseline (Table 1). The skill training condition had a significant increase (13.3%) in early hip excursion after treatment. No significant differences were found in early hip excursion for the strength and flexibility condition. No significant differences were found in early lumbar excursion from pre to post-treatment for either condition. Thus, the skill training condition increased early phase hip excursion to a greater extent than the strength and flexibility condition during a functional activity test of PUO (Table 1).

Table 1: Mean ± SD for early lumbar and hip excursion during a pick up an object task.

	ST	SF
Early Lumbar Excursion		
Pre-treatment	11.6 ± 3.7	11.9 ± 4.4
Post-treatment	11.7 ± 5.1	11.8 ± 4.3
Early Hip Excursion		
Pre treatment	$ 18.0 ± 7.3	17.1 ± 7.3
Post-treatment	*$ 20.4 ± 7.7	*17.1 ± 6.2

*Significantly different between treatments($p<0.05$)
$ Significantly different pre to post treatment ($p<0.05$)

Correlations. Pre-treatment early lumbar excursion explained 51% of the variance in post-treatment early lumbar excursion for the strength and flexibility condition, compared to 15% variance explained in the skill training condition (Figure 1A). A similar pattern of findings was observed for early hip excursion for each of the two treatment conditions (Figure 1B). These data suggest the strength and flexibility treatment has a more systematic effect on hip and lumbar spine movement from pre to post treatment. Alternatively, less variance explained in post-treatment movement in the skill training condition suggests this treatment induces a more variable hip and lumbar spine movement strategy. It is likely that the discrepancies in variability for post-treatment early hip and lumbar excursion are due to a more individualized treatment prescribed in the skill training condition.

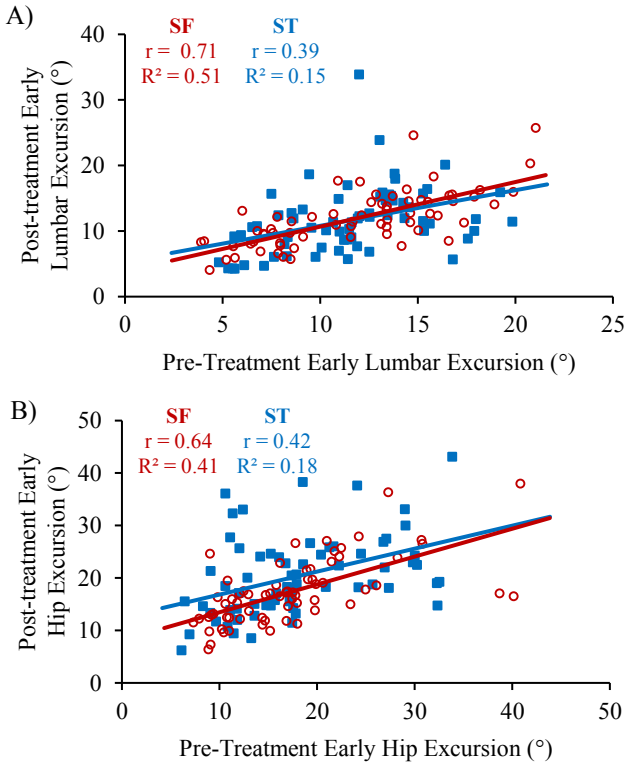

Figure 1: Relationship between A) pre vs. post-treatment early lumbar excursion and B) pre vs. post-treatment early hip excursion for skill training (ST) and strength and flexibility (SF) conditions

CONCLUSION

The skill training condition significantly increased early hip excursion and introduced greater early hip and lumbar spine movement variability after treatment in people with chronic LBP. Therefore, if the goal of treatment for people with chronic LBP is to modify direction-specific movement patterns and introduce greater variability of movement, our data suggest the skill training condition is superior to the strength and flexibility condition.

EFFECTS OF LOWER BACK AND HIP MORPHOLOGY ON WALKING KINEMATICS

INTRODUCTION

Bipedal walking is a fundamental aspect of human evolution. Humans are the only mammals that walk with an upright posture and extended limbs during stance. Chimpanzees, our closest living relatives, walk bipedally with flexed, abducted hind limbs, and a forward-leaning trunk [1]. Crouched walking should have a greater metabolic cost than upright walking, so why do chimpanzees walk on substantially flexed hind limbs?

Two main hypotheses have been proposed. First, chimpanzees lack a lumbar lordosis, so they are unable align the trunk over the pelvis when bipedal. Since their trunk is projected forward, chimpanzees may use a crouched posture to position their feet underneath their center of mass [2]. Second, due to their pelvis morphology (i.e., ischial length and orientation), chimpanzee hamstrings hip extension moment arm is near zero when the hip approaches full extension, which may preclude extended limb walking [3]. Experimental data alone are inadequate to isolate and test these hypotheses. However, musculoskeletal modeling and simulation techniques allow for the systematic manipulation of specific variables while others are held constant. Therefore, to test these hypotheses, we sought to determine if forward projection of the trunk and limitations on hip extension in a human musculoskeletal model would lead to crouched walking, similar to bipedal chimpanzees.

METHODS

A two-dimensional, 11 degree-of-freedom, 42 muscle human musculoskeletal model [4] was used within the OpenSim software package. Optimal control simulations of walking (1.3 m/s) were generated under ten different conditions using a direct collocation approach [5]. In the first set of five simulations, the model was modified such that the trunk was flexed 0, 15, 30, 45, or 60 degrees. This gradual progression of trunk flexion angles projected the trunk center of mass in front of the pelvis. In the second set of five simulations, the same five modified models were used to generate walking while constraining the hip to not pass 0 degrees of hip extension (i.e., no hyperextension). This constraint was a surrogate for the reduced hip extension moment capacity in chimpanzees. The optimization objective function was to minimize the sum of cubed muscle activations.

RESULTS AND DISCUSSION

In the first set of simulations, even substantial trunk flexion did not result in a chimpanzee-like crouched-limb gait (Table 1). At greater lumbar flexion angles, the model tilted the pelvis progressively posteriorly, resulting in less hip flexion, not more. For these conditions, the model did maintain a more flexed knee during stance, but the ankle was more plantar flexed (i.e., toe-walking), not more dorsiflexed. By tilting the pelvis posteriorly, the model was able to orient the trunk nearly perpendicular to the ground, positioning the whole-body center of mass over the base of support without flexing the hips. Thus, the minimum-activation solution for the first set of simulations did not involve walking with a crouched posture like a chimpanzee.

In the second set of simulations, restricting the hip to prevent hyperextension, combined with trunk flexion, resulted in the model walking with a slightly more chimpanzee-like crouched-limb gait, although differences still existed (Figure 1; Table 1). At greater lumbar flexion angles, the model still compensated with a more posteriorly tilted pelvis and a slightly more extended hip during stance, though to a lesser extent than in the first set of simulations. The adaptation most consistent with a crouched-limb gait was a progressively more flexed knee during stance at greater lumbar flexion angles, though by amounts considerably less than observed in chimpanzees [1]. There were small and inconstant effects at the ankle with increased lumbar flexion. Thus, while there were some elements of a crouched gait when trunk flexion and restricted hip extension were combined in the second set of simulations, it did not approximate walking like a chimpanzee.

The present results suggest that having a forward projected trunk does not necessarily lead to a chimpanzee-like couched-limb gait, even if restrictions are placed on hip extension. The gait patterns observed in chimpanzees are likely due as much to their specific pelvis and hind limb morphology as to the orientation of their trunk.

CONCLUSIONS

These results suggest that chimpanzee-like sagittal plane kinematics most likely arise from the interaction of multiple musculoskeletal traits. This may include pelvis and hind limb traits not studied herein. Future 3-D simulations of human and chimpanzee models will permit more direct testing of the effect of isolated musculoskeletal traits on bipedal walking kinematics.

DIRECT COMPARISON OF KINETICS AND LUMBAR FLEXION IN BARBELL BACK SQUATS AND DEADLIFTS

INTRODUCTION

The barbell back squat and traditional deadlifts are common resistance training exercises utilized primarily by athletes to elicit muscular adaptations in strength, power and hypertrophy. Recently, these exercises are gaining popularity in rehabilitation settings and are being applied towards goals such as restoring motor function and increasing bone mineral density [1,2]. Understanding the kinematic and kinetic demands placed upon the lower limb and lumbar spine during these exercises can help ensure they are prescribed in such a way that produces the desired training outcomes without jeopardizing the safety of the lifter with excessive joint loading, especially in the lumbar spine.

With the exception of a few studies examining muscle activation [3], most of the research to date characterizing the biomechanics of heavy weight lifting have treated barbell back squats and deadlifts independently. While some general assertions can be made between studies, differences in participants and protocols can make direct comparisons challenging. To our knowledge, only one study has examined the kinematics of these two lift types in the same study population [4] and none have looked at kinetics. The goal of this study was to compare the lower limb and lumbar joint torques and lumbar kinematics between the conventional deadlift and the back squat.

METHODS

Seventeen healthy adults participated in this study (12 males; age: 27±5 years; height: 176±5 cm; mass: 97.7±19.3 kg). Participants were competitive powerlifters (n=9), weightlifters (n=7) and CrossFit athletes (n=1). All participants had competed in their respective sports within the past year (overall lifting experience: 5.7±3.5 years).

Prior to testing, each participant performed a warm-up of light aerobic exercise, dynamic stretching, and progressive squats and deadlifts up to 65% of their self-reported one repetition maximum (1RM). Each participant then performed three sets of single self-paced repetitions of the squat and deadlift at 85% of their self-reported 1RM for each type of lift. The order of lift type was alternated between participants. The techniques for each lift were standardized based on published protocols [5,6]. The deadlift was based on the conventional Olympic weightlifting technique with the initial bar position above the first metatarsal phalangeal joint and directly beneath the shoulders. The squat was a conventional "high bar" back squat (bar near the C6 vertebra) with depth controlled so that the hip crease was just below the top of the patella.

Kinematic data were collected for all trials using a 3D motion capture system (VICON, Centennial, CO, fs=100Hz) with 44 reflective markers. Ground reaction force (GRF) data were collected simultaneously using platforms located under each foot (AMTI OR7-6, Watertown, MA, fs=2000Hz). The 3D kinematics of the bar, lower limbs and pelvis were calculated using custom routines in Matlab (R2006b, Mathworks, Natick, MA). Lumbar spine curvature and the L5-S1 joint position were estimated using a custom planar kinematic model implemented in Matlab based on published geometry estimates for the lumbar vertebral bodies and spinous processes [7] and relative vertebral kinematics [8]. The model was scaled for each participant and positioning for each frame of data was driven by the matching the location of kinematic markers placed over the spinous processes of L1, L3 and L5 via an optimization approach. Using the GRF and kinematic data, quasi-static inverse dynamics were used to calculate joint torques for the ankles, knees, hips and L5-S1 joint. Joint torques were normalized to total load (body weight + lift load) x height and

flexion axis peak values extracted. Paired t-tests were used to compare between lift types with significance set at α=0.05 and effect sizes (d) reported.

RESULTS AND DISCUSSION

Almost all participants (15/17) had a higher self-reported deadlift 1RM compared to their squat. As a result, the deadlift (DL) load was significantly higher than the squat (SQ) load (DL: 1.56±0.31 x body weight, SQ: 1.33±0.27, $p<0.001$, d=0.8). Despite this, the squat produced a significantly higher peak normalized vertical GRF compared to the deadlift (DL: 1.10±0.03 x total load, SQ: 1.29±0.08, $p<0.001$, d=3.1) due to the upwards acceleration required to slow down and change direction at the bottom of the squat movement.

The peak knee extensor torque was significantly higher in the squat compared to the deadlift ($p<0.001$, d=4.5); however no differences were seen in peak ankle plantar-flexor, hip extensor or lumbar extensor torques between the lifts (Figure 1).

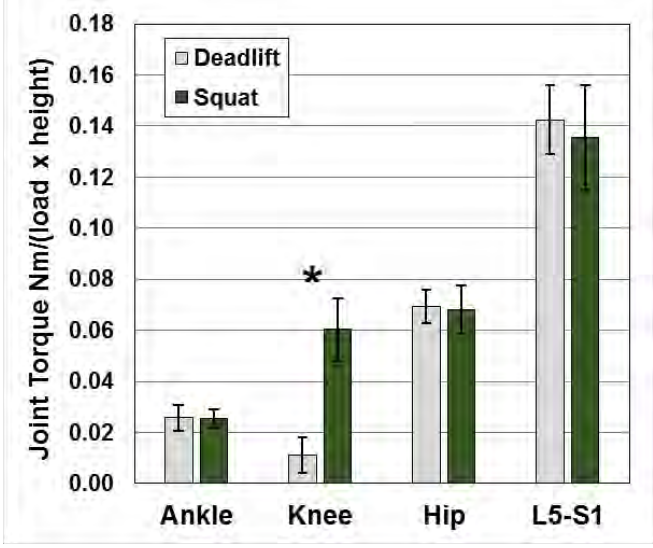

Figure 1: Mean peak joint torques (SD). Ankle, knee and hip torques are averages across legs. *significant difference between lift types

These data suggest that, for a given load, the back squat places much higher demands on the knee extensor mechanisms compared to the deadlift. This matches with what is generally believed in the training community and likely arises from the significantly increased forward lean of the tibia in the squat (unreported data).

Despite the differences in GRF and kinematics [4] between the deadlift and squat, the peak hip and lumbar torques in this study were similar. This may indicate an equivocal level of low back loading between the lift types but likely arising from different patterns of trunk muscle activation [3].

The spine model estimated significantly more lumbar flexion during the deadlift at the time of peak lumbar torque, however the effect size was relatively small (DL: 14.6±17.1°, SQ: 7.8±19.9°, p=0.001, d=0.3). Different lumbar angles could possibly affect the lines of action of the lumbar extensor muscles and result in different shear and compression loads at the L5-S1 joint even with similar joint torques.

Importantly, both the squat and deadlift have a number of technique variations that include different grips, foot positions, starting postures and movement ranges. This study focused on the more common techniques, but variations could have an impact on the lift kinetics.

CONCLUSIONS

This is the first study to directly compare lower limb and lumbar joint torques in the barbell back squat and deadlifts in the same population. Accounting for load, the main difference between the lifts is an increase in knee extensor torque in the squat. This should be kept in mind when prescribing these exercises.

Evaluating the Severity of Adult Spinal Deformity using Timed-Up and Go

INTRODUCTION

Adult spinal deformity (ASD) is a group of spinal pathologies that has a wide range abnormal radiographical patterns and is estimated to occur in up to 60% of the aging population [1]. Managing this patient population hinges on the balance of the amount of pain and disability each patient endures while correctional spinal surgery requires precision radiography [2,3].

Outcomes of these surgeries are assessed on post-operative questionnaires. The use of functional and quantitative measures can be used to accurately evaluate post-operative improvement in daily living activities instead of relying on subjective scales and perceived improvement from the patient. A simple battery of functional tests, e.g. walking, standing balance, and basic functions, such as rising from a chair, would provide more information about how the patient is functioning.

For example, the Timed-Up and GO (TUG) test is a simple and widely used clinical balance tool for assessing functional mobility [4,5]. In this test, the subject starts in a seated position and when told to "Go", they stand up, walk three meters, turn around, walk back to the chair, and sit back down. The TUG test can be subjective if only a visual assessment is performed, however, instrumented TUG testing can provide a wealth of quantitative data utilizing a single inertial measurement unit. The duration each subtask task and how well each task is performed can be evaluated.

We postulate that functional and quantitative measures can be used to better understand the effects of ASD on daily living activities before and after surgery. In this pilot study we ask eight ASD patients that are candidates for corrective spinal surgery to perform a TUG test.

METHODS

Eight patients with adult spinal deformity (ASD) were prospectively enrolled. Mean age was 65±4.2 years and 75% (6/8) of subjects are female. Subject must be diagnosed with ASD. Inclusion criteria for ASD using radiographic measurements: coronal cobb $\geq$ 20°, pelvic tilt $\geq$ 25°, Pelvic incidence-lumbar lordosis (PI-LL) mismatch >10°, and thoracic kyphosis $\geq$ 60°. Exclusion criteria: inability to stand, other confounding neurological conditions. In this study we asked subjects to perform a 3-meter TUG test while wearing four APDM sensors (APDM Portland, OR) using Mobility Lab. These sensor have a tri-axial accelerometer and tri-axial gyroscope. One sensor was place at the trunk, lumbar, and ankles of each foot.

The trunk acceleration data was denoised and filtered using a bandpass filter with cutoff frequencies between 2 Hz and 8 Hz. The time duration, range, root mean square (RMS) and jerk was calculated for the sit-to-stand and final stand-to-sit motions, respectively [6].

Standard radiographic measures, including lumbar lordosis (LL), pelvic incidence (PI), pelvic tilt, sagittal vertical axis, global coronal alignment, T1 and pelvic angle (TPA), and PI/LL mismatch were calculated for each patient using their preoperative x-rays. Correlation analyses between TUG parameters and radiographic measurements were performed using spearman's correlation. JMP Pro 13 was used for all analyses.

RESULTS AND DISCUSSION

We found several significant correlations between TUG parameters and radiographic measurements. Sit-to-stand and stand-to-sit duration increased as the pelvic tilt increased. As pelvic tilt increases, knee flexion increases resulting in retroversion of the pelvis as a compensatory mechanism to maintain the body's center of mass over its base of support. The Stand-to-sit duration also increased with the TPA. This angle is based on retroversion of the pelvis and the anteversion of the trunk; the larger the angle, the greater the deformity of the spine. The total duration of the TUG test increased as pelvic tilt and TPA increased. This is expected because pelvic tilt increases the duration of both sit-to-stand and stand-to-sit.

The Sit-to-Stand RMS in the anteroposterior direction increases as TPA, global coronal balance, sagittal vertical axis, and PI/LL mismatch increases. The RMS is a measure of variability, when RMS is low the movement is deemed to be smooth and more natural, while a greater RMS value evinces large amplitudes. In this case, the aforesaid radiographic measures increase as the spinal deformity worsens. Therefore, as the spinal deformity becomes more severe, the smoothness of the transition from sitting to standing becomes worse and requires greater effort.

Lastly, we found that the sit-to-stand jerk increased as the global coronal alignment decreased. In this instance, jerk can be used to evaluate efficiency of a motion. When jerk is high, the motion is easier and performed with less effort. Global coronal alignment is a measurement of decompensation of the spine. A higher absolute value of global coronal alignment is a sign of imbalance and scoliosis in the coronal plane. Therefore as the coronal scoliosis worsens the efficiency of standing from a seated position decreases.

CONCLUSIONS

We conclude that there is immense value in utilizing functional tests with inertial measurement unit data for increased understanding of how spinal deformities impact daily living activities and for evaluating post-operative improvements.

IN SITU CALIBRATION OF THE TENDON SHEAR WAVE SPEED-STRESS RELATIONSHIP

[1] Jack A. Martin, [2] Christina J. Stender, [2] William R. Ledoux and [1] Darryl G. Thelen

[1] University of Wisconsin-Madison, Madison, WI, USA

INTRODUCTION

We recently developed a non-invasive technique for measuring *in vivo* tendon stress which could be useful in a variety of biomechanics applications [1]. This technique is based on a simple tensioned beam model for tendon, which predicts that shear wave speed is directly dependent on axial stress. We have previously shown that our model is valid for *ex vivo* tendons loaded in a mechanical testing machine, and have demonstrated the potential to track *in vivo* tendon wave speeds during dynamic activities, e.g., the Achilles tendon during walking. However, the precise relationship between stress and wave speed is dependent on the effective density of the tendon, which is influenced by surrounding tissues. It is unclear whether effective density can be calculated for different tendons using analytical methods. Accordingly, our objective was to calibrate the *in situ* Achilles and tibialis anterior (TA) tendon wave speed-stress relationships by applying dynamic loads representative of gait while concurrently measuring wave propagation speed.

METHODS

We simulated gait [2] on a fresh-frozen cadaveric lower limb specimen. A 6-DOF robot moved a force plate relative to the plantar surface of the foot to mimic relative tibia-to-ground motion and ground reaction forces observed during normal gait. Tendon forces were concurrently modulated to track dynamic force profiles that arise in gait. Gait simulations were performed at one sixth physiologic speed and at 50% body weight.

We synchronously measured tendon wave speeds using a novel surface-mounted sensor [1] comprised of: 1) a piezoelectric-actuated (Thorlabs PK4JQP1) tapping device that induces shear waves, and 2) a pair of miniature single-axis accelerometers (Piezotronics 352C23) aligned in series along the tendon (10 mm spacing). After each tap (50 taps/s), the induced wave sequentially passes the two accelerometers. Wave speed was calculated from a time delay determined by cross-correlation of the two acceleration signals. Tendon wave speed and applied force data were collected during three simulated stance phases both before and after removing the skin overlying the tendon. The skin-on and skin-off conditions were tested to examine the effects of superficial tissue on the effective density of the tendon.

Measured tendon stresses were obtained by normalizing applied force by the tendon cross-sectional areas obtained from a CT scan. Predicted stresses were calculated from wave speed based on the theorized wave speed-stress relationship [1]:

$$c^2 = \frac{k'\mu + \sigma}{\rho_{eff}} \qquad (1)$$

where c is shear wave speed, σ is axial stress, ρ_{eff} is effective density, μ is shear modulus, and k' (= 0.9) is a shear correction factor which accounts for the shape of the cross-section. It is unknown how shear modulus changes with axial load in tendon, so a constant value was chosen based on values obtained for ligament at a moderate shear strain (μ = 500 kPa) [3]. The effective density, ρ_{eff}, is theorized to account for an increased effective mass of the tendon caused by entrained motion of the surrounding tissue [1]. However, in this case, we first used the tendon density (ρ_t = 1060 kg/m^3) to demonstrate the resulting error in predicted stress. Subsequently, we determined effective densities that optimized agreement between predicted and measured stress in each of the tendons. Optimization was performed using data from periods of the gait cycle where stress exceeded 1 MPa, which is the loading regime at which axial

stress is believed to be a major determinant of shear wave speed. We assessed the fits between predicted and measured stresses using the coefficient of determination (r^2) and root mean squared error (RMSE).

RESULTS AND DISCUSSION

Predicted and measured stresses were highly correlated for both tendons and conditions (Table 1). Stresses were substantially under-predicted when using the tendon density, ρ_t, in Eqn. 1 (Fig. 1). The error between predicted and measured stress was low for all conditions when using the optimized effective density, ρ_{eff}, to calculate predicted stress (Table 1). The density that minimized error between predicted and measured stress ranged from 2060 to 3720 kg/m^3 (Table 1). The highest effective density was estimated for the TA tendon in the skin-on condition, which could reflect additional effective mass that arises when the subcutaneous tissue and overlying skin tether the motion of the tendon. The skin-off condition resulted in similar effective densities for both the TA and Achilles tendons.

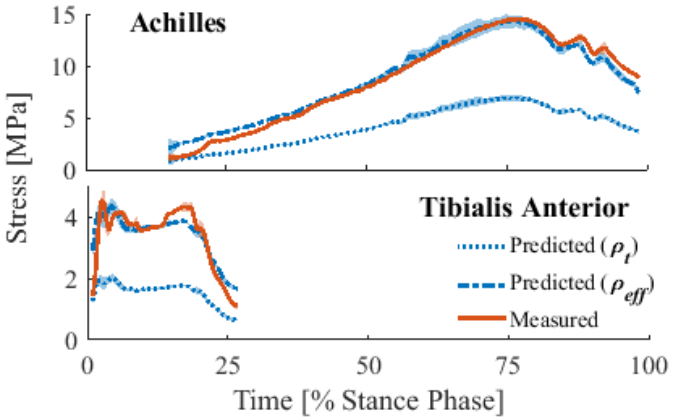

Figure 1: Predicted (using tendon density, ρ_t, and optimized effective density, ρ_{eff}) and measured stress across three trials for the skin-off conditions.

The excellent correlation between predicted and measured stress confirms that this technique can be useful for examining relative tendon loading under different conditions, even without consideration of uncertain parameters. However, absolute tendon stress estimates do require an estimate of effective density. These preliminary data suggest that effective density may be tendon dependent, and may be more affected by superficial tissue in the tibialis anterior tendon than in the Achilles.

Ongoing work is addressing the possibility of tendon specificity in calibration relationships. Ideally, calibration would not be necessary for *in vivo* applications since stress cannot be directly measured for such purposes. Future work will employ finite element modeling and *in situ* experimentation to investigate whether tendon and superficial tissue geometry modulate effective density in a predictable manner.

CONCLUSIONS

This work has demonstrated the potential for precisely estimating tendon stresses via non-invasive measurement of wave propagation speed. The availability of these data could lead to significant advances in a variety of applications in biomechanics, such as, guiding rehabilitative interventions by providing biofeedback on tissue loading, planning orthopedic procedures where tissue stresses are of high importance, and potentially examining the effects of tissue stresses on growth and remodeling.

IDENTIFYING BIOMECHANICAL WRIST IMPAIRMENTS WITH MACHINE LEARNING: A FEASIBILITY STUDY

[1] Jennifer A. Nichols, [2] K. Supreet Alguri, and [1] Joel B. Harley

INTRODUCTION

Traditional biomechanical methods often rely on the researcher to identify the key biomechanical features to analyze. For example, joint loading is frequently examined when studying osteoarthritis. Although analyzing a small number of pre-selected variables is sufficient for many biomechanics applications, it can be insufficient when studying complex, multi-joint systems, such as the wrist and hand. In these systems, the critical variables to analyze cannot always be readily identified.

Machine learning offers an alternative approach for analyzing large, multi-dimensional datasets without relying upon *a priori* assumptions regarding which variables are most important [1]. In biomechanics, machine learning has been applied in many different applications, such as analyzing gait [2], identify wrist ligament tears [3], and modeling EMG [4]. However, to our knowledge, machine learning has not yet been used to elucidate the complexity of the wrist/hand.

In this study, we examine how machine learning can guide analysis of the wrist and hand. We specifically evaluate whether three common machine learning algorithms can identify (i) wrist impairments and (ii) the features distinguishing those impairments. The wrist impairments studied represent two surgeries for wrist osteoarthritis (Fig. 1A). These surgeries are interesting, as their clinical outcomes are nearly identical [5]. Thus, identifying which surgery was performed given only biomechanical data is difficult.

METHODS

To evaluate whether machine learning can be used to identify wrist impairments, a biomechanical dataset was generated to simulate experimental motion capture data from nonimpaired, SE4CF, and PRC wrists. These simulations used published models and methods [6] to quantify dynamic changes in thumb-tip endpoint forces and posture during lateral pinch (Fig 1B). The 165 simulations represent unique combinations of lateral pinch force, model size, and wrist condition (Fig 2). Importantly, each simulation was dynamic, thereby providing time-varying data. Data-defined features were then used to train and test the machine learning algorithms (Fig. 2).

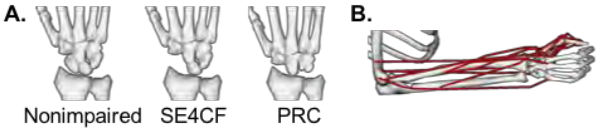

Fig. 1: We simulated (A) two surgeries for wrist osteoarthritis [scaphoid-excision four-corner fusion (SE4CF) and proximal row carpectomy (PRC)] performing (B) a lateral pinch task.

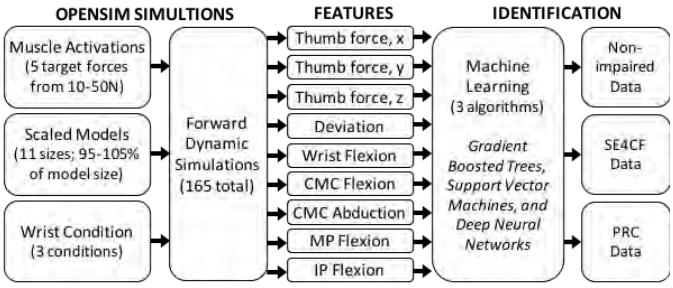

Fig. 2: Summary of machine learning approach.

Three common machine learning algorithms were evaluated for identifying data from nonimpaired, SE4CF, or PRC wrists. Multiple algorithms were examined, as differences in accuracy can inform future work. The algorithms are gradient boosted trees (GBT), support vector machines (SVM), and deep neural networks (DNN). Briefly, GBT uses layers of simple decision trees to model the relationship between features and categories [7]. Here, we employed 500 simple trees with a learning rate of 0.05 and a constraint that each node of each tree has at least 100 samples. SVM classifies data by identifying points (i.e., support vector) that optimally separates data from different categories and follows a known separation model, or kernel [8]. Here, we extend SVM for multi-category classification [8]. We use a Gaussian kernel with optimized scaling parameters. DNN use multiple layers to model and learn complex, non-linear relationships [9]. Here, our

DNN consists of an input layer, two hidden layers, and an output layer. The input layer is composed of input nodes corresponding to the number of features and is connected to a hidden layer with 16 tanh activated nodes. This hidden layer is then connected to a second hidden layer with 8 tanh activation nodes followed by an output layer with 3 output nodes, representing the three categories.

To evaluate each algorithm, we used a 20-fold cross-validation procedure [10], meaning each algorithm was trained with 80% of the data and tested with the remaining 20%. This procedure was repeated 20 times for each algorithm. The algorithm's accuracy is represented by the mean accuracy of all 20 tests. We performed this cross-validation procedure using all 9 features, the 2 most influential features, and the most influential feature. A feature's influence was determined as part of the GBT algorithm [7].

RESULTS AND DISCUSSION

The biomechanical dataset represents a wide range of dynamic behaviors. Importantly, the generated thumb-tip forces and joint angles overlap between the three wrist conditions (data not shown). Hence, distinguishing each condition from the simulated experimental data is a challenging problem. Optimal binary accuracies support this conclusion (Fig. 3). An optimal binary accuracy is the maximum accuracy for a single feature to categorize a single category versus all other categories. Some features classify one category well (accuracy > 0.95), but no feature accurately classifies all three categories.

The GBT algorithm indicates that radial-ulnar deviation followed by CMC ab/adduction are the most influential features for categorizing the three wrist conditions. This is an intriguing result, as the lead author's prior work [6] suggests that radial-ulnar deviation and wrist flexion-extension are the most important features differentiating these surgeries. CMC ab/adduction's substantial influence likely reflects its importance for producing well-directed thumb-tip endpoint forces. Examining different tasks that require varying wrist postures could lead to more insights regarding the role of wrist flexion/extension.

Regardless of whether one feature (deviation), two features (deviation and CMC abduction), or all nine features were used, the three machine learning algorithms performed well (Fig. 4). DNN achieved the highest accuracies, which is expected since DNN can learn the most complex relationships. As the number of features increased, the mean accuracy increased toward 100%. Although, this is not true for all test data, as evidenced by an outlier in SVM. The high accuracy results indicate that the presented algorithms can identify substantial musculoskeletal changes, such as those imposed by surgery. These results also suggest that these algorithms may be able to address more complex biomechanics problems.

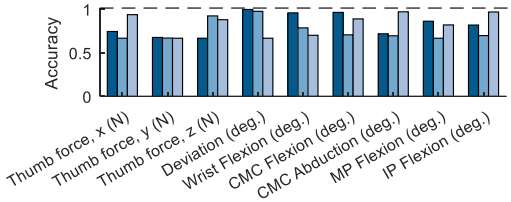

Figure 3: Optimal binary classification accuracies for each category and feature. The bars in each group (from dark to light) represents the accuracy of categorizing the nonimpaired, SE4CF, and PRC conditions versus all other conditions.

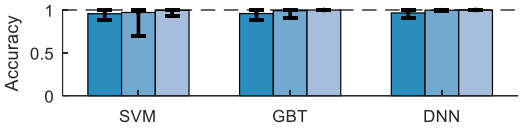

Figure 4: Mean accuracy (from left to right) using one, two, or nine features. Bars represent minimum and maximum accuracy.

CONCLUSIONS

This study demonstrates that it is feasible to use any of the three presented machine learning algorithms to identify simulated wrist impairments. Thus, this work lays the foundation for future analyses of the wrist and hand using machine learning. In the future, we plan to extend these algorithms to examine other biomechanical features, namely muscle parameters. This will inform our understanding of the relative importance of individual muscles for production of lateral pinch force. We also plan to evaluate how using experimental (instead of simulated) data influences the accuracy of each algorithm.

INTRODUCTION

Previously, our novel single validated -finite element (FE) model of the knee joint was used to investigate non-contact landing scenarios to understand the propagation of anterior cruciate ligament (ACL) injury [1]. In this study, the revised FE models, created using MR images of male and female subjects, were used to simulate more relevant scenarios for non-contact ACL injury. These FE models were validated against an *in vitro* study, undertaken by our group [2], designed based on *in vivo* driven biomechanical loading parameters. Validated FE models were then used to further investigate loading cases seen in the non-contact injury environment and sex related anatomical variations.

METHODS

MR images from four, healthy, 2 males and 2 females subjects were converted to 3D models of the bone and soft tissue across the knee joint using Mimics (Materialise, Leuven, Belgium). Meshes of C3D4 elements were constructed in Hypermesh (Altair, MI, USA) before final assembly in Abaqus/Explicit 6.14-5 (Simulia, RI, USA). Cruciate and collateral ligaments were modeled as Holzapfel-Gasser-Ogden hyperelastic materials with a Prony series defined viscoelasticity. The remaining joint capsule was modeled with uniaxial connector elements. Bone and cartilage were simulated as linear elastic materials, and menisci as transversely isotropic material.

FE models were subjected to different loadings using the explicit dynamic analysis. The joint was preconditioned (25° flexion with 441N quadriceps and 441N hamstrings loads) before the application of quasi-static loadings, Table 1. These loads were followed by an impact step that mimicked bipedal landing (half body- weight) from a height of 30cm. ACL strain was calculated post impact and compared with the experimental data.

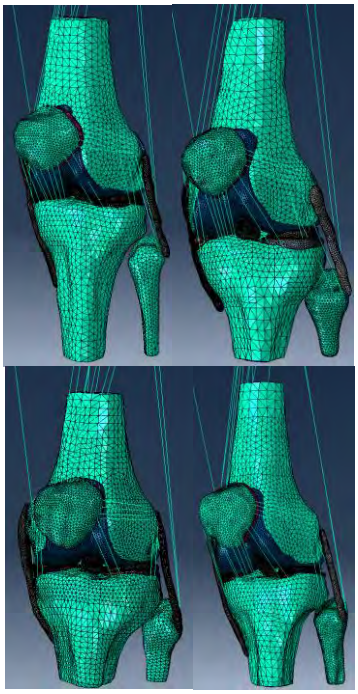

Figure 1: females (top) and males (bottom) FE models

RESULTS AND DISCUSSION

Table 2 shows the percent **c**hange in ligament strain at 100 ms post impact and wrt baseline (after 25° flexion). Cadaveric data are the mean percent change ACL strains for external sub failure loadings, knee abduction moment (KAM), anterior shear force (ASF), internal tibial rotation moment (ITR). Predictions were in good agreement with *in-vitro* data (close to and within 1.5SD) FE simulation predicted that ITR contribution to ACL strain was greater than ASF. ACL strain was up to 20% higher in case3 compared to case5, where KAM was held constant. Although, the loading magnitudes are not the same for comparisons of ITR and ASF, varying load magnitudes were matched to the corresponding

in vivo kinetics reported for the same percentile of the population.

ACL injury incidence was approximately six fold higher in female than male participating in jumping and cutting sports [3], However, relatively lesser ACL strain was predicted for female models compared to male models under the same loading cases. There are mainly two reasons for these findings. Our previous study [4] concluded that female athletes display greater valgus motion than males among basketball players during landing, which likely results in higher rates of knee injury in females. Similarly, our current FE model predicted higher abduction in female compared to male (Table 3). One can expect higher ACL strain in female models. However, as seen in Table 3, axial tibial translation was higher, meaning the joint is more compressed in female models, which would result in higher contact pressure on tibial cartilage. Therefore, ACL strain was much less in females compared to male models. In addition, the limited number of female and male models at present may contribute to this discrepancy as well.

CONCLUSIONS

FE models help understand how strain develops in the ACL due to multi-planar loading and moments seen in non-contact sport activities. Our validated models can predict engineering failure parameters for real case scenarios, which is not practical with *in vitro* and *in vivo studies*. Future studies will include more subject specific male and female models in combination with more loading protocols to conduct in-depth injury mechanism studies. The models will allow us to assess clinically relevant ACL injuries patterns using failure loading scenarios.

EFFECTS OF KNEE KINEMATICS ON ACL STRAIN DURING SIMULATED LANDING

Rena Hale, Nathan D. Schilaty, Nathaniel A. Bates, Christopher V. Nagelli, Aaron J. Krych, and Timothy E. Hewett

INTRODUCTION

Approximately 75% of anterior cruciate ligament (ACL) ruptures occur in non-contact scenarios [1]. This injury is often the result of a high impulse force within the first 50 ms of initial ground contact during a rapid deceleration or change in direction landing [2]. Subsequently, it is important to understand the underlying mechanisms of ACL injury, specifically the knee kinematics that correlate to ACL strain. Previous studies have looked at how *in vivo* knee kinematics correlate to increase risk of ACL injury [3]. However, the exact change in knee kinematics due to high impulse forces have not been correlated to ACL strain. The purpose of this study was to determine how knee kinematics affect ACL strain when high external knee abduction moment (KAM) is applied. The hypothesis tested was that in high KAM impacts, greater change in knee abduction angle and internal rotation would increase relative ACL strain. Improved knowledge of knee kinematics will enhance ACL injury prevention and rehabilitation.

METHODS

A previously developed mechanical impact simulator was utilized to simulate landing from a drop vertical jump (DVJ) in the lower extremity of 35 specimen's age 24 to 52 [2]. Specimens showed no evidence of significant trauma or extended chemotherapy. Specimens were prepared according to published specifications [2] and were equipped with 3D triad markers mounted on the tibia and femur (Northern Digital, Ontario, Canada), and a differential variable reluctance transducer (LORD, Willison, VT) implanted on the ACL.

To replicate a DVJ landing, varied magnitudes of KAM, anterior tibial shear (ATS), and internal tibial rotation (ITR) were applied to the limb in a randomized order, while the foot was impacted with a vertical impulse force from a height of 31 cm. The varied magnitudes of externally applied KAM, ATS, and ITR resulted in 46 trial types and were derived from *in vivo* kinetics that were calculated from 67 athletes who performed DVJs during 3D motion analysis. In all trials quadriceps and hamstrings were co-contracted with a 1:1 ratio.

Triad marker data was used to build a skeletal model in Visual 3D (Germantown, MD). Data was filtered with a 4th order Butterworth 12 Hz low-pass filter. Knee angles and translations were calculated with respect to the femur. ACL strain was calibrated from the individual specimen's maximum and neutral points. Knee kinematics and relative ACL strain were normalized to the pre-loaded position, calculated as right limbs, and specimens were averaged across trial conditions.

Statistical analyses were performed with JMP 13 (SAS Institute Inc., Cary, NC) with matched pairs and one-way ANOVA with an alpha level < 0.05. The analysis determined the significance between change in ACL strain and knee kinematics at 33ms, 66ms, and 100ms after impact in each trial condition.

RESULTS AND DISCUSSION

When a KAM of 57.3 Nm was applied to the specimens, correlations between ACL strain and knee kinematics were statistically significant ($P<0.05$) at 33 ms (Table 1) and 66 ms (Table 2) after impact. At 33 ms after impact, change in knee abduction angle (3.58°± 0.67) and internal rotation (3.95° ± 0.27) correlated to change of relative ACL strain (3.79% ± 1.23%). At 66 ms after impact, knee abduction (1.66° ± 0.29) and internal rotation (3.90° ± 0.81) correlated to change in ACL strain (5.99% ± 1.3).

Previous *in vivo* studies correlated knee abduction angles greater than 5° at initial contact or 50 ms after impact to a higher risk of ACL injury [1, 3]. The current results demonstrated that knees with 3° or higher abduction and/or internal rotation had increased ACL strain at 33 ms. However, at 66 ms after impact, knee abduction decreased while internal rotation remained constant which yielded continual high ACL strain.

Change in anterior tibial translation (ATT) did not correlate to change in ACL strain at 33 ms after impact. However, in two testing conditions at 66 ms, ATT (0.03mm ± 5.09 and 0.73mm ± 4.24) correlated to ACL strain (5.99% ± 1.3).

CONCLUSIONS

Results from this study indicate during landing, ACL strain is correlated to knee abduction and internal rotation angles after impact, but not ATT. Future work should focus on the prediction of ACL strain from knee kinematics.

KNEE JOINT AND QUADRICEPS DYSFUNCTION IN INDIVIDUALS WITH ANTERIOR KNEE PAIN, ACL RECONSTRUCTION, AND MENISCUS SURGERY

[1] Sungwan Kim, Daeho Kim, Yuyeon Roh, Minwook Kim, and Jihong Park

[1] Kyung Hee University, Yongin, Korea
email: jihong.park@khu.ac.kr

INTRODUCTION

Arthrogenous muscle inhibition (AMI) is common in patients with anterior knee pain (AKP) [1], anterior cruciate ligament reconstruction (ACLR) [2], and meniscus surgery [3]. Although AMI associated with knee injuries is evident, the relative magnitude of functional deficiency related to each individual knee pathology is unclear. A cross-sectional comparison using knee joint position sense (JPS), quadriceps maximal voluntary isometric contraction (MVIC), central activation ratio (CAR), and rate of torque development (RTD) in these populations would be beneficial. If a relative degree of AMI is observed, it would suggest a need for a particular intervention regarding each specific knee joint pathology.

Therefore, the purpose of this study was to examine knee joint (JPS at 15° and 75°) and quadriceps (MVIC, CAR, and RTD) function among knee joint pathologies, compared to healthy matched controls. Due to the presence of pain, we hypothesised that individuals with AKP would present higher deficits in knee joint and quadriceps function than individuals with other knee joint pathologies.

METHODS

Forty-four individuals with knee joint pathologies and 24 healthy matched controls participated in this study. Subjects with AKP were included if they felt pain during at least one of the following: 1) prolonged sitting, 2) step up and down, 3) patella compression, or 4) quadriceps voluntary isometric contraction. Subjects with AKP were excluded with history of lower extremity surgery within their lifetime. Subjects with ACLR and meniscus surgery were only included if there was no presence of current pain, isolated surgery and without other concomitant injuries and surgeries. Subjects with neurological disorder, cardiovascular disease, diabetes mellitus, or current pregnancy were excluded.

After a 10-min warm up on a stationary bike, subjects were performed three times each measurement in order (JPS at 15° and 75°, MVIC, CAR, and RTD).

Knee JPS was calculated by the absolute error of angle (°). Quadriceps MVIC was normalised to body mass (Nm/kg). The CAR was calculated by MVIC torque / superimposed burst torque (ratio). The RTD was calculated as voluntary torque of the torque-time curve, and the peak torque value was identified and normalised to body mass (Nm/s/kg).

Depending on normal distribution, we performed a parametric (mixed model analysis of variance and Tukey test) or a non-parametric test (Kruskal-Wallis and Duncan test) on each dependent measurement ($p<0.05$).

RESULTS AND DISCUSSION

The subject demographics are shown in Table 1. Age, height, mass, and body mass index were not statistically different ($p>0.16$). All pathology conditions had lower scores on the lower extremity functional scale ($\chi^2=43.02$, $p<0.0001$) than the healthy matched controls, but no relative differences were observed among them.

We did not observe differences on JPS 15° ($\chi^2=2.57$, $p=0.46$). However, AKP patients showed higher absolute errors on JPS 75° compared to other conditions ($\chi^2=8.71$, $p=0.03$, ES=1.00; Figure 1-A). The mechanisms behind this is unclear, but in speculation this is due to presence of current pain [4]. Although statistical differences were not observed, patients with ACLR (ES=0.74) and meniscus surgery (ES=0.55) showed joint function deficiency on JPS 75°.

Table 1. Subject demographics (mean ± 95%CIs).

	AKP (n=16)	ACLR (n=14)	Meniscus surgery (n=14)	Healthy controls (n=24)
Sex	14M, 2F	12M, 2F	12M, 2F	22M, 2F
Age	21.8 (1.3)	23.4 (1.4)	23.0 (1.2)	23.0 (1.0)
Height	174.4 (3.9)	175.9 (4.1)	175.2 (2.7)	175.7 (2.9)
Mass	74.3 (6.5)	75.0 (5.0)	75.8 (3.9)	74.8 (3.1)
BMI	24.3 (1.4)	24.2 (1.0)	24.6 (1.0)	24.4 (0.9)
MAI	33.6 (13.0)	32.2 (11.5)	50.1 (18.0)	N/A
MAS	N/A	31.6 (11.4)	45.4 (17.6)	N/A
LEFS	59.1 (5.5)	66.8 (5.7)	66.1 (5.1)	79.0 (1.0)

BMI: body mass index; LEFS: lower extremity functional scale; MAI: months after injury; MAS: months after surgery

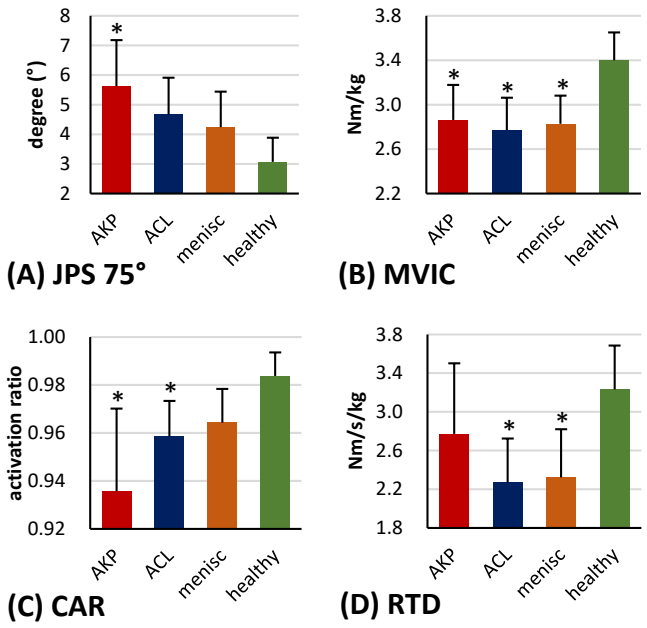

Figure 1: Changes in JPS at 75° (A), MVIC (B), CAR (C), and RTD (D). Error bars represent 95% CIs. * Indicate statistical differences from the healthy matched controls (p<0.05).

All conditions with knee pathologies showed quadriceps weakness ($F_{3,64}$=5.02, p=0.003; Figure 1-B), which is consistent with many previous observations. A relative magnitude of strength deficiency among knee pathologies were not observed.

Lower quadriceps CAR values (χ^2=13.94, p=0.003; Figure 1-C) were observed in patients with AKP (p=0.005, ES=0.99) and ACLR (p=0.02, ES=1.01) compared to the healthy matched controls. A longer time from injury (over four years) in patients with meniscus surgery may explain why this condition in our study did not show quadriceps activation deficiency.

Patients with ACLR (p=0.02, ES=0.92) and meniscus surgery (p=0.03, ES=0.85) showed lower values in quadriceps RTD than those in healthy matched controls (χ^2=11.28, p=0.01; Figure 1-D). Since RTD is related to force raise in a certain period of time, this may suggest that a surgical procedure, not presence of pain, can be a factor to reduce power output. More research is needed in this area.

CONCLUSIONS

Our data support previous evidence of AMI in knee joint pathologies. Restoration of joint function along with pain control in patients with AKP and power generating capacity in patients with ACLR and meniscus surgery should be addressed in rehabilitation process.

INCREASED ANTERIOR TIBIAL ACCELERATION MEASURED DURING ACL INJURY TRIAL

Alessandro Navacchia, Nathan D. Schilaty, Nathaniel A. Bates, Christopher V. Nagelli, Aaron J. Krych, Timothy E. Hewett

Mayo Clinic Biomechanics Laboratories & Sports Medicine Center, Rochester & Minneapolis, MN

INTRODUCTION

Anterior cruciate ligament (ACL) injuries, particularly among young athletes, represent a substantial burden for the healthcare system and it can have devastating effects on quality of life, both in the short- and long-term [1]. These injuries occur during highly dynamic motor activities, such as landing from a jump and cutting [2]. The impact forces occurring during these activities produce high accelerations at the knee, which likely contribute to injury risk. Accelerometers have been previously used to measure impact accelerations and shock absorption during landing activities *in vivo* [3], but these measures during ACL injury have not been reported. Previous studies have developed impact test devices that simulate *in vitro* landing from a jump and are able to generate ACL rupture in the specimens with applied anterior tibial shear forces (ATS), knee abduction moments (KAM) and internal tibial rotation moments (ITR) associated with injury risk [4]. The goal of this study was to compare tibial and femoral accelerations and their rate of change (jerk) between tests that did and did not rupture the ACL. Our hypothesis was that higher anterior tibial accelerations would be observed during injury trials.

METHODS

Six fresh-frozen cadaveric lower limbs (44 ± 7 years; 81 ± 22 kg) were tested in a custom-designed impact simulator described in Bates et al. [4] to simulate landing from a 31-cm-high jump. Pneumatic actuators were used to apply *in vivo* kinetics at the knee collected from a cohort of 67 athletes divided into minimal (1st percentile), low (33rd percentile), middle (67th percentile), and high (100th percentile) risk categories. The specimens were subjected to a randomized series of sub-failure impacts of the aforementioned external tibial loading profiles. Two ±16g accelerometers (SPPDG, Mayo Clinic, Rochester, USA) [5] were fixed to the femur and tibia of every specimen to measure accelerations that occurred during the simulated impacts. The devices had an embedded 50 Hz upper 3 dB frequency limit. Tibial and femoral acceleration data were synchronized and transformed to a common coordinate system oriented as the tibia coordinate system. Jerk was quantified as the first derivative of acceleration in the three spatial directions. Positive (e.g. anterior) and negative (e.g. posterior) peaks, and ranges (difference between positive and negative peaks) were calculated for tibial and femoral acceleration and jerk at each impact. Ratios between femoral and tibial peaks and ranges were calculated (tibial / femoral) to quantify inter-segment relations. These results were compared between injurious impacts and impacts that did not result in an ACL tear (indicated as 'intact'). Since not every trial was common to all specimens due to load randomization and because certain specimens injured earlier than others, only the impacts with loads common to all specimens were used for the comparison to the injurious trial. The comparison was performed with one-way ANOVA and a Bonferroni correction was used to account for multiple comparisons.

RESULTS AND DISCUSSION

The ACL was completely disrupted in all specimens. Two specimens presented femoral avulsion. Seven load combinations common to all six specimens were identified and used for the comparison to the injurious trial. Tibial and femoral accelerations at impact presented a number of positive and negative spikes (Fig. 1). The number of spikes was generally larger in tibial accelerations when compared to femoral acceleration, indicating that the knee joint contributed to shock absorption.

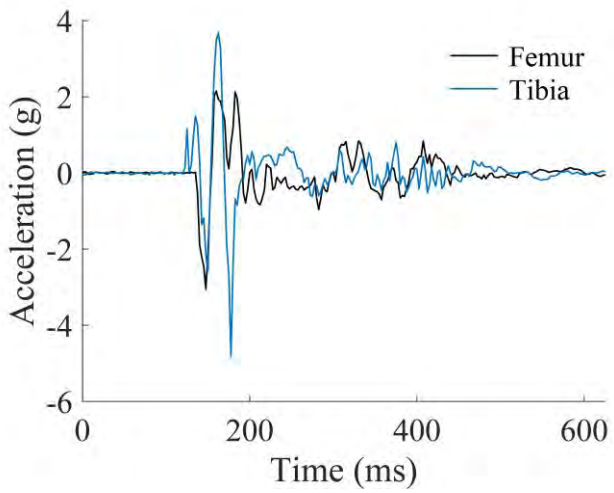

Figure 1: Example of femoral and tibial acceleration spikes during a simulated impact.

The comparison between anterior acceleration peak ratio (anterior tibial peak / anterior femoral peak) was the only one that resulted in a significant difference after the Bonferroni correction ($p < 0.004$, Fig. 2). Higher ratios during the ACL tear indicated that the anterior acceleration peak of the tibia was larger relative to the anterior peak of the femur during the injury. Ratios measured for 'intact' trials (black markers in Fig. 2b) ranged approximately between 1 and 2, whereas ratios during ACL tear presented a bimodal trend. Specifically, ratios were significantly larger at injury for four specimens, and similar to other impacts for the remaining two specimens. Larger anterior accelerations at the tibia and lower anterior accelerations at the femur (producing larger peak ratios) were expected during the injury, since the disruption of the ACL removes most of anterior restraint, and consequently deceleration, on the tibia.

CONCLUSIONS

The present study represents, to the authors' knowledge, the first attempt to measure acceleration and jerk on the femur and tibia during *in vitro* simulated landing and compare ACL-injurious impacts to intact 'impacts'. Additional specimens and work are required to establish whether the larger acceleration observed at the tibia was the cause or effect of ACL rupture.

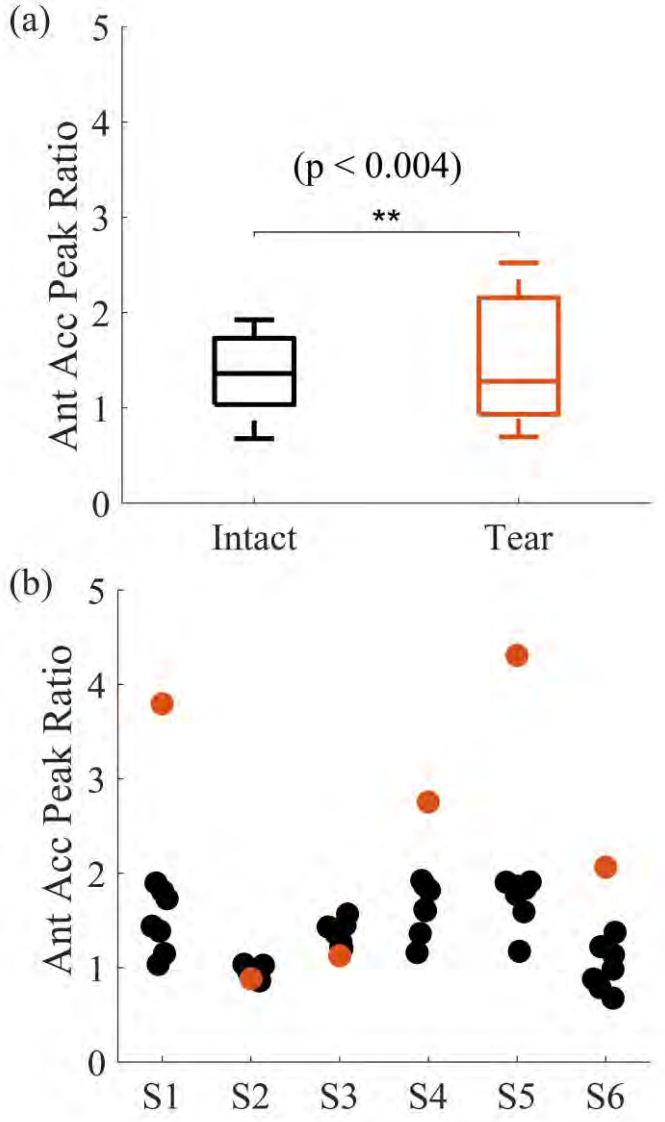

Figure 1: (a) Statistically significant difference between anterior acceleration peak ratios (tibia / femur) at injury ("tear") and "intact" trials. (b) Ratios for each specimen (S1 through S6): "intact" trials (black) vs. "tear" trials (red).

INTRODUCTION

Cadaveric experiments have sought to characterize the mechanical properties of adult knee tendons and ligaments for many years [1]; however, relatively little is known about the pediatric population due to the rarity of these specimens. Extrapolating data back to pre-pubescent ages is inadequate, and the clinical need for this data has grown along with the recent increase in diagnosed anterior cruciate ligament (ACL) tears in skeletally immature patients [2]. Ideally, surrogate grafts should closely parallel the native pediatric ACL in both its biologic properties and mechanical durability. Thorough characterization of the ACL and potential autograft options will help to improve surgical outcomes in pediatric patients, which is particularly important, as injury frequency continues to accelerate.

The purpose of this study was to characterize the mechanical properties of ACLs and the most common tendons used for reconstruction in the pediatric knee. These properties were compared with existing information for the adult population.

METHODS

Five fresh-frozen knee specimens from separate donors were used in this study (3M, 2F, average age 9.2 years). ACLs, patellar ligaments, quadriceps tendons, and semitendinosus tendons were fine dissected free from the knee and subsequently cut into dog-bone shapes at the mid substance (ACL, patellar ligament) or distal third (quadriceps and semitendinosus tendon) with a custom-built jig (**Fig. 1A**). Initial cross-sectional areas of the prepared specimens were measured with a non-contact laser-based measurement system (**Fig. 1B**). Specimen ends were placed in custom aluminum clamps and attached to a 4500N load cell on a universal testing frame (ElectroForce 3550, TA Instruments, Eden Prairie, MN) to perform uniaxial tensile testing (**Fig. 1C**). Specimens were subjected to a standard preload, cyclic preconditioning, and stress-relaxation protocol before a ramp to failure at a constant quasistatic strain rate of 0.03%/s. Force displacement and stress-strain curves were fit using a bilinear constitutive model and least squares method to approximate the ultimate strain, ultimate stress, stiffness, toe modulus, transition point, Young's modulus, stiffness, and strain energy density.

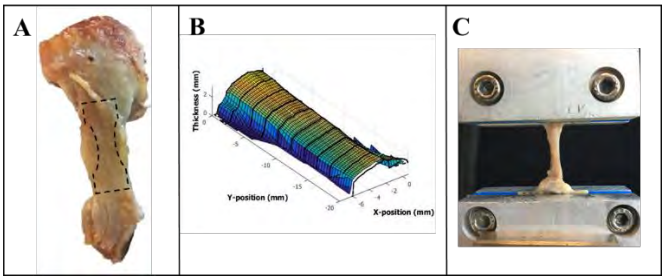

Fig. 1: A diagram summarizing A) the trimming of samples into dogbone shapes, B) laser measurement of cross-sectional area, and C) mechanical testing in a universal test frame.

RESULTS AND DISCUSSION

The patellar ligament exhibited mechanical properties that were most similar to that of the ACL, particularly for ultimate stress, ultimate strain, Young's modulus, and strain energy density (**Table 1**). The semitendinosus tendon provided the highest ultimate stress, but also had the lowest ultimate strain, while the quadriceps tendons provided the highest ultimate strain (**Fig. 2**).

The methods and results from different studies on the mechanical properties of adult knee tendons and ligaments vary markedly, which makes comparisons difficult. It is not surprising that the pediatric specimens have considerably weaker mechanical properties. In adults, hamstrings tendons have

previously been shown to exhibit significantly higher elastic modulus (1036±312 MPa) and ultimate stress values (120.1±30.0 MPa) than other graft candidates, including the patellar ligament (417±107 MPa, 76.2±25.1 MPa) [3]. This is in agreement with our data for a pediatric population, which showed that the semitendinosus tendons are stronger and less compliant than the quadriceps or patellar tendons.

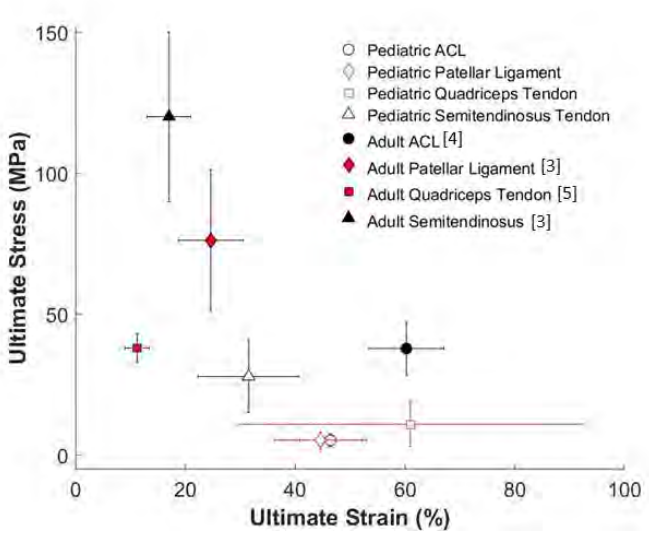

Fig. 2: Comparisons of ultimate stresses and ultimate strains for pediatric and adult specimens.

CONCLUSIONS

This suite of data can be used to inform the design and selection of grafts for reconstruction and also to develop constitutive computational models that can be applied to clinically relevant loading conditions that are difficult to test with bench-top experiments.

Based on the similarities of their material properties, the patellar ligament may be the better graft candidate for pediatric ACL reconstruction. However, it is important to take into consideration many factors can contribute to the strength and durability of an ACLR graft in vivo, including the extent of post-operative ligamentization and the femoral/tibial fixation method used [3]. Therefore, it may be more appropriate to utilize a hamstrings tendon graft, which is significantly stronger than the patellar ligament and could resist the loads that would otherwise lead to re-rupture.

ACL Loading During Unilateral Landing is Correlated to Dorsiflexion Range of Motion

[1]Joshua T. Weinhandl, [1]Shelby A. Peel & [2]Matthew C. Hoch

INTRODUCTION

Anterior cruciate ligament (ACL) injury is one of the most frequent and debilitating lower extremity injuries experienced by physically active individuals. Approximately 250,000 ACL injuries occur annually in the United States alone with 50% occurring in athletes who are 15-25 years old [1]. Furthermore, female athletes have demonstrated a 4- to 6-fold increased risk of ACL injury compared to their male counterparts playing at similar levels in the same sports [2].

The ACL injury enigma is likely multifactorial and a variety of risk factors that may predispose an athlete to injury have been identified, which can be divided into two categories. Risk factors associated with anatomical (e.g., Q-angle, ligamentous laxity, ACL size and strength, boney geometry) and hormonal characteristics are considered to be non-modifiable. On the other hand, risk factors that can be manipulated through training are considered modifiable risk factors [1]. These include neuromuscular factors (e.g. relative muscle strength and recruitment, relative joint stiffness and stability, muscle fatigue, and flexibility) as well as biomechanical factors in all three planes of motion, which have been theorized as potential mechanisms related to ACL injuries [1].

Combining clinical and laboratory techniques may provide the best approach for advancement in the field. One such modifiable clinical measure is dorsiflexion range of motion (DROM). DROM is essential for completing several functional tasks, and decrements in DROM have been linked to an increased risk of several lower extremity injuries and conditions [3-5]. Recently, reduced DROM has been theorized to contribute to modified lower extremity movement patterns that could encourage ACL injuries [6-7]. These systematic reviews indicate that restricted DROM may increase an individual's risk of knee injury due to its association with frontal and sagittal plane knee movement. Therefore, restricted ankle mobility may create a defective base of support for knee stability at the knee during dynamic activity. By establishing a relationship between ankle function and knee biomechanics, we hope to identify a modifiable contributing factor to assist in ACL injury prevention.

METHODS

Nine recreationally active women (22.9±3.1 yr, 63.2±6.6 kg, 1.67±0.07 m) volunteered to participate in this study. Prior to data collection, participants were informed of study procedures and provided written informed consent in accordance with institutional guidelines. Participants first performed a modified knee-to-wall lunge test [8] to assess maximal weight-bearing DROM. Participants then performed unilateral landings from a box set equal to their maximum vertical jump height on to their dominant legs. Dominant leg was defined as the preferred kicking leg. Marker coordinate data (200 Hz, Vicon) and ground reaction force data (2000 Hz, Bertec) were collected synchronously for all trials.

OpenSim (v3.3 http://simtk.org) was used to simulate all landing trials [9]. An 8 segment, 23 degrees-of-freedom (*dof*) musculoskeletal model, with 92 Hill-type muscle actuators (modified from Gait2392), was scaled to match each participant's anthropometry based on experimentally measured anatomical landmarks. The knees were modified to be 3-*dof* joints (i.e., flexion-extension, adduction-abduction, internal-external rotation). Knee adduction-abduction and internal-external rotation *dof* were modeled as universal joints, with the same center of rotation as the flexion-extension *dof*, which was modeled as a planar joint. This allowed the tibia to translate relative to the femur as a function of knee flexion angle. Static optimization was used to calculate the muscle forces required to reproduce the

joint moments of each trial. The optimization minimized the sum of muscle activations to distribute muscle forces. Simulated knee joint reaction forces and moments, along with hamstrings, quadriceps and gastrocnemius muscle force estimates were input into a three-dimensional knee model to estimate ACL loading [10].

Pearson correlations (r) along with the coefficient of determination (r^2) were performed to examine the relationship between the DROM, and ACL loading.

RESULTS AND DISCUSSION

Participants exhibited an average DROM of 12.9±3.7 cm, which is consistent with previous reports of weight-bearing DROM in individuals with no history of lower extremity injury [8]. Participants also experienced a peak ACL loading of 0.57±0.16 BW at 44±6 ms after initial contact. Peak ACL loading was primarily due to loading in the sagittal plane (79%), followed by frontal plane (16%) and transverse plane (5%) contributions.

There was a strong, negative correlation between weight-bearing DROM and total ACL loading ($r = -0.81$, $r^2 = 0.66$), as well as sagittal plane ACL loading ($r = -0.91$, $r^2 = 0.82$). Moderate correlations were observed between DROM and time to peak ACL loading ($r = 0.48$, $r^2 = 0.23$), as well as between DROM and transverse plane ACL loading ($r = 0.59$, $r^2 = 0.35$). Finally, a weak correlation was observed between DROM and frontal plane ACL loading ($r = -0.27$, $r^2 = 0.07$).

CONCLUSIONS

The results of this study suggest that individuals with reduced DROM experience increased peak ACL loading during unilateral landings, primarily due to increases in sagittal plane loading. Although, DROM has been associated with frontal plane knee motion, it was not correlated with frontal plane ACL loading. This may be due to the sagittal plane nature of the experimental task. Future work should investigate the relationship between weight-bearing DROM and ACL loading during tasks such as sidestep cutting which produce greater frontal and transverse plane ACL loading. Additionally, future work is necessary to determine if modifications in weight-bearing DROM yield significant reductions in ACL loading during athletic tasks. Such information may lay the groundwork for novel ACL injury prevention strategies to be applied to athletes and physically active individuals

STATISTICAL SHAPE MODELING TO ESTIMATE COORDINATE SYSTEMS FOR PARTIAL CAPITATE MODELS

[1] Mohsen Akbari-Shandiz, [2] Ryan E. Breighner and, [1] David R. Holmes III, and [1] Kristin D. Zhao

[1] Mayo Clinic, Rochester, MN, USA, [2] Hospital for Special Surgery, NY, USA
email: shandiz.mohsen@mayo.edu

INTRODUCTION

High spatial and temporal resolution 4D (3D + time) CT technique (4DCT) has been used for accurate quantification of key metrics during wrist motion in patients with ligament injury [1]. However, due to limited FOV, the entirety of a wrist cannot always be imaged. The limited longitudinal coverage under the 4DCT technique (38.4mm), results in partial views of the capitate when imaging wrist motions (Fig1a). Principal axes, derived from surface models, have been used to define carpal coordinate systems [2]; however, principal axes determined from a partial capitate (resulting from limited longitudinal coverage) would result in a disparate coordinate system and thus inaccurate reporting and comparison of kinematic findings. To overcome this limitation, a conventional static CT of the whole wrist (Fig.1b) can be obtained to acquire the entire capitate and 3D-3D registration can be performed between the static and 4DCT to reconstruct dynamic capitate motion. However, this static CT alone contributes nearly one-third of the total radiation exposure in a 4DCT kinematic wrist analysis.

As an alternative, this study proposes the use of statistical shape modeling (SSM) as a means to estimate the full capitate surface model. We assess the viability of this technique using partial capitate geometry from simulated 4DCT flexion/extension scans.

METHODS

Statistical shape models of the capitate were built from a set of 25 wrist CT datasets (11 male and 14 female; Voxel sizes = 0.234 × 0.234 × 0.4 mm^3; resampled to isotropic), from which the capitate was semi-automatically segmented using AnalyzePro software (Mayo Clinic, Biomedical Imaging Resource, Rochester, MN).

The coordinate system of the capitate model was determined using the technique proposed by [2]. In this technique, the origin of the coordinate system is defined at the centroid of surface mesh vertices. Coordinate axes were defined by calculating the principal axes of the capitate model automatically, without manual intervention [2] (Fig. 1d).

To build the SSM, corresponding vertices across the training shapes were determined using the 'shape context' algorithm [3]. The SSM was computed as the mean shape plus a set of eigenvectors obtained by applying Principal Component Analysis (PCA) to the model vectors: $\mathbf{x} \approx \bar{\mathbf{x}} + \boldsymbol{\phi}\,\mathbf{b}$, where x is the shape model, $\bar{x}$ is the mean shape, ϕ is the matrix of modes of variation (eigenvectors of the covariance matrix), and b is the shape parameter vector. By varying b_i (elements of b), new instances of the shape were generated and by applying limits of $\pm 3\sqrt{\lambda_i}$ to the b_i (where λ_i is corresponding eigenvalues) it was ensured that the shape changes in a plausible manner.

For a given bone model, shape parameter vector (b) as well as 6 DOF rigid registration parameters were computed by optimizing an objective function measuring how well the estimated shape fit to the ground truth shape from CT scans. Optimization minimized the sum of surface-to-surface distance between the estimated shape and the ground truth shape, measured using the k-nearest neighbors algorithm. The optimization routine was a nonlinear multivariable function with linear equality constraints for the shape parameters (Matlab, R2016a). To validate the model, we used the first 10 (of 21) modes of variation which covered 90% of the total variation in capitate geometry. Therefore, in each registration we simultaneously optimized 10 shape and 6 rigid transformation parameters (3 translations and 3 rotations).

The performance of our statistical shape modeling was evaluated using two metrics:

1) Surface-to-surface distances: Mean absolute error (MAE) and standard deviation (SD) of the distances between the closest surface points of the

estimated SSM and the ground truth were used to measure the capability of the SSM to capture morphologic variation within the patient population. Distances were computed using CloudCompare (v2.6.3, http://www.cloudcompare.org/).

2) Error of coordinate system computation based on principal axes: Since the main objective of the SSM in this study was to estimate an accurate capitate coordinate system from a partial capitate model, the accuracy of the SSM reconstruction was also evaluated by computing the MAE and SD of translational and rotational errors in the estimation of coordinate systems, from SSM, compared to the the ground truth capitate model.

Experiment 1. To measure the capability of the SSM to capture capitate morphology within the patient population, we used a leave-one-out cross registration with the CT data. In each step, we left out one patient for testing, created the SSM from the remaining 24 patients, and registered the created SSM to the left-out CT. This process was repeated for all 25 datasets.

Experiment 2. To assess the ability of our SSMs to estimate full capitate models from partial geometry, partial capitates at the extrema of wrist flexion-extension in 4DCT scanning were simulated and used for the SSM registration. Three artificial cuts were performed at wrist flexion, extension and neutral position using axial planar cuts consistent with the longitudinal coverage in 4DCT (Fig.1c).

For this experiment, we studied 10 of the capitate models using leave-one-out technique. The SSMs were applied to the three cut capitate models to estimate the full capitate models (Fig.1e).

Table 1: Accuracy of SSM in estimating the capitate surface model and its coordinate system

Accuracy (MAE±SD)		Surface distance error (mm)	Coordinate system error	
			translation (mm)	rotation (deg)
SSM from full bone		0.05±0.3	0.2±0.1	2.9±2.1
SSM from flex. cut		0.2±0.5	0.3±0.2	3.9±2.9
SSM from neut. cut		0.1±0.4	0.2±0.1	2.3±1.6
SSM from ext. cut		0.2±0.4	0.3±0.2	2.6±1.8
Partial capitate	flexion cut		1.8±0.3	24.5±8.4
	neutral cut		0.9±0.2	4.6±3.0
	extension cut		1.7±0.2	17.5±9.2

RESULTS AND DISCUSSION

Our SSM models were able to provide sub-millimeter accuracy in terms of *surface-to-surface distance error* (MAE). For capitate coordinate system evaluation, the average translational errors were less than 0.3 mm and average rotational errors were less than 3.9° for the estimated SSM, compared to the 1.8 mm and 24.5° for the partial capitate models (Table 1).

CONCLUSIONS

Experimental results demonstrate that our SSM is accurate and robust to reconstruct capitate models for accurate coordinate system estimation from partial capitate models. Our results show that performance of SSM reconstructed capitates from registration to the neutral-cut, in sagittal view, was descriptively superior to flexion-cut and extension-cut. Ongoing research is aimed at developing SSM of the radius for estimating the full radius surface model from partial 4DCT scans, which is a crucial step for defining the wrist joint coordinate system. Replacing the static CT with SSM may potentially reduce the overall radiation dose of dynamic wrist imaging and may enable trials incorporating more or longer dynamic 4DCT trials.

TIBIA CROSS-SECTIONAL ROUNDNESS IS RELATED TO AMBULATION, BUT NOT AGE, IN CHILDREN WITH MYELOMENINGOCELE

[1]Kyle P. Chadwick, [1]Nicole M. Mueske, [3]Rachel E. Horenstein, [3]Sandra J. Shefelbine, [1,2]Tishya A. L. Wren

[1]Children's Hospital Los Angeles, Los Angeles, CA
[2]University of Southern California, Los Angeles, CA
[3]Northeastern University, Boston, MA

INTRODUCTION

Skeletal loading through daily movement is important for normal development of bones. This loading is affected by the neurological and muscle deficits that result from myelomeningocele (MM). While children with MM have been shown to have atypical gait, decreased bone accrual, and increased fracture risk, it is still unclear what morphological bone differences exist and to what extent they relate to age and ambulation level. The objective of this study was to understand how tibia cross-sectional shape changes with age and how it differs in children with MM due to atypical and/or reduced ambulation.

METHODS

This study analyzed tibia computed tomography images from 77 children with MM and 169 typically developing (TD) children between the ages of 6 and 16yrs. Right tibias were segmented and isolated in OsiriX software [1]. The slices were aligned, thresholded, and analyzed in BoneJ [2]. To quantify bone cross-sectional "roundness", shape ratio (SR), defined as the ratio of minimum to maximum area moment of inertia (I_{min}/I_{max}), was calculated on cross-sectional slices along the length of the tibia. An SR value of 1 indicates a circular shape, and the degree of circularity decreases as SR changes from 1 towards 0. The SR values for all tibias were filtered and linearly interpolated to 200 slices to account for tibia length differences. The proximal and distal 20% were removed from all SR data to exclude the epiphyses. All analyses were performed on this diaphysis region, and are presented as 100% diaphysis length.

Ambulatory groups were defined based on Functional Mobility Scale (FMS) scores [3]; "non-ambulatory" was defined as crawling or using a wheelchair (score of 1) at all distances, "ambulatory with assistive devices" was defined as walking with a walker or crutches for one or more distances (2 or higher) without qualifying for "ambulatory independent", and "ambulatory independent" was defined as walking independently (5 or 6) for home and school distances. Differences in SR along the length of the tibias were examined across age groups (6-9, 10-13, 14-16 years) and ambulation level (all ages) using statistical parametric mapping (SPM), a methodology for making statistical inferences on spatially or temporally related datasets [4]. One-way SPM ANOVA was used to compare the three age groups and the four ambulatory groups; two-tailed SPM t-tests were used in comparisons of two groups (MM vs. TD and paired post-hoc comparisons). The significance level was set at $p<0.05$. For the post-hoc tests, Bonferroni adjustment was applied to adjust for multiple comparisons.

RESULTS

In TD children, tibia cross-sections became less round with age, particularly in the proximal 80% of the diaphysis (Fig 1a). However, tibia cross-sections of children with MM did not change shape with age (Fig 1b) and were rounder than those of TD children, particularly in the older age groups. Less ambulatory children with MM also had rounder tibia cross-sections (Fig 2). Even children with MM who walked independently had rounder tibia cross-sections than typically developing children.

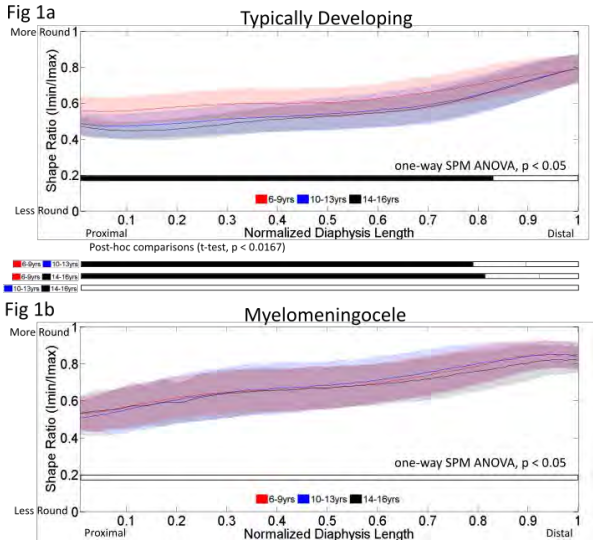

Figure 1: Comparison of shape ratio among age groups (all ambulatory levels)

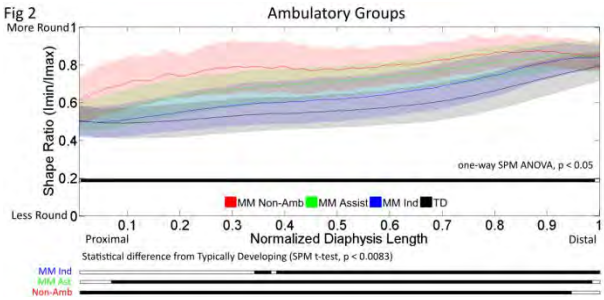

Figure 2: Comparison of shape ratio among ambulatory groups (all ages)

DISCUSSION

Loading associated with ambulation is needed to stimulate typical remodeling in tibia morphology. Children with MM have limited ambulation and atypical loading leading to the maintenance of rounder tibias compared to typically developing children. Bone cross-sectional shape greatly affects its bending strength. While circular cross-sections resist bending equally in all directions, more typical triangular or oval cross-sectional shapes can provide greater bending strength along common loading directions. This study emphasizes bone morphology's relationship with age throughout adolescence and the lasting impact of reduced and altered ambulation.

EFFECT OF BRACHIAL PLEXUS BIRTH INJURY LOCATION ON ALTERED GLENOHUMERAL MICROSTRUCTURE

[1,2] Emily B. Fawcett, [1]Nikhil N. Dixit, [1,2]Carolyn M. McCormick, [1,2]Ted A. Bateman, [1]Katherine R. Saul, and [1,2]Jacqueline H. Cole

INTRODUCTION

Brachial plexus birth injury (BPBI) is the most common nerve injury in children, causing muscle paralysis and ultimately leading to joint deformities and lifelong impairment of arm function in up to 30% of these children [1]. The injury is known to cause both muscle weakness and gross morphologic changes in the glenohumeral joint [2]. However, little is known about the underlying microstructure of both bone and muscle and how that correlates to the gross morphologic changes, including how it differs due to injury location along the nerve. Postural deformity is more severe with injuries occurring distal to the dorsal root ganglion (postganglionic) rather than proximal (preganglionic) [3]. This study uses unique rodent models of both injuries to improve understanding of factors contributing to glenohumeral joint deformities with BPBI.

The purpose of the study is to examine microstructural abnormalities in the bones surrounding the glenohumeral joint following BPBI and the impact of nerve injury location on the severity of these changes. Findings will help elucidate the differential progression of preganglionic and postganglionic injuries, a key first step to develop more effective treatments for children with BPBI.

METHODS

All animal work was performed under an approved IACUC protocol. Male and female Sprague-Dawley rat pups were separated into three groups. The postganglionic neurectomy group (n=8) underwent C5 and C6 nerve root excision distal to the dorsal root ganglion [4]. The preganglionic neurectomy group (n=14) underwent C5 and C6 nerve root excision proximal to the dorsal root ganglion [5]. The sham control group (n=8) underwent sham surgery without nerve injury. Interventions were performed at postnatal day 3-5 on one side (affected) with the contralateral (unaffected) side serving as an additional control. At 8 weeks after surgery rats were sacrificed, and bones (humerus, scapula)were harvested from both affected and unaffected sides.

Bone microstructure was assessed in the distal scapula and proximal humerus using micro-computed tomography (micro-CT) (μCT 80, SCANCO Medical). Scans were reconstructed using a 10-μm isotropic voxel size, reoriented along anatomical planes, and calibrated for bone mineral density. Several volumes of interest (Fig. 1) were evaluated for standard trabecular bone metrics, including bone volume fraction (BV/TV), trabecular number (Tb.N), thickness (Tb.Th), and separation (Tb.Sp), and connectivity density (Conn.D). Analyses are ongoing, and a subset of data is presented here. Group comparisons were made on affected/ unaffected ratios using one-way ANOVA with Tukey's posthoc tests (α=0.05). The relationship between microstructural changes and

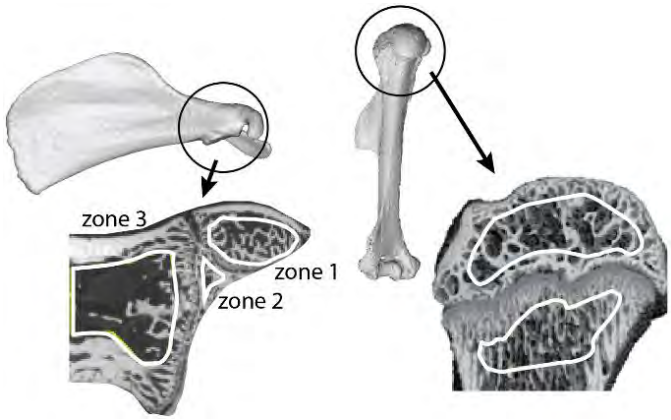

Figure 1: Micro-CT volumes of interest for the scapula (left) and humerus (right).

previously measured macrostructural changes in these animals will be examined with multivariate linear regressions (SAS).

RESULTS AND DISCUSSION

Trabecular bone microstructure in the scapular zone 3 region was significantly deteriorated in rats with postganglionic neurectomy compared with sham (Fig. 2). Bone volume fraction in the affected limb (relative to unaffected) was reduced more for the postganglionic neurectomy group than sham (-20.5%, p=0.0014). The same was true for trabecular number (-20.1%, p<0.0001) and connectivity density (-18.2%, p=0.0061). Relative trabecular separation was increased for postganglionic compared to sham (+34.8%, p<0.0001). The preganglionic group (n=2 preliminary data) also showed deficits in trabecular microstructure similar those observed in the postganglionic group.

We previously found, in these same groups of rats, macrostructural differences between the post- and preganglionic groups [6]. In particular, the glenoid inclination angle was significantly reduced in the postganglionic but not in the preganglionic group. These disparate effects with injury location for macrostructural (different pre- vs. postganglionic) and microstructural (similar pre- vs. postganglionic) properties suggests different drivers for these changes in the scapula following BPBI that warrants further study.

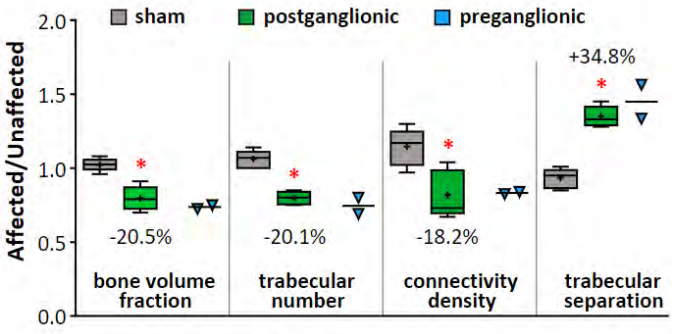

Figure 2: Compared to sham, postganglionic injury was associated with degenerated trabecular bone in scapula zone 3. Preganglionic rats (n=2) had similar changes compared to the sham group.
*p<0.05. + mean value.

CONCLUSIONS

Our work shows substantial losses in scapular trabecular bone within 8 weeks of neonatal post-ganglionic injury, and a trend for losses in preganglionic injury, relative to sham. Specifically, the trabeculae were fewer, less connected, and more sparsely arranged following neurectomy. Most notably, this study will provide new information on how bone microstructural changes correlate with the development of glenohumeral deformities following BPBI, and how injury location may modulate these relationships.

These results are limited by a small sample size for the preganglionic injury, but data analysis is ongoing. The current work also focuses only on changes in bone tissue; as part of a larger study we are also looking at parallel changes in muscle microstructure (morphology and fibrosis), as well as underlying cellular crosstalk between muscle and bone, to elucidate mechanisms contributing to the tissue- and joint-level changes observed post-injury. This knowledge will help guide future work in evidence-based treatment planning to improve the current wait-and-see approach used in clinical practice [7].

CHARACTERIZATION OF GLENOID BASEPLATE FIXATION IN THE PRESENCE OF OSTEOPENIC BONE

Michael W. Hast, Matthew Chin, Anthony Cresap, Elaine Schmidt, and Andrew F. Kuntz

University of Pennsylvania, Philadelphia, PA, USA
email: hast@pennmedicine.upenn.edu, web: https://www.med.upenn.edu/biedermann/

INTRODUCTION

Reverse total shoulder arthroplasty (rTSA) has become a widely accepted solution for patients with various shoulder pathologies. Despite its popularity, complications are prevalent in the elderly population due to a limited amount of bone stock that may also be of poor quality (1). While research in baseplate stability is abundant, the vast majority of existing studies have utilized synthetic bones to model implant stability (e.g. 1-3). This approach effectively reduces variability within datasets, but it has also limited our understanding of baseplate fixation in osteopenic or osteoporotic bone.

This study introduces a novel cadaveric testing method that simulates physiologically relevant loads that may be responsible for baseplate loosening. The goal of the study was to utilize this new model to investigate how the central screw changes micromotion, subfailures, and catastrophic failure at the baseplate-bone interface. We hypothesized that the use of a central screw would improve bone-implant fixation when compared to specimens that omit it.

METHODS

Eight matched pairs of cadaveric scapulae with DEXA-confirmed osteopenia were implanted with rTSA baseplates and glenospheres (Titan, Integra LifeSciences, Plainsboro, NJ) and randomly divided into groups that used a central screw (CS+) and did not use a central screw (CS-).

The custom testing apparatus was designed to improve upon on the existing ASTM standard that imparts a compressive force of 750 N and alternating shear loads of 750 N (4) (**Fig. 1A**). The new test still uses bi-axial loading but simulates an arm loaded at 30° abduction (**Fig. 1B**), rather than 90° of abduction with high shear loads.

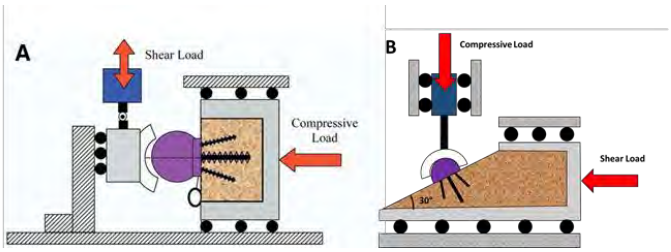

Figure 1: Diagrams of the ASTM standard (A), which does not apply physiologically relevant loads, and the current method (B), which simulates an activity similar to ambulating with a walker.

Each specimen was fatigue tested in the jig shown in **Fig. 2**. The glenoid and humeral stem were aligned to 30° abduction with a rotating vice (blue). 3-D marker clusters (inset) were fixed to the scapula and glenosphere to measure relative motions between the bone and implant. A vertical actuator applied monotonically increasing cyclic loads along the axis of the humerus (orange). The first cycle had a maximum load of 150 N, and 0.2 N of maximum load was added to each subsequent cycle. To simulate the compressive forces of muscles squeezing the joint, a pneumatic piston (pink) applied a constant 100 N load horizontally on the fixture, which was allowed to move freely on a linear bearing (brown). All tests were performed in a temperature-controlled circulating water bath and cyclically loaded until failure.

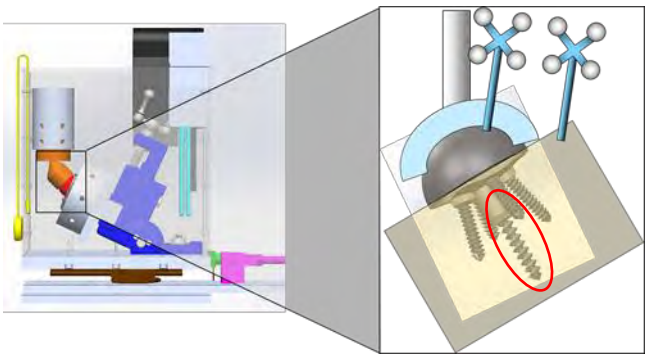

Figure 2: CAD representation of the test device with the central screw circled in red.

Deformation, load, relative 3-D displacement, and survived cycles were measured. Post-hoc analyses of sub-failure were defined as permanent creep between the bone-baseplate interface exceeding 1 mm. This was measured with actuator displacement and again with 3-D motion tracking. Groups were compared with 1-tailed paired student t-tests.

RESULTS AND DISCUSSION

Use of the central screw improved fatigue life before catastrophic failure, as the average maximum number of cycles survived for CS+ and CS- groups were 7281.88±2517.32 and 5911.63±2686.38 cycles, respectively (p=0.026) (**Fig. 3A**). There were no significant differences found between groups for subfailure when measured directly with actuator displacement (**Fig. 3B**) or with 3-D motion tracking (**Fig. 3C**). An analysis of cycle numbers survived as a function of DEXA T-score indicated no strong correlation, with R-squared values of 0.19 and 0.12 for the CS+ and CS- groups, respectively.

This study introduces a novel testing paradigm that successfully characterized the role of the central screw in baseplate fixation. Contrary to our hypothesis, the use of the screw did not improve the implant's resistance to 1 mm of creep. Interestingly, the use of a central screw improved the fatigue life of the implant before catastrophic failure.

There are several distinct differences between this experiment and previous experiments. The choice of 1mm of permanent deformation to determine subfailure is larger than previous reports of micromotion (on the scale of 0.15 mm) (1-3). Baseplate loosening in the clinic is typically determined with radiographic analyses and we believe that 1mm is the low threshold of implant motion that can be assessed with these techniques. Previous studies have used linear variable differential transformers (LVDTs), which provide high resolution measurements of micromotion. The use of cadaveric specimens, rather than bone blocks, precluded our ability to place LVDTs. We feel that 3-D motion capture with 0.2mm resolution was adequate to measure 1mm motions.

Optimizing baseplate fixation in poor quality bone is an important clinical issue that requires further

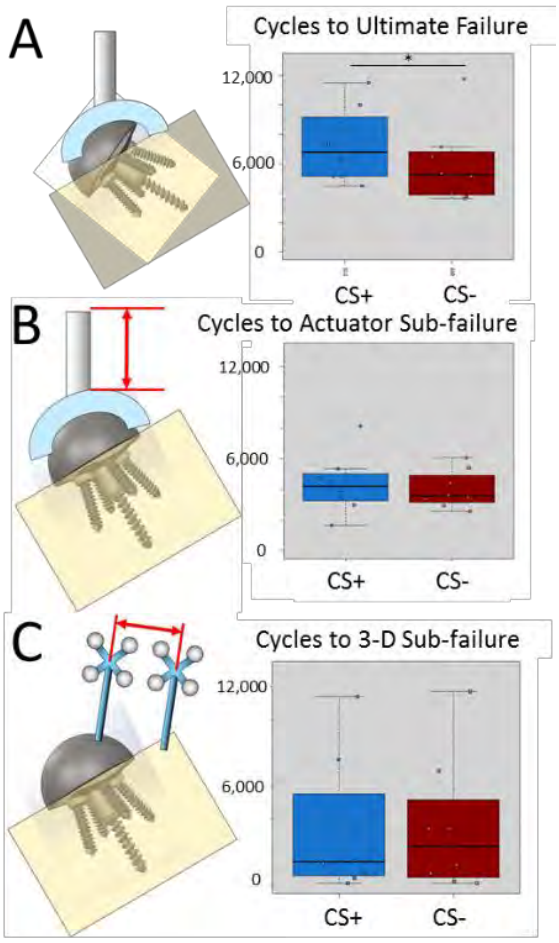

Figure 3: CAD images and boxplots of A) cycles to ultimate failure, B) cycles to actuator measured subfailure, and C) cycles to 3-D motion measured subfailure.

research. Our study suggests that central screw use is preferred, but omission of the central screw may be a reasonable tactic, especially if bone stock is sparse and the joint is only going to be exposed to small external forces.

BEYOND GROUND REACTION FORCES: TOWARDS WEARABLE TECH TO MONITOR BONE LOADING & PREVENT INJURY

Emily S Matijevich, Lauren M Branscombe, Leon Scott and Karl E Zelik

Vanderbilt University, Nashville, TN, USA
email: emily.matijevich@vanderbilt.edu

INTRODUCTION

Bone stress injuries (BSI) can result from repeated submaximal bone loading that causes an accumulation of microdamage. There is a high prevalence of BSI, particularly tibia stress fractures, in military trainees, recreational runners, and certain industrial workers. BSI can result in pain, missed work, reduced physical activity, decreased productivity and substantial healthcare costs.

We predict that BSI could be prevented if one could monitor bone loading in daily life, identify potentially injurious loading conditions, and then intervene before an excessive accumulation of bone microdamage. However, monitoring bone loading is challenging, particularly if the goal is to do so in daily life outside of a motion analysis lab. An ideal solution would be a wearable, non-invasive device that serves as an injury prevention tool for military trainees, runners and industrial workers.

Various researchers have attempted to understand BSI by measuring ground reaction forces (GRFs), with the hope that GRF peaks or loading rates might reflect bone loading. GRFs are appealing because, in contrast to bone loading, they can be measured directly and non-invasively; however, it can be shown analytically (via Newton-Euler laws of motion) that bone forces are a function of more than just GRFs. Typically, the vast majority of bone loading is due to muscle contractions. GRF magnitude is generally only a small fraction of the total bone loading. For instance, during running peak GRFs are typically 2-3 times body weight (BW), whereas peak tibia bone forces are typically 8-12 times BW, as evidenced by gait analysis [1], cadaver [2] and modeling studies. Moreover, peak bone loading occurs in midstance, while GRF impact peaks occur near initial foot contact.

Nevertheless, it is plausible that for a certain subset of tasks (e.g., running over a limited range of speeds) that GRF might positively correlate with bone loading, and thus still be a useful indicator of increases/decreases in bone loading. Given the ability to measure GRFs directly with wearable sensors, this possibility is worth exploring before investigating more complex multi-sensor solutions.

The purpose of this study was to determine if increases in GRF peaks or loading rate were correlated with increases in peak tibia bone loading during running. We focused on running and tibia bone loading, because of the high prevalence of tibia stress fractures in runners. We hypothesized that increases in common GRF metrics (impact and active peaks, impact loading rate) would not be strongly correlated with increases in peak tibia loading as runners varied speed, step frequency and terrain slope (i.e., $r<0.8$). The absence of strong correlation would suggest the need to fuse data from additional/alternative sensors, moving beyond GRF measures, to non-invasively monitor bone loading.

METHODS

Three healthy subjects (2 M, 1 F, height 1.8 ± 0.1 m, weight 66.8 ± 7.0 kg, age 24.6 ± 1.5 years) have participated in this ongoing study. Subjects performed various running trials on a treadmill: (i) 20 total trials at 4 different speeds, ranging from 2.0-3.0 m/s, using self-selected step frequency at each speed, and 5 different slopes ranging from –6 to +6 degrees, (ii) 7 trials at 2.6 m/s but varying step frequency from -15% to +15% of their self-selected step frequency (enforced via metronome). Parameter ranges were selected to reflect variability that a recreational runner might encounter.

Data collection & processing: Unilateral lower-limb kinematics (100 Hz) and GRFs (1000 Hz) were collected. Subjects provided informed consent prior to participation. For each trial, data were collected for 20 seconds, individual steps were

parsed out, and outcome metrics were computed on a step-by-step basis and then averaged.

Tibia bone loading: An established inverse dynamics analysis was used to estimate the total tibia compression force (F_{total}, Fig. 1a), due to internal (muscle) and external (GRF) sources [1]. The external contribution (F_{ext}) was calculated as the measured GRF projected onto the long axis of the tibia. The internal force contribution (F_{int}) was calculated as the estimated ankle moment divided by the Achilles tendon moment arm (5 cm, assumed constant). Peak tibia force ($F_{total,max}$) was calculated as the maximum of F_{total} across stance. Forces were normalized by subject BW.

GRF: Three common GRF metrics were calculated: F_{active} (vertical GRF active peak), F_{impact} (vertical GRF impact peak) and VALR (vertical GRF average loading rate, Fig. 1b). For each subject, individual GRF metrics were linearly correlated to peak tibia force. The Pearson correlation coefficient (r) was computed for all trials, and also for each parameter sweep, then averaged across subjects.

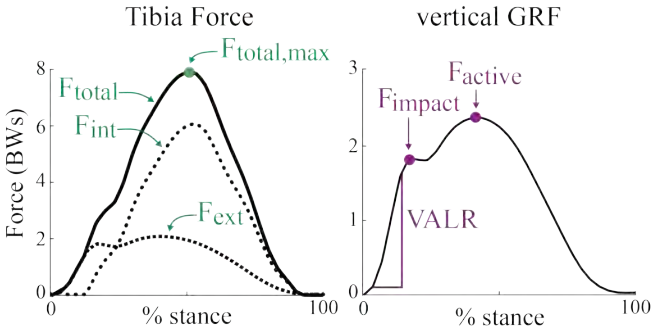

Figure 1. Running 2.8 m/s. (a) Total tibia load summation. (b) Vertical GRF metrics. Force in BWs

RESULTS AND DISCUSSION

All trials: GRF metrics were moderately or weakly correlated to F_{total} (Fig. 2). However, only the GRF active peak was positively correlated (F_{active}: r = 0.64 ± 0.26). Surprisingly, tibia bone force actually decreased with increases in GRF impact peak and loading rate (F_{impact}: r = -0.50 ± 0.29; VALR: r = -0.53 ± 0.28; Fig. 2). These preliminary results support our hypothesis. Increases in GRF metrics do not necessarily reflect increases in bone loading, signifying that GRFs alone may be of limited value in monitoring tibia loading or BSI risk. These findings complement prior evidence that higher impacts may not play a key role in the development of stress fractures [3].

Speed sweep: GRF metrics were strongly correlated to F_{total} (F_{active}: r = 0.86 ± 0.11; F_{impact}: r = 0.86 ± 0.10; VALR: r = 0.94 ± 0.10) with increasing speed on level ground. However, F_{total} was also strongly correlated to speed itself (r = 0.91 ± 0.10), which is generally easier to measure with wearable sensors.

Slopes sweep: F_{active} had a range of correlations with F_{total} (min r = -0.24; max r = 0.99), while F_{impact} and VALR were negatively correlated to F_{total} (F_{impact}: r = -0.75 ± 0.22; VALR: r = -0.78 ± 0.18). F_{active} had a range of correlations with slope itself (min r = -0.47; max r = 0.95). Even with this small sample size, large variability in correlation values indicates GRF may not adequately capture subject-specific running strategies or estimate bone loading trends.

CONCLUSIONS

Preliminary results suggest that trends in GRFs may be insufficient to track tibia bone loading. The most striking observation was that tibia loading tended to decrease with increasing GRF impact peaks and loading rates; though correlations were relatively weak. Additional or alternative measures may be needed to track tibia bone loading, with the long-term goal of predicting and preventing BSI risks.

INTRODUCTION

Shoulder joint disorders (arthritis or cuff tear arthropathies) lead to damaged bones, restricted function, and chronic pain. Shoulder joint replacement is regarded as a safe and effective procedure to relieve pain and help resume daily activities. Pre-planning software tools are prevalent in shoulder arthroplasties and play a vital role in successful surgical outcomes. However, any pre-surgery planning tool needs to create a 3D scapular shape from patient's complete shoulder images, which may not be available all the time.

The purpose of this study was to create and evaluate a statistical shape modeling (SSM) based pipeline that can accurately predict the missing part of the scapula bone due to incomplete image acquisitions.

METHODS

A: Scapula SSM building

An imaging database of dry bone samples and cadaveric scans (n = 81) was used for this study. CT scan images were acquired, manually segmented (Amira, FEI, Hillsboro, V5.4), and surface mesh models of each sample were created. Ten samples from this database were categorically selected for evaluation purpose and remaining samples were checked by the expert for anatomical normality and then used to build the SSM of scapula. The SSM pipeline can be summarized in three main stages: rigid alignment, non-rigid alignment to establish point-to-point correspondence, and principal component analysis. In this study, we used the Iterative Median Closest Point – Gaussian Mixture Model (IMCP-GMM) pipeline [1] to create the scapular SSM.

B: Virtual scapular defect creation

Two imaging defects were virtually created on ten external scapulae using 3D visualization software (Amira, FEI, Hillsboro, V5.4). These scapulae were selected to represent at least one type of anatomical classification of the scapular bone. For this purpose, shape of glenoid was classified as type 0, I, II, and III based on morphology of glenoid notch. Acromion was classified as type I, II and III based on flat, curved, and hooked morphology. Two samples each were selected to represent higher and lower critical shoulder angle (CSA) and glenoid ante- and retro-version. The virtual defects were represented in 1) Group 1: missing inferior part of the scapula (inferior scapular fossae), and 2) Group 2: missing superior part of the scapula (a part of the acromion and coracoid process).

C: Missing part prediction algorithm

The principal modes of variations that represented 95% of the population variability were retained and used in the missing part prediction algorithm. This algorithm was performed in three steps:

Step 1: Matching the centroids of the mean shape of the SSM (MS) and the target shape (TS).

Step 2: Rigid alignment: Depending on the group on which we are going to perform the fitting, a set of 5 or 10 landmarks were selected on both the MS and TS. Fifteen iterations of rigid Iterative Closest Point (ICP) algorithm were performed with a Procrustes analysis that applied the best rigid transform on the MS after each iteration.

Step 3: Model fitting: This non-rigid deformation algorithm aimed at finding the closest instance of the SSM to TS using following steps -

a) Find the identifiers (IDs) of the SSM: for each point in the TS, a closest point in the MS was found and corresponding IDs were recorded.

b) Create a posterior model (PM): The landmarks used for the rigid alignment in step 2 were used to create the PM [2] ,assuming a standard error for the landmark placement of 0.5mm. The landmark position of all the instances sampled from this posterior SSM were within the error parameter attributed to these landmarks.
c) Perform non-rigid ICP: 20 iterations of non-rigid ICP were executed. In each iteration, the algorithm suggested a candidate correspondence between the points of the PM associated to IDs, then a Gaussian process regression was performed based on the observed candidates and predicted shape was built.

D: Evaluation

Quality of the SSM was checked for its generality, specificity and compactness criteria. Each predicted shape was compared with the original shape using anatomical measures (glenoid inclination, glenoid version, glenoid center, and CSA), distance measures (mean, Hausdorff, RMS), and similarity measure (Dice coefficient).

RESULTS AND DISCUSSION

After checking for anatomical normality, five scapular shapes were discarded and SSM was built using n=66 scapulae. This number exceeds the required subjects to capture sufficiently the bone shape variation in the healthy population [3]. Generality of the SSM was found excellent for both the distance matrices (Hausdorff and RMS), whereas specificity and compactness criteria were well within the satisfactory levels.
Fifteen modes represented 95% variability in the SSM and were retained and used in the missing part prediction algorithm. Evaluation of predicted shapes revealed moderate to excellent outcomes (Table 1). All mean RMS metrics were predicted with high accuracy and predicted shape revealed excellent similarity index with the original shapes (Figure 1, Table 1). Results of the anatomical measures were encouraging and better than a recently published study [4] which predicted scapular glenoid shape.

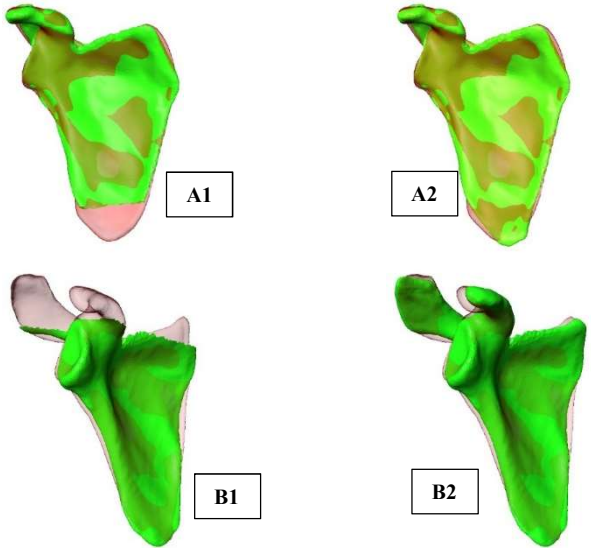

Figure 1: Sample data for missing part fitting. Green and translucent red scapulae indicate original and predicted shape respectively. A1 and B1 show imaging defects in inferior and superior parts whereas A2 and B2 show comparison with original.

CONCLUSIONS

Accurate scapular shape prediction is possible and can have strong applications in surgery planning and modeling.

DOES FOOT STRIKE PATTERN CHANGE DURING A MAXIMAL 800-METER RUN?

[1]Kathryn A. Farina, [1]Mark H. Langley, [1]Marco Meucci, [1]Alan R. Needle, [1] Natalie R. Kile, [1]Herman van Werkhoven
[1]Department of Health and Exercise Science, Appalachian State University, Boone, NC, USA
Email: farinak@appstate.edu

INTRODUCTION

Several studies have considered biomechanical differences between rearfoot (RF) and forefoot (FF) strike pattern during running. These differences include foot position, muscle activation, ground contact times, and ground reaction forces [1, 2, 3, 4]. It has also been suggested that the FF strike pattern is utilized more by faster runners and for faster running [5]. During a marathon, it has been shown that foot strike pattern (FSP) changes during the course of a race, with more runners initially running with a FF strike pattern, and then changing to a RF strike pattern [1].

During faster, shorter distances, such as an 800 m middle distance, it is unclear whether runners are able to maintain a certain FSP. Given the high intensity of the race, it is likely that onset of muscle fatigue would make it difficult for runners to maintain a given FSP throughout the race. The purpose of this study was to evaluate changes in FSP throughout a maximal 800 m run. We hypothesized that runners would not be able to maintain their initial FSP throughout the 800 m, and in general would move from a more FF strike pattern to a more RF strike pattern during the later stages of the run.

METHODS

21 healthy, trained subjects (14 female, 7 male; age: 24.29 ± 4.54 yrs) were recruited from the surrounding area running clubs, university, and collegiate track and field teams. The study was approved by the Appalachian State University Institutional Review Board. Subjects reported to the outdoor track where they completed an informed consent, health history, and training information form. Upon completion of a warm up, three sensors were placed on the subject's lower extremity. These sensors are equipped with a three 3-dimensional accelerometer, and 3-dimensional gyroscope, as well as unit capable of measuring electrical activity (BiostampRC, mc10, Lexington, MA, USA). One sensor was placed on the dorsal side of the right foot to measure accelerometer and gyroscope data. Although not reported here, additional sensors were placed on the lateral gastrocnemius and tibialis anterior to measure muscle electrical activity. A stopwatch was used to gather 100 m interval times over the course of the 800 m run.

To evaluate FSP, resultant acceleration peaks from the sensor attached to the foot were used to determine time of foot strike, similar to [6]. To quantify changes in FSP, FSP was evaluated on a continuum, instead of as a binary classifier (FF or RF). Two measures were calculated:

- Foot strike initial angular velocity **(ω_{FS})** – Sagittal plane gyroscope angular velocity over the first 30 ms after foot strike was averaged to get an indication of the direction of angular rotation directly after foot contact, with a more positive ω_{FS} indicating more RF strike pattern.
- Change in foot angle **($\Delta\theta$)** – Sagittal plane gyroscope data was integrated to get a change in foot strike angle. The difference in angle at foot strike and angle when the foot was deemed to be stationary on the ground (lowest mean resultant acceleration over a 50 ms interval after foot strike) was used to calculate a change in foot angle, with more positive $\Delta\theta$ indicating more RF strike pattern:

$$\Delta\theta = \theta_{STATIONARY} - \theta_{FOOTSTRIKE}$$

ω_{FS} and $\Delta\theta$ values for each foot strike was averaged across each 100 m interval ($\omega_{FS\text{-}ave}$ and $\Delta\theta_{ave}$). Only run was considered here (1st: 100m-200m, 2nd: 300m-400m, 3rd: 500m-600m, 4th: 700m-800m). One-way repeated measure analyses of variance (ANOVA) were used to (1) analyze time across each

100-meter straight interval and (2) investigate the factor of distance on i) $\omega_{FS\text{-}ave}$ and ii) $\Delta\theta_{ave}$ over each 100 m straight interval of the 800-meter run.

RESULTS and DISCUSSION

The 1st straight was run significantly faster than the other straights ($F[3, 60]=15.982$, $p<0.001$) (Fig. 1). The FSP indicator $\omega_{FS\text{-}ave}$ did not show significant differences between the 4 intervals ($F[3, 51]= 2.099$, $p=0.112$) (Fig. 2). Similarly, the FSP indicator $\Delta\theta_{ave}$ showed no significant differences between the different intervals ($F[3, 51]= 0.604$, $p=0.615$) (Fig. 3). It did appear that runners started with a more RF strike pattern (values less negative): 1st $\Delta\theta_{ave}$ = -2.04°; which them became more FF: 2nd $\Delta\theta_{ave}$ = -2.65°; 3rd $\Delta\theta_{ave}$ = -2.59° (Figure 3), however these differences were not significant.

Contrary to our hypothesis, runners did not move from a more FF strike pattern to a more RF strike pattern during the straight sections of the 800 m run. The runners in our study maintained a similar FSP throughout the run. The measure associated with initial angular velocity (ω_{FS}), as well as change in foot angle ($\Delta\theta$) both indicate that runners maintain a similar FSP. Further work is currently underway to determine to what extent muscle fatigue occur during the 800 m run. Understanding the potential mechanism whereby substantial muscle fatigue, which most like occur during an 800 m race, does not lead to changes in FSP, is of interest.

CONCLUSIONS

During a maximal 800 m, runners are able to maintain a relatively constant foot strike pattern throughout the duration of the run.

DIFFERENCES IN RUNNING BIOMECHANICS BETWEEN A MAXIMAL, MINIMAL, AND TRADITIONAL RUNNING SHOE

[1] JJ Hannigan, [1] Jacqueline Diulio, [1] Justin Ter Har, and [1] Christine Pollard

[1] Oregon State University – Cascades, OR, USA
email: jj.hannigan@osucascades.edu, web: https://osucascades.edu/force-lab

INTRODUCTION

Running shoes have traditionally been designed with the goal of cushioning the foot and protecting against injuries. However, despite significant advances in running shoe technology over the past 50 years, overall injury rates in runners have not significantly changed [1]. Within the past 10 years, two new types of shoes have gained popularity in the running community for their espoused benefits in injury-protection: a) minimal shoes, such as Vibram Five Fingers, and b) maximal shoes, such as the Hoka One One's.

Minimal shoes have been researched extensively over the past 10 years. In many runners, switching to a minimal shoe causes runners to switch from a rearfoot strike to a forefoot strike [2]. While wearing minimal shoes generally appears to decrease joint stress at the knee, minimal shoes have been shown to greatly increase joint stress and force at the ankle and calf muscles, respectively [2]. Consequently, injury rates for Achilles tendinopathy and calf strains are greater when consistently training in a minimal running shoe.

Maximal shoes, however, have received very little research since their inception less than 10 years ago. The Hoka One One company claims that maximal running shoes will decrease loading rates and impact forces, however, a recent study found the exact opposite trend [3]. No single study to date has looked at ground reaction forces and ankle kinematics in a minimal, traditional, and maximal running shoe. Also, no study has compared the effect of maximal and minimal shoes on both forefoot and rearfoot strikers. Thus, the purpose of this study was to investigate the effect of both a minimal and maximal shoe on vertical ground reaction forces (loading rate, impact peak, overall peak) and ankle kinematics (eversion and dorsiflexion) during running. It was hypothesized that rearfoot runners would display greater loading rates and impact peaks in the maximal shoe compared to the traditional and minimal shoe.

METHODS

Nineteen healthy females (age = 27.6 ± 5.2 yrs) and eight healthy males (age = 28.6 ± 5.8 yrs) participated in this study. All subjects signed an informed consent form approved by IRB at Oregon State University prior to participating. Twenty-one reflective markers and six marker clusters were placed on subjects who ran overground in the lab wearing three different types of custom-designed New Balance running shoes (Boston, MA): a) traditionally cushioned shoes, b) minimal shoes, and c) maximal shoes (Figure 1). Five successful running trials for each shoe were collected at 250 Hz with an 8-camera 3-D motion capture system (Vicon Motion Systems, Oxford UK). Two embedded force plates collected ground reaction forces and were used to determine heel strike and toe-off (AMTI, Watertown MA).

Figure 1: From left to right: minimal, traditional, and maximal cushioned New Balance shoes.

Ground reaction forces and ankle kinematics were calculated using Visual3D software (C-Motion, Germantown MD). Variables of interest included the impact peak, overall peak, and loading rate of the vertical ground reaction force (vGRF), as well as ankle eversion and dorsiflexion kinematics (angle at initial contact, peak angle, angle at toe-off, joint excursion). Because not all runners were rearfoot strikers (6 non-RF), data were analyzed using 2-way mixed effects ANOVA with shoe type as the within-subject effect and foot strike pattern (rearfoot or non-rearfoot) as the between-subjects effect. The alpha-level was set to 0.5 with appropriate Bonferroni corrections.

RESULTS AND DISCUSSION

No runners switched foot strike patterns between shoe conditions. The impact peak of the vGRF was higher in maximal shoes compared to traditional shoes (traditional: 2.3 ± 0.07 BWs; maximal: 2.4 ± 0.07 BWs, p = .039). There were no differences between shoes for any other ground reaction force parameter.

There was a significant shoe x foot strike interaction for peak eversion, with rearfoot strike runners displaying more peak eversion wearing maximal and minimal shoes compared to traditional (traditional: -10.6 ± 0.8°; maximal: -12.1 ± 0.8°; minimal: -12.6 ± 0.91°, p = .017).

There was a significant effect of shoe on the eversion angle at toe-off, with the maximal shoe displaying significantly less eversion at toe-off than the other two shoes (traditional: 1.8 ± 1.0°; maximal: 0.2 ± 1.0°; minimal: 2.9 ± 1.1°, p = .045).

There was a significant effect of shoe on peak ankle dorsiflexion, with greater dorsiflexion occurring in the minimal shoe compared to the maximal shoe (traditional: 21.4 ± 0.8°; maximal: 20.2 ± 0.7°; minimal: 21.8 ± 0.8°, p = .032). There was also a significant effect of shoe on dorsiflexion excursion, with the minimal shoe displaying significantly greater excursion than the traditional and maximal shoes (traditional: 17.9 ± 0.8°; maximal: 17.2 ± 0.8°; minimal: 21.0 ± 1.7°, p = .05).

The findings for the vGRF partially supported our hypothesis. While we did see a higher impact peak in maximal shoes compared to traditional shoes, we did not see a higher loading rate. Pollard et al. (2018) found that running in maximal shoes increased both the impact peak and loading rate compared to a traditional shoe [3]. This previous study only included rearfoot runners, and had runners wear Hoka shoes, which have markedly different midsole and heel construction than the shoes used in this study (Figure 2). Still, a greater impact peak during running may place runners at a greater risk of injury.

Figure 2: Difference in midsole and heel construction between the New Balance and Hoka One One maximal shoes.

Less eversion at toe-off may also be detrimental to injury risk. Becker et al. found that having less eversion at heel-off was a hallmark biomechanical pattern of runners suffering from Achilles tendinopathy and medial tibial stress syndrome [4].

CONCLUSIONS

Running in a maximal shoe may not be injury-protective. On average, running in the New Balance maximal shoe increased the impact peak and resulted in less eversion at toe-off, which may increase overall injury risk.

RUNNING BIOMECHANICS IN 4% MORE ECONOMICAL MARATHON SHOES

Wouter Hoogkamer, Shalaya Kipp and Rodger Kram

University of Colorado, Boulder, CO, USA
email: wouter.hoogkamer@colorado.edu, web: https://tinyurl.com/wouter-colorado

INTRODUCTION

Previously, we showed that a new prototype shoe reduced the metabolic cost of running for all 18 participants, by an average of 4%, as compared to two well-established racing shoes [1]. Based on these findings, the now commercially available shoe has been named "Nike Vaporfly 4%". While running in the prototype shoes, the subjects generally ran with slightly greater peak vertical ground reaction forces, slower step frequencies, and longer contact times than in the control shoes, however these differences were small (~1% or less) and do not explain all the metabolic savings [1].

Here, we compared joint kinematics and mechanics between the Nike prototype shoes (NP) with those of baseline marathon racing shoes: the Nike Zoom Streak 6 (NS) and the shoes used to run the official marathon world record, the Adidas Adizero Adios BOOST 2 (AB) – the same models used as baselines in our metabolic study.

We hypothesized that the more compliant midsole of the NP shoes would allow the runners to run with less knee flexion and smaller peak knee moments [2]. Furthermore, we hypothesized that the carbon fiber plate in the NP shoes would reduce dorsiflexion and negative work in the metatarsal-phalangeal joint [3].

METHODS

To date, 6 male (aged 24.6±3.8 years, mass 64.9±4.8 kg) high-caliber runners ($\dot{V}O_2$max: 72.9±2.8 mL O_2/kg/min) who wear men's shoe size US10 completed the testing protocol. They gave written informed consent that followed the guidelines of the University of Colorado Boulder Institutional Review Board.

The runners wore three pairs of shoes (NP, NS and AB) in a randomized order. Shoe properties have been described in detail previously [1]. In short, the NP midsole comprises highly compliant and resilient ZoomX foam made with PEBA (polyether block amide), combined with a stiff embedded carbon-fiber plate. The NS midsole comprises lightweight EVA (ethylene-vinyl acetate) foam and a rearfoot Zoom air bag. The AB midsole comprises resilient BOOST foam made with TPU (thermoplastic polyurethane). All shoes were equilibrated to 250g/shoe (the mass of the AB shoe, size 10).

We placed 44 reflective markers on the subjects' legs using a modified Helen Hayes marker set. Markers were placed bilaterally on the hip, knee, ankle and metatarsal-phalangeal (MTP) joint centers and clusters were placed on each segment. Subjects performed 5-minute running trials at 16 km/hr in each shoe condition on a motorized, force-measuring treadmill (Treadmetrix, Park City, UT, USA). In between trials, subjects took a 5-minute break, while they changed shoes.

We collected ground reaction force (GRF) data at 1000 Hz and kinematics data at 200Hz during the last 30 seconds of each biomechanics measurement trial (Vicon 512 System, Oxford, UK) and analyzed 10 strides (20 steps). We used a Butterworth low-pass filter (14 Hz) to process both GRF and target-marker data. For the hip, knee, ankle and MTP joints, we calculated sagittal joint angles, angular velocities, moments, powers and work during the stance phase, using Visual 3D and MATLAB software (C-Motion Inc., Germantown, MD, USA; MathWorks Inc, Natick, MA, USA).

RESULTS AND DISCUSSION

Generally, joint angles, angular velocities, moments and powers were similar between shoes (Fig. 1). Specifically, opposite to our hypothesis, peak knee flexion and moments were similar between shoes ($p=0.80$ and $p=0.65$, respectively).

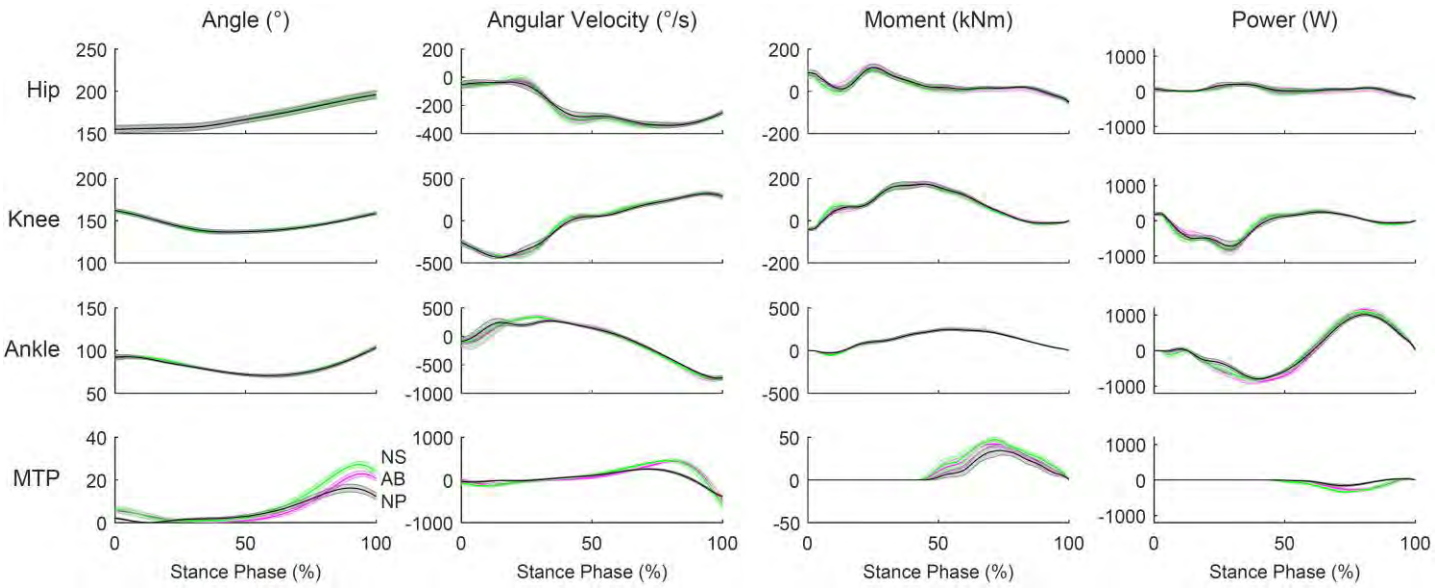

Figure 1: Joint kinematics and mechanics for running in the NP (black), NS (green) and AB (purple) shoes.

However, peak MTP dorsiflexion was significantly smaller in the NP shoes ($p<0.001$). Peak ankle and MTP moments were numerically lower in the NP shoes, but not statistically significant ($p=0.07$ and $p=0.15$, respectively). Furthermore, negative work at the ankle and MTP joints was significantly lower in the NP shoes (Table 1, both $p<0.001$).

CONCLUSIONS

Joint kinematics and mechanics were slightly different for running in the highly compliant and resilient prototype shoes as compared to running in the two other established marathon shoes. Differences were most prominent around the ankle and MTP joint, but knee mechanics were similar, suggesting that the earlier observed metabolic savings of 4% are not related to differences in knee mechanics.

INTRODUCTION

The forces due to vertical and torsional loading of the tibia during running are associated with injuries in general, and tibial stress fracture specifically [1, 2]. Runners with history of tibial stress fracture show higher per-step vertical average loading rate and absolute free moment than previously uninjured runners [1, 2]. However, per-step magnitudes of vertical loads increase as running speed increases in healthy runners [3], and interval training has been shown to have a protective effect on injury development [5]. Higher per-step loads associated with faster running may be beneficial when combined with slower speeds elsewhere in training.

Recent studies have investigated the accumulation of loads over a specific distance, rather than per-step comparisons. Per-step knee loads increased but cumulative loads were similar between walking and running [4]. At faster speeds, longer step lengths mean fewer steps are required to travel a distance, and may not necessarily lead to increases in accumulated load. The question of how speed distribution within a training program affects cumulative load (and ostensibly injury risk) is important because speed distribution is an easily modifiable factor of training.

Therefore, the purpose of this study was to compare the accumulated vertical average loading rate (accumulated LR), accumulated peak absolute tibial free moment (accumulated FM), and accumulated peak compressive tibial load (accumulated TL) between two distributions of speeds: i) all mileage at normal speed (N) and ii) a combination of slow and fast speeds with the same average speed as normal (ASN). We hypothesized that all accumulated loads would be greater for ASN than N program due to a larger proportion of fast running.

METHODS

Approval was obtained from the local Institutional Review Board. We recruited 56 healthy, recreational runners (age: 25±8 yrs, mass: 67.2± 13.0 kg, height: 1.70±0.12 m). Subjects wore 33 reflective markers on the pelvis and lower limb. They ran around a 50-m indoor track for three laps each at three speeds: self-selected slow, normal, and fast paces. Kinematic data were captured using a 13-camera motion capture system sampling at 200 Hz. Ten embedded force plates recorded ground reaction forces (GRF) at 1000 Hz.

For each self-selected speed, velocity (VEL), step length (SL), steps per kilometer (SPK), loading rate (LR), peak absolute free moment (FM), and peak tibial compressive load (TL) was calculated. Steps per kilometer were calculated by dividing 1000m by step length in meters. Loading rate was calculated as the slope of the vertical GRF between 20-80% of the time period from initial contact to impact peak and scaled by body weight [5]. Free moment was calculated according to Milner et al. [5]. TL was calculated by: i) estimating the Achilles tendon (AT) moment arm length [6], ii) dividing the resultant ankle moment during stance by the moment arm estimate to get AT force, iii) summing AT force with proximal foot forces, iv) identifying the peak value. Because subjects' speeds were self-selected, within-subjects repeated measures ANOVA was performed to compare the VEL, SL, SPK, LR, TL, and FM. For variables with significant main effects, post-hoc analysis using Tukey's contrasts were calculated with a Bonferroni adjustment for multiple comparisons.

Per-kilometer accumulated load was calculated for N by multiplying the normal speed SPK by the per step load for LR, TL, and FM. ASN was calculated by determining the fractions of slow and fast speeds required to average normal speed and multiplying

these fractions by the respective SPK. These slow and fast SPK were combined and multiplied by the per-step LR, TL, and FM. A paired-samples Wilcoxon test was performed to compare accumulated LR, accumulated FM, and accumulated TL between N and ASN speed distributions. Effect sizes for significant differences were calculated as Cohen's *d.* Significance between speed distributions was determined at $p < 0.05$.

RESULTS AND DISCUSSION

There was a main effect of speed for VEL, SL, LR, FM, and SPK (all $p < 0.001$). Post-hoc analysis showed that each variable increased with speed ($p < 0.01$) except FM, which was similar between *slow-normal.* Self-selected speed outcomes are shown in Table 1. The hypothesis that accumulated loads would be greater in the ASN than AN program was not supported. The comparisons of accumulated LR, accumulated TL, and accumulated FM showed no differences between the speed distributions (Fig. 1).

The proportions of slow and fast speed required to average the normal speed condition were nearly equal, at 51% and 49%, respectively (Fig. 1). The per-step FM was similar between slow and normal, therefore we expected the proportion of fast speed in the ASP distribution to lead to even greater accumulated FM in particular. However, the large contribution of fast running was insufficient to lead to increased accumulation of loads for any variable.

CONCLUSIONS

These results suggests runners can include substantial fractions of fast speeds in their training without accumulating significantly greater loads (Fig. 1). Nonetheless, too much "intensity", typically defined as too much fast running, is commonly suspected to cause injuries. Further research is therefore needed to determine the association between accumulated loads and injury development.

INTRODUCTION

Stride rate and foot strike pattern are common parameters examined as a profile of a runner's biomechanics. Accurately measuring stride rate and foot strike position requires precise determination of initial contact (IC) and toe-off (TO). Preferably, these variables are determined from a force plate / instrumented treadmill. However, studies performed in the field or on a standard treadmill rely on identification of IC and TO from kinematic data.

Kinematic based algorithms for determining IC and TO are available, but are often specific to a runner's foot strike pattern [1,3,4,5] or a limited range of speeds [2,3,4,5]. Developing a reliable method of identifying initial contact and toe-off for all foot strike patterns and over a large range of speeds is beneficial for running gait analysis based on kinematic data. Thus, the purpose of this study was to determine the validity of previously published kinematic based IC and TO algorithms across foot strike patterns and a range running speeds for treadmill running.

METHODS

As part of another study, 10 healthy active participants, five males and five females between the ages of 20 and 55 (age 29 ± 11 y; 170 ± 6.74 cm; 69.8 ± 9.24 kg), gave their written informed consent to participate and completed 6 treadmill running trials (20-60s depending on speed) at 6 speeds: 2.24, 2.69, 3.14, 3.5, 4.03, and 4.48 ms^{-1}.

Reflective markers were placed on the lower extremities and pelvis using the Plug-In-Gait marker set (Vicon, Centennial CO, USA). Participants wore their own running shoes and completed a three-minute warm up of light jogging. Data were collected for the last 20 s of each trial using a Vicon Nexus 2.5 (Vicon, Centennial, CO, USA) motion capture system (200Hz). Two force plates (AMTI, Watertown, MA, USA) sampling at 1000Hz were placed under the front of the treadmill for identification of IC and TO. Data were analyzed in Visual 3D (C-motion, Baltimore, MD, USA).

Two algorithms for finding IC, Alvim [1] and Milner [4], and one algorithm for finding toe off, Fellin [2], were chosen for analysis. IC and TO time from the three algorithms (IC_{Alvim}, IC_{Milner}, TO_{Fellin}) were compared to IC and TO times as determined from the forces from the force plates (IC_{FP} and TO_{FP}). Foot strike pattern, RFS versus nRFS, was determined from foot angle at initial contact.

Two-way repeated measures analyses of variance (ANOVA) were used to compare algorithm and force plate IC and TO identification times (JASP V0.8.1.2). Alpha = 0.05. Algorithm accuracy by foot strike pattern was examined using root mean square errors (RMSe).

RESULTS AND DISCUSSION

Seven RFS and three nRFS runners were identified totaling 3218 foot contacts (2468 RFS and 750 nRFS). IC_{Alvim} was identified 0.089 ±0.061 s before IC_{FP} ($p<0.011$). There was not a significant speed effect ($p=0.867$). IC_{Milner} was not significantly different from IC_{FP} ($p=0.155$) and was identified 0.010±0.040 s before IC_{FP}. $TO_{Fellin.}$ was not significantly different from TO_{FP} ($p=0.555$) and there was no significant speed effect on TO_{Fellin} accuracy ($p=0.610$).

IC_{Alvim} RMSe tended to be smaller for RFS runners (0.075±0.0.36 s) as compared to nRFS runners (0.086 ± 0.063 s); this difference was greater at faster

running speeds (Figure 1a). IC_{Milner} RMSe was similar for both RFS (0.015±0.008 s) and nRFS (0.015±0.008 s) decreasing in a linear pattern with running speed (Figure 1b). RMSe between TO_{Fellin} and TO_{FP} ranged from 0.012 to 0.014 s (Figure 1c).

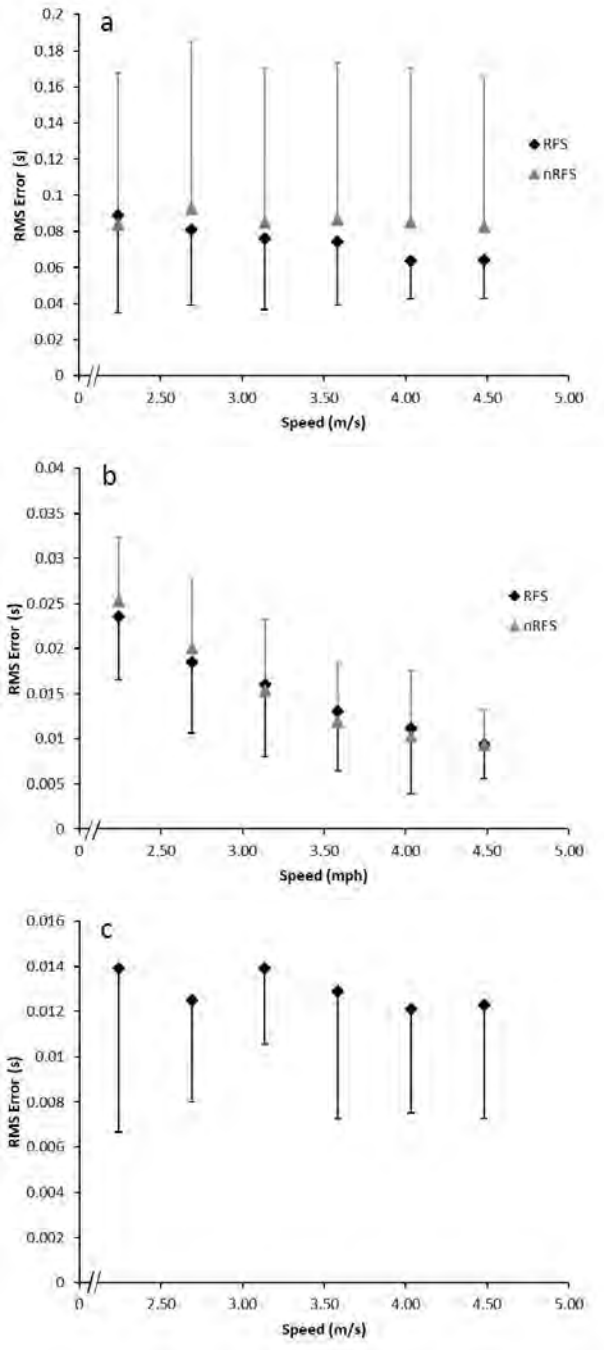

Figure 1: (1a) RMSe for IC_{Alvim} for RFS and nRFS, (1b) RMSe for IC_{Milner} for RFS and nRFS, (1c) RMSe for TO_{Fellin}. Values are means ±SD.

A linear regression analysis of 1598 randomly selected ICs provided a speed correction to IC_{Milner} of -0.0064 × speed + 0.0348 with $R^2 = 0.976$. This equation applied to the remaining 1598 ICs identified 98% of ICs within 20 ms, 4 frames at 200 fps, of IC_{FP} and 68% of IC within 10ms, 2 frames at 200 fps, of IC_{FP}.

IC_{Milner} outperformed IC_{Alvim} regardless of running speed and worked equally well for RFS and nRFS. IC_{Milner} accuracy depended on running speed. Based on the regression equation developed in the current study, the slowest speed of 2.24 ms^{-1} needed to be adjusted by 20 ms. At the fastest speed of 4.47 ms^{-1}, IC_{Milner} needed to be adjusted by 6 ms. IC_{Milner} was developed with RFS and nRFS over-ground running at 3.7 ms^{-1} [4]. The RMSe of 13 ms at 3.58 ms^{-1} in the current study agrees with the three frame (15 ms) offset reported for the similar 3.7 ms^{-1} over-ground running speed [4]. Of importance, at least for treadmill running, is that the offset observed with IC_{Milner} linearly decreased with speed. However, the linearity of the algorithm's accuracy at slower or faster running speeds than those tested in the current study should not be assumed.

CONCLUSIONS

The IC_{Milner} algorithm adjusted with the speed based linear regression equation and TO_{Fellin} are recommended for RFS and nRFS treadmill running between 2.2 and 4.5 m/s when IC and TO must be determined from kinematic data. The range of speeds used in this study, while broad, does not cover running speeds often performed by top competitive runners. Future research should validate the algorithm at faster speeds and for both treadmill and over-ground running.

WHAT DETERMINES THE METABOLIC COST OF HUMAN RUNNING ACROSS A WIDE RANGE OF VELOCITIES?

Shalaya Kipp[1], Alena M. Grabowski[1,2] and Rodger Kram[1]

[1]University of Colorado, Boulder, CO, USA
[2] Colorado Healthcare System, Department of Veterans Affairs, Denver, CO
email: shalaya.kipp@colorado.edu

INTRODUCTION

The cost of generating force hypothesis [1] proposes that the metabolic rate during running is determined by the rate of muscle force development ($1/t_c$, t_c = contact time) (Eq. 1). Roberts et al. [2] assumed that the recruited muscle volume remains constant and reported that the rate of force development alone explains ~70% of the increase in metabolic rate for human runners across a moderate velocity range (2-4 m s^{-1}).

$$\frac{\dot{E}_{met}}{W_b} = c \cdot \frac{1}{t_c} \qquad \text{(Eq. 1)}$$

The Effective Mechanical Advantage (EMA) is the ratio of the muscle moment arm (r) to the ground reaction force moment arm (R); EMA= r/R [3]. EMA determines the muscle force (F_m) required and thus the amount of active muscle volume (V_m) recruited for running.

We hypothesized that: 1. over a wider range of velocities, the EMA of the lower leg would overall decrease at faster velocities, necessitating a greater volume of active muscle recruitment and 2. $1/t_c$ and V_m together would better explain the metabolic cost of running (Eq. 2).

$$\frac{\dot{E}_{met}}{W_b} = k \cdot \frac{1}{t_c} \cdot V_m \qquad \text{(Eq.2)}$$

METHODS

10 high-caliber male runners (VO_2max = 72.7 ± 3.9 mlO_2/kg/min) participated over two visits. During the first visit subjects ran at 8, 10, 12, 14, 16, 18 km hr^{-1} in a randomized order, each for 5 min. We measured O_2 uptake and CO_2 production to determine metabolic rate for each velocity [4]. We determined blood lactate concentration following the 14, 16 and 18 km hr^{-1} trials to assure a primary reliance on the oxidative metabolism. During a second visit, subjects ran at the same 6 velocities, in the same randomized order as visit 1, for 2-min. We measured ground reaction (1000Hz) forces and joint kinematics (200Hz). Then, we calculated net internal joint moments (M_{joint}) and muscle force (F_m) using published [3] moment arm (r) data.

$$F_m = M_{joint} / r$$

We calculated V_m at each joint using published [3] fascicle length (L) data and assuming muscles exert an isometric force/unit of cross sectional area (σ=20N/cm^2) [5].

$$V_m = L \cdot F_m/\sigma$$

RESULTS AND DISCUSSION

From 8 to 18 km hr^{-1}, metabolic rate increased 132% from 9.01 to 20.92 W kg^{-1} (Fig 1).

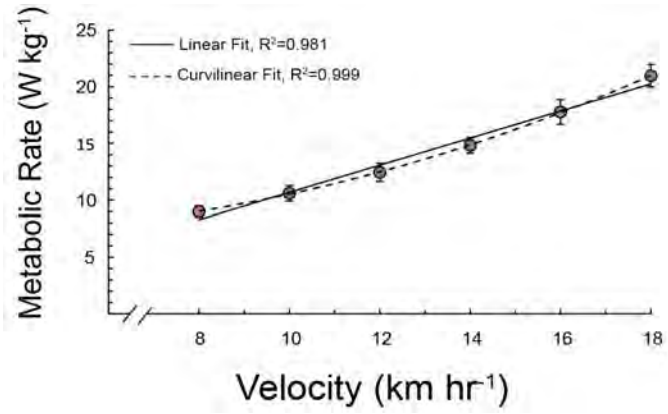

Figure 1: Metabolic rate vs. velocity. Error bars indicate ±1 SD.

Contact time (t_c) decreased from 0.280 sec to 0.190 sec, and thus the rate of force development ($1/t_c$) increased by 48%.

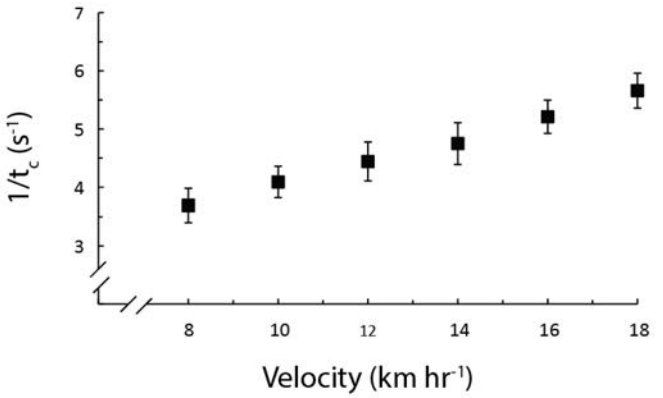

Figure 2: The rate of force production ($1/t_c$) vs. velocity. Error bars indicate ±1 SD.

Ankle EMA decreased by 19.7±11%, knee EMA increased by 11.1±26.9% and hip EMA decreased by 60.8±11.8%. Thus, active muscle volume increased by 65.5±28.7% at the ankle, 19.0 ± 14.3% at the knee and 102.3 ± 23.3% at the hip (Fig. 2). Overall, across the velocity range, total active muscle volume per leg increased 54.1% from 1663±152 cm^3 to 2550±169 cm^3. 86% of the increase in metabolic rate could be accounted for by the rate of force production ($1/t_c$) alone. 98% of the increase in metabolic rate could be accounted for by using both $1/t_c$ and V_m (Fig 3.).

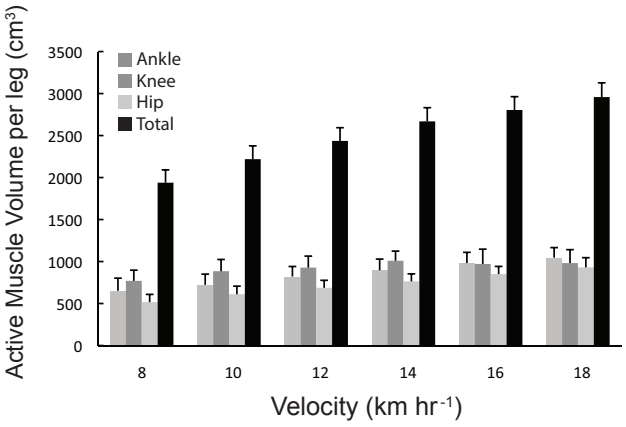

Figure 3: Mean estimated active muscle volume per leg across velocity for ankle, knee, and hip extensor muscles. Error bars indicate ±1 SD.

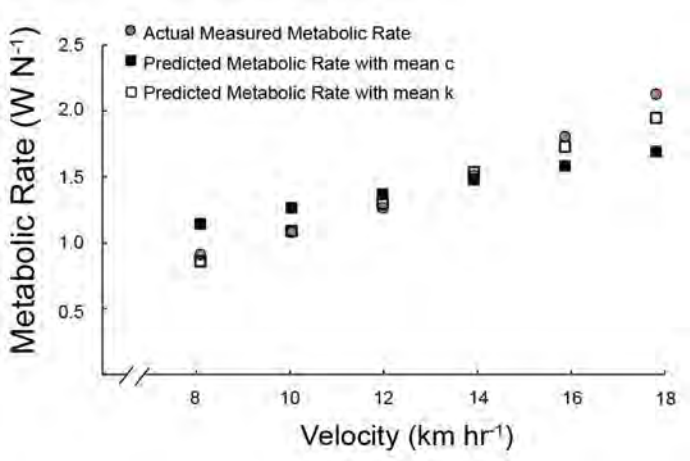

Figure 4: Measured metabolic rate (solid circles), predicted metabolic rate using mean c (closed squares), and predicted metabolic rate using mean k (open squares) vs. velocity in km hr^{-1}.

These results link the biomechanics and metabolic costs of running and may give greater insight into individual differences in metabolic rate.

CONCLUSIONS

We accept both of our hypotheses. Over the wider range of velocities tested, EMA of the lower limb joints overall decreased contributing to the increased volume of activated muscle. The rate of force production ($1/t_c$) and active leg muscle volume (V_m) together almost completely account for the increased metabolic requirements of human running across the entire aerobic velocity range.

SEX IMPACTS LEG STIFFNESS WHEN INCREASING STRIDE LENGTH TO RUN WITH BODY BORNE LOAD

[1] Nicholas J. Lobb, [1]AuraLea C. Fain, [1]Kayla D. Seymore, and [1]Tyler N. Brown

INTRODUCTION

During military training, personnel are often required to run at a fixed cadence with heavy body borne loads. These loads routinely weigh between 20 kg and 40 kg, and alter lower limb biomechanics leading to increased risk of musculoskeletal injury (MSI) [1]. When running with load, personnel increase leg stiffness to attenuate larger GRFs and prevent collapse of the lower limb. Increased stiffness may elevate risk of MSI by transmitting GRFs to the lower limb's soft-tissues [2]. When running without load, individuals purportedly decrease leg stiffness by increasing lower limb flexion as stride lengthens [3]. Military personnel, however, may not possess the lower limb strength to similarly decrease leg stiffness as they lengthen their stride to run at a fixed cadence with heavy body borne loads. Female military personnel, who are purportedly weaker than males [4], may be especially at risk for injury as they may not possess the strength to safely attenuate large GRFs. The purpose of this study was to quantify leg stiffness for male and female participants as they lengthened their stride to run with body borne load.

METHODS

Seventeen male and ten female participants (21.2 ± 2.3 yrs, 1.7 ± 0.1 m, 75.5 ± 11.3 kg) had 3D lower limb biomechanics quantified while running with four load conditions: 20 kg, 25 kg, 30 kg, and 35 kg. For each load, participants wore a helmet, weighted vest, and carried a mock weapon. The vest weight was systematically adjusted to apply the load necessary for each condition. For the run task, participants were required to run at 4 m/s ± 5% using one of three stride lengths: preferred stride length (PSL), 15% shorter than PSL (SSL), and 15% longer than PSL (LSL). Participants performed five successful trials at each stride length. A successful trial required participants run with the correct stride length and speed, and only contact the force platform with their dominant leg.

During each running trial, lower limb biomechanics were quantified from the 3D trajectories of 34 reflective markers. A kinematic model with seven segments (bilateral foot, shank, and thigh and pelvis) and 24 DoF was created from a static trial. Synchronous GRF data and marker trajectories were low pass filtered with a fourth-order Butterworth filter (12 Hz). Then, filtered marker trajectories were processed using Visual 3D (C-Motion, Rockville, MD) to solve joint rotations at each instant.

Leg stiffness was calculated as the GRF vector directed from the center of pressure through the hip joint center (F_e) divided by the maximum change in leg length (L_e). Leg length was calculated as the linear distance between the center of pressure and the hip joint center.

$$\text{Leg Stiffness: } K_l = \frac{F_e}{\max(\Delta L_e)}$$

For analysis, peak of stance (PS, 0%-100%) leg stiffness, vertical GRF (vGRF), change in leg length, and hip, knee, and ankle flexion angles were quantified. Each variable was submitted to a RM ANOVA to test the main effect and interaction between load (*20 kg, 25 kg, 30 kg, 35 kg*), stride length (*SSL, PSL, LSL*), and sex (*Male, Female*). Significant interactions were submitted to a simple effects analysis, and a Bonferroni correction was used for multiple comparisons. Alpha was $p < 0.05$.

RESULTS AND DISCUSSION

Body borne load increased leg stiffness (P=0.006) and risk of MSI during running. Specifically, leg stiffness increased 12% with the 35 kg load compared to the 20 kg load (P=0.002). Participants may have increased leg stiffness to prevent collapse of the limb and help attenuate the larger peak vGRFs

evident with the addition of load (Fig. 1, $P<0.001$). These large vGRFs may increase strain on both the passive and active soft-tissue structures of the lower limb, increasing risk for MSI.

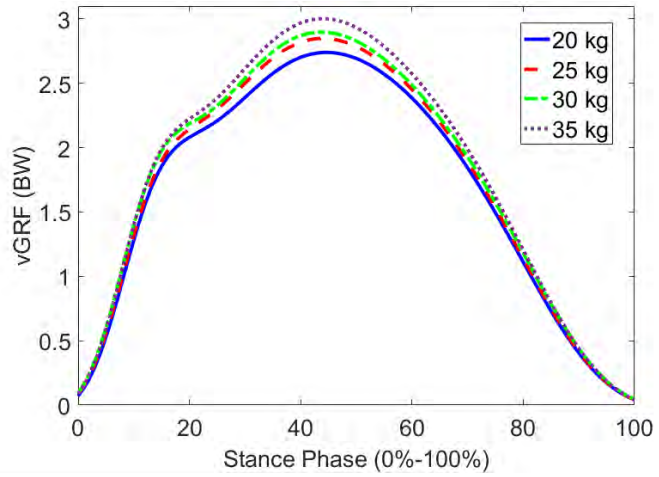

Figure 1: Depicts vGRF during stance for each load configuration (20 kg, 25 kg, 30 kg, 35 kg).

Risk of MSI may further increase when running with longer strides. Participants increased peak vGRF with LSL compared to PSL ($P<0.001$) and SSL ($P<0.001$). But, males may possess the ability to attenuate these larger vGRFs and decrease leg stiffness with longer strides (Fig. 2). Specifically, males decreased leg stiffness when using LSL compared to PSL ($P<0.001$) and SSL ($P<0.001$), and PSL compared to SSL ($P=0.026$). Whereas, females exhibited no significant difference in leg stiffness between strides ($P>0.05$). The discrepancy in leg stiffness may be attributed to a sex dimorphism in lower limb biomechanics as stride lengthens. Although, females adopted greater PS hip and knee flexion compared to males with SSL ($P=0.013$; $P=0.001$), only male participants significantly increased PS hip and knee flexion as stride length increased from SSL to PSL ($P=0.008$; $P=0.001$) and from PSL to LSL ($P=0.041$; $P<0.001$). Males may possess lower limb strength that affords them the ability attenuate the larger vGRF evident with longer strides by using greater lower limb flexion and reduced leg stiffness. Females, who are reportedly weaker [4], may not possess the strength to allow for greater lower limb flexion and, subsequently a reduction in leg stiffness when running with longer strides. Further, a significant stride by load interaction was evident for PS knee flexion angle ($P=0.028$). Participants increased PS knee flexion with LSL compared to PSL when carrying 20 kg ($P=0.001$), 25 kg ($P<0.001$), and 30 kg ($P=0.004$), but not 35 kg ($P=0.760$). The current participants may not have the lower limb strength to increase lower limb flexion, and attenuate the larger vGRF evident with longer strides, when running with heavy body borne loads.

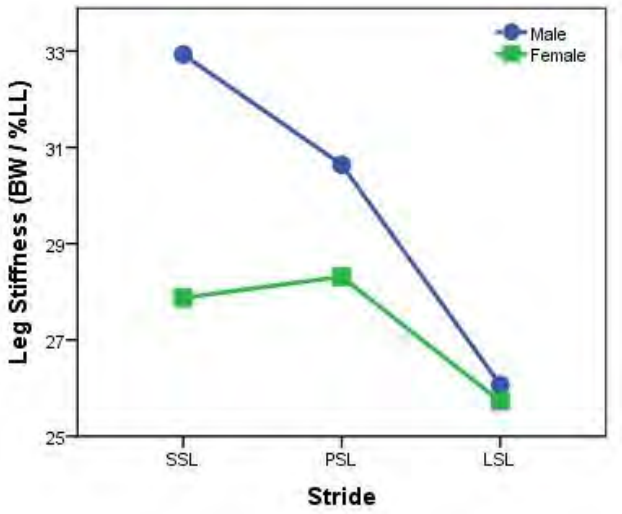

Figure 2: The leg stiffness exhibited by male and female participants running with SSL, PSL and LSL.

CONCLUSIONS

Body borne load increased leg stiffness and potential risk of MSI during running. This increased stiffness may help attenuate the greater peak vGRFs and prevent collapse of the lower limb when running with heavy body borne loads. Only male participants, however, demonstrated the ability to reduce leg stiffness and potentially risk of MSI by increasing hip and knee flexion when running with longer strides. Further study is warranted to determine if lower limb strength, rather than sex, determines the ability to adjust leg stiffness and lower limb biomechanics when altering stride length to run with heavy body borne load.

Minimum Number of Strides to determine Stable Symmetry during Running

Shane P. Murphy, Zach B. Barrons, and Jeremy D. Smith

University of Northern Colorado, Greeley, CO, USA
email: shane.murphy@unco.edu, twitter: @UNCBiomechanics

INTRODUCTION

Gait symmetry is often used to characterize the quality of gait in both healthy and clinical populations [1]. In running, generally a mean of two to ten strides has been used to characterize symmetry [2,3]. Consecutive strides are often considered in these analyses, but in others, particularly overground studies, the strides are not consecutive.

Due to differences in study methodologies and the inherent variability of gait, it is not understood how the number of strides influence the outcomes of a given study. Further, it is not fully understood if a stable mean is only found in consecutive strides, or if subsets of strides will result in different mean symmetries.

The purpose of this study was to determine how many strides should be used to quantify the mean symmetry of a lower extremity variable during running. An additional purpose of this study was to determine if the order of strides analyzed would alter findings.

METHODS

Ten participants free of lower extremity injury for six months and no history of surgery (F = 6, 1.73 ± 0.12 m, 66.0 ± 12.0 kg, 25 ± 3 years, 326 ± 178 min/week of activity) completed two sessions of running at 2.5 $m \cdot s^{-1}$. Each session consisted of running for nine minutes (3 minutes of acclimation and 6 minutes of collection), in which 60 seconds of data were collected at the three and five minute marks. The last 75 strides of each 60 second trial were analyzed. Motion (100 Hz) and ground reaction force (2000 Hz) data were captured using a ten camera system (VICON, Englewood, CO) and an instrumented treadmill (AMTI, Watertown, MA), respectively.

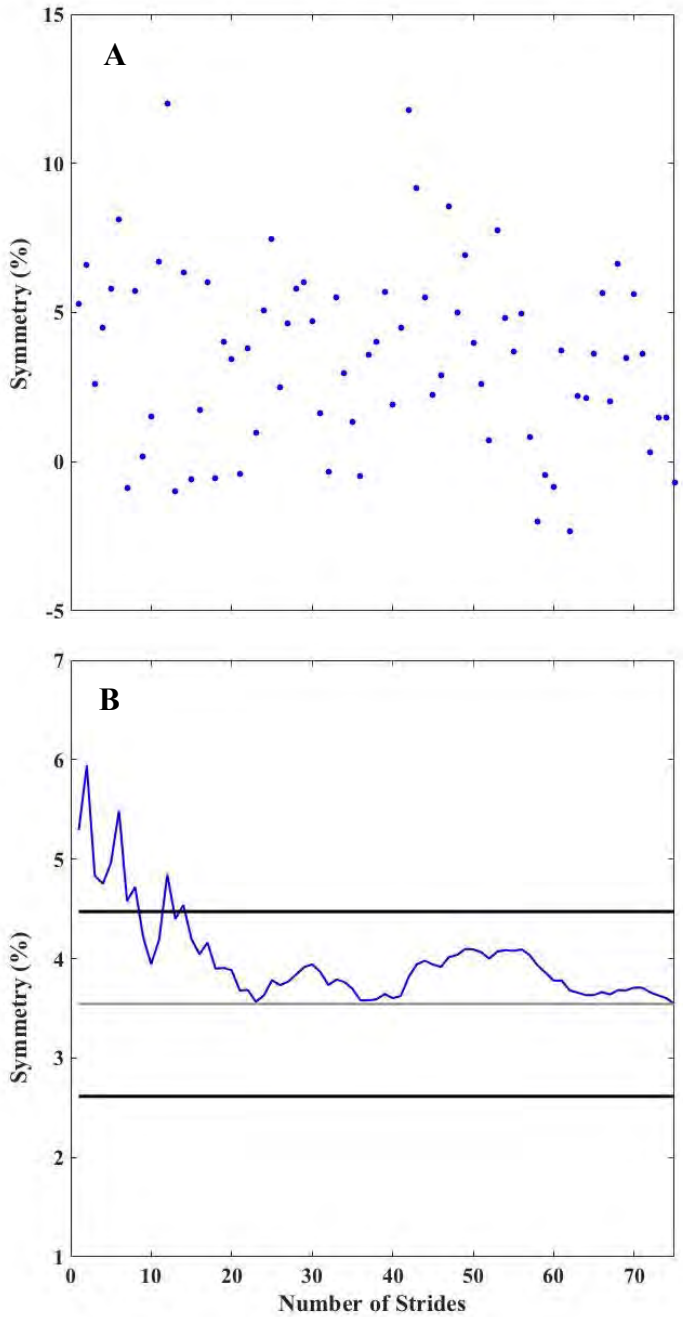

Figure 1: Symmetry of hip angular position at initial foot contact. **A)** Symmetry index for each stride and **B)** Mean symmetry indices with an increasing number of strides used in the mean (blue line). The mean of all stride symmetries (gray line) with a window of ±2SD (black lines) was used as a window to determine how many strides were needed to create a stable mean.

Data were filtered with a lowpass 4th order, zero lag, Butterworth filter at 10 Hz for ground reaction force data and 6 Hz for motion data. Spatiotemporal, joint kinematic and joint kinetic variables were determined in Visual 3D (C-Motion, Germantown, MD).

Symmetry for each measure was determined as the difference between each leg's values, and then divided by the average value of both legs (Fig. 1a) [4]. Mean symmetry for each running trial was determined by computing an average with an increasing number of strides until all strides from that trial were included. To determine the stable point for a variable's mean, the value had to fall within 2 standard deviations of the overall mean (Fig. 1b) [5].

Trials were removed prior to analysis if extreme values of symmetry were calculated. Fifteen stride symmetries were selected randomly to compare the first, middle, and last fifteen stride symmetries of each trial. Multiple repeated measure analyses of variance were used to determine if differences between random, first, middle, last, and all stride symmetries were statistically significant (SPSS 24, IBM, Armonk, NY), with each trial treated as individual subjects. An alpha of 0.05 was used to determine significance.

RESULTS AND DISCUSSION

A stable mean for all variables was achieved with an average of 16.4 ± 6.3 strides. This average includes variables, such as ankle angle at initial contact and minimum knee angle, which had a large variance in calculated symmetry values. This large variance was due to magnitudes of the variables being close to zero prior to determining symmetry. For variables near zero, on average 27.5 ± 5.3 trials were required to reach a stable mean. Without these highly variant variables, a stable mean was met in 14.1 ± 3.2 strides. Therefore, 15 strides were used to determine if order of strides analyzed would alter findings. No differences were found between all bins of strides, for all variables ($p < 0.05$; Table 1 presents the spatiotemporal outcomes).

In previous literature, 200 strides of continuous walking were required to describe variability in kinematics [5]. It is possible that the current findings do not fully capture the variability of symmetry between limbs during running, but instead provides a reference to how many strides are necessary to describe differences between means.

Future research should examine if the number of strides necessary for a stable mean changes between different symmetry calculations, and if the number of strides necessary for a stable mean changes with a smaller window about the mean.

CONCLUSIONS

Fifteen strides of running data, regardless of order, is sufficient to produce a stable mean symmetry index for lower extremity variables. Data collection procedures looking at limb symmetry should allow for at least 15 strides, regardless of overground or treadmill running. Caution should be used with variables with averages near zero, even when analyzed with upwards of 30 strides.

AN EXPLORATION OF MUSCLE ACTIVITY IN YOUNG AND OLDER RUNNERS AND THE RELATIONSHIPS WITH RUNNING ECONOMY

[1] Barbara J. Schornstein, [2] Kevin D. Dames, and [1] Gary D. Heise

email: Barbara.schornstein@gmail.com

INTRODUCTION

While there have been studies comparing homogenous groups of runners and the relationship between their running economy (RE) and the duration of muscular activity of lower extremity muscles, there is an unclear relationship between the two [1,2,3]. Studies have shown both positive [3] and negative [1,2] relationships between RE and the duration of muscular activity. In these studies, the participants have been of a younger age group (mean ages of 22-34 years). The purpose of this exploration was to compare two age groups of runners and the relationship between their RE and the duration of muscular activity in the lower extremity biarticular muscles.

METHODS

This study was approved by the Institutional Review Board. Participants (9 young (22±2 years, range 18-24 years): 7 women, 2 men; 13 older (37±8 years, range 27-50 years): 4 women, 9 men) ran for 5 minutes at three speeds (3.3, 3.5, 3.7 $m \cdot s^{-1}$) on an instrumented force-measuring treadmill while motion (Vicon, 100 Hz), forces (AMTI, 2000 Hz), electromyographic (EMG, DELSYS, 2000 Hz), and metabolic (Parvo Medics) data were collected. EMG data were collected from rectus femoris (RF), biceps femoris (BF), and lateral gastrocnemius (LG) from the right leg only.

Motion and force data were imported into Visual 3D (C-Motion) to determine stance phase for five consecutive foot strikes. These data were then imported into MATLAB (MathWorks) for determining the percentage of stance that muscles were active. The EMG data were analyzed after full-wave rectification and a low pass filter (f_c=15 Hz), using manual determination of on- and off-set [1].

For each speed, the durations of activity in both the individual muscles and pairs of muscles were correlated with each participant's RE using Spearman's Rank correlations. Spearman's Rank correlations were used since the group membership was not equal and historic studies also used this measure [1,2,3].

RESULTS AND DISCUSSION

Age was different between the groups; however, height, mass, maximal oxygen consumption, heart rate at maximal oxygen consumption, and RE at the three speeds were not different between the age groups. One difference between the age groups was demonstrated in respiratory exchange ratio during the maximal oxygen test ($p \leq .05$; young:1.02 ± .04, old: 1.06 ± .04).

Younger runners appear to have shorter durations of muscular activity and coactivity than the older runners (Table 1). Younger runners also demonstrated more significant relationships between RE and RF, LG, and the corresponding RFLG. Older runners only showed relationships between RE and muscular activity/coactivity at 3.5 $m \cdot s^{-1}$ in RF, BF, RFBF and BFLG.

The significant relationships for the younger runners were all negative correlations, while the older runners' significant relationships were all positive. Eighteen relationships were studied in each group of runners. When considering all relationships, even the non-significant ones, the young runners had 16 negative relationships, leaving 2 positive; while older runners showed 3 negative relationships, leaving 15 positive.

The contrasting direction of relationships between the age groups is significant; as young runners have more activity in their muscles, there is an association with decreased metabolic cost. Older runners, however, have more muscle activity associated with increased metabolic cost. This may have an interaction with elastic energy use. In future studies with a larger and more distinctive age group difference, it is possible to see more of a disparity between the relationships of muscular activity and RE. In addition, the number of women and men runners in each age grouping was not equal as the younger group had more women and the older group had more men.

CONCLUSIONS

This is an exploration, as the groups were not balanced in number, nor in the gender split; however, there needs to be further studies in this area as there appear to be meaningful differences between younger and older runners. These differences in younger and older runners, that young runners show negative relationship between RE and muscular activity while older runners show positive relationships, may have implications on how physiology and neuromuscular adaptations to physical training occurs as a runner ages.

HIP WORK DURING RUNNING USING DAILY-USE AND RUNNING-SPECIFIC PROSTHESES

[1] Lauren A. Sepp, [2] Brian S. Baum, [2] Erika Nelson-Wong, and [1] Anne K. Silverman

INTRODUCTION

Running has many health benefits, but can be difficult for people with a unilateral transtibial amputation (TTA). Running-specific prostheses (RSPs) can be cost-prohibitive, and thus people with TTA often run with their daily-use prosthesis (DU). However, biomechanical differences between using RSPs and DUs are unclear.

During walking, people with TTA compensate for the functional loss of the ankle plantarflexors with greater amputated and intact leg hip work compared to people without TTA [1]. In addition, people with TTA have a greater peak hip moment in the intact leg compared to the amputated leg during running [2]. However, differences in hip biomechanics have not been compared when using different types of prostheses during running. Similar to prior results during walking, we hypothesized that people with TTA would have greater positive hip work as compared to people without TTA at all speeds and regardless of leg. As RSPs are specifically designed for running, we expected that use of an RSP would reduce asymmetric biomechanics. Thus, we also hypothesized that positive hip work would be greater for TTA using DUs compared to RSPs at all speeds and regardless of leg. Finally, also similar to prior results during walking, we hypothesized that amputated side hip work would be greater than intact side hip work in people with TTA at all speeds, regardless of prosthesis type used.

METHODS

Sixteen participants (nine with TTA: (5F/4M), 32 years old (yrs) ± 8.8yrs, 69.0kg ± 10.9kg, 1.75m ± 0.073m, seven without TTA: (4F/3M), 28yrs ± 6.3yrs, 69.0kg ± 4.57kg, 1.70m ± 0.071m) ran at five speeds (2.5, 3.0, 3.5, 4.0, 5.0 m/s) on a force-sensing treadmill (2000 Hz, Bertec Corporation, USA). People with TTA performed trials twice, once with their prescribed RSP and once with their prescribed DU. Kinematics were collected using a whole-body marker set (100 Hz, Northern Digital Inc., Canada). Kinematics and ground reaction forces were filtered using a fourth-order Butterworth filter, with cutoff frequencies of 10 Hz and 15 Hz, respectively. An inverse dynamics analysis was performed to compute net hip joint power. Hip joint work was computed as the integral of sagittal hip joint power over the running gait cycle and normalized by body mass.

Hip work differences were assessed using three, three-factor ANOVAs with main effects of running speed, prosthesis type (DU vs. control, RSP vs. control, or DU vs. RSP), and leg (amputated/left vs. intact/right). The speed and leg main effects were all within-subjects comparisons. The prosthesis type main effect was a within-subjects comparison for RSP vs. DU, and a between-subjects comparison when comparing control participants (people without TTA) to people with TTA using either type of prosthesis. Tukey's correction factor for multiple comparisons was used for post-hoc pairwise comparisons when significant main or interaction effects were found (α=0.05).

RESULTS AND DISCUSSION

Our first hypothesis was partially supported. Positive hip work was greater for people with TTA using DUs compared to people without TTA, regardless of leg at 3.0 m/s, 3.5 m/s, and 4.0 m/s ($p \leq 0.040$) and increased with speed for people with and without an amputation ($p<0.01$). There were no differences between people with TTA using RSPs and people without TTA.

There was a significant group effect ($p<0.01$) for people with TTA wearing DUs as compared to RSPs.

People with TTA using DUs had greater positive hip work compared to using RSPs at every running speed ($p \leq 0.025$), consistent with our hypothesis.

Positive hip work was greater in the intact leg compared to the amputated leg for people wearing RSPs at 3.5 m/s, 4.0 m/s, and 5.0 m/s ($p \leq 0.024$), contrary to our hypothesis. People with TTA wearing DUs did not have any differences in positive hip work between amputated and intact legs, contrary to our hypothesis.

Over the running gait cycle, positive work results from the hip extension moment in early to mid-stance and a flexion moment in early to mid-swing. In addition, an extensor moment in late swing as the hip is extending in preparation for heel strike creates another period of positive work. The differences in hip work were driven by hip extension power in early stance and hip flexion power in late stance and swing.

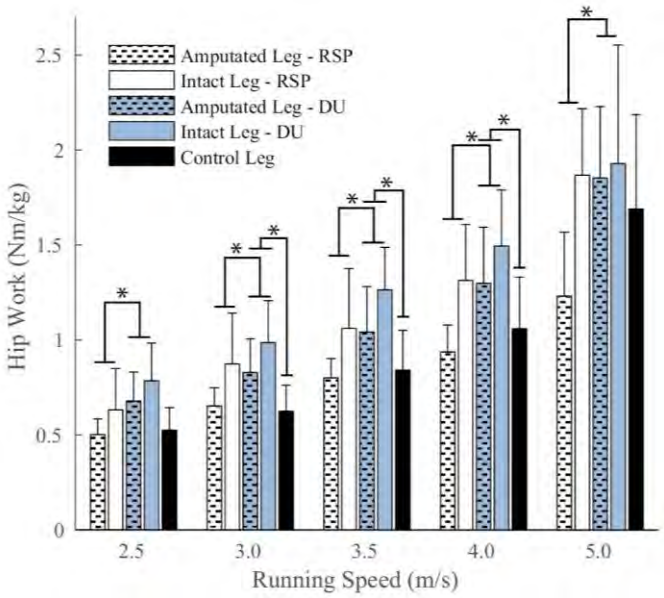

Figure 1. Positive hip work over the gait cycle for people without TTA (control) and for people with TTA using running-specific prostheses (RSPs) and daily-use (DU) prostheses (significance '*').

Energy storage and return (ESAR) prostheses provide more energy return during late stance compared to non-ESAR feet [3-5]. The RSPs and DUs included in this study were all ESAR designs, although RSPs do not have a heel and can also return more energy during late stance as compared to DUs [3-5]. Greater energy storage and return from RSPs may reduce the overall required hip extensor work on the amputated leg compared to DUs. Hip extensor work in early stance has been associated with a lack of positive ankle work in late stance during walking [1], which may also be reflective of running with an amputation. In addition, the hip moment in the intact leg has been shown to be greater than the amputated leg in people with TTA using RSPs [2]. Thus, greater energy return from the RSP may reduce the demand from the hip extensors in early stance.

The hip flexors are important for generating energy to the leg for swing initiation during walking [6], and this demand likely increases with running as speed increases. The RSPs in our study were generally lighter than the DUs, and thus could reduce the demand from the hip flexors for leg swing initiation.

CONCLUSIONS

Using RSPs reduces overall positive hip work during running compared to using DUs. Increased energy return from RSPs compared to DUs may reduce the demand at the hip during running. Differences in biomechanics of running between people with and without amputation, and between RSPs and DUs, should be further investigated to understand how individual muscles work with different device designs to achieve running mechanics.

INTRODUCTION

Several lines of evidence indicate that sensory feedback plays a role in various mechanical aspects of running. In particular, the plantar surface of the foot provides essential afferent information regarding the nature of the foot's contact with the ground during running. It is thought that peripheral sensory feedback plays a key role in adjusting step-to-step limb trajectories in order to maintain balance during locomotion, and is essential for adjusting ground contact to avoid uncomfortable stimuli [1]. However, the integration of plantar afferent information and the mechanical control of running is a complex process, and many aspects remain to be elucidated.

A primary area that has seen little attention in the literature is the relationship between sensory feedback and gait variability. Normal variability in the foot's contact with the ground may be indicative of the successful integration of plantar sensory feedback and neuro-mechanical control of the running gait. Alternatively, absence or disorders of this sensory-motor integration may lead to reduced variability in the foot-ground contact during running and subsequently result in localized tissue loading that may potentially lead to injury. For example, it has been suggested that individuals with peripheral sensory deficits (such as diabetic peripheral neuropathy) have a less variable gait than those with intact sensory feedback, and this reduced variability may lead to abnormal tissue loading and subsequent ulceration [2]. Further, it has been hypothesized that shoes limit sensory feedback [3], and therefore individuals may run with a less variable gait when running shod as compared to running barefoot.

The aim of our research was to eliminate plantar sensory feedback by anesthetizing the feet in order to further understand the role of plantar sensory feedback in controlling the variability of foot-ground contact during running. We hypothesized that with the loss of sensory feedback from the plantar surface of the foot, individuals would run with less variable ground contact when both barefoot and shod.

METHODS

12 healthy active subjects (5 female, 7 male); mass: 62.6±12.2 kg; age: 28±7.3 years, participated in this study. Subjects completed 4 trials that consisted of 3 minutes of treadmill running in each of two sensory conditions: normal (NORM) and anesthetized (ANEST). For each sensory condition the participant's gait was analyzed while running both barefoot (BF) and shod (SHOD). For the ANEST conditions bilateral tibial nerve blocks were performed, which consisted of injecting 3 mL of 2% lidocaine surrounding the posterior tibial nerve according to the procedure of Fiolkowski et al. [4].

Following the anesthetic procedure, sensation was evaluated by standard clinical sensory testing techniques, including the Semmes–Weinstein monofilament and vibratory sensation tests. According to the Semmes–Weinstein monofilament test, anesthesia was confirmed when the subject did not have sensation when a 10 g monofilament was pressed on the foot sole with enough pressure to buckle. The vibratory sensation test was used to evaluate deep sensation of the plantar foot (sensory receptors located deep in the dermal layer and subcutaneous tissue, and/or free nerve endings located in joints and the calcaneal fat pad) and anesthesia was confirmed when the subject could not sense a vibrating 128 Hz tuning fork placed against the plantar surface.

For the treadmill running trials velocity was set at the subject's preferred running speed (mean velocity 2.41 $\pm$ 0.41 m/s), which was determined in the NORM SHOD condition and maintained for all other trials. Data was recorded for the 2nd minute of each 3 minute treadmill running trial. Variability in ground contact was evaluated as the standard deviation of stride time and stance time for all strides completed during the 1 minute of data collection. Stance and stride times were measured via footswitches sampling at 1,000 Hz that were located on the plantar surface of each subject's right foot.

Repeated measures ANOVA tests were performed to compare the differences in the standard deviation of stride and stance times among the four conditions. Statistical significance was defined as $p<0.05$.

RESULTS AND DISCUSSION

The tibial nerve block procedure eliminated superficial and deep sensory feedback in all subjects as evidenced by the lack of sensation when evaluated with the Semmes-Weinstein monofilament and vibratory sensation tests.

In support of our hypothesis, in both the BF_ANEST and SHOD_ANEST conditions participants exhibited significantly decreased variability in stride and stance time, as compared to the intact sensory conditions (SHOD_NORM *vs.* SHOD_ANEST, $p=0.04$; BF_NORM *vs.* BF_ANEST, $p=0.03$) (Fig. 1). Despite the hypothesis that shoes inhibit sensory feedback, there was no statistically significant difference in the standard deviation of stride or stance time between the BF and SHOD running conditions ($p>0.05$, Table 1). It is possible that shoes may reduce or alter sensory feedback when running, but the remaining sensory feedback is adequate for maintaining stride and stance time variability.

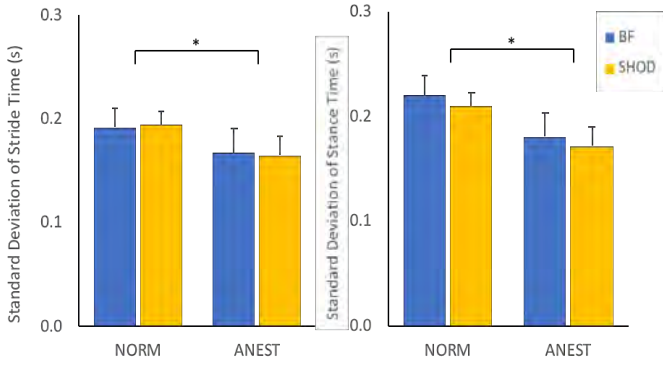

Figure 1: Standard deviation of stride time and stance time for both BF and SHOD running in the NORM and ANEST conditions. *Significant difference between NORM and ANEST condition, for a given shoe condition (BF or SHOD) $p<0.05$.

CONCLUSIONS

The results of the present study indicate that plantar sensory feedback plays an important role in controlling the variability of ground contact in running. With intact sensory feedback the timing of ground contact and the stance duration was more variable, indicating that plantar sensory feedback is integrated into the neuro-mechanical control of the running gait. The finding that there was no difference in stride or stance time between BF and SHOD running, indicates that shoes do not limit sensory feedback to the extent that gait variability is affected.

INTRODUCTION

A number of studies have investigated the influence of maximal isolated muscle fatigue [1] and cardiovascular fatigue [2] on lower extremity biomechanics during running. However, the majority of runners do not run to exhaustion regularly. As such, researchers and footwear companies are interested in the biomechanical changes over the course of a typical prolonged run. Studies have shown that runners choose their habitual motion path (i.e. preferred joint kinematics) during running to either minimize energy cost and/or reduce stress on the tissues [3]. However, it is uncertain whether the same optimization strategies exist over the entire course of a run. Additionally, stability shoes with medial posting have been shown to reduce rear-foot eversion angle [4]. However, it is unknown as to whether this is beneficial to reducing injury risk and whether this can be maintained throughout a run.

The purpose of this study was to investigate the influence of a 42-minute prolonged treadmill run on lower extremity biomechanics during which footwear were changed from a neutral to a stability shoe at the midpoint of the run. It was hypothesized that: 1) lower extremity biomechanics would differ between sessions in the second half of the run (*intervention* run) where runners wore either neutral or stability running shoes and 2) lower extremity biomechanics would change over the course of the prolonged treadmill run.

METHODS

Fourteen male (age 24.1 ± 4.4 years, height 1.8 ± 0.1 m, mass 71.2 ± 8.3 kg) habitual rear-foot recreational runners participated in two 42-minute prolonged treadmill running sessions at their preferred speed (3.3±0.4 m/s) one week apart.
During the first 21 minutes (*baseline* run) of both sessions, participants ran in a neutral shoe. Following this, they changed into either another neutral shoe of the exact same construction but in a different colour (Session A) or a stability shoe of the same construction with an added medial post (Session B) and ran for another 21 minutes (*intervention* run). Three-dimensional kinematic data were recorded with an 8-camera motion capture system (Qualysis, Inc., Gothenburg, Sweden) sampling at 200Hz synchronously with ground reaction forces from the instrumented treadmill at 2000Hz (Treadmetrix, Park City, UT). Data were collected for 30 seconds at minutes 1, 21, 24 and 44. Ratings of perceived exertion (RPE) and percentage of maximum heart rate (%HR_{max}) were collected at the same time intervals. Two-way repeated measures ANOVAs (time/shoe) were implemented using statistical parametric mapping to compare joint angle and moment waveforms over stance [5].

RESULTS AND DISCUSSION

This study investigated lower extremity biomechanics during prolonged running in neutral and stability shoes. Exertion increased over the course of baseline and intervention runs where both HR_{max} (Min_1: 74±6%, Min_{21}: 85±6%, Min_{24}: 75±5%, Min_{44}: 84±4%) and RPE (Min_1: 10±2, Min_{21}: 12±2, Min_{24}: 10±0, Min_{44}: 12±2) increased (P<0.001) with no differences observed between sessions.

Influence of footwear. As a group, no differences in lower extremity biomechanics were observed during the *intervention* run for the neutral and stability shoes. However, runners do not all respond to

footwear conditions similarly [3]. Individual and subgroup analyses from these data have revealed some runners did have a beneficial effect of stability shoes (lower deviation from habitual motion path), while others did not.

Influence of time. To support our second hypothesis, there were differences in biomechanics at the hip, knee and ankle over the course of the prolonged run (Figure 1). Hip extension angle increased just prior to toe off during the baseline (95-100%, P=0.049) and intervention (94-100%, P=0.041) runs. Hip internal rotation angle increased during the baseline run (18-40%, P=0.019 and 46-55%, P=0.042) and intervention run (21-31%, P=0.041 and 50-66%, P=0.028). Knee flexion angle increased during the baseline and intervention runs for 26-32% (P=0.047) and 62-82% (P=0.021) of stance respectively. Knee abduction angle and internal rotation angles increased during the baseline run for 20-62% (P=0.001) and 22-66% (P=0.002) of stance respectively. Dorsiflexion angle decreased during the baseline and intervention runs for 0-14% (P=0.025) and 0-13% (P=0.027) of stance. Foot eversion angle increased during the baseline run for 16-69% of stance (P<0.001). The kinematic changes observed at the knee and foot are in agreement with the literature and are a likely mechanism to reduce effective mass of the leg [2]. However for every 5º increase in knee flexion at mid-stance, there is an approximate 25% increase in oxygen cost [6]. Knee abduction moment decreased during the baseline run for 25-42% of stance (P=0.001). Ankle plantarflexion moment increased during the baseline and intervention runs for 12-23% (P=0.009) and 45-58% (P=0.009) of stance respectively. While reducing effective mass may be a strategy to minimize stress applied to the tissues (i.e. peak knee moments did not increase) over the course of a prolonged run, this may come at a cost of running economy and may also be the product of changes in muscle coordination.

CONCLUSIONS

Runners deviate from their habitual motion path over the course of a prolonged run. Particularly, increased knee flexion and rear-foot eversion observed during mid-stance may exhibit a strategy to reduce the effective mass and minimize joint loads applied to the foot and knee. Additionally, individuals respond to footwear differently. With respect to the changes observed in kinematics throughout a prolonged run, running shoe design should focus on: 1) materials to allow runners to maintain baseline kinematics (i.e. habitual motion) for longer; and/or 2) materials for greater energy return when kinematics are altered and the muscles may not be performing optimally.

A SENSOR FUSION ALGORITHM FOR ESTIMATING CENTER OF MASS KINEMATICS IN HUMAN WALKING AFTER SPINAL CORD INJURY

INTRODUCTION

Spinal cord injury (SCI) is a debilitating condition that results in loss of function due to paralysis of muscles of the body. Functional Neuromuscular Stimulation (FNS) is a technology that can be used to restore the activity of muscles paralyzed by SCI. This is achieved by applying low-level electric currents to the peripheral motor nerves to elicit contractions of the muscles and thus restore some or all of the lost functions. Restoring stable walking is an important desire expressed by individuals with SCI [1]. Reciprocal stepping motions are possible with either cyclic patterns of neural stimulation, or switch based triggering of pre-programmed stimulation for successive stance and swing phases [2]. The stability of these feed-forward walking systems needs to be significantly improved by developing and implementing feedback control systems to appropriately modulate stimulation for balance and propulsion. Such controllers depend on robust sensor signals that accurately reflect the state of the system.

Common walking stability measures include whole body kinematic/kinetic quantities such as center of mass position (CoMP) and acceleration (CoMA), center of pressure (CoP) and angular momentum. Inertial measurement units (IMUs) are ubiquitous in a wide variety of human motion and rehabilitation studies [3] and are a suitable choice to provide feedback information for stabilizing human walking with FNS because of their low cost and small size. Our laboratory is developing a completely implanted stimulation system, the Networked Neural Prosthesis System (NNPS) that contains IMUs embedded in its internal modules [4].

The main goal of this study was to design a sensor fusion algorithm based on the Kalman Filter (KF) for estimating the kinematics of whole body CoM using signals from IMUs mounted/implanted at strategic locations on the body.

METHODS

One subject with SCI (T4, AIS A) walked within the work volume of 16-camera Vicon motion capture system (Oxford Metrics, UK) with six Xsens (Xsens Technologies, BV, Enschede the Netherlands) wireless IMUs attached to the body at the chest (sternum), back, flanks, and posterior thighs. Retroreflective markers were affixed to the body in accordance with the Vicon Plug-in Gait marker set [5]. CoMP was computed analytically from the marker coordinates and segmental mass properties.

The underlying structure of the stochastic system defining the dynamics and measurement on which the KF is defined is given by equations (1) and (2):

$$x_k = Ax_{k-1} + Bu_k + w_{k-1} \quad (1)$$

$$z_k = Cx_k + v_k \quad (2)$$

Here, x is the state vector, z the measurement vector and A, B and C are the coefficient state transition matrices. w and v are independent white noise processes that are normally distributed as follows: $p(w) \sim N(0, Q)$ and $p(v) \sim N(0, R)$. Q is the state noise covariance and R the measurement noise covariance. Equation (1) specifies how the system state is propagated while equation (2) specifies the relationship between the state and the measurement. Details of the KF equations are available in most textbooks on systems theory and KF design [6].

It has been well documented that during normal walking, *changes* in all 3 components of whole body CoMP follow a sinusoidal profile [7] thereby making it possible to define each with an equation of form:

$$X(t) = F\sin(\omega t) \quad (3)$$

From this, V(t) and $\dot{V}(t)$ can be computed as:

$$V(t) = \omega F\cos(\omega t) \quad (4)$$

$$\dot{V}(t) = -\omega^2 F\sin(\omega t) = -\omega^2 X(t) \quad (5)$$

The discretized equations for displacement and velocity for each component of CoM are defined as:

$$X(t+\Delta t) = X(t) + \Delta t V(t) \quad (6)$$

$$V(t+\Delta t) = V(t) + \Delta t\dot{V}(t) \qquad (7)$$

Thus if we define the state vector as: $\vec{x}_k = [X_k \quad V_k]^T$ the unforced state equation (1) takes the form:

$$\underbrace{\begin{bmatrix} X_k \\ V_k \end{bmatrix}}_{x_k} = \underbrace{\begin{bmatrix} 1 & \Delta t \\ -\omega^2\Delta t & 1 \end{bmatrix}}_{A} \underbrace{\begin{bmatrix} X_{k-1} \\ V_{k-1} \end{bmatrix}}_{x_{k-1}} + \underbrace{\begin{bmatrix} w^X_{k-1} \\ w^V_{k-1} \end{bmatrix}}_{w_{k-1}} \qquad (8)$$

The measurement, z, which is hypothesized to be related to the *acceleration* measure from the sensors, can be written as:

$$Z(t) = G\dot{V}(t) = -\omega^2 GX(t) \qquad (9)$$

That is, the measurement equation (2) can be written as:

$$z_k = -\omega^2 G x_k + v_k = \underbrace{\begin{bmatrix} -\omega^2 G & 0 \end{bmatrix}}_{C} x_k + v_k \qquad (10)$$

Here v_k is the measurement noise and G an estimation gain. To improve estimation accuracy, 3 backpropagation artificial neural networks (ANNs) were designed to estimate CoMA from a pair of sensors each selected at random. The outputs of the ANNs were then fused using the time-invariant KF designed with matrices A and C and vectors w and v in equations (8) and (10) replicated for each of the 3 components.

RESULTS AND DISCUSSION

Figure 1 shows the results of the sensor fusion algorithm combining the outputs of the ANN and KF for each of the 3 components of CoMP. These results show the anterior posterior (AP) and the inferior-superior (IS) components with the trends/means removed from the plots to emphasize the changes that occur in these variables. From the results, the estimates from the KF matched the actual CoMP data with regression coefficients as high as 0.92 with the best fit obtained in the medial-lateral (ML) direction.

While good estimates are obtained with a sensor fusion algorithm that combines KF and ANNs, a preferred algorithm will be one that uses only a KF. This will minimize training effort for the ANNs. In addition, better estimates may be possible with a time varying KF rather than a time-invariant filter defined by equations (8) and (10). Time variance can be introduced by assuming that the frequency ω is a time-varying quantity to be estimated in an adaptive version of the KF. In addition, higher estimation accuracy may be possible by using a sum of sines for the CoMP defined by equation (3).

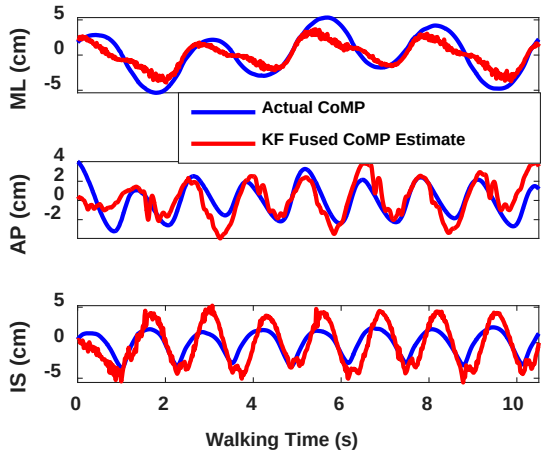

Figure 1: Changes in ML, AP* and IS* components of CoM Position as estimated by a Kalman Filter for SCI walking over 4 cycles of gait. Regression coefficients between the actual and estimated CoMP were 0.92, 0.68 and 0.78 respectively. *(*-detrended)*

CONCLUSIONS

With a simplified sensor fusion algorithm made up of a Kalman filter and backpropagation ANNs we have successfully extracted good estimates of whole body CoM position from multiple independent and anatomically distributed IMUs. The estimates will be invaluable in developing feedback control systems for stabilizing walking in individuals with SCI using FNS systems.

INTRODUCTION

Warfighter performance is inherently challenging to quantify due to task complexity, technique variation, warfighter environment, and limited knowledge of measures that truly characterize task performance beyond simple success or failure. Obstacle courses are one approach to assess the effects of fatigue and/or load on warfighter performance [1-2], but typically measures of the total time to complete an obstacle course or time required to complete each obstacle are the only quantitative metrics obtained from such tests. To address this shortcoming, we have employed inertial measurement units (IMUs) to measure the underlying biomechanics that define performance for obstacles in the Marine Corps Load Effects Assessment Program (MC-LEAP) [3 – 5]. Because each obstacle requires different algorithms to calculate performance metrics from the IMU data, the IMU data must first be parsed according to obstacle before analysis. The goal of this study is to develop and test an algorithm that accurately and automatically identifies when a participant begins and finishes each obstacle in an obstacle course using only the data from body-worn IMUs.

METHODS

A total of 39 participants (16 females, age = 20.1 ± 2.0 years, mean ± standard deviation) were recruited to complete an abbreviated version of the MC-LEAP [2] consisting of 11 obstacles: functional calibration movements (needed for data analysis), sprint, vertical jumps, casualty drag, window, balance beam, wall, agility run, bounding rush, high crawl, and vertical transfer. All subjects wore an array of 13 IMUs (Opal, APDM, Portland OR) attached to the head, upper arms, forearms, torso, sacrum, thighs, shanks, and feet. Participants carried a mock plastic rifle (3.4 kg) with another attached IMU and an additional IMU was placed in the load used for the vertical transfer obstacle [5]. Data was manually marked by depressing a binary switch synchronized with the IMUs at the beginning and end of each obstacle, which provides the ground truth data for the automated algorithm developed herein. The University of Michigan IRB approved the study and all subjects gave informed consent.

Data from the participants were collected during two different phases of our research project, and therefore belongs to two different data sets: data set 1 (DS1) and data set 2 (DS2). DS1 contains data from 19 participants (9 females, age = 20.4 ± 1.8 years, weight = 68.1 ± 13.2 kg, height = 1.73 ± 0.11 m) who completed the MC-LEAP a single time without added load for a total of 19 trials. DS2 contains data from 20 participants (7 females, age = 19.9 ± 2.1 years, weight = 78.0 ± 15.5 kg, height = 1.78 ± 0.13 m) who completed the MC-LEAP four times with varying amounts of added load (2×0%, 1×15%, and 1×30% body weight) for a total of 80 trials. DS2 was used to develop and test the obstacle parsing algorithm and DS1 was used to further validate the obstacle parsing algorithm.

Our basic approach was to utilize the distinctive kinematic features of the obstacles that can be derived from the body-worn IMUs (Table 1) to parse the data. The approach was implemented using the following steps:

1. Define the obstacle course (included obstacles and order of obstacles).
2. Identify the functional calibration movements, bounding rush, high crawl, and vertical transfer by using obstacle specific kinematic features for both data segmentation and data classification.

3. Use the sum of the magnitudes of the acceleration from the feet, sacrum, and torso-mounted IMUs to define an activity measure to identify candidate data segments.
4. Identify sprint and agility run data segments using obstacle specific kinematic features (Table 1).
5. For remaining candidate data segments, calculate the kinematic features listed for casualty drag, wall, window, vertical jump, and balance beam (Table 1).
6. Using obstacle specific support vector machine models [6] trained using DS2 and using obstacle order, classify the remaining data segments as casualty drag, wall, window, vertical jump, balance beam, or none.

Table 1: Kinematic features used for classification.

Obstacle	Kinematic features
Functional calibration	Foot angular velocity when contralateral foot is still (unilateral pedaling motions)
	Torso angular velocity when feet are still (toe touches)
	Low angular velocity of all segments (quiet standing)
Sprint	Maximum sum of magnitude of acceleration from feet, sacrum, and torso
Agility run	Duration of data segment
Bounding rush	Estimated orientation of torso (five transitions from prone to upright)
High crawl	Estimated orientation of torso (prone)
	Upper arm acceleration impact peaks
Vertical transfer	Acceleration of the load-embedded IMU
Casualty drag	Distance between foot trajectory start and end point
	Area enclosed by foot trajectory
	Length of foot trajectory
	Width of foot trajectory
	Height of foot trajectory
Wall	Maximum vertical velocity of sacrum
	Minimum vertical velocity of sacrum
Window	Time difference between locations of maximum and minimum sacrum vertical velocity
Vertical jump	Slope of curve between maximum and minimum sacrum vertical velocity
Balance beam	Slope of velocity curve prior to minimum sacrum vertical velocity
	Estimated drop height of sacrum
	Minimum sacrum vertical velocity that occurs after maximum sacrum vertical velocity
	Number of times the sacrum heading angle passes through -45 degrees
	Maximum sum of magnitude of acceleration from feet, sacrum, and torso
	Duration of data segment

We tested our obstacle parsing algorithm on both DS1 and DS2. A successful obstacle identification was defined by an overlap in the start and end times identified by our activity recognition algorithm and the start and end times manually marked using the binary switch.

RESULTS AND DISCUSSION

DS1 contained 573 data segments and DS2 contained 2461 data segments for classification. Our algorithm was able to correctly identify obstacles with a high rate of success (Table 2), with error rates below 0.87% for both data sets. Some errors were caused by missing sensor data, incorrect protocol during completion of the course, and obstacle repeats.

Table 2: Obstacle parsing results for both data sets.

Obstacle	Data set 1 (DS1)		Data set 2 (DS2)	
	False positive	Missed	False positive	Missed
Calibration	0	0	0	1
Sprint	0	0	0	0
Agility run	1	1	1	1
Bounding rush	0	0	1	1
High crawl	0	0	0	2
Vertical transfer	1	0	0	1
Casualty drag	0	0	0	0
Wall	1	1	1	1
Window	0	0	0	0
Vertical jump	0	0	4	0
Balance beam	0	0	0	0
Error rate	5/573 = 0.0087		14/2461 = 0.0057	

Our obstacle parsing approach can accurately identify when a participant begins and finishes each of 11 obstacles in an obstacle course using solely data from body-worn IMUs. We implemented this algorithm as part of an automated measurement system for warfighter performance quantification. Future work will test our approach on new data sets and add additional error checking capabilities.

WEARABLE TECHNOLOGY TO MONITOR HAND MOVEMENT DURING CONSTRAINT-INDUCED MOVEMENT THERAPY FOR CHILDREN WITH CEREBRAL PALSY

[1]Brianna M. Goodwin, [2]Emily Sabelhaus, [2]Kristie F. Bjornson, [2]Kelly Pham, [2]William Walker, and [1]Katherine M. Steele

INTRODUCTION

Cerebral palsy (CP) is a non-progressive neurologic disorder of movement and posture that affects approximately 2 in every 1000 children in the United States [1]. Of these children, 40% have unilateral or hemiplegic CP, with abnormal tone, decreased strength, dystonia, and other muscle impairments impacting movement on one side of the body [2].

Constraint-Induced Movement Therapy (CIMT) is an evidence-based treatment for children with hemiplegic CP [3]. CIMT uses a constraint, typically a rigid cast, to restrict motion of the unimpaired hand, forcing the child to use their impaired hand during therapy and daily life. While CIMT has been shown to improve hand function, the protocols and results are often variable [4, 5]. CIMT is both time and resource intensive for the children, their families, and providers. Understanding the extent to which casting influences hand use both in therapy and in daily life, as well as the outcomes after therapy are critical to optimizing treatment protocols.

Wearable technology, including accelerometers, has been used to quantify hand movement and evaluate hand function for both children with CP and adult stroke survivors [6, 7]. The goal of this research was to use accelerometry metrics to quantify hand use in clinical and home environments before, during, and after CIMT for children with CP and compare it to typically-developing (TD) peers.

We hypothesized that (1) paretic hand use would increase during CIMT, both at home and in the clinic, and (2) that increased paretic hand use during CIMT would be associated with enhanced bimanual use in daily life after CIMT.

METHODS

We recruited eight children with hemiplegic CP undergoing CIMT (age: 3yr 5m – 9yr 2m, 4 boys/4 girls) and five TD children (age: 2yr 8m – 9yr 10m, 1 boy/4 girls) from a pediatric tertiary care facility.

Per the institution's CIMT protocol, the non-paretic hand of each child in the CP cohort was placed in a cast for three weeks. Unilateral hand training of the paretic hand occurred in the clinic for 2 hours/day, 4 days/week. On Fridays, the cast was removed and the children received bimanual training for 2 hours before replacing the cast. The CP cohort wore ActiGraph GT9X Link (ActiGraph Corp., Pensacola, FL) tri-axial accelerometers on both wrists for 3 consecutive days during three time periods: 1-week before, during, and 6-8 weeks after CIMT. Functional tests (grip strength and Box & Blocks) and the Canadian Occupational Performance Measure (COPM) were completed before and after CIMT. The TD cohort did not receive therapy, but wore the Actigraph accelerometers on both wrists for three consecutive days at home, on three occurrences temporally aligned with the CP cohort time periods.

Accelerometry data were analyzed using the magnitude ratio (MR) and bilateral magnitude (BM) [6]. The MR is the natural log of the vector magnitude of the paretic limb divided by the non-paretic limb. Values outside of the range ±7 were set to ±7 to constrain the range of values, similar to prior research. The BM is the sum of the vector magnitude of the paretic and non-paretic hands. Density plots were created to compare MR and BM before, during, and after CIMT, with the centroid of these plots as the primary outcome metric (Fig.1.).

RESULTS AND DISCUSSION

The MR results in Table 1 suggest that although CIMT encouraged children with CP to use their paretic hand more compared to their non-paretic hand during therapy, they returned to baseline values 6-8 weeks post CIMT. Although the BM decreased for children during CIMT, the increase after CIMT demonstrated that children were using their hands together at the same magnitude as the TD cohort. This may be reflective of the non-paretic hand being casted and therefore not being able to move. Similarly after CIMT, the CP cohort scored higher on paretic hand functional measures: grip strength increased by 7.5±4.9 lbs. and the number of blocks transferred in 60 seconds increased by 3.5±6.6 blocks. Furthermore, COPM scores increased 5±2.8 points, indicating that children in the CP cohort felt more confident achieving specific self-identified goals.

The combination of the baseline MR levels with increased BM levels and functional scores suggest that although the CIMT cohort is not using their paretic hand as much as their non-paretic hand in daily life after CIMT, they are using both hands in combination more.

CONCLUSIONS

The increase in MR levels and functional measure scores suggests that children feel more confident using their paretic hand following CIMT. However, the subsequent return to pre-intervention BM values, as measured by accelerometry data, indicates that further interventions (*i.e.*, a larger dose of CIMT and/or weekly follow-up therapy sessions) and strategies may be needed to maintain increased daily paretic hand use after CIMT.

Table 1: Comparison of Magnitude Ratio and Bilateral Magnitude for TD and CP participants

	Magnitude Ratio		Bilateral Magnitude	
	Mean ± Standard Deviation	**Range**	**Mean ± Standard Deviation**	**Range**
Typically Developing	-0.3 ± 0.2	-0.7 – 0.3	92.9 ± 22.3	43.2 – 119.6
CP – Before CIMT	-1.9 ± 0.4	-2.3 – -1.2	73.4 ± 21.4	45.4 –109.8
CP – During CIMT	1.9 ± 0.4	1.1 – 2.5	48.2 ± 15.6	23.5 – 70.9
CP – After CIMT	-2.0 ±0.3	-2.2 – -1.6	95.0 ± 28.3	74.6 – 127.3

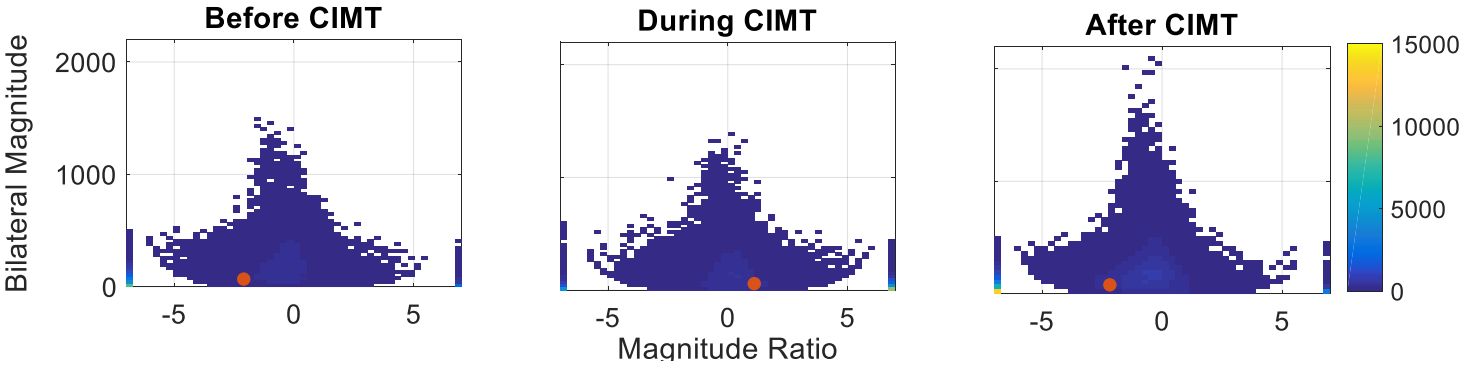

Figure 1: Density plots before, during, and after CIMT. The Magnitude Ratio compares how much the paretic hand is used compared to the non-paretic hand and Bilateral Magnitude compares the overall magnitude of both hands, with negative values indicating greater non-paretic hand use. The red dot is the shape's centroid.

PREDICTING VERTICAL GROUND REACTION FORCES WITH ACCELEROMETERS AND ARTIFICIAL NEURAL NETWORKS

Alec C. Miller, Marwan Aljohani, Hoon Kim, Kristof Kipp

Marquette University, Milwaukee, WI, USA
email: alec.miller@marquette.edu

INTRODUCTION

The repetitive nature of distance running often results in high incidence of overuse injury [7]. Variables related to the vertical ground reaction force (vGRF) are often used to assess risk of overuse injury, and are targeted during interventions [6]. However, measuring vGRF requires expensive, and often inaccessible, force platforms or instrumented treadmills.

Researchers have used a video-based kinematic data in combination with a two-mass model (i.e., lower leg and rest of the body) to predict vGRF during running [8]. Other researchers have used wearable technologies (i.e., accelerometers) to predict vGRF during locomotion [3,5]. However, most studies have only attempted to predict the peak vGRF during running from trunk and tibia accelerations.

Machine learning techniques, such as Artificial Neural Networks (ANN), have been used to predict entire vGRF time-series data during walking with great accuracy [1,2]. To date, no study has tried to predict vGRF time-series from accelerometer data during running. The combination of wearable technology and ANN may provide a low cost alternative to predict vGRF during running. The purpose of this study was to develop and train an ANN to predict the vGRF time-series from tibial and sacral accelerometry during running.

METHODS

The current study was approved by the Institutional Review Board at Marquette University. All subjects were informed of the study's purpose and signed an informed consent document before participation in the study.

Seven well-trained female distance runners (age: 21.4 ± 2.7 years; body-mass: 56.2 ± 6.7 kg; average weekly mileage: 37.9 ± 9.1 miles) participated in this study. Accelerometers were securely attached to the skin over the first sacral vertebrae and medial aspect of the distal tibia of the dominant leg.

Runners were then asked to run on a pressure treadmill at the speed where they spend most of their training time. After a six-minute warm-up, runners confirmed their pace as long-slow distance pace. vGRF and triaxial accelerations of the sacrum and distal tibia were recorded for 30 s at 100 Hz and 200 Hz, respectively. Collection of vGRF and accelerometer data was synched via an electrical pulse. All data were exported to Matlab for processing.

Cutoff frequencies for the vGRF and triaxial accelerations were determined with a residual analysis. Data were filtered with a dual-pass, fourth order low-pass Butterworth filter at cutoff frequencies of 14 Hz and 36 Hz, respectively.

Triaxial accelerations of the distal tiba were used to calculate the resultant tibial acceleration (RTA).

$$RTA = (X^2 + Y^2 + Z^2)^{0.5}$$

Heel strike and toe-off were defined by vGRF thresholds of 10 N. vGRF, RTA, and vertical sacral acceleration were time-normalized and averaged over the stance-phase of the first ten strides.

A nonlinear autoregressive ANN with external input was developed and trained for each subject. The ANN had one input layer, one hidden layer with 10 neurons, and one output layer. Average stance-phase RTA and vertical sacral acceleration were fed into the input layer, and used to predict the vGRF in the output layer (Figure 1). Performance of the ANN was

evaluated based on the root mean square error (RMSE) and Pearson correlation coefficient. In addition, the percent difference between actual and predicted peak vGRF were calculated to provide pragmatic interpretations of the ANN performance.

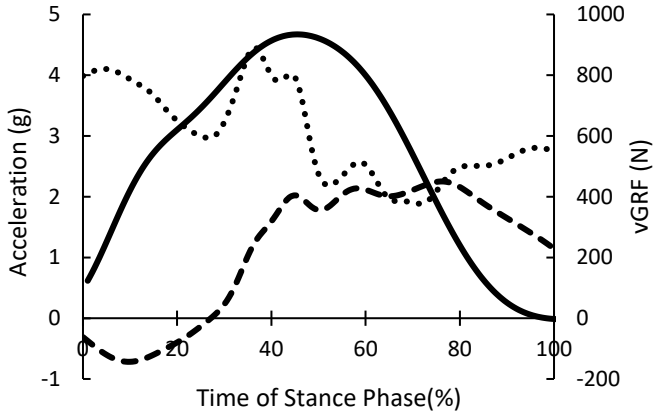

Figure 1: Vertical sacral acceleration (dashed line) and RTA (dotted line) were ANN inputs and used to estimate output vGRF (solid line).

RESULTS AND DISCUSSION

The RMSE for all ANN were very low (Mean ± SD: 0.71 ± 0.06 [N]). Linear regression analysis showed that the group average actual and predicted peak vGRF from all runners were highly correlated (r = 0.992; p = 0.0001; Figure 2). Furthermore, the percent difference between actual and predicted peak vGRF was 0.004%.

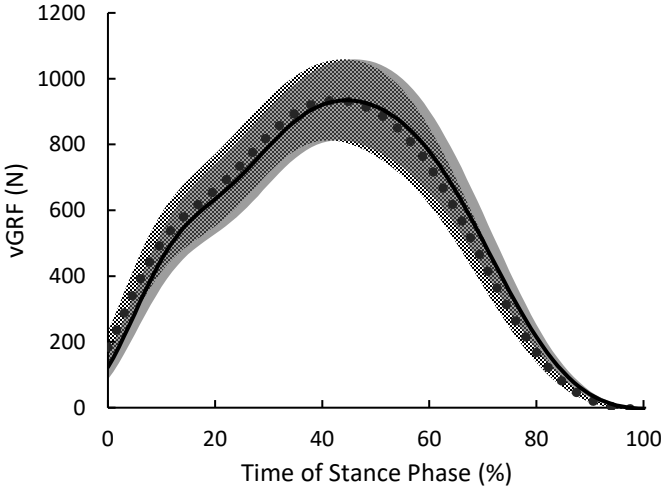

Figure 2: Ensemble average (Mean ± SD) of actual vGRF (solid line ± solid shade) and predicted vGRF (dotted line ± patterned shade).

The performance and prediction capacity of the ANN developed and trained in the current study is much better than previously reported for peak vGRF during running [4]. Niemelä et al. (2017) reported mean standard errors of 0.107 bodyweights in their ANN prediction of peak vGRF. The discrepancy in these results may stem from the difference in input parameters, as Niemelä and colleagues (2017) used primarily stride parameters (e.g., contact time, stride length) as ANN inputs, whereas the current study accelerometer data. Given the close relationship between tibial accelerations and GRF parameters during running [4], the use of accelerometers may present a better option to predict vGRF than stride parameters

The results of this study suggest that wearable technology (i.e., accelerometers) and machine learning techniques can be used to accurately predict vGRF during running. In combination, accelerometers and ANN may therefore provide a simple and cost effective alternative to force plates or an instrumented treadmill for researchers who strive to obtain vGRF data during running. One limitation of this study is that vGRF were collected while runners ran on a treadmill, which may not replicate over-ground running. Future studies should extend the current research into field-based testing.

EFFECT OF FOOT-MOUNTED IMU DESIGN ON IMU-ESTIMATED RUNNING GAIT ACCURACY

Michael V. Potter, Lauro V. Ojeda, Noel C. Perkins, and Stephen M. Cain

University of Michigan, Ann Arbor, MI, USA
email: mvpotter@umich.edu

INTRODUCTION

Body-worn inertial measurement units (IMUs) are increasingly becoming a viable technology for measuring biomechanical parameters outside of traditional laboratory environments. While kinematic measurements obtained from IMUs can be subject to large integration drift errors, such errors can also be minimized through appropriate algorithms. One example is zero-velocity update (ZUPT) algorithms used to estimate full three-dimensional foot trajectories from foot-mounted IMUs [2]. These algorithms exploit the fact that in human walking, the foot reaches nearly zero velocity at some instance during each stance phase. Thus, drift in velocity estimates can be corrected on each stride. While these algorithms are validated for human walking, little validation exists for running speeds. One major barrier to obtaining accurate foot trajectory estimates from such algorithms is understanding the limitations of the inertial sensors that constitute the IMUs.

Bailey, et al. [1] investigated the effect of sampling frequency and accelerometer range on some stride parameter estimates for speeds up to 3.4 m/s, that is speeds much lower than those found in competitive distance running. Additionally, only two accelerometer ranges were considered. This work advances beyond that by simultaneously considering multiple ranges for both the accelerometers and the angular rate gyros and for speeds commensurate with walking through competitive running. In particular, we investigate how various accelerometer and gyroscope ranges typically found in commercial IMUs affect estimates of the total distance travelled at various speeds up to 6.5 m/s.

METHODS

Six subjects (3 male) were recruited for this University of Michigan IRB approved study. Each subject was equipped with one IMU (Opal, APDM, 128 Hz, ±200g, ±2000 deg/s) on each foot. Each subject was asked to complete ten 100-meter walks/runs. A straight 100-meter section of pavement was marked for this study. For each trial, subjects started with both toes on the starting line and were asked to finish with both toes on the finish line. Subjects completed each trial at self-selected paces, but were asked to complete the first trial at a slow walk and gradually increase their speed on each successive trial until completing their tenth trial at a maximal sprint.

For each trial, the subject's average speed was estimated using the time it took a subject to get from the start line to the finish line. Trajectory estimates for each foot were calculated from raw IMU data using a ZUPT foot trajectory algorithm similar to that described in [2]. For each foot, the total distance traveled was then estimated by summing the calculated stride lengths during that trial. The total distance travelled by the subject was then computed as the average of the total distance estimated from the left and right foot-mounted IMUs. The error in the average estimated distance was then reported as the percent deviation from the known 100-meter distance (negative error implying underestimated distance).

We hypothesize that the accelerometer range must be sufficiently large to resolve the major dynamical characteristics of the foot acceleration signal. To investigate this hypothesis, we consider the effects of systematically decreasing the accelerometer range on the aforementioned estimated total distance travelled. In particular, the raw accelerometer data was numerically saturated by setting all values outside a prescribed range to the limits of that range (e.g. to simulate a 6 g accelerometer, all readings above +6 g and below -6 g were set to +6 g and -6 g respectively). The resulting data (including saturated values) were used to estimate the total distance

travelled by the subject using the same method described above. This process was repeated by considering seven accelerometer ranges; namely, 100, 75, 50, 24, 16, 10, and 6 g. Similarly, we repeated the same study considering the effects of decreasing gyroscope range by considering five ranges; namely, 2000, 1500, 1000, 750, and 500 deg/s. The selected ranges in both accelerometers and gyroscopes are typical of commercially available MEMS sensors.

RESULTS AND DISCUSSION

The results for modifying accelerometer range are presented in Fig. 1. Note that even at moderate running speeds, the estimated distance travelled degrades greatly with insufficient accelerometer range. Additionally, for a given accelerometer range, degradation in estimated distance is approximately linear with speed. Best fit lines to the data confirm that errors increases with speed and with smaller acceleration range. For example, the slope of the linear fit for a 100 g accelerometer yields an error rate of -0.4 %/(m/s) while the slope (error rate) for 6 g accelerometer is -6.1 %/(m/s); that is, more than an order of magnitude increase in error rate.

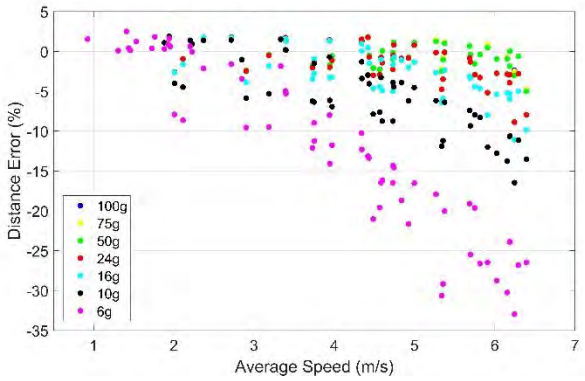

Figure 1: Distance error vs. speed for each accelerometer range investigated.

The results for modifying gyroscope range are presented in Fig. 2. Note again the significant errors in the estimated distance with decreasing gyroscope range and with increasing running speed. Linear fits yield slopes of -0.4 %/(m/s) for a 2000 deg/s gyroscope and -3.5 %/(m/s) for a 500 deg/s gyroscope.

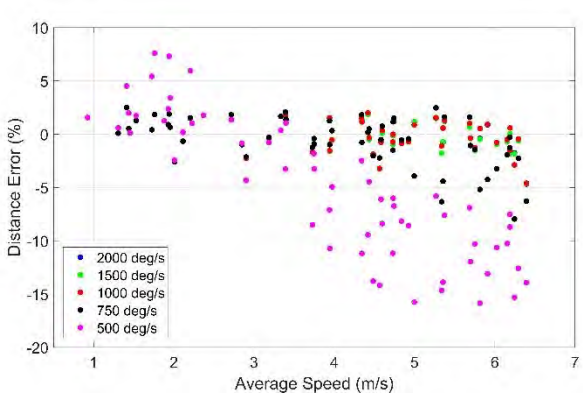

Figure 2: Distance error vs. speed for each gyroscope range investigated.

CONCLUSIONS

The accuracy of the total distance travelled derived from foot-mounted IMUs depend critically on the ranges of the constituent accelerometer and angular rate gyros. In general, accuracy degrades with increased running speed and decreased accelerometer and gyroscope ranges. For the speeds considered in this study (up to 6.5 m/s), the estimates converge for accelerometers having a range of 50 g or higher and a gyroscope having a range of 1000 deg/s or higher. Conversely, significant degradation in accuracy arises when these ranges are at or below 16 g and 750 deg/s respectively, especially at higher running speeds. Future work should investigate the effect of sensor design at even higher speeds such as those observed in elite sprinting. Additional work should also further investigate the cause of the slight degradation observed in estimates with increased speed despite accelerometer and gyroscope ranges that were large enough to prevent saturation.

FEASABILITY OF USING THE HTC VIVE SYSTEM TO COLLECT KINEMATIC DATA

[1]Kate A. Spitzley, [1]Kieley Trempy and [1]Andrew R. Karduna

[1]University of Oregon, Eugene, OR, USA
email: kspitzle@uoregon.edu

INTRODUCTION

Recent improvements in Virtual Reality (VR) technology have exciting implications for the research and rehabilitative sciences. Various modes of VR have been used successfully as intervention modalities in these settings with great success [1,2]. However, VR systems have not yet been used as a method of kinematic data collection. The use of these systems for both intervention and collection has the potential to greatly lower cost and increase portability of motion capture.

The HTC VIVE VR system currently costs $600, a fraction of the cost of research grade optical motion capture systems. Additionally, the entire setup consists of two small lighthouse boxes (about 9 cm x 9 cm x 6 cm), two lightweight handheld controllers and a fully immersive headset. While previous studies have looked at using the VIVE headset as a tracking method with little success, use of the handheld controllers has not yet been explored [3].

The aim of this study is to gather preliminary data to investigate the feasibility of using the VIVE VR handheld controllers to collect position and orientation data. To do so, we will compare the VIVE Virtual Reality sensors and Polhemus Liberty sensors to determine whether kinematic data can be accurately collected from this VR system. The Liberty system has been robustly validated for scientific data collection, we therefore feel comfortable using it as a gold standard for comparison.

METHODS

The VR system was setup as dictated by the VIVE owner's manual, with the lighthouses 6 m apart and connected by the sync cable. Lighthouses were mounted directly to the wall at a height of 2.1 m and angled downward at an angle of 30°, as recommended by the manufacturer. The VIVE headset was placed on a stable shelf within the calibrated space. The magnetic tracking system (Polhemus Liberty, Colchester, VT) transmitter was placed approximately 0.5 m from the sensor. All metal was cleared from the area to eliminate interference. Both systems sampled at a rate of 120Hz.

The VIVE controller and Liberty sensor were mounted to opposite ends of a rigid segment with a common central point of rotation. The rigid segment was mounted to a stable surface with a pegboard setup dictating five angular positions at approximately 0°, 20°, 50°, 70°, and 90°. The rigid segment was moved through fifty permutations of these angular targets. Data were collected from both sensors simultaneously using a customized Unity program.

In order to account for the difference in coordinate systems between the Liberty and VIVE systems, helical axis calculations were used to quantify the angular change in position. This calculation uses the α, β, and γ components of the signal to determine a rotation about a helical axis between trials. As long as the two sensors were rotated about the same axis, they should register the same rotation.

Angular measurement error between the two sensors was quantified as the absolute value of the difference in helical angles as measured by the Liberty sensor and the VIVE sensor in each trial. Additionally, an RMS calculation was used to quantify drift in the signal when the sensors were held in a stable position. Measures of angle and position were taken from ten different trials, two at each of the five angular targets.

RESULTS AND DISCUSSION

Helical angles calculated from Liberty sensor and the VIVE sensor data were similar over the fifty rotations tested (Figure 1).

The average helical angle measurement error between the two sensors was 0.2°± 0.1° and the largest error was 0.5°. Errors were then broken down by degree of angular movement (Figure 2). The highest average errors were seen at 90° of rotation and the lowest at 0° of rotation.

Average RMS over the ten trials did show some differences between sensors (Table 1). The VIVE demonstrated consistently higher measures of drift than the Liberty. However, both systems exhibited translational drift in the sub-millimeter range and rotational drift in the sub-degree range.

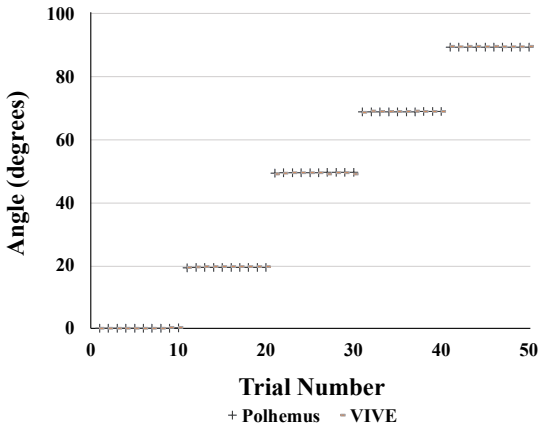

Figure 1: Helical angle of the Liberty and VIVE sensors throughout a series of rotations to angular targets of 0°, 20°, 50°, 70°, and 90°.

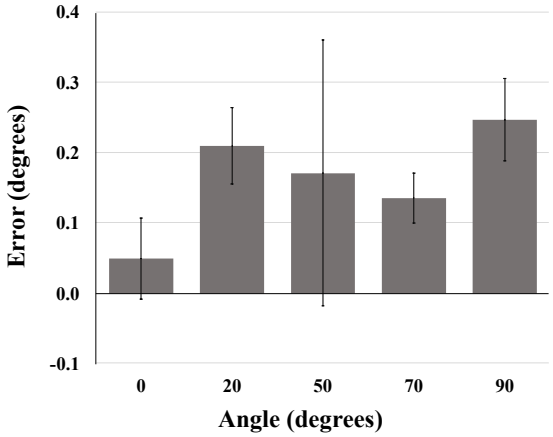

Figure 2: Difference in helical angle measurement between Liberty and VIVE sensors throughout a series of rotations to angular targets of 0°, 20°, 50°, 70°, and 90° (mean +/- sd).

CONCLUSIONS

While previous studies have used the VIVE headset as a tracking mechanism with little success, the handheld controllers are yet to be validated as a viable mode of data collection. Although the data presented here are preliminary in nature, they show promise for future measures of accuracy. It is our hope that with further validation, these controllers will be usable for kinematic data collection.

INTRODUCTION

A higher prevalence of low back pain (LBP) is reported in persons with lower limb amputation (LLA) vs. uninjured individuals; moreover, persons with LLA often report that LBP negatively impacts quality of life [1]. In uninjured persons, movement impairments at the trunk and pelvis during gait, as well as altered trunk muscle activities, have been associated with increased risk for LBP [2]. However, there has yet to be a comprehensive study which examines both trunk kinematic and electromyographic (EMG) data while walking in persons with LLA, and more specifically, compares the influences of spine health (i.e., presence/severity of LBP). Therefore, the purpose of this study is to examine the relationship between patterns of trunk/pelvis kinematics and trunk muscle activations while walking, specifically comparing individuals with LLA with and without LBP.

METHODS

Seventeen persons with traumatic unilateral LLA – 9 with LBP (BP; 8 transtibial (TT), 1 transfemoral (TF), mean±standard deviation age (yrs): 34.7±7.8, stature (cm): 176.8±7.8, mass (kg): 85.4±11.6, and time since injury (yrs): 5.1±2.5) and 8 without LBP (NP; 5 TT, 3 TF, age: 36.8±7.6, stature: 179.9±5.4, mass: 91.8±15.8, and time since injury: 10.0±3.2) – and 6 uninjured controls (CTR, age: 28.2±9.0, stature: 174.5±4.5, and mass: 68.9±7.8) participated in this study. LBP was characterized via the NIH recommended minimal dataset [3]. Individuals walked across a 15m overground walkway at 1.3 m/s, with speed enforced by auditory feedback. An 18-camera motion capture system (Qualisys, Göteborg, Sweden) tracked (120Hz) trunk and pelvis kinematics via 10 reflective markers. Kinematic data were low-pass filtered (Butterworth, 6 Hz). Tri-planar trunk and pelvis angles and angular velocities were calculated in Visual3D (C-motion, Germantown, MD). Global trunk and pelvic ranges of motion (ROM) were determined and trunk-pelvic continuous relative phases (CRP) were calculated in MATLAB (Mathworks, Natick, MA). EMG data were collected (1200 Hz, Motion Lab Systems, Baton Rouge, LA) bilaterally at two levels of the erector spinae (T9 (TES) and L2 (LES)), high-pass filtered (Butterworth, 20 Hz), and full-wave rectified. A 50ms RMS smoothing window was then applied. EMG data were normalized to the signal mean and down-sampled to match kinematic capture rate. EMG data were processed bilaterally for individuals with LLA (i.e., on both the intact and affected side) and for the right side of CTR as no differences were observed between left and right sides. Both kinematic and EMG data were time-normalized to stride. Cross-correlations related EMG and trunk and pelvic rotation time series during both intact and affected strides. Separate one-way repeated measures ANOVAs assessed the effect of group (CTR, BP, NP) on ROM, mean CRP, and magnitudes of cross-correlation coefficients (R), with significance concluded at $P<0.05$. Bonferroni-corrected t-tests assessed pairwise differences ($P<0.0167$).

RESULTS and DISCUSSION

Larger frontal plane trunk ROM were observed in both BP and NP vs. CTR ($P<0.008$). Transverse plane trunk ROM were larger in BP than CTR ($P<0.001$) and tended to be larger than NP ($P=0.032$). A main effect was observed in frontal plane mean CRP, with NP exhibiting smaller (i.e., more in-phase) CRP than CTR ($P=0.013$). Main effects were observed in the R-values of both intact and affected side LES and sagittal trunk angles (Figure 1). Affected-side LES activations more strongly correlated with sagittal trunk angles in BP

and NP vs. CTR (P<0.003). Intact-side LES more strongly correlated with sagittal trunk angles in NP vs. CTR (P=0.005), and with transverse trunk angles in NP vs. BP (P=0.010). R-values of affected -side LES and sagittal pelvis angles were greater in NP vs. CTR (P=0.011) and tended to be larger in BP vs. CTR (P=0.023). R-values of trunk and pelvis angles and TES did not differ between groups.

The observed changes in frontal plane CRP are consistent with prior work and posited to be a trunk stiffening strategy to prevent injury and/or mitigate pain [4]. Though sagittal plane kinematics were similar between groups, R-values of LES activation patterns and sagittal plane trunk and pelvis angles were larger in both BP and NP vs. CTR. This suggests persons with LLA utilize LES to control sagittal plane trunk and pelvis motion during walking. Such an active control strategy may be especially important in the BP group as they tended to walk with more anterior trunk lean than CTR (P=0.023); this anterior shift in center of mass has been associated with an increased risk of falls [5]. While increased LES contributions may compensate for decreases in passive stability, the increased demand on the muscles may contribute to LBP development. NP may minimize this risk by using LES bilaterally to regulate sagittal trunk motions, and distributing the associated demand across both sides. BP, meanwhile, seems to rely more heavily on affected-side LES, which may increase the risk of injury on that side. In the transverse plane, smaller trunk ROM and stronger correlations between intact LES and trunk angles were observed in NP vs. BP. This suggests NP individuals are better able to control transverse plane trunk rotations, likely using LES to limit axial rotations. As increases in trunk and pelvic rotations are associated with increased spinal loads [6], the observed reductions in transverse plane trunk ROM may help mitigate the risk of LBP in the NP group. Thus, interventions training low-back musculature and enhancing trunk postural control strategies in persons with LLA are likely warranted.

INTRODUCTION

Paraplegia due to a spinal cord injury (SCI) results in an impairment of walking function and drastically lowers the quality of life of the affected persons. The use of Functional Neuromuscular Stimulation (FNS) to reanimate lower-limbs to restore walking function is highly desired by the affected population [1]. FNS is the application of an electric field across a nerve to produce a desired muscular contraction and is prescribed as an intervention to rehabilitate or restore gait function in individuals with mobility impairments. Currently, most research efforts focus on using FNS to restore swing phase [2], but little research has been undertaken on the double support phase (DSP) of gait.

During the DSP, when the body is supported by both legs in tandem stance configuration, the body weight load transfers from the trailing leg to the leading leg in anticipation of the subsequent swing phase in able bodied individuals. However, for subjects with SCI using FNS to restore gait, preprogrammed stimulation patterns only keep the subjects standing upright during DSP and does not actively help with weight shifting. This results in the subjects relying more heavily on their upper extremities (UE) to maintain balance and propel the body forward. Normalizing the DSP in FNS driven walking would stabilize transitions between the gait phases and help reduce the voluntary UE effort required, thus prolonging walking durations.

The main goal of this study was to explore the potential of improving the stability of the DSP of gait to reduce UE effort by modulating the stimulation to the available hip and back extensor muscles to actively shift the weight from the trailing leg to the forward leg.

METHODS

The load transfer during DSP in able-bodied subjects was analyzed by asking a male subject to stand in a tandem stance, feet shoulder width apart and one foot in front of the other. He was then asked to shift his weight forward from trailing to leading leg. Using smart insole sensors (iEE, Luxembourg), which measure contact forces at eight points of the foot (as shown in **Figure 1**), the ground reaction forces (GRFs) and center of pressure (CoP) of each foot were captured. The CoP is an epiphenomenon that occurs as a result of the position and movement of the center of mass (CoM) over the base of support and is often used as an indicator for balance.

To explore the potential of recreating the shift in DSP in individuals with SCI, extensive simulations were carried out with an anatomically realistic 3D musculoskeletal model of human standing developed in OpenSim [3]. The model is characterized by 35 degrees of freedom in the lower extremities, torso, and arms and 68 muscle actuators. Passive muscle dynamics were included to account for the hyper flexion and hyper extension restraints. Eight Hunt Crossley contact spheres where included at each foot (same location as the insole sensors) to model ground interaction and provide the GRFs and CoP measurements. Model simulations along with dynamic optimizations were performed to solve for a stimulation paradigm that achieves anterior-posterior (AP) shift of the CoM during tandem stance. To find a stimulation paradigm that is translatable to an FNS system, only 12 muscles that are readily accessible to stimulation, the hip/knee extensor/flexor muscles and the erector spinae bilaterally, were included in the simulations.

The optimization objective cost was to minimize the whole body CoM position error between the actual CoM and the desired shifted CoM to achieve that AP shift by modulating the stimulation inputs to the model.

The stimulation profiles obtained from optimizations were tested on a subject with a C5

tetraplegia (AIS C) and the recipient of a 16-channel implanted FNS system for standing. While standing in a tandem stance the stimulation was modulated in a feed forward manner to coincide with the activation profiles computed through optimizations, which specified increasing activation of the hip extensors. The GRFs and CoP were monitored using the smart insole sensors.

RESULTS AND DISCUSSION

The body weight normalized GRFs and CoP trace from the simulation and human subject experiments are displayed in **Figure 1**. The plots in the Figure show the progression of the CoP and GRF of each foot as the subjects shifted their weight forward. From the able-bodied data, a clear transition of the GRF between the trailing foot and the leading foot can be seen, i.e. the force decreases in the trailing foot (left) and increases in the leading foot (right). This weight transition trend was replicated in the simulation results and in the preliminary testing in the subject with an SCI and implanted FNS system.

As for the CoP profiles, in the able bodied subject (solid blue line) there is a lateral-medial shift of the CoP in the trailing leg and an posterior-anterior shift of the CoP in the leading leg. However, this is not the case for the simulation result (dotted cyan line) and experiments with the SCI subject (dashed red line). For these cases the AP shift of the CoP occurred in the trailing leg and the CoP in the leading leg remained near the heel of the foot. The differences in the CoP traces between the SCI and able bodied subject can be attributed to the limitations of the current system, i.e., the lack of activity of the ankle/foot (i.e., plantarflexor) muscles and limited control of how the foot interacts with the ground.

The preliminary data also demonstrate the feasibility of using the smart insole sensors to provide CoP measurements as feedback for closed-loop control to help maintain balance in real-time.

CONCLUSIONS

Through the appropriate modulation of the stimulation we have successfully produced a more dynamic DSP in subjects using an implanted FNS system. The inclusion of such stimulation paradigms, along with appropriate activation of the ankle/foot muscles, may improve the DSP in a walking neuroprosthesis and should greatly improve the gait stability of individuals with SCI walking with FNS. In addition, the potential extension of these results could lead to the development of a closed-loop control system to further stabilize walking in this population.

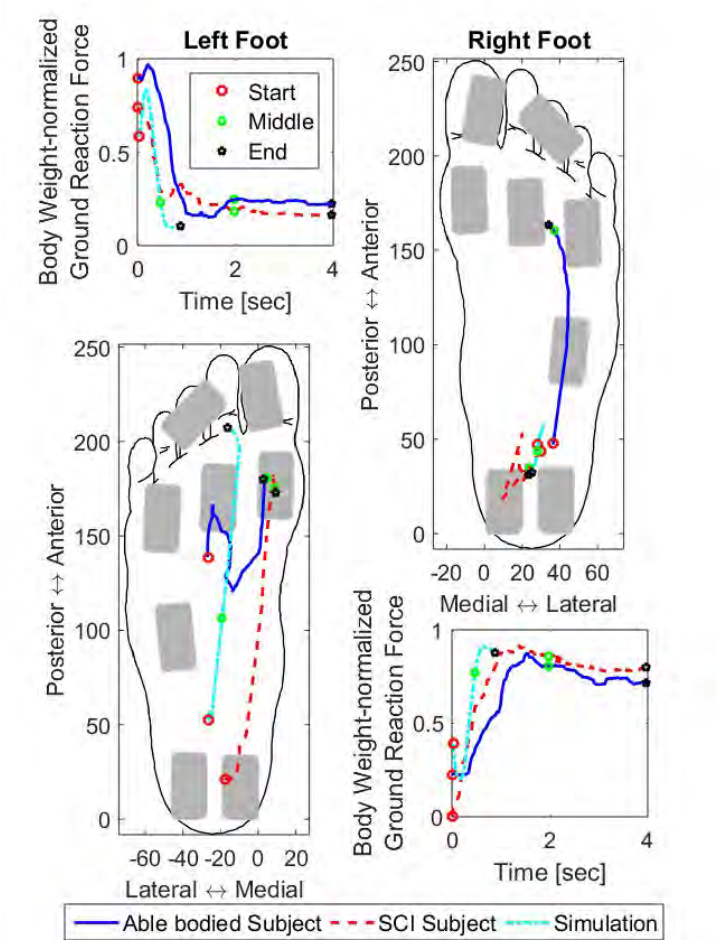

Figure 1: Experimental and simulated body weight normalized GRFs and CoP of each foot in tandem stance pose. The sensing locations of the smart insole sensors are indicated by rectangular grey regions.

INTRODUCTION

Task-specific, perturbation-based balance training has emerged as a method to address the problem of falls among older adults, and it has been shown to improve reactive balance following large postural perturbations [1]. Several studies have implemented this type of training using treadmills to elicit trip-like perturbations [2,3]. In these studies, common outcome measures to assess reactive balance include trunk and stepping kinematics measured using a motion capture system [2,3]. A more "low-tech" method to assess reactive balance, that does not require a motion capture system, may help facilitate this training approach outside of the research setting.

The goal of this study was to develop and validate a low-tech reactive balance rating (RBR) method in the context of trip-like treadmill perturbations. RBR was validated as a surrogate measure of reactive balance by evaluating the strength of association of RBR with kinematic measures that discriminate between falls and successful balance recoveries, and as an indicator of fall risk by evaluating the strength of association with clinical tests that predict fall risk.

METHODS

Thirty-five independent-living residents of senior congregate housing facilities completed the study (24 women, mean age = 82 years). This study was approved by the university Institutional Review Board, and written consent was obtained from all subjects prior to participation.

Trip-like perturbations were induced using a treadmill (Freemotion 800, Freemotion Fitness, Logan, UT). The treadmill was modified to elicit a sudden (~40ms) change in treadmill belt speed (from stationary to an operator-selected walking speed) to induce a forward loss of balance (Figure 1). The RBR protocol involved six posterior treadmill perturbations, including two at each of three speeds (0.36, 0.72, and 1.07 m/s). At the start of each perturbation, subjects stood on the stationary treadmill belt. A rectangular foam block (4×4 cm cross section) was positioned 3-7 cm in front of the toes to elicit a step over an obstacle. Subjects were instructed to, upon treadmill movement, take steps to clear the obstacle to prevent a fall into a safety harness and establish a consistent gait. Subjects were also instructed to take their first step over the block with a particular foot. The safety harness, supported by an overhead gantry, was used to prevent knee or hand contact with the treadmill in the event of an unsuccessful attempt to recover balance.

Figure 1. Example of a treadmill perturbation

Each perturbation was rated using video recordings (recorded at 100 Hz), based upon the quality of the stepping response and the amount of harness or spotter support. For each perturbation, the overall reactive response was rated on a three-point scale (0, 1, or 2; Table 1). These ratings were then summed across the six perturbations to arrive at the RBR, which ranges from zero (worst) to 12.

Table 1: Reactive balance rating rubric

0	substantial harness and/or spotter support **OR** no attempt to step is made **OR** block remains in front of toe after first attempt to step
1	all other cases
2	minimal harness and spotter support **AND** correct foot clears block during first attempt to step (without shuffling) **AND** second step clears block

Four measures of reactive balance kinematics were determined for each perturbation using video recordings (100 Hz) and an inertial measurement unit (APDM, Inc., Portland, OR) worn inferior to the suprasternal notch. These measures included the time from treadmill movement to liftoff of the recovery step (step LO time), time from the onset of treadmill movement to touchdown of initial step over the block (step TD time), length of initial step over the block (step length), and maximum sagittal plane trunk angle from vertical.

Six clinical tests of balance and mobility that predict fall risk were also obtained, including: timed-up-and-go test (TUG), unipedal stance time (UST), maximum step length (MSL), Berg Balance Scale (Berg), Performance-Oriented Mobility Assessment (POMA), and Activities-specific Balance Confidence Scale (ABC).

The strength of association between RBR, reactive balance kinematics, and clinical tests were determined using Spearman rank correlation coefficients. These coefficients were compared using the method described by [4].

RESULTS AND DISCUSSION

RBR had a median of 4 (range 0-11). RBR was significantly associated ($p < .05$) with reactive balance kinematics (Spearman's rho correlations 0.19-0.55), suggesting RBR to be a valid surrogate measure of reactive balance kinematics. RBR had a stronger association with clinical tests than reactive balance kinematics had with these same tests (Table 2), and RBR was 42-60% lower for subjects predicted to be at a high risk of falling, suggesting RBR to be a promising indicator of fall risk.

In conclusion, a reactive balance rating method was developed that associates with important reactive balance kinematics after tripping, and with clinical tests that are predictive of fall risk. RBR has the added benefit over kinematic measures in that it requires minimal research equipment (only a video camera), minimal training, and encompasses multiple aspects of reactive balance after tripping. Therefore, RBR may provide a low-tech, valid measure to assess reactive balance kinematics and indicate fall risk after trip-like postural perturbations.

POSTURAL STABILITY IN UNILATERAL TRANSTIBIAL AMPUTEES USING TWO SUSPENSION SYSTYEMS: SMARTPUCK™ VS LOCK AND PIN

Ashley N. Alunan, Vanessa A. Kellems, Gabby M. Rentuma, Jeremy D. Smith & Abbie E. Ferris
School of Sport and Exercise Science, University of Northern Colorado, Greeley, CO

INTRODUCTION

Individuals with transtibial amputation (TTA) are at an increased risk of falling in comparison with non-amputees due to increased center of pressure (COP) displacements and velocities during quiet standing [1-3]. Quiet standing is often assessed to understand postural stability deficits associated with fall risk in this population [4].

One factor that may contribute to stability is choice of socket suspension system used to attach the residual limb to the prosthetic [5]. Most commonly, lock and pin (PIN) and elevated vacuum systems are prescribed. Research has examined differences in functional outcomes between vacuum and PIN suspension systems and found an improvement in balance, gait, and transfers with vacuum systems [5]. However, differences in postural stability have not been thoroughly examined. Improvements in functional measures may be due to the interaction between the socket and residual limb and an improved fit of the residual limb in the socket.

Furthermore, current vacuum systems tend to experience small leaks which can lead to limb volume fluctuations and ultimately poor socket fit. The SmartPuck™ (PUCK) is a newly developed elevated vacuum suspension system. The PUCK is unlike traditional vacuum systems in that it is housed within the socket and vacuum levels are controlled with a smart phone. Housing the PUCK internally to the socket helps to address the flaw in current vacuums: loss of pressure. The purpose of the present study was to compare postural control of individuals with unilateral TTA using PUCK and PIN socket suspension systems.

We established the null hypothesis there would be no differences in COP displacements, velocities, or frequencies between PUCK and PIN under multiple surface and vision conditions. We hypothesized that stability would decrease as surfaces changed from rigid to compliant and visual input was removed.

METHODS

Four individuals with TTA (71.34 ± 41.52 kg, 1.39 ± 0.08 m; 49.2 ± 27.79 years, K3 - K4) have participated in this study thus far. Inclusion criteria included: amputation resulting from trauma (and otherwise healthy), currently wearing a PIN or PUCK suspension system, at least 6 months of experience in their current prosthesis, healthy residual limb, no neurological cardiac, vascular problems that could limit their function, and able to walk continuously for 10 minutes without assistance.

Two visits occurred in a random order with participants wearing 1) PUCK and 2) PIN. Before each visit participants had at least one week accommodation time for each suspension system.

Participants stood shod with a self-selected stance, with each foot positioned on a separate force plate (AMTI, Watertown, MA). Foot location was measured to ensure similar placement between trials/visits. For each trial, COP and vertical ground reaction forces (GRF, 1000 Hz) were collected. Participants maintained a quiet standing position for 30s for four separate conditions: 1) rigid surface eyes open (RSEO), 2) rigid surface eyes closed (RSEC), 3) compliant surface eyes open (CSEO), 4) compliant surface eyes closed (CSEC). The compliant surface consisted of a viscoelastic mat placed on each force plate. The middle 20s of each trial were analyzed. Dependent variables were calculated according to methods described by Prieto et al. [4]. Vertical GRF was expressed as a percentage of body weight (% BWT) supported by each limb. Due to the small sample size and preliminary nature of the data, statistical analyses were not performed.

RESULTS AND DISCUSSION

Asymmetries in loading of each limb existed between systems and conditions. The intact limb was loaded ~5% more during the rigid surface conditions with both systems. However, the amputated limb was loaded more than the intact limb for the compliant surface conditions. While, asymmetries (~5% BWT) persisted in the PIN across conditions, the PUCK became more symmetrical and only a ~2% BWT difference was seen during the CSEO and CSEC conditions. Proprioception from the feet contributes to maintaining postural control during quiet standing [6]. Amputees experience some loss of proprioceptive feedback due to the absence of one foot. Therefore, the intact foot might assume more responsibility in maintaining balance as seen in the RSEO condition. Interestingly, the amputated limb, in both systems (especially the PUCK), loaded a greater %BW than the intact limb during CSEC which may facilitate proprioceptive feedback in this population.

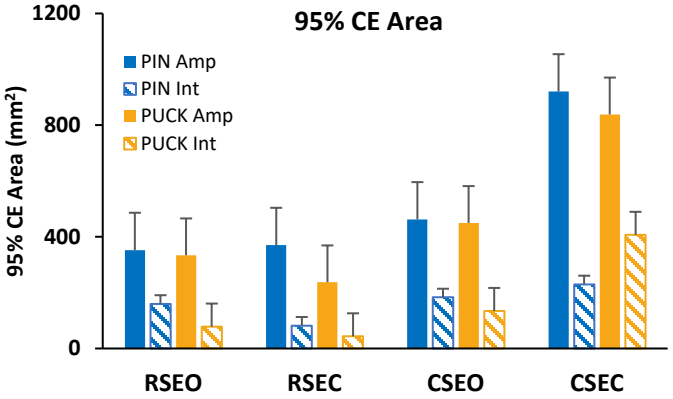

Figure 1. Mean (sd) 95% CE Area for each condition.

In general, the amputated limb had larger 95% confidence ellipse (95% CE) areas than the intact limb regardless of suspension system or condition. It is not unexpected to see increased 95% CE areas in the amputated limb as proprioception has been altered [6]. However, the PUCK amputated limb showed smaller 95% CE areas during the RSEO and CSEC conditions compared to the PIN (Figure 1). Smaller 95% CE areas in PUCK, may suggest improved COP control in the conditions with removed vision, and a lower fall risk [3].

Anteroposterior (AP) velocities increased across eye and surface conditions regardless of suspension type; the amputated limb AP velocities were generally 2-3 times larger than the intact limb. The PUCK showed smaller inter-limb asymmetries and smaller intact mediolateral (ML) COP velocities than the PIN across all conditions except for the RSEO condition (Figure 2). Reduced ML velocities observed in PUCK intact limbs compared to PIN, may also translate to a lower fall risk [3].

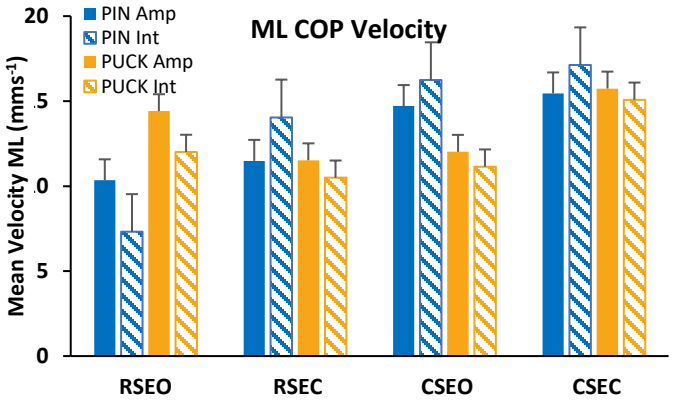

Figure 2. Mean (sd) COP ML velocities for each condition.

CONCLUSION

Our hypotheses were partially supported. Our data did show an increase in 95% CE and velocities as surfaces changed from rigid to compliant and from eyes open to eyes closed. However, a few trends were seen which may suggest differences exist between the PUCK and PIN systems. The decreases in 95% CE and ML velocity may suggest the PUCK improved postural control compared to the PIN systems as surfaces changed from rigid to compliant and from eyes open to eyes closed. The improvement in these measures may be linked to a better fit between the residual limb and the socket. Patients commonly report that the PUCK "feels like a part of me." This sensation may enhance proprioceptive feedback resulting in improvements in postural control. As more participants are added to the current dataset, these trends may become more clear.

Effects of Sound on Static Postural Stability

[1]Chad Anderson, [1]James Aubrey, [1]Alyssa Haley, [1]Thuy-Vi Le and [1]Rahul Soangra

INTRODUCTION

According to the C.D.C., 800,000 patients a year are hospitalized because of fall injuries. Falls are a significant health concern in the US, and can be life-threatening for the most fall-prone population groups.Human beings use several body systems to maintain balance. These include our vision, somatosensory, vestibular, and musculoskeletal systems.

In addition to the sensory input and efferent cues mentioned above, there is also some data indicating that we also utilize our hearing system to maintain our equilibrium or balance in a static state. Kanegaonkar et al. (2017) found that a decrease in auditory input in subjects led to greater postural sway as measured with a Nintendo Wii with a balance board. Rumalla et al. (2015) found that people wearing hearing aids scored significantly higher in both the Romberg on foam test and the tandem stance test than those unaided by hearing aids. In addition to the absence or presence of sound impacting our balance, there has also been some research showing that sound input can have a positive impact on our ability to maintain balance. Ross et al. (2016) found that white noise reduced the radius of the sway patterns of both younger participants and participants over the age of 65. Ross, et al. (2015) also found that the introduction of white noise reduced the sway pattern radius in participants in both vision and non-vision conditions.

There is some paucity in research regarding the effects of white noise and pink noise on postural stability. This study explores the effect of white and pink noise with and without vision. We hypothesize that white noise and pink noise may not affect sway radius, circular area of sway, and ellipse area of sway. The independent variables for this study were: i) ambient noise, ii) no noise, iii) white noise, iv) pink noise, with and without vision.

METHODS

Four healthy subjects, two male and two female, who were recruited from Chapman University. All participants were healthy with no orthopedic, neurological, or balance issues. Also, participants reported no problems with hearing. The protocol for this study was approved by Chapman University Institutional Review Board (IRB#1718H020). All participants provided written informed consent prior to the experiment.

Table 1: Anthropometrics

	Mean	***Standard Deviation***
Age (years)	27.5	+/- 7.77
Height (in.)	66.75	+/- 4.03
Weight (lb.)	158.75	+/- 34.73

Participants were instructed to stand on a force plate in a comfortable position with their hands down to their sides and looking forward. They were instructed to focus on a spot 2 meters infront and fix their gaze on that during trials. The conditions included a combination of either Eyes Open (EO) or Eyes Closed (EC) for vision and either Ambient Noise (AN), No Noise (NN), White Noise (WN), or Pink Noise (PN). Three trials were conducted for each condition. The trials were one minute in duration with 3 minutes in between trials to rest. Each participant completed all twenty-four trials consecutively. The order of the trials and participants were randomized. This eliminated learning effect to some degree and also eliminated the anticipatory ability to prepare for any particular forthcoming trial conditions. The participants used headphones, Sony Model MDR-7506, for the WN, PN and the NN condition. The sound levels were set to 65dB. A 40cm by 60cm Bertec force plate (BP4060, Bertec, Columbus, OH 43229 USA) was used with Motion Analysis Cortex software to

measure center of pressure (COP) displacement over 60 seconds of participants.

RESULTS AND DISCUSSION

Some of the measured COP variables include: range, mean radius, circular area, ellipse area, and mean power frequency. The Romberg ratio (EC/EO) was computed.

We found 18% higher COP sway ranges with pink noise as shown in figure 1a but 13% lower COP way ranges with white noise when compared to ambient noise. We also found that exposure to pink noise increased sway area by 28% while the elliptical sway area decreased by 23% when exposed to white noise from that of ambient noise. We also found that no noise condition increased postural sway area by 19% (Figure 1b).

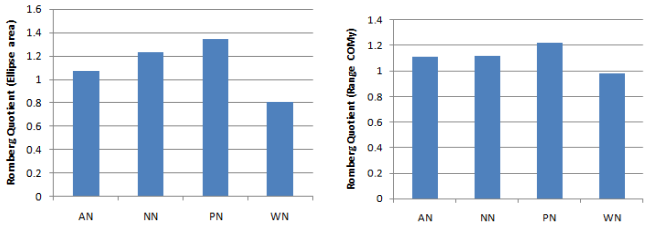

Figure 1: Romberg Quotient

Figure 2: Experiment picture of postural sway

We found improved postural stability for white noise and ambient noise conditions while no noise and pink noise conditions were found unstable.

We found that the trends of Romberg ratios for the white noise condition similar to ambient noise condition. These results corroborate previous study conducted by Bateni, et al. (2013), which found no statistical difference in subjects' COP maintenance between white noise and environmental noise conditions. We also found that the pink noise exposure deteriorated postural stability among the participants. We found that exposure to auditory white noise had improved postural sway variability similar to ambient noise in the subjects and may be useful in therapeutic and rehabilitative settings. These results are consistent with previous studies that assessed the effects of white noise on balance and found a reduced sway variability in the presence and absence of visual information (Ross et al., 2015). Similarly, Lockhart et al. (2011) researched the effects of varying frequencies of sounds on postural swaying during static standing and found that the frequency of sound was directly correlated with swaying in the anterior-posterior direction. Additionally, we also found that the no noise condition induced instability, thus eliminating any environmental noise decreases the amount of information the body is receiving about where it is in space and thus makes it more difficult to maintain balance. Contrary to this, the pink noise consistently showed increased in postural sway or instability. This is an interesting result to note because it is worth investigating whether environments with pink noise are associated with greater losses of balance. For populations that are at an increased fall risk, this is a possibly dangerous environmental factor. A study conducted by Dozza, et al. (2007) found that auditory biofeedback improved postural sway significantly in individuals with bilateral vestibular interruptions when the environment presented with minimal amounts of somatosensory and visual information. Thus, elderly individuals who have reduced visual and vestibular capabilities could be more at-risk of a fall if they are exposed to pink noise at a level or intensity that blocks out some of the natural yet subtle auditory biofeedback that one experiences with ambient noise.

CONCLUSIONS

This is the first study investigating the relationship between pink noise and its effect on postural stability both with eyes open and eyes closed. While previous studies have looked at white noise and no-noise relationship (Ross et al. 2015; Ross et al. 2016), this specific study provided new information on the effects of types of sound on postural stability. Although the sample size is small, it was shown that pink noise was often as dangerous as no noise and deteriorated postural control, especially with eyes closed.

PRELIMINARY INVESTIGATION ON THE EFFECTS OF XBOX 360 KINECT TRAINING ON GAIT AND LIKELIHOOD OF INITIATING A LOSS OF BALANCE

[1] Sara L. Arena, [2] Kevin R. Ford, and [2] Jeffrey B. Taylor

email: sarena@vt.edu

INTRODUCTION

Falls are a major source of injury among adults over the age of 65. Over 57% of falls in older adults are due to slips and trips, which may be due, in part, to an increased likelihood of initiating a loss of balance [1]. Commercially available video gaming systems, such as the Nintendo Wii and Xbox 360 Kinect, have potential as a fall prevention intervention among older adults. Previously, older adults who participated in a training program playing Xbox 360 Kinect games were shown to improve functional balance scores [2] as well as modulate declines in HG strength and improve TUG scores [3] compared to controls. It is possible that these improvements in balance and physical function may also translate to changes in gait and decrease the likelihood of initiating a loss of balance. Therefore, the purpose of this study was to examine the effect of a 6-week Xbox Kinect training program on gait, slip propensity, and trip propensity in older adults.

METHODS

Twelve subjects (78.6 ± 4.7 years; 5 males and 7 females) participated in this study and were randomly assigned to a control group (79.7 ± 5.3 years; 3 males and 3 females) or a treatment group (77.2 ± 4.6 years; 2 males and 4 females).

All participants reported to the laboratory twice for measurement of gait and physical function (baseline and post intervention). Results on physical function have been reported previously [3]. Participants completed three gait trials down a walkway at a self-selected speed. The position of select anatomical landmarks were sampled at 200 Hz using a 14-camera motion capture system (Motion Analysis Corporation, Santa Rosa, CA, USA). Ground reaction forces (GRF) were sampled at 1200 Hz using in-line force platforms (AMTI, Watertown, MA, USA).

The required coefficient of friction (RCOF), the ratio of resultant shear to vertical GRF generated during gait, was used to quantify slip propensity. A higher RCOF value implies a greater shear force is needed to keep the foot from slipping [4]. Minimum toe clearance (MTC), the lowest vertical position of the foot during the swing phase of gait, was used to quantify trip propensity. A smaller toe clearance value implies an increased risk of tripping [5].

The treatment group participated in a 6-week Xbox 360 Kinect training program in which each participant completed 3 training sessions per week, each session lasting 30 minutes. Participants played 6 different games from Kinect Adventures!, with game order randomized for each training session. In brevity, the games challenged participants to squat, move around the room, and reach with arms and legs to control their avatar for the various game objectives.

Dependent variables included gait speed, step length (normalized to body height), cadence, RCOF, and minimum tow clearance (normalized to foot length). Independent t-tests were performed on pre-intervention data to ensure groups (control, treatment) had similar gait characteristics and propensities prior to implementation of the intervention. Differences between pre and post intervention were then calculated for each dependent variable. Independent t-tests were used to examine the influence of group (control, treatment) on change in all dependent variables. Statistical analyses were performed using JMP Pro 13 (SAS Institute, Inc., Cary, NC) with a significance level of $p \leq 0.05$.

RESULTS AND DISCUSSION

No significant differences were found between the control and treatment group prior to the implementation of the intervention ($p > 0.28$).

Minimum toe clearance was found to decrease in the treatment group (6.66 ± 4.47 %FL) while minimally changing in the control group (0.02 ± 2.83 %FL) (p=0.01; Figure 1). Treatment and control groups had similar changes in gait speed, step length, step width, cadence, and RCOF (p>0.31).

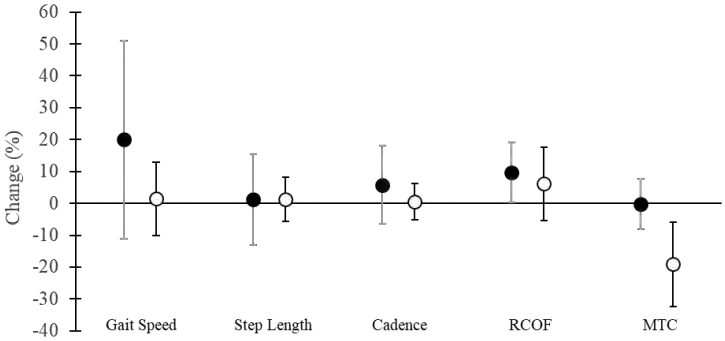

Figure 1: Change in dependent variables for control (black) and treatment (white) participants as a percentage of pre-intervention measurement.

Previous work has demonstrated a change in clinical measure of balance and physical function in older adults with the implementation of an Xbox 360 Kinect training program [2, 3]. Our results suggest that despite improvements in these clinical measures, training on the Xbox 360 Kinect for 6 weeks may not translate to activities of daily living, such as gait, and may not positively influence risk factors for falling. In contrast, Lee and Shin [6] found gait speed and cadence to increase with longer training sessions (50 minutes) and program (10-weeks) in older adults with diabetes mellitus. It is possible that a longer training program with longer sessions could result in changes in mobility and likelihood of initiating a fall, but it is not clear if the results of Lee and Shin [6] are applicable to otherwise healthy older adults.

Interestingly, MTC was found to decrease with Xbox 360 Kinect training, indicating a greater risk of initiating a trip. This may be due to an unintended training effect. The selected games require sudden, and quick movements, and repeated exposure to these games may have lead participants to adopt smaller amplitude motion in order to achieve the goal in the desired time. Additionally, we have previously found higher Xbox 360 Kinect game scores were associated with a higher RCOF, indicating a greater risk of initiating a slip [7]. In contrast, in the current study, RCOF did not change significantly with training on these games despite an increase in game scores (data not shown), and indicates that the training does not influence the likelihood of initiating a slip.

Several limitations warrant discussion. First, all participants were highly functioning older adults and it is possible that our participants exhibited a ceiling effect. Second, 6-weeks may not have been a long enough program to generate changes in gait or likelihood of initiating a fall. Third, the small sample size limits the statistical power of our results.

CONCLUSIONS

A 6-week training program utilizing the Xbox 360 Kinect resulted in an increased likelihood of initiating a trip and no significant changes in gait speed, step length, cadence, or likelihood of initiating a slip. Our results imply benefits previously demonstrated by an Xbox 360 Kinect training program may not translate to changes in mobility or frequency of initiation of a loss of balance. Future research should explore if a longer program and session time may achieve desired changes in a healthy older adult population and if higher risk populations may incur a more positive effect of such training programs.

POSTURAL STABILITY, VERTICAL STIFFNESS, AND LOWER-EXTREMITY JOINT MOTION DURING MULTI-DIRECTION SINGLE-LEGGED JUMP-LANDINGS

INTRODUCTION

Diminished time to stabilization (TTS) may be a risk factor for ACL injury [1]. While TTS does not directly evaluate the biomechanical mechanisms associated with ACL injury, the kinetic profile displayed during a jump-landing task serves as a surrogate measure of the capacity of the lower-extremity neuromuscular system to achieve stability during a shift from a dynamic movement to a stationary position over the base of support. High vertical stiffness (K_{vert}) during a jump-landing may indicate poor attenuation of ground reaction forces through controlled sagittal plane knee flexion, which may challenge the lower-extremity's passive stability and increase the risk for ACL injury [2]. The purpose of this study was to compare TTS, K_{vert}, and knee joint motion during a backward, forward, medial, and lateral single-legged jump-landing. It was hypothesized that TTS and K_{vert} would be greatest during the backward jump-landing.

METHODS

Seventeen male and female recreational athletes (22.2 ± 3.0 yr, 1.75 ± 0.08 m, 73.4 ± 12 kg) participated in this study. A randomized, repeated measure design was used so that three trials of a backward, forward, medial, and lateral single-legged jump-landing were completed barefoot on the non-dominant leg.

Landings were performed on an in-ground force plate and three-dimensional motion capture was used to quantify lower-extremity kinematics. For the forward direction, participants took two steps, hopped on the test leg over a 15-cm hurdle placed equidistant to their leg length from the center of the force plate, and landed on the same leg on the force plate. For the other directions, the hurdle was placed directly next to the force plate, and the participants hopped over the hurdle on the test leg and landed on the same leg on the force plate. Participants were instructed to keep their hands on their hips, stabilize as quickly as possible, and remain motionless for the remainder of the 10 s sampling period.

Initial contact and peak vertical ground reaction force (vGRF) were identified to determine sagittal plane knee angles during weight acceptance. TTS was quantified as the time it took for the vGRF to stabilize within 5% of the subject's body mass for 1 s after landing. K_{vert} was calculated as the relative peak vGRF divided by the change in the participant's center of mass vertical position during the weight acceptance period. Separate one-way repeated measures ANOVA were used to examine the effect of jump-landing direction on TTS, K_{vert}, and knee angles. Tukey corrected pairwise comparisons were used where appropriate to identify the source of the effect. P was initially set to < 0.05.

RESULTS AND DISCUSSION

There was a significant effect of jump-landing direction on TTS ($F = 3.45$, $P = 0.03$)(Fig. 1). Participants took longer to stabilize during the medial jump-landing direction than during the forward direction ($P < 0.01$). A significant effect for jump-landing direction on K_{vert} was also identified ($F = 55.0$, $P < 0.01$)(Fig. 2). Participants landed with greater stiffness during the forward jump-landing than during the other three directions ($P < 0.01$). Finally, a significant effect of jump-landing direction on knee angle excursion during weight acceptance was identified ($F = 45.8$, $P < 0.01$)(Fig. 3). Participants had less weight acceptance knee flexion excursion during the backward jump-landing than during the forward ($P < 0.01$), lateral ($P < 0.01$), and medial ($P < 0.01$) directions.

Participants had greater weight acceptance knee flexion excursion during the forward jump-landing direction than during the lateral ($P < 0.01$) and medial ($P < 0.01$) directions.

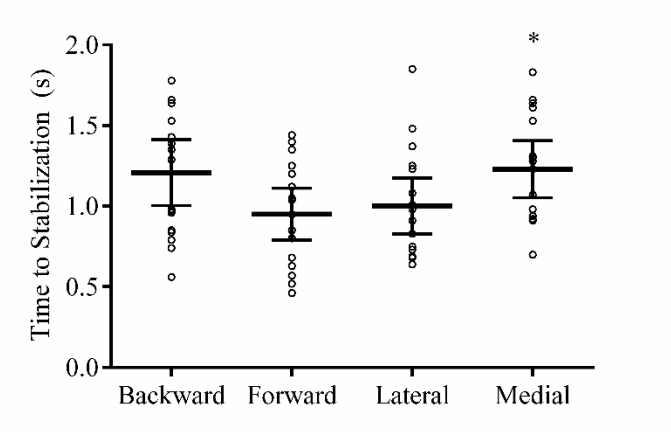

Figure 1. Time to stabilization for the backward, forward, medial, and lateral single-legged jump-landing directions. Thick lines: means; whiskers: 95% confidence interval; circles: participants. * significantly different from forward direction.

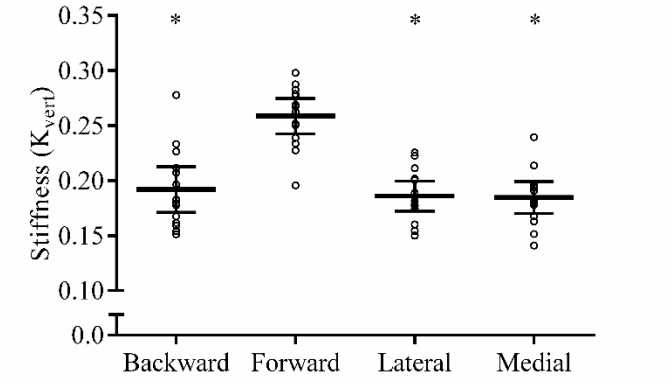

Figure 2. Vertical stiffness for the backward, forward, medial, and lateral single-legged jump-landing directions. Thick lines: means; whiskers: 95% confidence interval; circles: participants. * significantly different from forward direction.

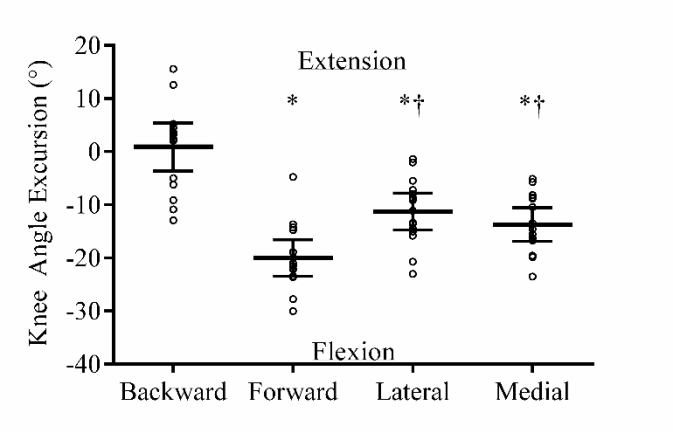

Figure 3. Change in sagittal plane knee angle between initial contact and peak vertical ground reaction force. Positive values indicate movement towards extension, negative values indicate movement towards flexion. Thick lines: means; whiskers: 95% confidence interval; circles: participants. * significantly different from backward direction. † significantly different from forward direction.

Different jump directions appear to challenge different aspects of landing biomechanics. Although TTS seems to be the best during the forward jump-landing, participants tended to land with greater stiffness than in the other directions. This is possibly due to greater horizontal velocity of the center of mass at take-off. Despite demonstrating comparable stiffness to the lateral and medial directions, participants' weight acceptance knee flexion excursion was close to 0° during the backward jump-landing. This may be due to the unique proprioceptive demands of a backward jump-landing.

Jumps should be performed from multiple directions in order to fully elucidate potentially injurious landing biomechanics. This is because one injury mechanism may be displayed for a given direction while others are not.

PERTURBATION-EVOKED LATERAL STEPS IN OLDER ADULTS: WHY TAKE TWO STEPS WHEN ONE WILL DO?

INTRODUCTION

Many older adults at risk for falls have difficulties stepping sideways as a protective response to a lateral loss of balance. Younger adults tend to use a single lateral step while older adults are more prone to taking multiple steps [1]. Multistep strategies are associated with an increased risk of inter-limb collisions, more complex step trajectories [2], and an increased risk of falls [3]. The first step of a multistep strategy has been suggested to be preparation for executing a subsequent lateral step with the ipsilateral leg, relative to the fall direction [4]. Although the first step of a multistep strategy has been proposed to be less stable [4,5], it may be easier to execute due to passive unloading that facilitates more rapid swing-foot lift off [4]. The characteristics of the second step in a multistep step strategy are largely unknown.

The primary purpose of this study was to characterize: 1) the spatio-temporal step parameters; and 2) the stability of single and multi-step strategies of older adults to unpredictable lateral waist-pull perturbations. We hypothesize that the first step of a multistep strategy is less stable than a single lateral sidestep. Furthermore, we hypothesize that the first step of a multistep strategy is preparation for a subsequent lateral step. Therefore, we expect lateral steps to have similar spatio-temporal and stability characteristics whether they are the first or second step.

METHODS

This study focused on strategies that consisted of a medially directed sidestep (MSS) followed by a lateral sidestep (LSS2) or a single lateral sidestep (LSS1, 19 and 14 of 51 trials respectively). The stepping strategies were evoked from seventeen community dwelling older adults (11 females and 6 males; 72.7±5.7 years old; 165±2 cm; 72±3 kg) out of a group of 21 subjects that received 36 randomly applied, motor-driven lateral waist-pull (described previously [6]) perturbations at six displacements (5, 8.6, 12.1, 15.7, 19.3, 22.8 cm), velocities (9, 18, 27, 36, 45, 54 cm/s), and accelerations (180, 360, 540, 720, 900, 900 cm/s^2). Trials with a leftward pull at the perturbation level at which the mean protective stepping response became a multistep reaction were considered for analysis.

Three-dimensional motion-capture (Vicon) was used to collect kinematic data (sampling rate = 120 Hz, low-pass filtered at 6 Hz using a dual-pass fourth-order digital filter). Forty-four retro-reflective markers were used to calculate whole-body center of mass (COM) position [7]. Step initiation was defined as the time that the lateral ankle marker's vertical velocity exceeded 0.07 m/s [8] and was verified visually. Step termination was defined as the 2nd zero crossing of the lateral ankle vertical velocity.

Stability was quantified using the margin of stability (MOS) defined by Hof [9],

$$MOS = BOS - \left(x + \dot{x}/\sqrt{g/L}\right),$$

where BOS is the base of support, g is gravitational acceleration, L is the average body COM height prior to perturbation, and x and $\dot{x}$ are the COM displacement and velocity. Positive MOS values indicate a stable state while negative values imply instability. The MOS and COM velocity were calculated at step initiation, during swing (maximum COM velocity and minimum MOS), and at step termination. The lateral limit of the BOS was the most lateral marker of the toe, lateral malleolus, or 5th metatarsophalangeal joint depending on the orientation of the foot.

A one-way repeated measures analysis of variance was used to test the effect of step type (LSS1, MSS, and LSS2) on the dependent variables (pull magnitude, step initiation, swing time, step length, COM displacement, COM velocity, and MOS). Data were rank transformed to avoid violating the underlying assumptions of the ANOVA. The method of Benjamini and Hochberg [10] was used to control for multiplicity of testing.

RESULTS AND DISCUSSION

Step initiation, step length, COM displacement, COM velocity during swing, and MOS were significantly affected by step type (Table 1). Step length was shorter, COM displacement and COM velocity during swing were smaller, and the MOS was larger at step initiation and during swing for MSS compared to LSS1. The MOS at step termination was smaller for MSS compared to LSS1. Step initiation occurred later, COM displacement and COM velocity during swing, and MOS at step initiation were smaller for LSS2 compared to LSS1. The MOS for LSS1 was smaller than LSS2 during swing.

The results do not entirely support our hypothesis. A MSS is less stable than a LSS1 only at step termination. Even though all three step types do not reach the limit of stability (the point at which a step must be taken) at step termination, a LSS2 was required to regain balance following a MSS. The MOS at step termination is comparable between a LSS1 and a LSS2, which is likely an important factor in avoiding additional compensatory steps. This result is consistent with previous studies of lateral balance that reported stepping may occur before the limit of stability is reached (e.g. [11]).

While a MSS may be taken in preparation for a LSS2, a MSS also appears to modify the subsequent LSS2 (delayed step initiation, shorter COM displacement, slower COM velocity during swing, and improved MOS during step initiation and swing) compared to a LSS1. Taking a MSS then a LSS2 extends the time it takes to recover balance and achieve a MOS sufficient to terminate compensatory stepping, introducing the risk of inter-limb collisions, more complex step trajectories [2], and increased incidence of falls [3] compared to LSS1.

INVESTIGATION OF EXPOSURE TIME ON DYNAMIC STABILITY MEASURES DURING COMMON ASSESSMENT TASKS

K. Otto Buchholz, Sara Nash, Arastoo JahanAfrooz, Gary D. Heise and Jeremy D. Smith

University of Northern Colorado, Greeley, CO, USA

INTRODUCTION

Dynamic stability is the postural control system's "ability to maintain balance while transitioning from a dynamic to a static state" [1]. Commonly used in clinical and research settings, dynamic stability assessment tasks include the forward hop (FWH), drop landing (DPL), and lateral hop (LAH). Differences between testing protocols, particularly the amount of exposure individuals have to the task prior to data collection, may influence the measures used to quantify stability in many of these tasks. In many instances, the amount of exposure to the task provided prior to the data collection is not reported. For example, in a forward hop landing task the same research group in one article [1] described that participants were given as many practice trials as they needed without providing the number of trials, but in a subsequent article [2] reported that participants completing the same task on average used ~5 practice trials. In the latter paper [2], the dynamic stability indices were slightly lower than the first for the same task [1].

Other measures of hopping performance have been shown to improve with further exposure to the task, such as total hop distance [3, 4]. In addition, rarely is landing velocity (LV) reported in dynamic stability studies. The combination of exposure time and landing velocity at impact may provide insights into differences in stability measures across studies. Thus, the purpose of this study was to determine whether measures of dynamic stability, such as Time to Stabilization (TTS) and the Dynamic Postural Stability Index (DPSI), are influenced by the amount of exposure to the task and landing velocity at impact.

METHODS

Seventeen healthy participants (10 males: 24 ± 3 years, 174 ± 9 cm, 80.1 ± 15.4 kg; and 7 females: 23 ± 2 years, 167 ± 8 cm, 65.2 ± 5.2 kg) from the general population who were not currently participating in any formal stability training were recruited for this study. All subjects were injury-free for six months prior to the study.

Each participant performed 30 barefoot repetitions of one hop task (DPL, FWH, LAH) per day, with a different task each day. At least 24 hours were required between collection sessions to allow for recovery. No practice trials were allowed prior to collection. The foot the participant would use to kick a ball determined leg dominance. Each repetition required jumping from both feet and landing on their dominant leg to balance for 20 seconds. The participant repeated the trial if balance was lost. The DPL was performed from a 30 cm box placed at the edge of the force plate. Participants stepped off of the box and landed to stabilize. For FWH and LAH tasks, subjects started at a line 70 cm from the center of the force plate, clearing a 15 cm hurdle. For FWH, their toes were at the line and the lateral edge of their dominant foot for the LAH. Each task was performed in 3 sets of 10 repetitions with five-minutes of seated rest after each set.

The DPSI (based on 3 s) [1] and TTS (vertical force) [5] trial means were analyzed for trend as 30 individual trials using a second order polynomial, as well as being grouped into bins (3 or 5 means per bin) and tested with a repeated measures ANOVA ($\alpha < 0.05$). Individual scores were also assessed with ICC. LV was analyzed as a correlation with each measure.

RESULTS AND DISCUSSION

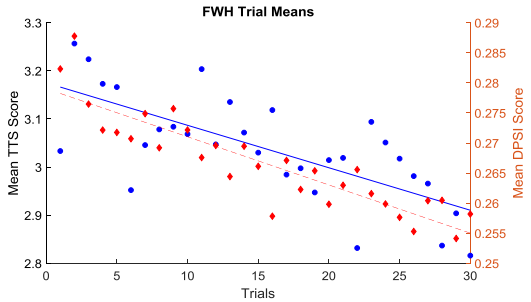

Figure 1: TTS and DPSI trial means of all participants

Individual trials were examined for trend (Fig. 1). The derivative of the second order polynomial fit to the DPSI trial means indicated the minimum of the curve occurred at trial 20 (DPL), 35 (FWH) and 23 (LAH). This indicates that the overall trend was decreasing up until that point, with FWH not reaching a minimum within the protocol.

Means were then grouped into bins (Fig. 2), which did not show a significant decrease in score (RM-ANOVA) between bins, except within DPSI scores for FWH (Table 1).

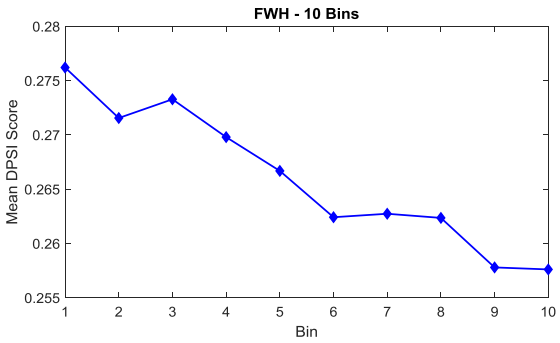

Figure 2: DPSI mean score grouped by 3 means per bin

Model Significance	DPL	FWH	LAH
6 Bins	0.100	0.025*	0.287
10 Bins	0.156	0.043*	0.128

Table 1: Model significance (p-value) in two different analysis methods by task using DPSI

Using individual participant scores per trial, overall ICCs were calculated to assess reliability of the scores over each protocol. The ICC dot plot for FWH DPSI is shown in Figure 3.

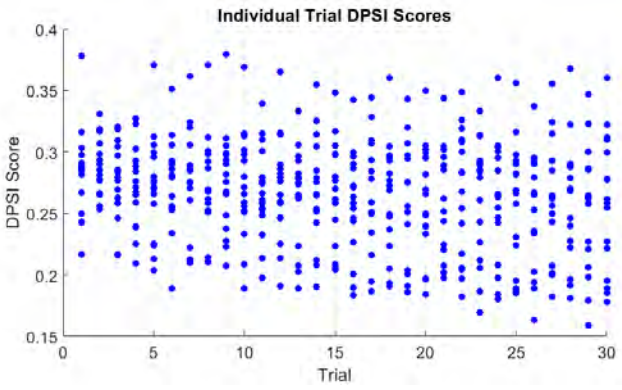

Figure 3: ICC (0.197) dot plot of FWH DPSI calculation

ICC values indicated very low reliability for both TTS (0.015 - 0.191) and DPSI (0.048 - 0.197) over the course of the 30-trial protocol for all conditions. Thus, these low ICCs indicate that data from trial to trial were not repeatable. Previous researchers [2–4] have also suggested continued score improvement with more trials, with Bolgla et al. [3] indicating that after three practice trials (FWH) subjects still consistently improved over the five test trials. They suggested that optimal performance may require more than eight trials. Our results were consistent with this trend, but more importantly indicated that this improvement continued over the course of 30 trials.

Correlations between DPSI, TTS and landing velocity are shown in Table 2.

Correlations	DPSI Vs. TTS	DPSI Vs. LV	TTS vs. LV
DPL	0.656	0.759	0.612
FWH	0.553	0.768	0.576
LAH	0.207	0.467	0.210

Table 2: Correlations (Pearson's r) between scores and each score with landing velocity

Landing velocity showed moderate to strong correlations with the TTS and DPSI scores. This indicates that an increased landing velocity was related to worse stability (higher DPSI and TTS). When testing stability indices of dynamic tasks, landing velocity should either be controlled for or accounted for during the analysis phase.

CONCLUSIONS

These results indicate that exposure time to the task influences DPSI and TTS. If using these measures, every participant should have the same amount of practice and test trials to ensure equal task familiarity between participants. In addition, landing velocity influenced these stability measures and should be controlled for when using these measures to assess stability. One other interpretation of these outcomes might be that DPSI and TTS are not quality measures of stability given the lack of repeatability from trial to trial.

INFLUENCES OF LOW BACK PAIN ON THE ENERGY CONTRIBUTIONS OF THE HIP AND SPINE DURING GAIT AMONG PERSONS WITH LOWER LIMB LOSS

INTRODUCTION

Persons with vs. without unilateral lower limb loss (LL) walk with altered trunk-pelvic mechanics that, with repeated exposure, presumably represent a mechanistic pathway for low back pain (LBP) [1,2]. Specifically, persons with LL walk with increased lateral trunk motion over the stance limb, posited as an adaptive strategy to compensate for absent or weak musculature in the lower extremity. Moreover, hip ab/adduction moments may compensate for increased lateral trunk motion over the stance limb, suggesting an altered motor pattern that redistributes energy/power during gait [3]. Among uninjured individuals, impaired hip abductor strength is associated with LBP, suggesting impaired load/energy transfer between the lower extremity and lumbar spine. While persons with vs. without LL demonstrate increased positive phases of joint powers at L5/S1 in the frontal plane, the contributions of the unaffected hip powers to lumbar spine mechanics are unknown. Further, to date, no study has compared frontal plane low back and hip movement strategies among persons with limb loss and varying degrees of disability associated with LBP. Thus, the objective of the current study was to determine the contributions of hip and low back joint powers (L5/S1) to LBP-related disability among persons with limb loss, hypothesizing that persons with greater LBP disability will demonstrate larger power generation through the unaffected hip and low back.

METHODS

Nineteen persons with traumatic unilateral lower LL (n = 7 transfemoral, n = 12 transtibial; mean ± standard deviation age: 31.9 ± 12.5 yrs, stature: 1.8 ± 0.1 m, body mass: 89.1 ± 13.7 kg, and time since injury: 8.6 ± 7.0 yrs) participated in this cross-sectional study after providing written informed consent to study procedures approved by the local IRB. Acute LBP was characterized using a Visual Analog Scale. The presence of chronic LBP was determined via self-report using the Oswestry Disability Index (ODI; "I have 'chronic pain' or pain that has bothered me for 3 months or more"), and was further quantified using ODI percent disability. Participants walked at 1.3 m/s (±10%) along a 15m walkway with full-body biomechanical data captured using an 18-camera system (Qualisys, Göteborg, Sweden) and six force platforms (AMTI, Watertown, MA) embedded within the walkway. Marker positions and ground reaction forces (GRF) were smoothed using a fourth-order dual-pass Butterworth filter with cutoff frequencies of 6 Hz and 45 Hz, respectively. L5/S1 and hip joint powers were calculated as the product of joint moment and angular velocity using 6DOF inverse dynamics in Visual3D (C-motion, Germantown, MD) and normalized to body mass. Positive/negative work at the L5/S1 and hip joints, calculated as the total areas under the joint power curves, respectively indicate mechanical energy generation/absorption.

Multiple regression was used to determine the influences of frontal plane L5/S1 and hip joint powers on ODI percent disability among persons with LL. Independent t-tests were used to determine differences in work between persons with and without chronic LBP at L5/S1 and hip joints throughout the gait cycle ($P < 0.05$).

RESULTS AND DISCUSSION

After controlling for time since amputation and stride width, the total positive and negative powers for both L5/S1 and hip joints significantly predicted

LBP-related disability ($F_{(6,18)}$ = 5.11, P = 0.008), with all but positive hip power significantly contributing to the prediction. Total positive and negative work through the unaffected hip and low back explain 58% of the variance in the model. While there were no significant (P > 0.11) differences in the total work at L5/S1 or hip joints between persons with LL whom identified themselves as having chronic LBP (acute pain = 1.4 ± 1.7, ODI percent disability = 26.5 ± 24.7) and those who did not (acute pain = 0.1 ± 0.3, ODI percent disability = 11.3 ± 12.4), there were distinct differences in joint power waveform characteristics throughout the gait cycle. At L5/S1, persons with LL and chronic LBP demonstrate greater energy absorption during loading response, whereas those without LBP demonstrate greater energy absorption just prior to toe-off (Figure 1). Persons with LL and chronic LBP walk with greater trunk motion during early stance yet demonstrate larger energy absorption at the hip. Although not reported here, this is likely the result of greater hip joint angular velocity, counteracting larger trunk lateral flexion and contralateral pelvic drop during early stance, as a means to maintain mediolateral balance. Such a hip dominant strategy could also have implications for the increased joint loading and prevalence of hip osteoarthritis among persons with LL [5]. The two distinct negative power phases at L5/S1 among persons with LL without chronic LBP are similar to previous reports [4]; in contrast, persons with LL and chronic LBP demonstrate a smaller L5/S1 negative peak power at toe-off that is coupled with a larger positive peak power at the hip. The larger power generation at the hip suggests an active hip strategy to control the mediolateral movement of the center of mass as it moves from peak lateral flexion over the stance limb towards the subsequent heel-strike of the affected limb. Thus, persons with limb loss and LBP may adopt a compensatory strategy to avoid pain and/or to account for impaired neuromuscular control of the trunk. Future research should focus on developing interventions geared towards improving neuromuscular control strategies of the trunk-pelvic-hip complex, thereby reducing possible mechanisms of LBP-related disability.

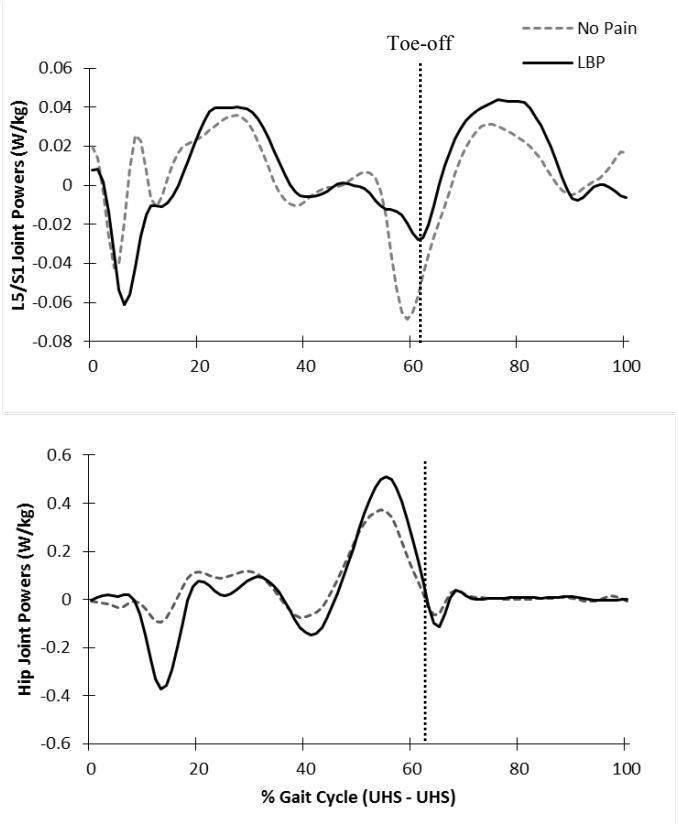

Figure 1: L5/S1 (top) and unaffected hip joint (bottom) powers during the gait cycle (unaffected heel strike (UHS) to unaffected heel strike (UHS)) among persons with limb loss with vs. without self-identified chronic LBP.

UNWINDING THE CONTROL OF WALKING TURNS

[1] Carolin Curtze

[1] Oregon Health and Science University, Portland, OR, USA
email: curtze@ohsu.edu

INTRODUCTION

The concept of the extrapolated center of mass (XcoM) suggests a simple rule for stable walking: at initial contact the foot is placed at a certain distance behind and lateral to the XcoM, thereby redirecting the movement of the XcoM into a sinusoidal trajectory [1]. In a simulation of walking turns, Hof [1] showed that turns can be achieved by rotating these forward and lateral offsets over a certain angle.

The goal of this study is to experimentally test the proposition that turning is controlled by changes in the mediolateral foot placement relative to the XcoM. It was hypothesized that an increase in lateral foot placement leads to a change in walking direction during the subsequent step.

METHODS

Three healthy participants (2 male / 1 female, age 66-76 years, height 1.62-1.77 meter, and weight 63-78 kg) were recruited for this study.

Participants performed preplanned turns to the left and right, at different turn angles (45, 90, 135, and 180 degrees) while walking at normal and fast speeds. Floor markings similar to a clock face consisting of a turning point in the center and turn angle marks in the periphery were used to indicate turn angle. The experimental protocol was approved by the local Medical Ethics Committee. All participants gave their informed consent.

Full-body kinematics were acquired using 12 infrared motion capture cameras (Report-H (8) and Osprey (4), Motion Analysis Inc.) sampling at a frequency of 120 Hz. A total of 30 reflective makers were attached bilaterally to the following bony landmarks: head (front, back, and lateral), thorax and arms (acromion, sternum, offset, lateral epicondyle of humerus, and distal radius), pelvis (sacrum, anterior superior iliac spine (ASIS)), legs (thigh, lateral epicondyle of the femur, shank, lateral and medial malleolus), and feet (1st and 5th metatarsal head, and posterior calcaneus). All data were low-pass filtered at 6Hz using a fourth-order Butterworth filter.

The position of the XcoM [1] was defined based on the inverted pendulum model:

$$\mathrm{XcoM} = \mathrm{CoM} + v_{\mathrm{CoM}} / \omega_0$$

in which CoM denotes the positon of the center of mass, and v_{CoM} the velocity of the CoM. The eigenfrequency of a pendulum is denoted as

$$\omega_0 = \sqrt{g/l},$$

where l is the effective pendulum length defined as mean CoM height.

During straight walking the mediolateral direction can be defined as perpendicular to the overall walking direction. During turning, the coordinate frame changes with the arc of the walking path. This constant change in reference frame is accounted for by transforming position data from a global (Figure 1) to a local/pelvis based coordinate system. Subsequently, the offset between the center of mass of the foot and XcoM in mediolateral (b_{ml}) and anteroposterior (b_{ap}) direction was determined.

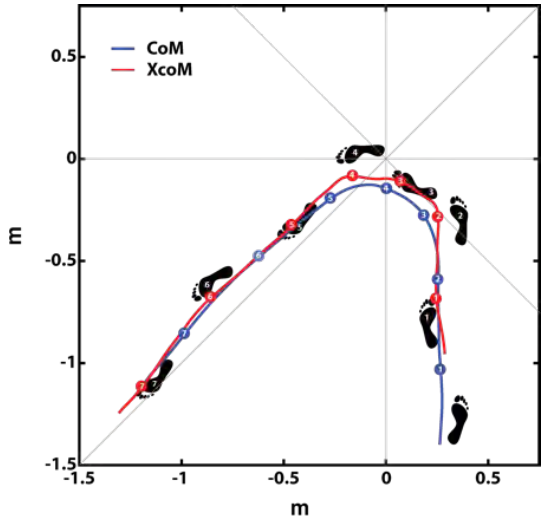

Figure 1: Planar view of the stepping pattern with CoM and XcoM trajectory for a 135-degree turn.

To determine the relationship between mediolateral foot placement on the change in walking direction, linear regression models were fit for the outside and inside limb for each of the participants.

RESULTS AND DISCUSSION

Figure 2 describes the phase dependent offset between the center of mass of the left and right foot and the XcoM throughout the gait cycles. To execute the 135-degree turn to the left, both feet are placed with an offset lateral to the right of the XcoM.

At initial contact, participants placed their outside limb more lateral to the XcoM, than the inside limb (β_0, Table 1; Figure 3). By linear regression it was found the for larger changes in walking direction participants place their outside and inside limb further lateral to the XcoM (β_1, Table 1). Participant #3, however, maintained a large margin of stability (β_0, Table 1) for the inside limb with only a marginal effect of turn angle (β_1, Table 1), suggesting a more conservative, mediolaterally stable turning strategy.

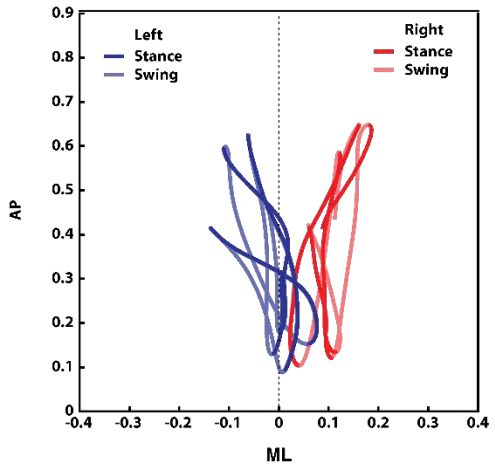

Figure 2: Phase-plot of b_{ml} and b_{ap} for a 135-degree turn to the left (Figure 1).

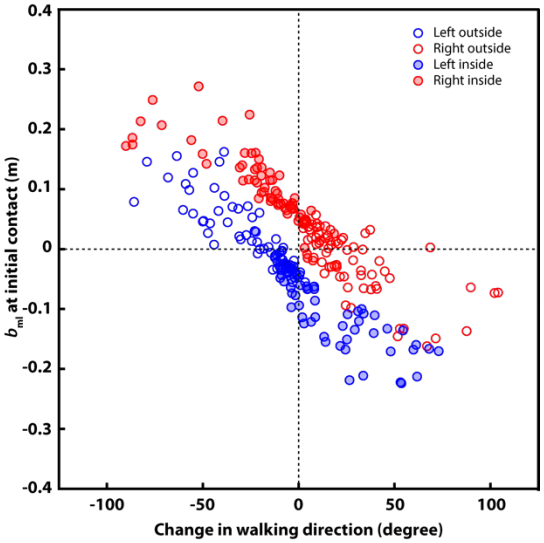

Figure 3: Mediolateral offset (b_{ml}) at initial contact against the change in walking direction during the subsequent step. Limbs are categorized as either outside or inside, based on the overall direction of a turn. Experimental data of participant #1.

CONCLUSIONS

Walking in turns requires a tradeoff between mediolateral stability and ability to change walking direction.

REACTION TIME OF YOUNG ADULT AND MIDDLE-AGED MEN AND WOMEN DURING A FORWARD FALL

Margo Donlin, Kurt DeGoede, Ph.D., Dan Panchik, Ph.D.

INTRODUCTION

Middle-aged (MA) women fracture their wrists more than twice as frequently as MA men, partly due to falling more frequently [1, 5]. A potential reason for this disparity is that MA women may have slower reaction times than MA men, leading to increased falls and an increased risk for wrist fractures. However, few studies have used MA subjects, resulting in a gap in scientific knowledge. The purpose of this study was to test for differences in reaction time (RT) to initiate a recovery step during a forward fall (trip).

METHODS

The tether-release method, which has been shown to be a consistent fall simulator, was used to initiate a forward fall in young adult (YA, 18-30 years old) and MA (40-59 years old) men and women [2, 4]. PASCO Force Plates and a load cell collected data at 2 kHz, and a MotionNode accelerometer collected data at 100 Hz during the fall trials. Subjects were suspended at a 15±2° forward lean and were released at a random time within 30 seconds of the beginning of data collection.

Reaction times in milliseconds (ms) were calculated by the difference between the release time and the initiation of a recovery step. Release time was determined to be when the load cell registered less than 50% of the voltage that the subject initially generated. Step time was determined to be when the force plate under the subject's dominant foot registered less than 40% of the force on that plate at the time of release. Each subject performed one practice trial, two undistracted trials, and two distracted trials. Subjects were given a maze with a washer on it and told to maneuver the washer along a printed path while leaning for the distracted trials. The reaction times were averaged into one undistracted reaction time and one distracted reaction time.

RESULTS AND DISCUSSION

Average undistracted and distracted reaction times are shown in Figure 1. Two-tailed t-tests showed that there was no difference between the reaction times of YA and MA females in distracted or undistracted scenarios (p=0.355, p=0.153). Average undistracted and distracted reaction times for males and females are shown in Figure 2. There was no difference between reaction times of MA males and MA females in undistracted or distracted scenarios (p=0.221, p= 0.288).

Paired t-tests showed that there was no difference between undistracted and distracted reaction times in YA subjects (p=0.189), MA subjects (p=0.067), or overall (p=0.750). However, MA subjects tended to have slightly faster distracted reaction times than undistracted reaction times.

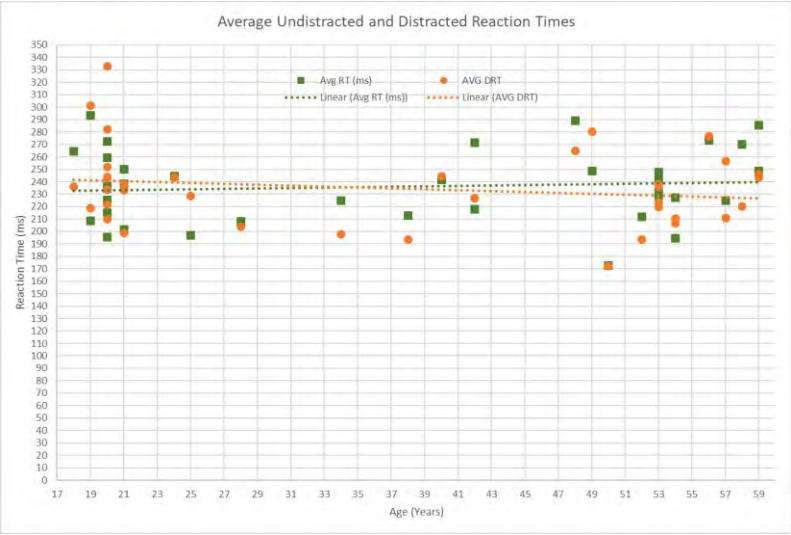

Figure 1: Graph showing age of subject plotted against their average undistracted and distracted reaction times. YA reaction times were not faster than MA reaction times in undistracted or distracted conditions (p=0.656, p=0.165).

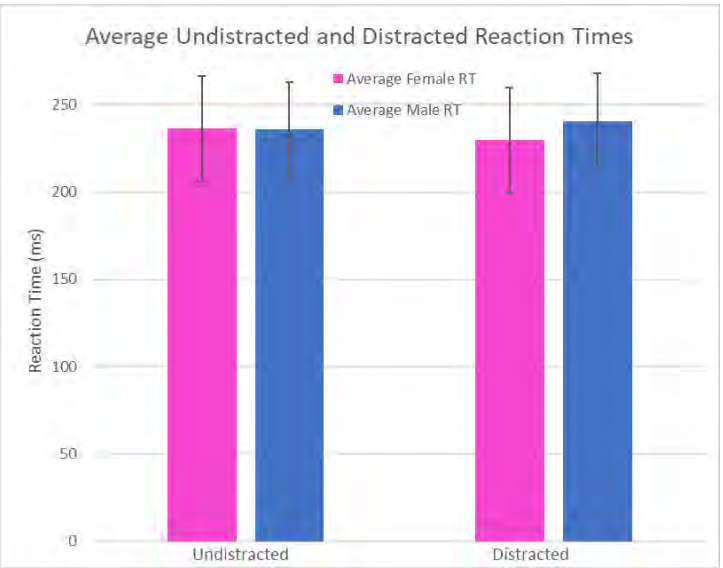

Figure 2: Graph showing male and female average distracted and undistracted reaction times and standard deviation. Male and female undistracted and distracted reaction times did not differ.

Although more MA women fall than MA men (5), reaction time is not why MA women fall more frequently. However, it is still unknown why MA women experience this phenomenon that puts them at greater risk for wrist fractures. Although osteoporosis would be a logical assumption for why MA women fracture their wrists more frequently than MA men, osteoporosis was found to be infrequent in women under 65 years old; therefore, osteoporosis cannot be the main reason that MA women experience more wrist fractures than MA men [3].

Since undistracted and distracted reaction times did not differ across all subjects, the distraction clearly did not affect the vestibular system, which is responsible for maintaining balance and spatial positioning. Although the mind and body were distracted by the maze task, the vestibular system was still able to respond to the impending fall in the same amount of time, indicating that a someone who trips while walking in a distracted state should have the same potential to recover from that trip as if they were not distracted.

The variability of the data was very large, and it is difficult to determine if that variation was due to natural differences in reaction time or due to age differences or the maze distraction. The average difference in a subject's undistracted reaction times was 3.816 ms, and the average difference between distracted trials was 2.355 ms. The average difference between the average undistracted and distracted times was 1.362 ms, indicating that the subjects responded to the simulated trip very consistently. The distraction caused no more variation in the trials than a subject's natural variation between trials.

Furthermore, the consistent angle of lean may have affected the reaction times, specifically for the YA subjects. Pierre's study used increasing lean angles to determine the maximum recoverable lean angle and showed that MA subjects could recover from a less severe lean than YA subjects (4). Using the same lean angle for all subjects may have resulted in differing levels of urgency for the different age groups. A more threatening lean for the MA age group may have resulted in faster MA reaction times compared to YA reaction times. In order to rectify this, an additional study could be performed using a lean angle based off the subject's age.

CONCLUSIONS

The primary conclusion from this study was that for mild trips with mild distractions, there is no noticeable age or distraction effect on reaction time. However, more serious trips or more involved distractions may show an effect on reaction time.

THE EFFECT OF SPINAL DECOMPRESSION SURGERY ON THE GAIT EFFICIENCY AND BALANCE OF CERVICAL MYELOPATHY PATIENTS THROUGH SIX-MONTH FOLLOW-UP

Emily Dooley, Jason Horowitz, Hamid Hassanzadeh M.D., and Shawn Russell Ph.D.
University of Virginia, Charlottesville, VA, USA
email: sdr2n@virginia.edu

INTRODUCTION

Cervical myelopathy is a condition caused by compression of the spinal cord in the neck that results in difficulty walking and sensory loss at the extremities.[1] This difficulty walking is characterized by a shuffling gait pattern and a wider base of support during the stance phase. These characterizations stem from postural and dynamic instability, which can result from reduced sensation and motor control in the legs. To prevent further disability and spinal cord deterioration surgical decompression of the spinal cord can be performed.[2] Multiple studies have been conducted characterizing this difficulty walking and noting gait improvements following decompressive surgery.[2,3] However, in this population, gait and energy expenditure during normal walking is not well defined and could influence future therapy and rehabilitation.

Specifically, for this study we hypothesize that cervical decompression and stabilization:

(1) results in improved gait parameters during the first six months of follow-up with associated improvement in energy expenditure;
(2) results in improved postural stability

The overall aim of this study is to fully characterize stability, gait, and energy expenditure during the first six months following decompressive surgery and stabilization in patients with Nurick grade 2 or 3 cervical spondylotic myelopathy, as defined by walking difficulty that does not require assistance.

METHODS

Experimental data was collected for 12 subjects: 6 controls (4 female and 2 male, 57 ± 7.4 y.o.) and 6 subjects with cervical myelopathy (4 female and 2 male, 58 ± 13.4 y.o.). The myelopathy group was tested at -1, 3, and 6 months after surgery. Subjects were instructed to complete two tasks:

(1) stand as still as possible for 30-seconds
(2) walk at a self-selected comfortable speed

Walking trials were completed on a 15m walkway. A minimum of five standing sway trials and six walking trials were used for analysis. Subjects were recorded using Vicon Nexus and five Bertec force plates. Kinematic and kinetic data were exported for Matlab analysis.

To characterize gait we looked at the spatio-temporal parameters of walking speed, percent of gait cycle in double support, and stride length. Gait efficiency was determined by measuring the total mechanical work during walking. Balance was assessed with two methods: path length normalized by time, and area of 95% confidence ellipses of that path. Path length refers to the path of the center of pressure of the subject's stance on a single force plate as the person attempts to stand as still as possible for 30-seconds.

RESULTS AND DISCUSSION

The myelopathy group tended to have slower walking speeds than the control population. After surgery this group tended to increase their walking speed and develop more efficient gait. Differences

Table 1. Summary of results on cohorts thus far. Significant differences are denoted with *.

	Path Length (mm/s)		**Ellipse Area (mm^2)**		**Walking Speed (m/s)**		**Double Support (% gait cycle)**		**Stride Length (m/LL)**		**Total Body Work (J/kg*m)**	
	Mean	*St. Dev.*	*Mean*	*St. Dev.*	*Mean*	*St. Dev.*	*Mean*	*St. Dev.*	*Mean*	*St. Dev.*	*Mean*	*St. Dev.*
Control	11.0 *	1.79	253	143.8	1.08	0.04	16	1	1.27	0.03	3.19	0.10
Baseline	17.7 *	2.88	740	320.0	0.96	0.07	18	1	1.23	0.03	3.21	0.12
Three Month	13.5	1.74	471	137.9	0.94	0.04	19	2	1.20	0.04	3.08	0.12
Six Month	14.1	1.39	381	97.9	0.98	0.04	20	4	1.24	0.08	2.79	0.12

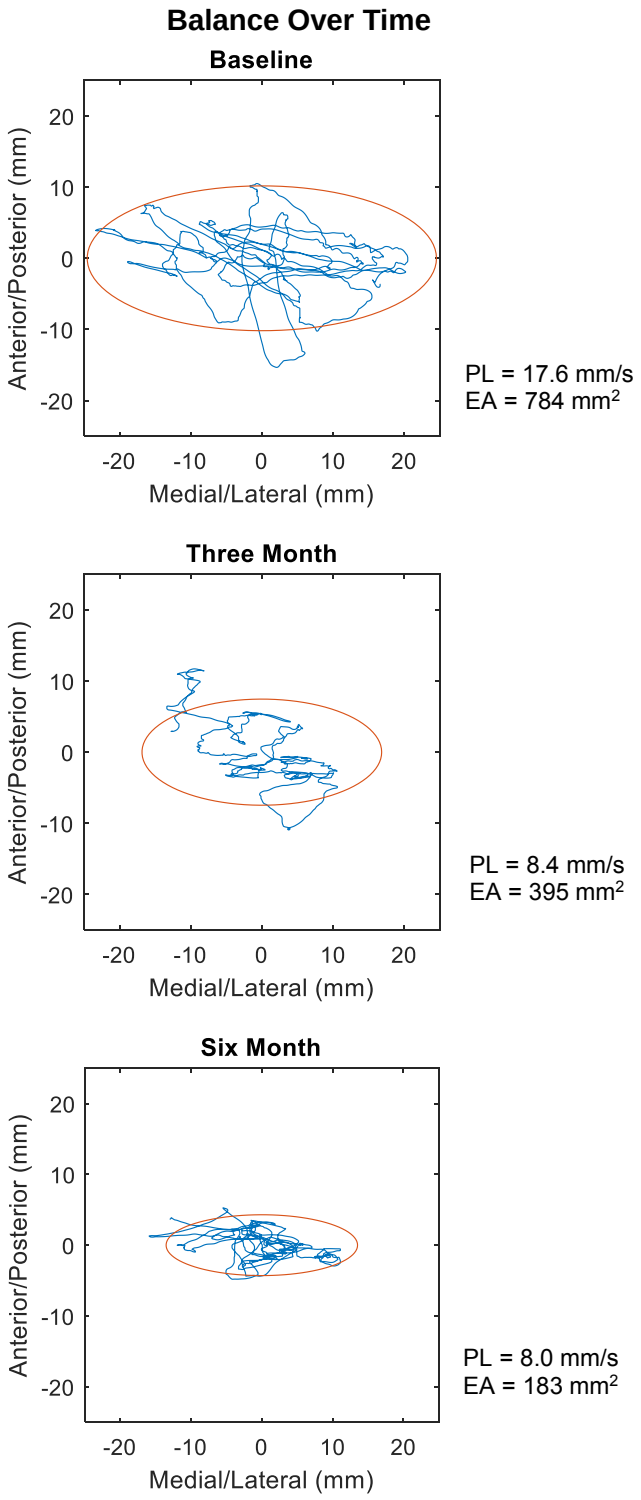

Figure 1. Best balance plot for one myelopathy subject at baseline, three month, and six month visits. Best meaning shortest path and smallest ellipse. The blue line is the path of the center of pressure over the duration of the trial. Total length per time is PL. The red oval is 95% confidence ellipse for the given path. The analyzed ellipse area (EA) is the area inside of the red oval.

seen in the time spent in double support and stride length were at the resolution of collection. With only six subjects in each group this study has not yet achieved full power. We anticipate these trends to become significant when the study is fully powered with 26 subjects in each group.

Despite the study not being fully power, significant differences in balance were found (*Figure 1*). The path length of the center of mass is significantly longer in the baseline population than the control group ($p < 0.05$). When looking at the area of the 95% confidence ellipse of that path differences are approaching significance between the control and both the baseline and the three-month post-surgery groups, as well as between the three-month post-surgery and the six-month post-surgery groups ($p = 0.07$).

CONCLUSIONS

The above results suggest that spinal decompression surgery improves the patient's stability and gait efficiency. This result was anticipated as difficulty with walking and balance are characteristic markers of cervical myelopathy.[4] Increased differences between the controls and the earlier time points of the myelopathy patients shows that the patients are approaching the control measures for balance and gait efficiency by six-months post-surgery.

Age-related kinetic imbalances during gait

Eranda Ekanayake, William Estep, Osama Ramadan and Jerome Hausselle

INTRODUCTION

Muscle co-contractions in the lower limbs correlate with high joint contact forces, which in turn increases the risk of osteoarthritis (OA) onset [1]. Since half of Americans older than 65 suffer from this disease [2], there is no denying that age plays a significant role. Thus, assessing age-related effects on biomechanical parameters leading to increased joint contact forces is critical to prevent OA progression.

Although many studies have focused on analyzing single gait cycles, only a few have studied the fluctuations of variables related to imbalance over hundreds of cycles. Our aim was to quantify age-related variations in muscle co-contractions and mediolateral peak vertical ground reaction forces.

METHODS

The 18-25 control group consisted of eight younger subjects (age: 22 ± 1 years old), whereas the 50-60 study group consisted of eight older subjects (age: 57 ± 3 years old). The protocol was approved by the Institutional Review Board and each participant signed an informed consent form. Subjects walked barefoot at a self-selected speed on an instrumented treadmill (Noraxon, Scottsdale, AZ, USA) for 10 minutes. Vertical ground reaction forces (vGRF) were recorded at 100 Hz, as well as EMG signals of eight muscles of the right leg: rectus femoris (RF), vastus lateralis (VL), vastus medialis (VM), biceps femoris (BF), semitendinosus (ST), tibialis anterior (TA), lateral (LG) and medial (MG) gastrocnemius.

The vGRF signals were filtered using a 4th-order lowpass Butterworth filter (cutoff frequency: 20 Hz) [3]. To study side-to-side imbalances, we computed a GRF index using the peak vGRF during heel strike for two consecutive steps:

$$GRF\ index = 100 * \frac{|Right\_GRF - Left\_GRF|}{Right\_GRF}$$

EMG data was filtered using a 4th order Butterworth filter at 40-400 Hz, rectified, RMS-smoothed (50 ms window) [4,5], and normalized using the maximum value over the 10-minute trial. Co-contractions were computed during the stance phase for the thigh muscles (RF+VM+VL vs. BF+ST) and leg muscles (TA vs. LG+MG) by using the areas under the EMG envelopes for agonist and antagonist muscles (*Area* 1 and *Area* 2) and the common area [6].

$$Co\text{-}contraction = 100 * \frac{2*common\ area}{Area\ 1+Area\ 2}$$

We used Matlab to test for differences in the GRF index between genders and in the GRF and co-contraction indices between age groups. The Jarque-Bera test was used to test for normality. Normal data was analyzed using F-test to determine variance relationship of samples and independent 2-sample t-test to compare means. Non-normal data was analyzed using Mann-Whitney U test. *p*-values were set at 0.05.

RESULTS

The average number of gait cycles was 543 ± 25 for the 18-25 group, and 458 ± 127 for the 50-60 group. There was no significant differences in the GRF indices between sides for any of the subjects and between genders. We thus combined left and right data for each subject and sorted solely by age.

The mean GRF index was higher for older subjects (Fig. 1), but the difference was not significant ($p = 0.86$). The interesting finding is the larger range of values found for older subjects (4.4%) than for younger subjects (2.3%). This finding highlights that aging may hinder force modulation during the heel strike phase, due to impaired joint proprioception or potential emerging pain [7]. This kinetic imbalance may result in the consistent overloading of a particular side, thus increasing joint contact forces and the risk of potential OA onset.

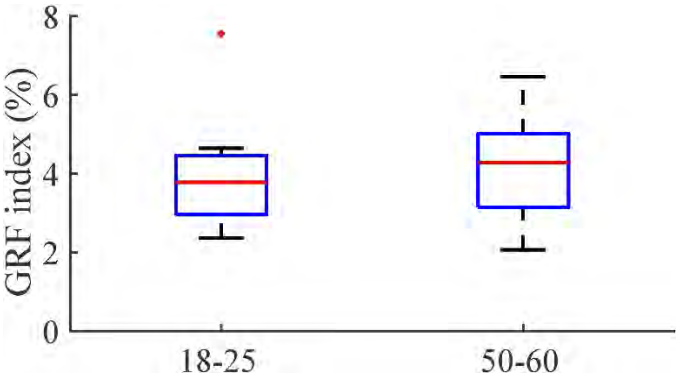

Figure 1. GRF Indices for each age group. Red lines represent median values, top and bottom of boxes represent 25th and 75th percentiles, respectively. Whiskers represent maximum and minimum values and cross displays outliers (1.5*Interquartile range [IQR], away from box limits).

The co-contraction index for thigh muscles was not significantly different between age groups ($p = 0.22$). However, it was significantly higher for older subjects in the leg muscles ($p < 0.01$) (Fig. 2). Since older subjects exhibit less plantarflexion muscle force [8], eccentric co-contraction of the TA may be a strategy to increase the propulsive force necessary to progress forward. Though not significant, the higher co-contraction index found for the thigh muscles of older subjects is a cause for higher-than-normal joint contact forces

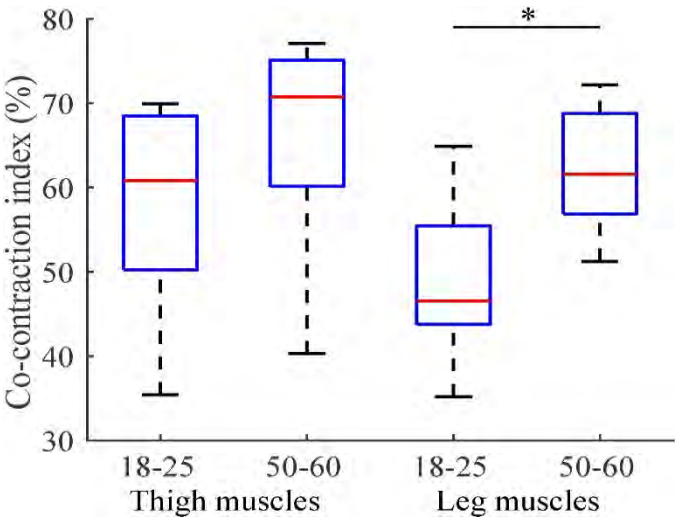

Figure 2. Co-contraction indices for each muscle and age groups. Symbols are similar to figure 1. The asterisk represents a significant difference ($p < 0.05$).

Even if not individually significant, combining higher side-to-side peak vGRF and muscle co-contractions should lead to higher-than-normal joint contact forces for older subjects. We are currently developing musculoskeletal models to estimate joint contact forces and confirm that these kinetic imbalances lead to increased forces and thus potential long-term cartilage damage.

One limitation of this study is the low number of subjects. Future work will target a larger population. Based on the data already collected, we will also select a gait speed suitable for all subjects to eliminate any potential speed-related effects.

CONCLUSIONS

Though not statistically significant, older subjects exhibited larger kinetic imbalances than younger subjects, even while walking at a self-selected speed. If confirmed by testing a larger population, our results indicate that older subjects may be at higher risk of overloading one side of their body, thus leading to increased joint contact forces and potential OA onset.

This study is the first critical step towards the development of efficient screening protocols to detect older adults at risk of developing OA in one or more of their lower limb joints.

INTRODUCTION

Disruptions to balance are alarmingly regular occurrences on a daily basis. Whether it is being bumped walking down a busy street, traversing an icy sidewalk, tripping over an unexpected obstacle, or encountering a slippery contaminant, there are countless situations that can result in a loss of balance, and a subsequent fall. Thus, it is no surprise that falls account for large rates of injury in multiple populations. The process of an unexpected slip is divided into four distinct phases (environment, initiation, detection, and recovery) [1]. Researchers have commonly classified slips in a severity range based on the magnitude of this heel slip distance, as well as the velocity of the heel slip [2-4]. Though, more recent work has attempted to quantify the slip response as a fall or recovery through the use of a force criterion in the fall arrest harness system [5]. Previous research using equilibrium scores during sensory organization tests have suggested that individuals with decreased EQ scores slipped longer when exposed to unexpected slips [1]. The purpose of this study was to examine postural control parameters between those classified as a fall, or recover during an unexpected slip.

METHODS AND PROCEDURES

This study was conducted in a case-controlled design, with 40 healthy adults (20 male, 20 female; age: 21.96 ± 3.178; height: 171.37cm ± 13.79; weight: 75.69kg ± 16.51), who had no history of musculoskeletal, orthopedic, neurological, or vestibular abnormalities. Standing postural control measures were recorded using the six conditions of the Neurocom® sensory organization test (SOT) [eyes open (EO), eyes closed (EC), eyes open with sway referenced vision (EOSRV), eyes open with sway referenced support, (EOSRP), eyes closed with sway referenced support (ECSRP), and eyes open with sway referenced vision and support (EOSRVP). The variables were the sway velocity components in the medial-lateral (M/L) and anterior-posterior (A/P) directions, and root mean square (RMS) of CoP displacement in the anterior-posterior (A/P) and medial-lateral (M/L) directions. An 8 camera Vicon Nexus (Oxford, UK) 3D motion capture system was used to collect and analyze kinematic gait data. A lower body plug-in gait model from the Helen–Hayes marker system was used for the participant configuration and the kinematic data was sampled at 100 Hz and collected using the Vicon Nexus software. A back-pack type fall arrest system with a movable trolley was used to prevent any undesired falls. Glycerol mixed with water in the ratio of 75% glycerol and 25% water was used as the slippery agent [3]. During the slip trials, glycerol was applied and evenly distributed on a force plate for contact of the leading left leg. Participants were strapped to a harness and performed multiple gait trials until normal self-selected pace walking with appropriate foot positioning onto the force plate was achieved. Participants turned away and listened to music on noise cancellation head phones for about 1 minute between each of these normal gait trials. One trial was then chosen to be the unexpected slip (US) and the contaminant was applied. Each slip trial was classified based on a force criterion using a digital crane scale inline with the overhead harness system. The slip was classified as a fall if the peak body weight measured by the scale exceeded 30% of body weight during the slip, and confirmed with visual inspection. After classification, sway

parameters were analyzed for each SOT condition, using independent samples t-tests between falls and recovers.

RESULTS AND DISSCUSSION

For the postural control measures, we have evidence of significant differences in the EO condition for ML velocity ($t(38) = -2.200$, $p = 0.034$), and AP velocity ($t(38) = -2.246$, $p = 0.031$). For ML velocity, fallers presented with increased sway velocity compared to those who recovered during the slip (mean sway velocity of 0.879 ± 0.11 vs. 0.791 ± 0.13). Similarly, for AP velocity, increased sway velocity was found in fallers, compared to those who recovered from the slip (mean sway velocity of 1.16 ± 0.24 vs 1.00 ± 0.20). No other statistically significant findings were observed for the sway parameters. Previous research using equilibrium scores during sensory organization tests have suggested that individuals with decreased equilibrium scores slipped longer when exposed to unexpected slips [1]. Other previous findings have suggested that adults with one or more sensory impairments have increased odds of having dysfunctional balance [6] Our findings using postural sway measures, and classified slip outcomes corroborate those findings. Suggesting that individuals who were unable to recover after a slip, have increased sway velocity, suggesting worse balance performance compared to those who were able to recover.

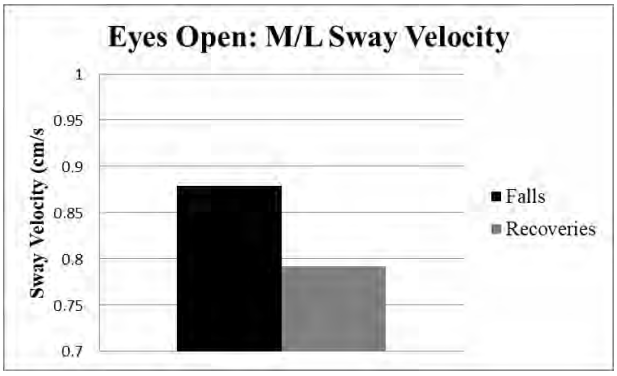

Figure 1: Medial/Lateral Sway Velocity in the EO condition between those who fell, and those who recovered.

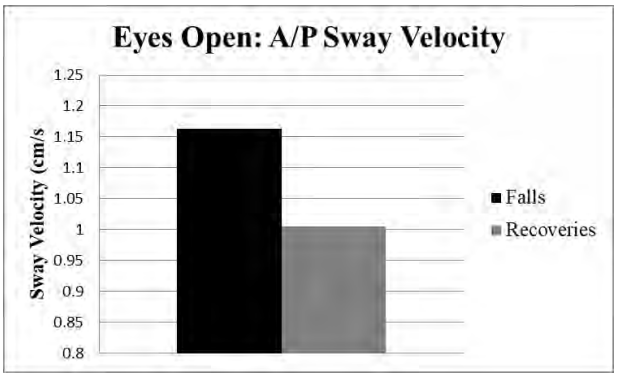

Figure 2: Anterior/Posterior Sway Velocity in the EO condition between those who fell, and those who recovered.

CONCLUSION

Our findings suggest that possible decrements in standing balance, as measured through postural sway parameters could be indicative of an individuals inability to recover following an unexpected slip. This could be due to an impairment in slip detection, leading to an increased propensity of a subsequent fall.

THE IMPACT OF OBESITY ON GAIT STABILITY IN OLDER ADULTS

INTRODUCTION

Falls are common in adults over the age of 65, and can result in injury or even death. Older adults who are also obese are at a higher risk of falling and have a greater risk of disability after a fall [1]. However, the mechanisms to explain falls by obese older adults are unclear. There is a growing body of evidence that obesity interferes with postural stability [e.g. 2]. However, the relationship between postural stability and falls is also not necessarily clear. In addition, the majority of falls by community dwelling adults occur during gait and not from standing postures [3].

Obese gait can be characterized by reduced walking speed, a longer stance phase duration and a greater period of double support compared with normal-weight individuals [4]. These characteristics are generally thought to be compensatory strategies to increase stability when dynamic balance has been compromised. However, these are not direct measures of stability – i.e. the ability of the system to respond to small perturbations – and these metrics have had limited ability to predict falls. Measures of local dynamic stability based on trunk motion, which directly quantify the stability of the system, have been able to identify older adults with and without high fall risk [5] as well as older adults with and without a fear of falling (FOF), which is a risk factor for falls [6].

The purpose of this study is to determine the impact of obesity on gait stability in older adults. Secondarily, we determined whether walking stability was related to history of falls in older adults.

METHODS

A total of 12 obese older adults (73 ± 5 yrs, BMI: 34.8 ± 4.2) and 12 age and gender matched healthy weight controls (74 ± 7 yrs, BMI: 23.7 ± 0.9) participated in this IRB approved study. As part of a larger study, participants walked on a treadmill at self-selected walking speed. Up to 10 minutes of walking was recorded in 30 second trials, 6 trials of which were used for analysis. We tracked the position of a marker placed on the C7 vertebra at 100 Hz throughout all walking trials using motion capture (Vicon, Oxford Metrics, Oxford, UK). In addition, participants completed several test of functional mobility including the 10 meter walk test (at maximum speed) and the timed-up-and go (TUG). They also completed the Survey of Activities and Fear of Falling (SAFE) which asks if they regularly perform a series of activities of daily living; if so it asks for their level of FOF while completing the activity (0-4 point scale); if not it asks whether or not the activity is avoided due to FOF. Participants also completed the SF-12 to quantify mental and physical health [7].

Local dynamic stability was quantified using short-term local divergence exponents (λ_s*) which indicate the rate of divergence of neighboring trajectories. Positive exponents indicate local instability, with larger exponents indicating greater instability [8]. State spaces were constructed from five time delayed copies of the C7 marker velocity for each direction of motion. We then calculated λ_s* for each state space using previously published methods [8]. The average λ_s* across 6 trials of 20 strides (120 total strides) was calculated for each individual in each plane of motion [9].

We used a two-factor ANOVA to test for differences in λ_s* between weight groups (obese, healthy-weight) and fall history (yes/no). Walking speed is known to influence local stability, and as such we first compared the self-selected speeds between the groups. The obese participants tended to walk slower (0.78 ±0.23 m/s) than the healthy weight controls (0.94 ±0.24 m/s). Therefore, walking speed was

included as a covariate in the ANOVA. This covariate was significant in the M-L direction, only. All other measures were compared using single-factor ANOVAs to test for differences between healthy-weight and obese older adults. All statistical analyses were performed in SPSS v 24 (IBM, Armonk, NY) with an $\alpha = 0.05$.

RESULTS AND DISCUSSION

Obese and control participants had a similar incidence of falls in the prior year (5/12 per group). They also had similar fear of falling ($p = 0.228$). The obese participants generally performed worse on functional tests. They had a significantly longer TUG time ($p = 0.002$), and trends toward slower 10-m walk ($p = 0.087$, figure eight walk ($p = 0.071$), and four-square step ($p = 0.119$) times. Obese participants were not able to stand on one leg for as long as healthy weight controls ($p = 0.001$).

Obese participants were less stable in the medial-lateral (M-L) direction ($p = 0.002$) compared to healthy-weight controls. However, there were no significant differences in stability between groups in the anterior-posterior (A-P: $p = 0.888$) or vertical (VT: $p = 0.632$) directions (Fig. 1). There were no significant effects of fall history or significant fall history x weight group interactions for any comparison.

CONCLUSIONS

Older adults who are obese have decreased medial-lateral stability compared to their healthy weight counterparts. They also have decreased functional performance measures, but not a greater fear of falling. Future work will include a larger sample size and incidence of falls after assessment. This data is essential to determine the factors related to fall risk in this population

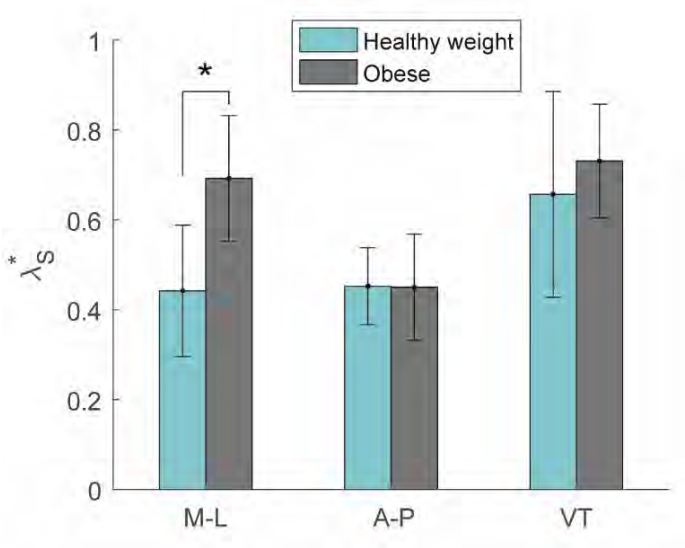

Figure 1: Average λ_s* for Obese (black) and Healthy-Weight (cyan) subjects in the medial-lateral (M-L), anterior-posterior (A-P), and vertical (VT) directions.

INTRODUCTION

The recovery of locomotor *stability* – the ability to maintain a desired walking trajectory amid perturbations – and *maneuverability* – the ability to change walking trajectory – are major gait rehabilitation challenges for ambulatory individuals with incomplete spinal cord injury (iSCI). Although essential for community ambulation, it is difficult for people with impaired sensory motor function to effectively control both. Instead, they may select conflicting locomotor control strategies that are either stable or maneuverable. For example, increasing lateral margins of stability (MOS) increases resistance to lateral perturbations and also increases resistance to volitional efforts to move laterally [1]. We sought to quantify the interaction between stability effort and maneuver performance in an iSCI population. We hypothesized that following walking practice in a force field that increased effort required to maintain straight walking, individuals would adopt gait patterns that are more resistive to lateral maneuvers, and, conversely, following practice in a force field that decreased stabilization effort, individuals would adopt less resistive gait patterns during maneuvers.

METHODS

12 ambulatory individuals with iSCI (age: 54.9 ± 8.2, 10 males, 2 females) provided informed written consent and participated in the study. We quantified lateral maneuvers during treadmill walking immediately following three straight-ahead walking conditions during which a cable robot [2] applied external force fields to the center of mass (COM) to modify the effort required to control lateral motion (Figure 1). The conditions were:

Null: No external forces.

Damping: Force field proportional in magnitude and opposite in direction to lateral COM velocity. This field made it easier to control mediolateral COM position.

Amplification: Force field proportional in magnitude and in the same direction as lateral COM velocity. This field made it more difficult to control mediolateral COM position.

During all walking, real-time mediolateral COM position was projected along the length of the treadmill surface (Figure 1). To ensure that participants were trying to control lateral COM motion during straight walking in each force field condition, they were tasked with maintaining their COM projection within a dynamic target lane. The width of the lane updated every 10 seconds based on performance (narrowing if the participant was successful or widening if they were not) to maximally challenge the participant's ability to control lateral COM motion. After 2 minutes of straight walking, the force-field shut off and the center of the target lane immediately jumped to the left side of the treadmill. Participants were instructed to maneuver to the new target lane as quickly as possible. This was followed by three more lateral maneuvers with the target lane moving to either the left or right (target centers located 0.45m apart) one second after each maneuver was completed.

We quantified minimum step width and minimum lateral margin of stability [3] during the first maneuver on the side ipsilateral to the direction of the maneuver. One-way repeated measures ANOVAs tested for differences in gait measures. When significant differences were found Bonferroni-corrected pairwise comparisons were made between conditions.

Figure 1: Experimental Setup. During straight walking a cable robot applied lateral forces to a pelvic harness. During all walking mediolateral COM position was projected on the treadmill surface. Participants were instructed to maintain their COM within a dynamic target lane.

RESULTS AND DISCUSSION

We found significant differences between conditions for minimum left step width (repeated measures ANOVA; $p < 0.0005$), and minimum left lateral margin of stability (repeated measures ANOVA; $p = 0.001$) during the first maneuver performed to the left immediately after straight walking (Figure 2). Post hoc tests revealed that compared to maneuvers performed immediately after the Null condition, both step width ($p = 0.006$) and lateral margin of stability ($p < 0.031$) were significantly larger during maneuvers after straight walking in the Amplification field. Conversely, when compared again to maneuvers performed immediately after the Null condition, both left step width and left lateral margin of stability tended to decrease after straight walking in the Damping field. This change was only significant for minimum left step width ($p = 0.015$).

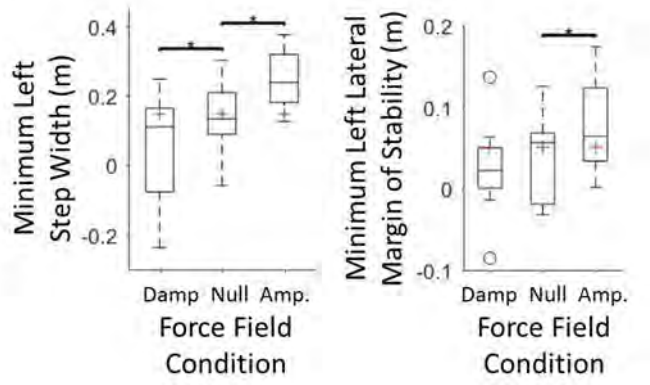

Figure 2: Minimum left step width and minimum left lateral margin of stability during maneuvers performed to the left immediately after two minutes of straight walking in three different force fields: Damping, Null, and Amplification.

These results support our hypotheses. When the effort required to maintain lateral COM stability during straight walking was altered in a force field, we observed changes in how individuals with iSCI executed lateral maneuvers after the field was removed. Following straight walking in the Amplification field, individuals demonstrated increased step width and lateral margin of stability during maneuvers compared to the Null condition. These changes likely increased lateral stability – resistance to perturbations – but also resisted the participants' own volitional efforts to change direction [1]. Conversely, after walking in the Damping field that reduced the effort required to stabilize lateral COM motion during straight walking, individuals decreased step width and lateral margin of stability during lateral maneuvers. These changes should decrease resistance to both lateral perturbations and volitional changes in direction.

CONCLUSIONS

Our results suggest that the control strategies used by individuals with incomplete spinal cord injury to create stability have consequences for maneuvering. During community ambulation there are instances when it is necessary to be both stable and maneuverable. Developing interventions that improve the ability to either rapidly switch between control strategies or to learn alternative strategies that facilitate simultaneous control of both stability and maneuverability [4] would expand the variety and complexity of environments in which individuals with iSCI can safely and effectively walk.

THE RELATIONSHIP BETWEEN STAR EXCURSION BALANCE TEST JOINT ANGLES LIMB ASYMMETRY AND NORMALIZED REACH DISTANCE IN 12 WEEKS POST HIP ARTHROSCOPY PATIENTS

Rena Hale, Allison Mumbleau, Aaron J. Krych, and Timothy E. Hewett

Mayo Clinic Biomechanics Laboratories & Sports Medicine Center, Rochester & Minneapolis, MN, USA
email: Hale.Rena@Mayo.edu

INTRODUCTION

Due to the recent advancements in clinical examination skills and diagnostic imaging, the number of hip arthroscopies (HA) performed in the United States increased nearly 6-fold from 2004 to 2009 [1]. HA can include but are not limited to labral debridement and repair, femoroacetabular impingement correction, chondroplasty, osteoplasty, microfracture, synovectomy, repair of the ligamentum teres, and treatment for capsular hyperlaxity [2]. Previous studies have shown promising functional outcome improvements in short and mid-term patient follow ups after HA [3]. Despite this progress, recommendations for postoperative rehabilitation are minimal [3, 4].

Multiple metrics are available to assess patient performance after HA. The modified Star Excursion Balance Test (SEBT) is a reliable and low cost functional test commonly performed to assess lower extremity dynamic stability and neuromuscular control. The SEBT measures performance via limb symmetry of reach distance. Despite the clinical utility of the SEBT, performance standards to determine patient readiness to advance with rehabilitation activities for patients post HA have not been defined. The purpose of this study was to correlate sagittal plane trunk, hip, knee kinematics and reach distances of the surgical and nonsurgical limb during a modified SEBT with 12 week postoperative HA patients. The first hypothesis tested was that sagittal plane trunk, hip, and knee flexion would be decreased on the surgical limb when compared to nonsurgical limb. The second hypothesis tested was that reach distance asymmetries would correlate to sagittal plane kinematic asymmetries.

METHODS

Nine patients 12 weeks post HA (15-50 years old) were recruited for participation in this study. Average participant height and weight were 155.3cm ± 33.4 and 67.5kg ± 11.4. Patients with bilateral HA were excluded. Prior to participation, informed consents were obtained. The study was reviewed and approved by the Mayo Clinic Institutional Review Board.

3D motion analysis (Motion Analysis Corp, Santa Rosa, CA) was collected on patients while the SEBT was performed. Patients wore compression shorts and spandex tops. Twenty-nine reflective markers were placed on anatomical landmarks following the Helen Hayes marker set. For the SEBT, participants were instructed to balance on one leg while using their free leg to reach as far as possible with the reach indicator. Three reaches on the injured then uninjured limb were performed in the anterior, posterolateral, and posteromedial direction relative to the stance leg.

A musculoskeletal model (Visual3D, Germantown, MD) was developed to calculate trunk, hip, and knee angles. Kinematics at maximum reach were reported. Limb asymmetry (surgical/nonsurgical) was calculated for joint kinematics and reach distance. Paired t-tests were used to determine significance of reach distance between reach directions. Linear regressions were used to examine the correlation of sagittal plane kinematics with limb asymmetries in reach distances for each test direction. Significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

Mean reach distances for the surgical limb were significantly shorter in the anterior reach than the

posterolateral or posteromedial directions (P<0.05; Figure 1) when compared to nonsurgical limb.

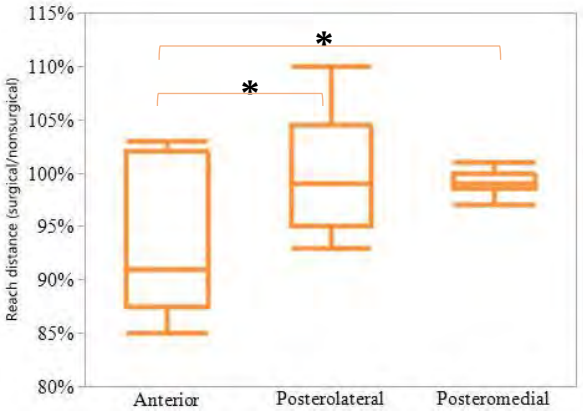

Figure 1 Average and standard deviation reach distance limb asymmetries. Asterisk denotes significant correlation between reach directions (P<0.05).

Hip (R_2 0.49) and knee flexion (R_2 0.47) of the surgical limb when compared to the nonsurgical limb were significantly less in the anterior reach direction of the SEBT (P<0.05; Figure 2). Joint kinematics in neither the posterolateral (R_2 0.36) nor the posteromedial (R_2 0.12) directions correlated to reach distance limb asymmetries.

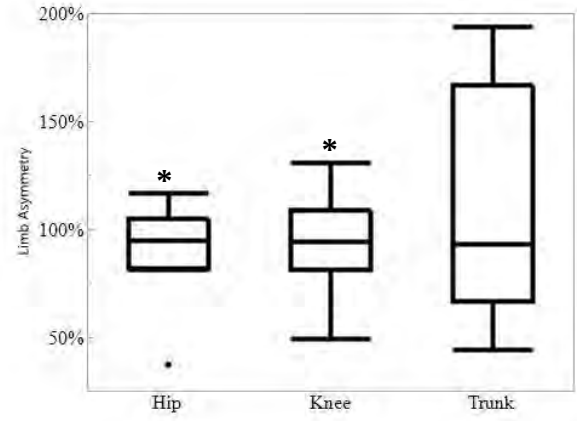

Figure 2 Average and standard deviation anterior reach limb kinematics represented as limb asymmetries. Asterisk denotes significant correlation with reach distance (P<0.05).

Clinically, a reach asymmetry with magnitude < 90% as compared to the uninvolved limb has been associated with increased lower extremity injury risk. Interestingly, most (7 of 9) of the current patients had limb symmetry reach distances ≥ 90% the uninvolved limb, which would qualify them as low injury risk. However, kinematic limb asymmetry analysis of individual patients showed that over half were below 90% asymmetry threshold in hip flexion in all three reach directions.

These results agree with previous literature that correlates hip and knee flexion with reach distance [6]. Movement patterns with limited sagittal plane flexion are undesirable, as decreased sagittal plane excursion during jump landing is associated with increased ground reaction forces and increased injury risk [7].

CONCLUSIONS

Though decreased reach distance in the anterior direction correlated to decreased hip and knee flexion angles, kinematics in the posteromedial and posterolateral directions did not correlate to reach distance in the surgical limb. Results from this study indicate that reach distance asymmetries alone may not describe the underlying movement mechanics of the patient specifically in the posterior reach directions. Future studies should compare absolute reach distances and joint kinematics between HA patients and a healthy cohort, as well as measure HA patient's limb asymmetries at six and twelve month follow-ups.

REPEATED MOTOR CONTROL TESTING DECREASES CO-CONTRACTION INDEX IN HEALTHY YOUNG ADULTS

INTRODUCTION

Automatic postural responses are the first line of defense against environmental disturbances to postural equilibrium. Rapid adaptation of the neuromuscular system's reactive and anticipatory mechanisms to novel perturbations decreases the possibility of fall and musculoskeletal injury [1]. In order to react to balance perturbations, co-contraction of agonist antagonist pairs of the lower extremity muscles increases to create stability around a joint, by generating stiffness in the agonist and antagonistic muscles [2]. The postural control system modifies neuromuscular responses and habituates with repeated exposure to surface perturbations. Previous literature has demonstrated a decrease in muscular co-contraction index with repeated exposure to balance perturbations suggesting the adoption of a feedforward control after initial exposure [3, 4]. A commonly used device to elicit balance perturbations in research and clinical settings is the Neurocom® EquiTest®'s Motor Control Test (MCT). Novel laboratory equipment has been used in previous studies to disturb postural equilibrium, yet no study has evaluated the effect of repeated MCTs on automatic postural responses. Thus the purpose of this study was to determine whether exposure to repeated MCTs elicit changes to neuromuscular responses in the lower extremities of healthy young adults.

METHODS AND PROCEDURES

The study was conducted in a repeated measures design with twenty healthy adults (10 male, 10 female age: 25 ± 4.73 years; height: 183.8 ± 8.5 cm; mass: 85.2 ± 15.6 kg) with no history of musculoskeletal, orthopedic, neurological, and vestibular abnormalities. Data collection procedures included an initial familiarization that consisted of a single, full MCT. Following familiarization, participants performed five fully randomized MCTs over six testing sessions, in which they were not given knowledge of the direction or magnitude of the perturbations. The first five sessions occurred on consecutive days, with the sixth occurring two days after the fifth. Muscle activity was collected on medial gastrocnemius (Plantar Flexor-PF), tibialis anterior (Dorsi Flexor-DF), vastus medialis (Q) and semitendinosus (H) using the Noraxon TelemyoTM T2400 G2 wireless EMG system (Scottsdale, Arizona) with a sampling frequency of 1500 Hz. Response times were assessed using Motor Control Test (MCT) (backwards small [BWS], medium [BWM] and large [BWL], and forward small [FWS], medium [FWM], and large [FWL]). Co-contraction between of muscle pairs were calculated using the Co-Contraction Index (CCI) with mean muscle activity agonist-antagonist pairs of Q & H and DF & PF using the following equation [6]:

$$(EMG_{Least} + EMG_{Most}) x EMG_{Least} / EMG_{Most}$$

The first trial of a perturbation on each testing day was analyzed using a 1 (Participant) x 6 (Day) repeated measures ANOVA at an alpha level of 0.05 using SPSS25.

RESULTS AND DISSCUSSION

Significant main effect was found for Q-H CCI Day-Trial 1 BWM [F (1.949, 14) =4.037, p= 0.027, η^2 =0.175] and Day-Trial 1 FWM (1.949, 14) =4.037, p= 0.027, η^2 =0.175]. Day-Trial 1 BWM Q-H CCI Day 1 was significantly higher than Day 3 (p=0.017), Day 4 (p=0.024), Day 5 (p=0.024), and Day 6 (p=0.023) but not Day 2 (p=0.160). Day-Trial 1 FWM Q-H CCI Day 1 was significantly her than Day 2 (p=0.160), Day 4 (p=0.014), Day 5 (p=0.017), and

Day 6 (p=0.012), but not Day 3 (p=0.063). Day 3 was significantly higher than 4 (p=0.034), Day 5 (p=0.01), and Day 6 (p=0.01), but not Day 2 (p=0.113).

Significant main effect was found for PF-DF CCI in Day-Trial 1 BWS [F (3.290, 14) =3.204, p= 0.025, η^2 =0.144], Day-Trial 1 FWL [F (3.342, 14) =3.679, p= 0.014, η^2 =0.185], and Day-Trial 1 FWM [F (2.056, 14) =6.535, p= 0.003, η^2 =0.256]. Day-Trial 1 BWS PF-DF CCI Day 1 was significantly higher than Day 6 (p=0.019). Day-Trial 1 FWL PF-DF CCI Day 1 was significantly higher than Day 2 (p=0.011), Day 3 (p=0.003), Day 4 (p=0.015), Day 5 (p=0.005), and Day 6 (p=0.008). Day-Trial 1 FWM revealed Day 1 was significantly higher than, Day 3 (p>0.001), Day 4 (p>0.001), Day 5 (p>0.001), and Day 6 (p>0.001) but not Day 2 (p=0.257).

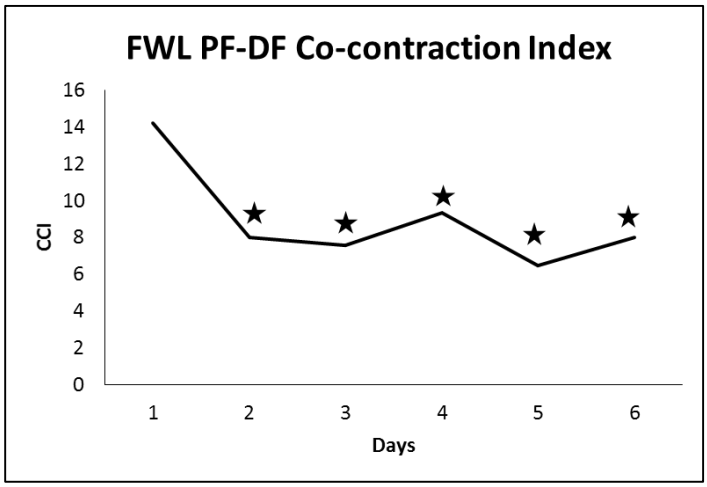

Figure 1: Muscle co-contraction index for backward medial gastrocnemius (PF) and tibialis anterior (DF). ★ denotes significant differences from Day 1.

Initial exposure to the postural perturbations of the MCT increased co-contraction indices across both sets of agonist and antagonist muscle pairs. However a decrease was noted after the third testing session and was maintained after a two day retention period. Previous literature has described similar findings as "The First Trial Effect" in which postural responses shift from feedback control to feedforward [5]. Exposure to the novel perturbations of MCT activates the lower extremity musculature via a proprioceptive feedback loop. After the initial encounter with a particular type of perturbation, the need to utilize feedback from the lower extremity is diminished, thus resulting in a decrease co-contraction between the agonist and antagonist pairs. The Q-H muscle pair decreased in their co-contraction when repeatedly exposed MCT. Paradigms utilizing repeated postural perturbations have demonstrated a decrease in the activation of proximal musculature [1, 6]. The hip and knee fixed support strategy requires the activation of proximal lower extremity muscles to maintain balance. However, after repeated exposure and upright stance is maintained successfully, the postural control system shifts to the more efficient ankle fixed support strategy to decrease muscle exertion.

After two days of non-exposure to the MCT balance perturbations, a similar CCI to that found during the repeated exposure was maintained. Previous findings have noted that participants with prior experience with a postural disruptions, decrease CCI when exposed to the perturbation again suggesting a change in pre-perturbation anticipatory control [1, 3]. Prior experience with the MCT perturbations allowed the central nervous system to implement a more efficient anticipatory control strategies to counteract the upcoming perturbations.

CONCLUSION

Reactive postural response are needed to maintain balance and must rapidly adapated to meet enviormental demands. Perturbing balance with MCT elicits lasting changes to reactive balance responses via feedforward control and alterations to anticpatory mechanisms via prior experinance. Such changes create more efficent postural control strategies that decrease muscle exertion of the lower exterimity.

Texting while walking influences Step Width

[1] Tyler Hofstee, [1]Don Hoang, [1]Cory Barella, [1]Justin DeGuia and [1]Rahul Soangra*
[1] Department of Physical Therapy, Crean College of Health and Behavioral Sciences, Chapman University, Orange, CA, USA
email: soangra@chapman.edu, web: https://www.chapman.edu/our-faculty/rahul-soangra

INTRODUCTION

Dual tasking has become a necessity in today's fast-paced society. Nowadays it seems as though it's more preferable to perform multiple tasks with a limited focus of attention rather than perform each task individually and give each task your full focus and attention. Walking and texting is something which we commonly see or perform in our daily lives. The ownership of a mobile smartphone has increased significantly over the course of the last few years along with the individual use of emailing, social media scrolling, internet browsing, and above all texting. Specifically, texting while walking can have a profound impact on an individual's gait and fall risk. The dual task of texting and walking carries with it the risk of normal gait deviation which can lead to variances in gait pattern, destabilization, tripping, colliding and can result in an injury to the person texting or an innocent bystander. License and Smith's studied the effect that texting had on gait characteristics while negotiating common pedestrian obstacles such as curbs and steps *(License et al. 2015).* Agostini et. al. studied gait modifications due to texting on a smartphone while walking, with an emphasis on distal motor control *(Agostini et al. 2015).* This study looks into effects of dual-tasking on fall risk. We hypothesize that walking while texting with a cell phone will increase stride width and reaction time, and decrease stride length and stride interval in comparison to normal gait tendencies. The inclusion of the Stroop test will rule out that the significant differences in gait are due to the cognitive tasks of texting, rather than the motor tasks of flexion of the head, elbows and fingers.

METHODS

Four healthy adult males aged 22-34 from Chapman University Department of Physical Therapy were recruited. The protocol for this study was approved by Chapman University Institutional Review Board (IRB#1718H020). All participants provided written informed consent prior to the experiment. The participants were devoid of any other neurological or musculoskeletal conditions and had previous experience using their cellular device.

Participants were assessed in the Gait Real-time Analysis Interactive Lab (GRAIL) and were instructed to wear comfortable, tight-fitting clothing for walking without any reflective material. Twenty-five reflective markers were placed on several bony landmarks of these participants.

The preferred pace of the participant was found and recorded for each participant, and held constant for each of their trails. Participants were instructed when to start and stop walking and data was collected for three minutes using the VICON motion capture and D-Flow programs in the GRAIL lab for assessing stride length, stride width, stride interval, and reaction time after perturbation. The participants used www.typingtest.com using the parameters: 3 minutes, English, and "Zebra - Africa's striped horse" script and "Rules of Baseball" script. The typing test assess the typing speed in words per minute, the amount of errors made, and the adjusted typing speed.

Figure 1: Participant walking on Split belt treadmill with a virtual reality environment

RESULTS AND DISCUSSION

We found that Step width of participants increased significantly while performing dual-task (texting with walking) (p=0.018). Average step width for subjects was 0.195m with no texting, 0.2003m with texting. Average Step length was 0.67 meters when no texting and reduced to 0.66 meters in dual task condition. We also found that during dual tasking the participants decreased their gait speed.

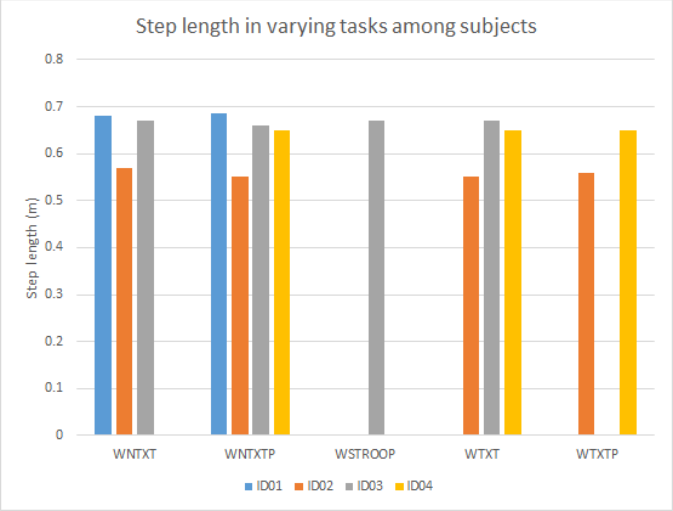

Figure 2: Measurement of average step length (in meters) per gait cycle among participants in WNTXT, WNTXTP, WSTROOP, WTXT, WTXTP.

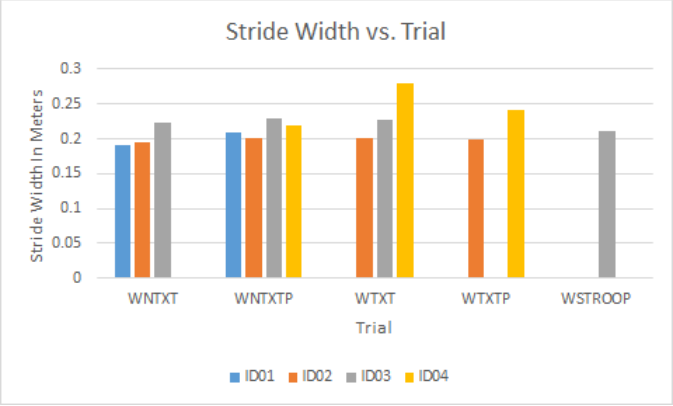

Figure 3: Measurement of average stride width (in meters) per gait cycle among participants in WNTXT, WNTXTP, WSTROOP, WTXT, WTXTP

CONCLUSIONS

This study examined the effects of dual tasking more specifically, texting on a phone on gait. We hypothesized that texting while walking will increase the step width in comparison to normal gait tendencies. *Licence et al.* and *Plummer et al.* found that a decrease in gait velocity during dual tasking (*Licence et al., 2015)*. We also found decrease in gait speed during dual tasking.

In *Texting and Walking:* We found that when the participants were walking and texting they had an increased step width. This is similar to the findings in Schabrun et al. This increase in stride width was due to the human body's natural response to being off balance while in the single-limb support phase of gait; the body will compensate by increasing the base of support to prevent the person from falling over. With a decrease in spatial awareness due to increased prioritization in texting (brain executive function), it seems that the body tries to protect itself from any harm of not being aware of the surrounding, and in this case, it does that by increasing stride width (*Jongil et al., 2015)*.

INTRODUCTION

Falls are the leading cause of injury related death in older adults [1]. One in three older adults 65 years or older fall once per year [1]. Given the frequency and severity of falls, research in the past decade has focused on identifying factors that predict and prevent falls. Impaired postural stability is a consistent predictor of falls in older adults but is rarely assessed in clinical settings [2]. Clinical tests are subjective and lack sensitively, while objective measures require expensive equipment (i.e. force plates, motion capture cameras) and lack of expertise.

Mobile technology such as smartphones are emerging as a tool to measure postural stability. Because smartphones are commercially available and owned by a large proportion of the population across all age groups, they may serve as a solution to measure postural stability in clinical or home settings [3]. The purpose of this study was to determine if a smartphone can measure static postural stability and distinguish between fall risk in older adults compared to a force plate. We hypothesized that smartphone measures would be comparable to force plate measures during progressive, static balance conditions, and that smartphone measures would be able to distinguish between older adults with low and high risk of falling.

METHODS

Thirty healthy, older adults (age=67.17 ± 6.00) underwent static balance tests while standing on a force plate (Bertec Inc, Columbus, OH) and holding a Samsung Galaxy S6 (Samsung, Seoul, South Korea smartphone) with their dominate hand medially against the chest and along the sternum. Seven static balance tests were conducted in the following order: 1) eyes open, 2) eyes open with concurrent cognitive challenge (dual task), 3) eyes closed, 4) eyes closed with dual task, 5) semi tandem stance, 6) tandem stance, and 7) single leg stance. Two trials of each static balance task were performed. During the dual-task, participants simultaneously subtracted by seven from a random number between 100 and 200.

Center of pressure (COP) data from the force plate was extracted, and various parameters including velocity in the anterioposterior (AP) and mediolateral (ML) directions and 95% confidence ellipse were calculated. Acceleration from the smartphone was extracted and peak acceleration and root mean square (RMS) in ML, AP and vertical directions were calculated. To maximize reliability data was averaged across two trials for each condition. Spearman rank-order correlations were conducted between the force plate and smartphone measures, and receiver operating curves (ROC) and the area under the curves (AUC) were constructed to distinguish between low and high fall risk. Per guidelines, a physiological profile assessment score, a test that measures fall risk, of above one was considered high risk and below one was considered low risk [4].

RESULTS AND DISCUSSION

Peak acceleration ML ranged from 0.403-0.841 m/s^2, peak acceleration vertical ranged from 10.051-10.403 m/s^2, and peak acceleration AP ranged from

1.754-1.998 m/s^2. RMS ML ranged from 0.072-0.120 m/s^2, RMS vertical was 9.81 m/s^2, and RMS AP ranged from 0.181 m/s^2 to 0.242 m/s^2. COP velocity AP ranged from 9.628 mm/s to 27.050 mm/s and COP velocity ML ranged from 3.817 mm/s to 27.612 mm/s. COP 95% confidence ellipse ranged from 172.440 mm to 1135.500 mm. These values are similar to previously reported values of older adults.

Spearman's correlations found moderate correlations between COP measures from the force plate and acceleration measures from the smartphone. There were significant correlations between COP velocity from the force plate and RMS from the smartphone during eyes open dual task, eyes close dual task, semi-tandem, tandem, and single leg stance (ρ=0.423-0.812; p<0.01-0.05). Correlations were greater with more challenging balance conditions.

Table 1 indicates the AUC from constructed ROCs. For brevity, the first five conditions are included. The AUC for COP velocity in the AP direction ranged from 0.61-0.82 and in the ML direction ranged from 0.70-0.75. The AUC for RMS AP ranged from 0.58-0.77, RMS ML ranged from 0.47-0.72, and RMS vertical direction ranged from 0.60-0.82.

CONCLUSIONS

Our results support our hypothesis that acceleration from a smartphone is a valid measure of postural sway in older adults. In addition, RMS AP from a smartphone was capable of distinguishing between older adults at a low and high risk of falling.

This study provides evidence that smartphones are a valid way to measure postural stability and assess fall risk in older adults. Because smartphones are portable, cost-effective, and commercially available, there is potential for smartphones to be used in clinical or home settings to help provide objective, balance assessments for older adults. Future work should measure postural stability with a smartphone in a non-laboratory setting and determine the usability of smartphone technology to measure fall risk in older adults.

INTRODUCTION

Adult degenerative scoliosis (ADS) patients comprise a variety of conditions that affect the normal spinopelvic alignment in the coronal and or sagittal planes. In spinal deformity patients a variety of postural changes in the spine, pelvis and lower extremities are observed in their effort to compensate for the anterior shift in the gravity line. Spinal alignment surgery was found to improve balance and overall function. Balance is defined as the ability of the human body to maintain its center of mass within the base of support with minimal postural sway. Sway can be measured as the center of pressure (COP) movement when a person is standing in a static position.

Objective of this study is to investigate the effect of surgical alignment on postural sway in ADS patients both before and 3-months-after-surgery.

METHODS

Clinical gait analysis was performed on eighteen ADS patients. Each patient performed a series of functional balance tests one week prior (Pre) and 3 months post-surgery (Post) one week prior and 3 months post-surgery. The functional balance test was similar to a Romberg's test in which the patients were asked to stand quietly with each foot on a force platform (i.e., total two force platforms) in a self-selected posture with eyes open for a full minute. Force platform data were used to compute COP measures in both anterior-posterior (AP) and medial-lateral (ML) directions. Two postural sway assessment techniques were used for analysis: 1. traditional summary COP descriptive measures [1]; and 2. invariant density analysis [2] which describes the dynamic COP distribution over time.

Traditional COP measures, *Range* and *Mean Velocity* of COP were also examined to provide statistical description. The stochastic structure of postural sway was analyzed using a reduced-order finite Markov-chain model [2]. The location of the COP can be categorized as different states emanating from the centroid. It has been shown that the distribution of COP over the state space converges to a unique steady state distribution π, known as invariant density [2]. Therefore, by understanding the invariant density, we can observe the long-term postural sway behavior. Five parameters were used to characterize the invariant density to better understand the system dynamics. This technique is called Invariant Density Analysis (IDA) [2]. In this study, we examined five IDA parameters: *Ppeak*, *MeanDist*, *D95*, *EV2*, and *Entropy*. *Ppeak* is the largest probability of π. *MeanDist* is the average location of the COP. *D95* is the largest state at which there is a 95% probability of containing the COP. *EV2* is the 2nd largest eigenvalue of the transition matrix and describes the convergence rate of the system to the invariant density. *Entropy* is the measure of randomness.

In addition to the existing IDA parameters, we introduced one more new metric that provides insight into the control mechanisms of the postural control system. As suggested in [3], the eigenvector corresponding to the second largest eigenvalue is of our interests. Hur [3] noted that investigation of the second eigenvector has the potential to provide a complete understanding of the embedded dynamics

in the reduced order model. Recently, [48] reported that the state space could be subdivided into two subsets depending on the sign of the corresponding second eigenvector (i.e., positive vs. negative). Each subset shows different dynamic behavior. Using this idea, we will investigate the zero crossing point of the second eigenvector, *ZeroCross*, to measure how much the central nervous system (CNS) is actively involved in the control of the standing balance. We report only the results in the AP direction, which showed statistical significance. A paired *t*-test was performed. Level of significance was set to p=0.05 (SPSS, v21, Chicago, IL).

RESULTS AND DISCUSSION

Surgical alignment revealed a significant decrease in the *ZeroCross* from the IDA. The *ZeroCross* in AP were Pre: 10.43±5.82 vs. Post:8.49 ± 3.78mm (*p*-value: 0.05) (Table 1, Fig. 1). The other variables did not detect the significant differences (Table 1).

CONCLUSIONS

The smaller *ZeroCross* from IDA post-surgery indicates that the surgical intervention and re-alignment allows the human postural control system to provide more active and robust balance. In other words, the CNS became more actively involved in the control of standing balance and thus the patients regain more efficient standing balance after the surgical re-alignment. The only significant change in *ZeroCross* and the insignificances from all the other measures suggest that 3 months after surgery may not be a sufficient time for ADS patients to fully recover. A long term follow-up is required. Objective motor performance measures such as *ZeroCross* from IDA will improve the evaluation and understanding of the biomechanical effects of spinal disorders on locomotion.

MOVING BEYOND TRIPS AND SLIPS WITH PROXIMAL DETERMINANTS OF FALLS IN OLDER ADULTS: THE MOBILIZE BOSTON STUDY

Hyun Gu Kang*, Jonathan Hsu, Jasper Angeles

California State University San Marcos, San Marcos, CA, USA

email: hkang@csusm.edu, web: http://faculty.csusm.edu/hkang

INTRODUCTION

Although falls are common in older adults, the immediate circumstances surrounding a fall, particularly its biomechanics, are not well known [1]. The biomechanics of some types of falls, such as trips and slips, are well characterized, but it is clear if some types of falls are also common or need to be characterized better.

Distal risk factors for falls as such as age, gender, fall history, medical history, disability, gait speed, gait variability, etc. are often collected in large epidemiological studies of falls. Unfortunately, almost always all falls are studied as a single outcome, even though the biomechanics of each fall is unique. This is because it has been difficult to determine biomechanics of falls *in situ*, because the immediate circumstances of a fall are often difficult to measure in real life. Understanding the wide range of biomechanical and environmental factors that influence the immediate circumstances of a fall would allow for better preventative strategies.

Therefore, our goal was to determine (1) the immediate circumstances surrounding the falls, the *proximal* determinants of falls from an interview narrative, (2) our reliability in determining these determinant, and (3) their relationship with traditional *distal* risk factors, in order to better understand the specific biomechanics related to each fall.

METHODS

We used a structured interview data of self-reported falls from the MOBILIZE BOSTON STUDY database. The MOBILIZE Boston Study (MBS), which stands for "Maintenance of Balance, Independent Living, Intellect, and Zest in the Elderly of Boston" is a prospective study examining risk factors for falls, including pain, cerebral hypoperfusion, and foot disorders in the older population [2]. The study includes a representative population sample of 765 elderly volunteers age 70 or above from the Boston area. They were 77.9±5.3 years old, with height of 1.63±0.10 m and weight of 74.1±19.7 kg. 64% were female. The dataset is available to the public.

Standing postural data was collected on a Kistler force place. Participants stood 30 seconds at a time, eyes open. Postural sway and stiffness (Ke) were calculated per Winter's method [3].

Falls data was collected through monthly mail-in fall calendars, where the participant marked the days when a fall occurred. Once the calendars were received, the participant completed a structured interview over the phone. The circumstances, injuries, and the type of fall was recorded from the interview. Over the study period, a total of 1425 verified falls and narratives were identified.

Proximal determinants of falls were determined through (1) reading and sorting of fall narratives into categories by the investigators, (2) refining the categories, definitions, and the classification algorithm then iterating the process, (3) training two naïve readers to categorize the narratives, and (4) comparing the reliability of the algorithm. Each fall was allowed to enter multiple categories.

The incidence rates of these proximal determinants were compared to distal risk demographic, medical, functional, and biomechanical factors, such as age, gender, cognitive function, disability, gait speed, and postural sway, stiffness and damping. Negative

binomial regression was used, using R software 3.4.1.

RESULTS

Trips and slips: Of the 1425 verified falls, 581 (41%) were self-reported trips, 315 (22%) slips, and 529 (37%) neither. 49% of trips occurred outdoors and 51% indoors. 70% of slips occurred outdoors, and 30% indoors. 39% of other falls occurred outdoors and 60% indoors. Lower postural stiffness (p=.05) and damping (p=.004) predicted trips. Lower damping (p=.05) predicted slips. Increased sway predicted other falls. (p<.004).

Proximal determinants: 14 proximal determinants and frequencies were identified (Table 1). 74.67% of falls had only one proximal determinant. The classification algorithm produced 89% agreement between the raters.

Table 1: Proximal Determinants

Proximal determinant of fall	**Count / %**	**Associated with**
Obstacles	378/ 21%	
Texture change	272/ 15%	
Platform Height	358/ 20%	AP Ke
Perturbation	22/ 1%	AP sway
Impaired Vision	30/ 2%	
Sit-to-stand	87/ 5%	AP sway, ML sway
Push-pull	21/ 1%	
Carrying Object	42/ 2%	
Bending over / Reaching overhead	43 /2%	ML Ke
Dual-task	170 /10%	
Absentmindedness	90 /5%	
Speed (too slow or fast)	78 /4%	
Rotation	43 /2%	
Internal (felt dizzy, etc.)	140 / 8%	AP Ke, AP sway, ML sway

Distal Factors:
Falls due to internal issues were negatively associated with AP Ke (p = .003) and positively with AP and ML sway (p = .003, .001). Platform height changes were negatively associated with AP Ke (p = .03). Perturbations were positively associated with AP sway (p = .03). Sit-to-stand was positively associated with AP sway (p = .01). Sit-to-stand was positively associated with ML sway (p = .003). Bending-over-reaching-overhead was positively associated with ML stiffness (p = .01).

As shown previously, postural sway was positively associated with fall rates, and postural stiffness was negatively associated with fall rates.

DISCUSSION

Our goal was to determine the proximal determinants of falls. A greater variety of proximal determinants were identified given that 37% of falls were neither slip or trip. The most common proximal determinants were obstacles (21%), platform height change (20%), texture change (15%), and dual tasking (10%). Postural stiffness appears to be protective of platform height changes and internal issues, suggesting that these situations particularly require the ability to stabilize the body. However, postural sway is predictive of falls due to perturbations, internal issues, and sit-to-stand, which require better COM control. Further work is needed to understand specific physiologic and biomechanical reasons for these associations.

Although the proximal determinants were derived from verbal rather than video or inertial sensors, the falls data were collected from a representative community-dwelling population and therefore the results have strong external validity. Our work suggests that the biomechanics and neurophysiology of falls due to platform heights and dual tasking need further study, beyond obstacles/trips, and texture changes/slips.

Ethnic differences in lower extremity static and dynamic postural measures as a potential risk factor for Anterior Cruciate Ligament (ACL) Injury

Chang-Young Kim [1,2], Sae-Yong Lee [1,2]

Integrated Sports Science Research Laboratory (ISSRL) [1]
Yonsei Institute of Sports Science & Exercise Medicine (YISSEM)[2]
E-mail: cykim1204@gmail.com

INTRODUCTION

More than 70% of Anterior Cruciate Ligament (ACL) injury is related to sports with incidence of 1 per 3000 for the general population and injury rate for female is as much as eight times the higher as male in the United States[4]. However, Korean National Health Insurance Service (KNHIS) data analysis reported that, male have higher knee injury rate as compared to female in South Korea[3]. The risk factor of anterior cruciate ligament (ACL) injuries is generally associated with quick deceleration, hyperextension or rotation, muscle fatigue, and gender differences. It is well known that female has different kinematics and kinetics during landing and cutting, as compared to male in the United States[1,2]. However, there is a lack of study regarding ethnic differences in static and dynamic LEAs. Therefore, the purpose of this study is to determine whether ethnic differences exist in lower extremity static and dynamic postural measures between Caucasian female and Asian female.

METHODS

A total of 30 subjects were voluntarily participated. 15 Caucasian female (age: 21.3 ±1.58 yrs; weight: 63.9±7.42 kg; height: 169.6±4.60 cm) and 15 Asian female (age: 20.4±1.20 yrs; weight: 57.8±3.86 kg; height: 164.0±2.72 cm). Without any past history of lower extremity surgery. The definition caucasian includes persons of Scottish, New Zealander, Greek, English, Canadian, Welsh, Irish, and-in the United State[5]. This research choose the subject who parents were born in above countries.

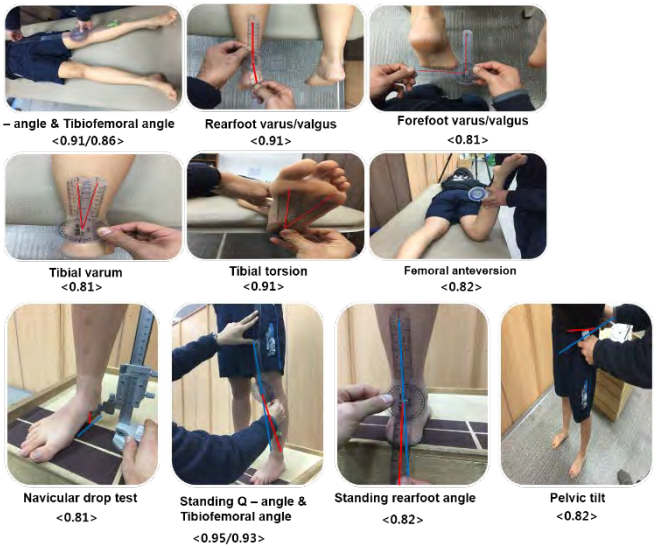

Figure 1. Static alignment measures. <ICC Level>

All subjects performed drop jump and static alignment measure. Drop jump was performed a 30cm-box, which was set at the half of their height distance away from the force plate. A single investigator measured the static alignment variables with lying and standing from all subjects.

Three-dimensional knee joint kinematics were extracted from 2 different type of motion analysis system (Vicon Inc, Oxford, UK; BTS Bioengineering, Milano, Italy).

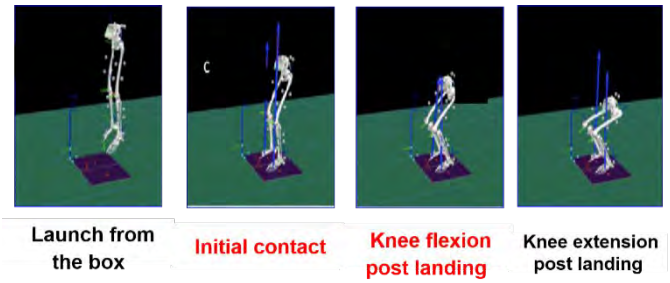

Figure 2. 3D motion capture during drop jump from a 30cm box.

All joint kinematics were analyzed at one discrete point which was 30° knee flexion during Drop jump from a 30cm-box. Independent sample t-test was performed to analyze mean differences between ethnicity.

RESULTS

<Static>

There were significant differences between Caucasian and Asian female at static lower extremity alignment measure. Asian female had significantly greater Q-angle (t= -3.782, p=0.00), Anteversion angle (t=.263, p=0.00), Rear, Fore foot angle (t= 2.020, p=0.00) compared to Caucasian female. Caucasian female had significantly greater TF-angle (t= 3.435, p=0.00), Tibial-varus angle (t=2.351, p=0.00), Tibial torsion angle (t= 2.645, p=0.00) compared to Asian female.

Variable	Caucasian		Asian		Effct size (η^2)
	Female (n = 43)		Female (n = 43)		Ethnic effect
	M	SD	M	SD	
Q-angle	15.3	2.79	19.01	4.40	1.01 (0.23~1.79)
TF angle	19.66	3.44	12.92	1.95	-2.41 (-3.01~-1.82)
Anteversion	7.15	2.36	10.19	6.52	0.62 (-0.42~1.66)
Rear-foot	1.14	4.08	5.98	4.26	1.16 (0.28~2.04)
Fore-foot	15.23	4.55	18.16	6.41	0.53 (-0.65~1.71)
Tibial-varus	5.27	1.6	3.51	1.97	0.98 (-1.36~ 0.61)
Tibial-torsion	19.66	4.58	16.58	6.44	-0.55 (-1.73~0.63)
Q-angle(WB)	7.05	2.68	10.58	3.6	1.11 (0.44~1.78)

Table 1. The variables from static alignment of Caucasian female and Asian female (p<.05).

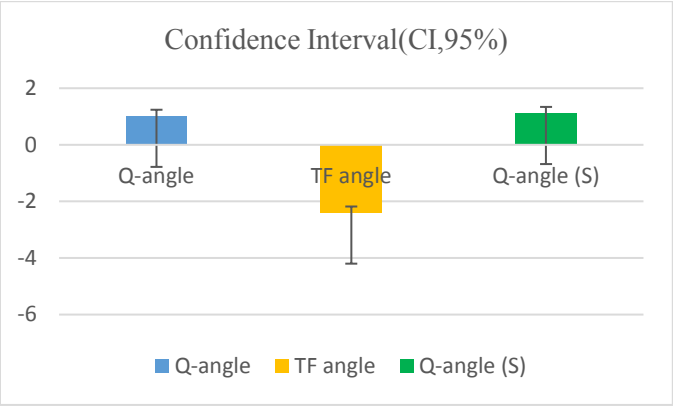

Table 2. The confidence interval from static alignment of Caucasian female and Asian female (p<.05).

<Dynamic>

There were statistically significant differences between Caucasian and Asian female at max angle during initial contact to 30° knee flexion. Caucasian female had significantly greater knee valgus angle (t= -3.293, p=0.03, Caucasian: -3.15°±6.12°; Asian: 3.19°±3.94°) and knee internal rotation (t= 2.143, p=0.41, Caucasian: 12.58°±9.54°; Asian: 5.05°±9.35°) compared to Asian female in drop jump from a 30cm-box.

Variable	Caucasian		Asian		Effct size (η^2)
	Female (n = 15)		Female (n = 15)		Ethnic effect
	M	SD	M	SD	
Hip Flexion	44.7	8.12	39.8	5.00	0.73 (-0.01~1.47)
Hip Adduction	-5.60	4.48	-5.88	4.36	0.06 (-0.65~0.78)
Hip Internal rotation	-9.22	9.31	-2.26	10.28	-0.71 (-1.45~0.03)
Knee Flexion*	31.2	3.15	29.0	2.48	0.78 (0.03~1.52)
Knee Valgus*	-3.15	6.12	3.19	3.94	-1.23 (-2.01~-0.45)
Knee Internal rotation*	12.6	9.54	5.05	9.35	0.8 (0.06~1.54)
Ankle Dorsi Flexion	-5.99	8.60	-6.12	8.69	0.02 (-0.7~0.73)
Ankle Eversion	1.31	2.25	.92	2.29	0.17 (-0.55~0.89)
Ankle Internal rotation	-4.08	8.11	-6.17	10.9	0.22 (-0.5~0.94)

Table 3. The variables from drop jump of Caucasian female and Asian female at max angle during initial contact to toe off (p<.05).

CONCLUSION

Our results showing that significantly differences between Caucasian female and Asian female in static and dynamic alignment. Greater knee valgus and internal rotation in a Caucasian female may support the difference of ACL injury rates between Caucasian female and Asian female. The difference of dynamic angle between Caucasian and Asian may one of the key factor for ACL injury rate. Possibly reducing knee valgus and internal rotation may drop the injury rate of female to similar with a male as found in South Korea. Further study is necessary to investigate the relation between static and dynamic angles in different ethnic and whether static LEAs contribute to dynamic LEAs or not in dynamic movements during numerous sports event.

INTRODUCTION

More human-like driver models could realize improved driving in various driving environments and could be useful for advanced safety design of human-operated vehicles as well as autonomous vehicles [1]. We attempted to implement a robotics-based control algorithm on the OpenSim [2] human model with a driver-vehicle feedback system [1, 3] to simulate human-like posture control in a moving vehicle as Figure 1.

Although Proportional, Integral and Differential (PID) control is widely accepted for many purposes, PID allows feedback control only for a single-input-single-output (SISO) system, e.g. independent joint control. Some studies have applied PID control for occupant balancing problem, however, simulated postures could not fully predict the postural response of braking drivers due to limitation of SISO [3]. On the other hand, motion control algorithms for a human driver may require multiple inputs, such as positions and contact forces, and produce multiple outputs, one for each actuated degree of freedom. In addition, since human body is modeled as a coupled multi-body system, a single link of a human body may receive forces and torques from adjacent or connected other links. As a result, the control system for a human driver requires a multiple-input-multiple-output (MIMO) feedback system. Therefore, this study employed the inverse dynamics control algorithm to enable MIMO feedback system.

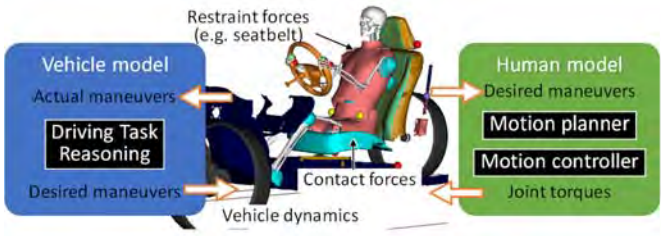

Figure 1: Driver-vehicle feedback system with OpenSim model.

This paper presents balancing driver's posture with consideration for dynamics.

METHODS

The OpenSim driver-vehicle model has more than 90 bodies and around 200 state variables. Human driver model consists of head/neck [5], lumbar/torso [6], upper extremity [7], and lower extremity [8] models. Muscle elements were replaced with ideal torque actuators at the joints for the simplicity. Anthropometry of the model is assumed as height of 1.8 m and weight of 77.4 kg. The OpenSim vehicle model represents 2012 Toyota Camry. Model geometry and inertial properties were obtained from a finite element (FE) model of Toyota Camry [9]. This model includes major components of vehicular exterior and interior such as driver seat, pedals, and steering wheel. Joint center, mass center, inertial properties for all components were estimated from properties of FE models. Elastic foundation definition of OpenSim is used in modeling the contacts of lower extremities against brake/gas pedals, floor of vehicles as well as upper bodies against steering wheel and interior components. In particular, the contact geometry of foot is obtained from shoes model of Hybrid III 50th percentile male dummy [10], and contact forces are validated against sole impact test data [11].

The inverse dynamics control is valid in a system with known mass, Coriolis, and gravity [12] as following equation:

$$M(q)\ddot{q} + C(q,\dot{q}) + N(q) = \tau \qquad (1)$$

where q is the state variables in joint space, $M(q)$ is mass matrix, $C(q,\dot{q})$ is velocity vector which is the product of Coriolis matrix and velocity of state variables, $N(q)$ is gravity vector, and τ is the joint torques. We utilized SimBody API [13] to extract dynamics parameters from OpenSim model during runtime. For the dynamic system as in equation (1),

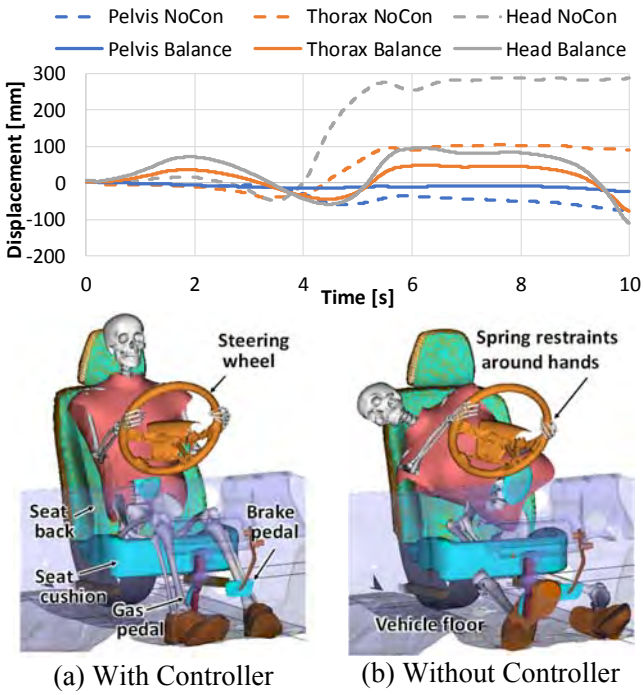
the inverse dynamics control in joint space will compute the joint torque τ via the coefficients K_P and K_D and designed control law as following:

$$\tau = M(q)a_q + C(q,\dot{q}) + N(q) \quad (2)$$

$$a_q = -K_P(q - q^d) - K_D(\dot{q} - \dot{q}^d) \quad (3)$$

where a_q is a new transformed input term, q^d is desired joint state variables. In case of balancing control, initial joint angles set q^d with $\dot{q}^d = 0$. Because we desire the error to converge to zero, this control law will make the system asymptotically stable when K_D is positive.

The base body of vehicle model was enforced to move as desired acceleration pulses. The 2 DOF acceleration data in lateral translational motion and yaw rotation were obtained from a linear driver – vehicle model [3] to express vehicle dynamics of slalom driving. Custom joint between seat cushion and pelvis performs as free joint, however, pelvic motions are constrained by contacts with friction and non-linear point-to-point forces which represent seatbelt tensions. The inverse dynamics control in balancing upper body was operated with 50 Hz of feedback frequency. The utilized gains for K_P and K_D were 200 and 20 respectively.



(a) With Controller (b) Without Controller

Figure 2: Comparison of relative displacements on head, thorax, and pelvis against vehicle frame during slalom lateral vehicle motions (upper), and driver model kinematics at 5 [s] (lower).

RESULTS AND DISCUSSION

Figure 2 shows body kinematics of human driver model in vehicular lateral motions. Human driver model with no controller fold up the upper body during vehicular lateral motions because of no active joint torques. On the other hand, the controller maintained the human body in human-like upright posture. The balancing controller reduced the maximum displacements.

Although lateral motions of vehicle would create non-linear body kinematics of human driver, the balancing controller based on inverse dynamics control with gravity compensation succeeded in maintaining upper body balance during lateral vehicular motion. The results of balancing control indicate that extracted parameters using SimBody API from the model were appropriate for requirements of the inverse dynamics control. Previous studies published occupant response data using real human volunteer subjects in moving cars. Further simulation with similar simulation setup as previous study would be necessary for validation of system and assumed parameters.

JOINT ANGLE COORDINATION STRATEGIES DURING ROTATIONS IN DANCE

Melanie B. Lott

Denison University, Granville, OH, USA
email: lottm@denison.edu

INTRODUCTION

The motion of any rigid body is fully characterized by the sum of two independent components: translational motion of the center of mass (CM) and rotational motion of the body around the CM. Previous work on step and spin turns has shown that these movements require larger ranges of motion outside of the sagittal plane and different muscular demands than straight-line gait [1]. Given the prevalence of rotational maneuvers in everyday life, more studies on whole-body rotations and balance maintenance in particular are needed.

A pirouette is a whole-body rotation in which rotational momentum is generated from a double stance, then some number of revolutions are completed about a vertical axis on a single support. It has been shown that dancers are likely to make adjustments for balance maintenance during pirouettes [2]; however, the nature of these adjustments has yet to be measured.

The goal of this study was to perform principal components analysis (PCA) on joint angle data of dancers performing pirouettes to determine whether joint angle coordination strategies were utilized. Previously, PCA has found relative contributions of body segments' motion to postural control in quiet standing [3]. It is hypothesized that dancers utilize coordination strategies in pirouettes, but the particular joints and directions involved in these strategies may vary between individuals.

METHODS

Six injury free, advanced female dancers (20.2 ± 5.5 years) participated after giving informed consent (parental consent). Dancers performed triple-turn pirouettes until 4-5 clean trials were obtained, i.e. the dancer landed after three complete revolutions (1080°). Position data of 70 reflective markers attached to dancers were recorded with a 6-camera system (100 Hz; Oqus 5+, Qualisys). Marker data were low-pass Butterworth filtered (6 Hz) and used to define and track body segments.

Lower extremity joint angles (ankle, knee, hip) and pelvis-trunk angle were determined from LCS orientations of adjoining segments. The Cardan sequence of rotations was performed in Visual3D (C-Motion) to compute flexion/extension (X), abduction/adduction (Y), and internal/external rotation (Z). To isolate the turning phase, joint angle data were time-normalized, beginning at 360° and ending at 900° (1.5 revolutions).

PCA was performed on the joint angle time series data for each dancer (4 or 5 trials x 21 joint angles) using R Studio. Eigenvalues of the covariance matrix, mean centered and normalized to unit trace, were computed and provided the proportion of variance in the data explained by each PC (Table 1). Coefficients of the corresponding eigenvectors were determined and indicate the contributions of each joint angle to the PC (Fig. 2).

RESULTS AND DISCUSSION

Evolution of the data along PC1 and PC2 show two distinct patterns (Fig. 1). One PC had a clear upward trend ("PC_{Drift}") and the other PC exhibited oscillatory behavior ("$PC_{Oscillate}$"). The period of oscillation of $PC_{Oscillate}$ was calculated from the time between the global minimum and peak maximum (average = 66 ± 5%). In time normalized units, the period of oscillation of the pirouette is 66.7% (1/1.5 rev^{-1}). The movement characteristic of $PC_{Oscillate}$ (average eigenvalue = 0.2514) is joint angle oscillations near the characteristic frequency of the pirouette. A Fourier analysis is necessary to further determine the frequency spectrum. The joint angles contributing most greatly to $PC_{Oscillate}$ vary by dancer (Fig. 2).

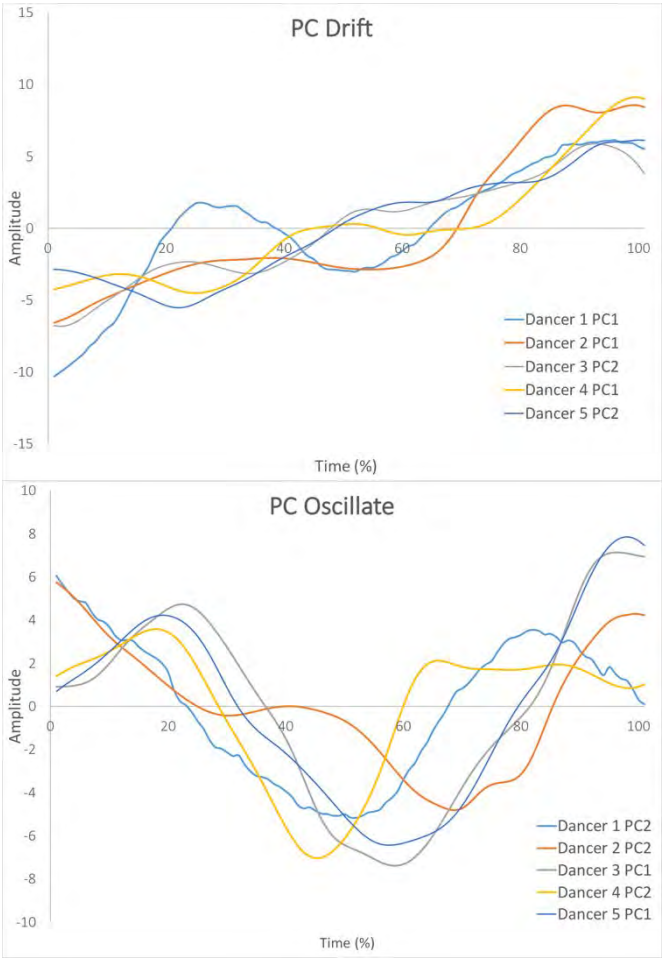

Figure 1: Evolution of the data along the first two PCs (i.e., "eigenmodes). Note that PC2 (PC1) for Dancers 3 and 5 is included in PC_{Drift} ($PC_{Oscillate}$).

Fewer joint angles typically contributed meaningfully to PC_{Drift} than $PC_{Oscillate}$. For example, AnkleX, KneeZ, and Pelvis-TrunkZ had the most significant contributions to PC_{Drift} for Dancer 5. This dancer employed a strategy to descend from "demi-pointe" (ankle plantarflexion) in coordination with pelvis-trunk external rotation. She also experienced knee external rotation during this maneuver. The movements characterized by PC_{Drift} often captured early landing mechanics.

Further research on joint coordination strategies, and in particular which strategies are correlated with CM motion, could provide dancers with methods for enhancing pirouette performance and could potentially lead to understanding of balance maintenance strategies during whole body rotations more generally.

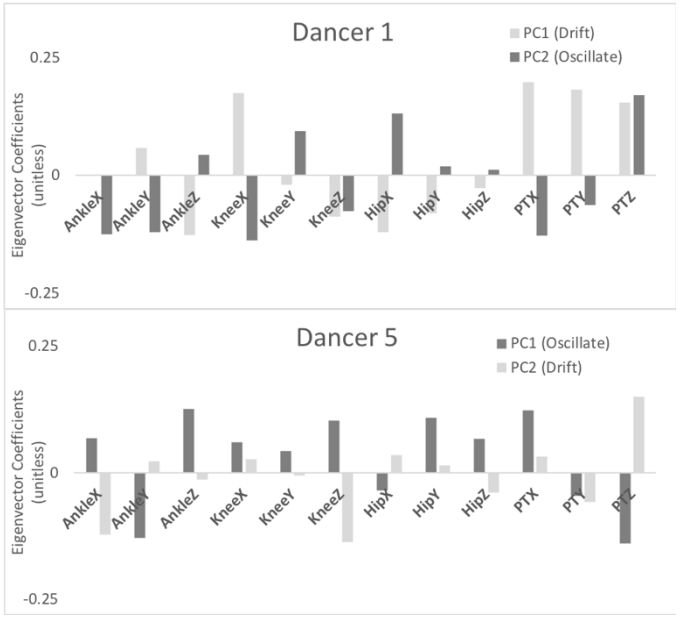

Figure 2: Coefficients of the eigenvectors of PC1 and PC2 for Dancer 1 and Dancer 5.

A POWERED 3D COMPASS WALKER: ENERGETICS AND STABILITY OF PERIOD-1 GAITS

Soumyabrata Maiti, Jonathan B. Dingwell, and Joseph P. Cusumano

The Pennsylvania State University, University Park, PA, USA
Email: sxm710@psu.edu

INTRODUCTION

Simple anthropomorphic models play an important role in research on human locomotion, particularly for studies concerned with energy consumption and stability. Kuo's analysis of a 3D passive dynamic walker [1] showed that lateral stability may present an inherently greater challenge to the nervous system than sagittal plane stability, a prediction supported by experiments with humans [2]. In other studies, an open-loop stable, impulse-driven planar walker was used to examine the relationship between preferred speed and step length [3], and to compare the energetics of toe-off impulses to hip actuation [4]. To date, however, a powered version of the 3D "compass" walker has not been studied. We here present such a model, find its period-1 gaits, and examine their basic dynamic and energetic properties.

METHODS

Following [1], governing equations in the angles q_1, q_2, and q_3 (see Fig. 1) are derived using angular momentum balance about the ground contact point, O, the joint between the foot and stance leg, A, and the hip of the swing leg, B.

Conservation of angular momentum across the heel strike can be written in matrix form as

$$[H]^{+}\begin{bmatrix}\dot{q}_1^{+}\\ \dot{q}_2^{+}\\ \dot{q}_3^{+}\end{bmatrix} = \begin{bmatrix}h_{\mathrm{O}}^{-}\\ h_{\mathrm{A}}^{-}\\ h_{\mathrm{B}}^{-}\end{bmatrix} + \begin{bmatrix}M_{\mathrm{O}}\\ M_{\mathrm{A}}\\ 0\end{bmatrix} \qquad (1)$$

where: $-/+$ superscripts denote before/after impact; $h_{\mathrm{O}}, h_{\mathrm{A}}, h_{\mathrm{B}}$ are angular momentum components about O, A and B in the n_3, f_1 and i_3 directions, respectively (Fig. 1); $\dot{q}_i$ $(i = 1, 2, 3)$ are angular velocities; and $[H]^{+}$ is a state-dependent matrix. Impulsive moments M_{O} and M_{A} in the sagittal and frontal planes, respectively, arise from the toe-off impulse P (Fig. 1). During application of P we assume an impulsive moment acting at the ankle to counteract M_{A}.

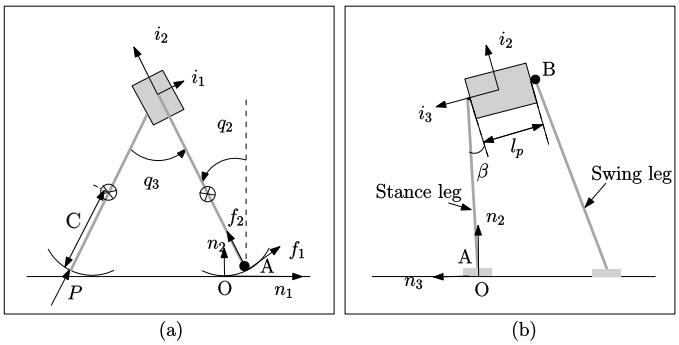

Figure 1: Powered 3D walker at heel strike/toe off: point O is the ground contact, B the hip joint, and A the stance foot "ankle" (see Eq. 1). Center of mass of each leg is a distance C from each foot. Just before toe-off, impulse P is applied along swing leg.

Simulations of the governing equations were carried out using `ODE15s` in Matlab to find the time evolution of the system during the single support (i.e., swing) phase, that is, between visits to the Poincaré section determined by heel strike [1]. A shooting method and arc-length continuation were used to study the system's behavior as a function of P.

RESULTS AND DISCUSSION

Period-1 gaits (i.e., fixed points of the impact Poincaré map) of the powered walker are shown in Fig. 2. The stability properties at each point on the curve were also determined via eigenanalysis, as required for controller design. All solutions shown were found to be open-loop unstable, with each possessing an unstable roll mode; some have additional unstable modes that stabilizing control must account for. Also shown are bifurcation points corresponding to saddle node (I,III, V), period doubling (II, IV, VII), and secondary Hopf (VI) bifurcations. At these points, the number of unstable directions that need to be controlled changes.

As in [1], splay angle control is used to stabilize the roll direction of the long period gait, however, for gaits possessing a sagittal plane instability we implemented

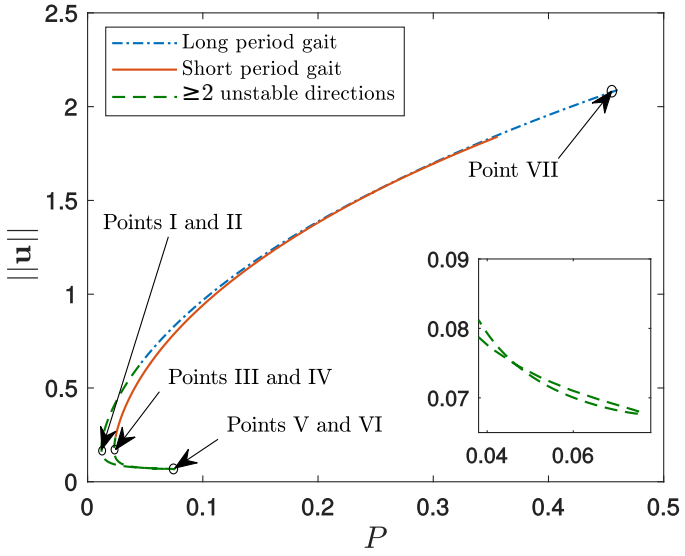

Figure 2: Magnitude $\|\mathbf{u}\|$ of period-1 fixed points vs. toe-off impulse P. Without feedback control, all solutions have at least one unstable mode. Bifurcation points I–VII are also shown (see text).

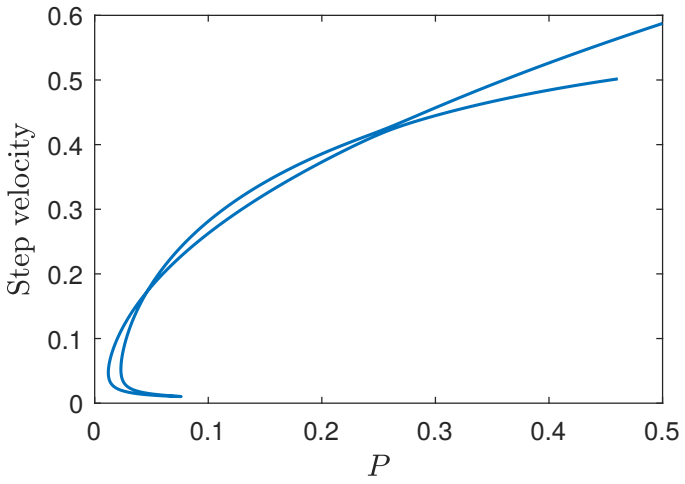

Figure 3: Step velocity (step length/step time) vs. P for system, corresponding to the steady state solutions displayed in Fig. 2.

an additional toe-off impulse controller. Figure 3 shows the step velocity (step length divided by step time) along the curve of Fig. 2.

Figure 4 shows the work done by the toe-off impulse P for the period-1 gaits of Figs. 2, normalized by the maximimum leg swing kinetic energy. For a given toe-off impulse, we find the short period gait (Fig. 2) is more efficient than the long period gait, dissipating less energy during heel strike. The relative power requirement is lowest for the portion of the solution

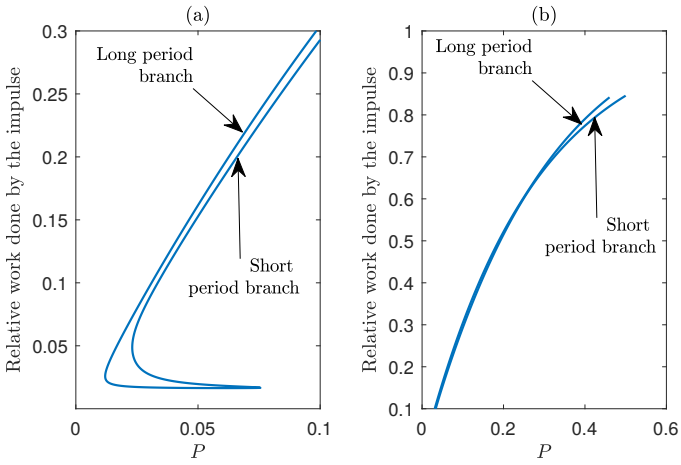

Figure 4: Work per step done by P, relative to the maximum kinetic energy during swing phase along solutions of Fig. 2.

curve connecting long and short period gaits, at the expense, however, of a low step velocity (see Fig. 3).

CONCLUSIONS

We presented a variant of the 3D compass walker powered by toe-off impulses, and found its period-1 gaits as a function of impulse strength. Stability analyses showed that all of these gaits are open-loop unstable, and also identified seven bifurcation points where the number of unstable directions change. Thus, we find that some period-1 gaits (those with a higher number of unstable directions) are relatively more difficult to stabilize than others. We also computed the energy cost for the period-1 gaits: for a given value of toe-off impulse, we found that the short period gait is energetically more efficient.

EQUILIBRIUM DURING SINGLE-LEG STANDING WITH HEEL RAISED UP IN INDIVIDUALS WITH ANKLE INSTBILITY

Morikawa M, Urabe Y, Takeuchi T, Hashimoto R, Maeda N

Hiroshima University, Hiroshima, Japan
email: m-masanori@hiroshima-u.ac.jp, web: https://yurabelab.wixsite.com/sportsrehabilitation

INTRODUCTION

Lateral ankle sprain is the most common injury in sports. Since the frequency of recurrent is also high, athletes suffer from chronic symptoms such as swelling, pain and ankle instability. Wikstrom *et al.* reported individuals with ankle instability had exhibited less postural stability during single-leg and found that less single-leg standing ability developed ankle injury risk [1]. Therefore, the evaluation of single-leg standing plays an important role for clinicians.

Although ankle sprain tends to occur with plantar flexed, there is no consideration about ankle joint during single leg standing. Therefore, it is possibility that evaluation of single-leg standing with heel raised up is more useful. The purpose of this study was to clarify whether COP variables can discriminate individuals with ankle instability during single-leg standing with heel raised up.

METHODS

A total of 9 men participated in this study and undertook Cumberland Ankle Instability Tool to divide into 2 groups of individuals with and without ankle instability (CAI and Control) [2]. The cut-off score were more than 25 points. The demographic characteristics was showed as follow; [CAI group - 5 men, age 24.3 ± 1.0 years old (mean ± SD); height 1.76 ± 0.05 m; body weight 74.3 ± 9.72 kg, Control – 4 men, age 25.0 ± 1.0 years old (mean ± SD); height 1.71 ± 0.02 m; body weight 60.8 ± 1.95 kg]. Study procedures were carried out in accordance with the Declaration of Helsinki.

All subjects conducted single-leg standing with heel raised up on a force platform (T.K.K.5810; Takei Scientific Instruments Co., Ltd., Japan) during 5 seconds. Subjects wore T-shirts, spats, no sox and no shoes. The authors instructed each subject to flex the knee at 30 degrees and raise up your heel as high as possible within not losing upright posture. The knee flexion angle of contralateral side set at 90 degrees. Both of hands placed on the hip. Finally, subjects were called to look forward and to maintain posture as stably as possible.

A total of 5 successful trials were recorded, and COP data was collected in 100 Hz. Then, total length (TL) [mm], speed [mm/s], root-mean-square (RMS) amplitude [mm] and RMS speed [mm/s] in anterior-posterior (A-P) and medial-lateral (M-L) directions were calculated respectively.

The unpaired t-test was used for testing the difference between CAI and control. The statistical analysis was performed in SPSS for Windows, version 20.0 (IBM Japan Co., Tokyo, Japan). The significance level was set at 5%.

RESULTS AND DISCUSSION

The total length and RMS amplitude in M-L direction statistically increased in CAI compared to control (Fig.1,2). On the other hand, the other variables showed no significant (Table.1). Results suggested total length, RMS amplitude and RMS speed in M-L allowed to discriminate CAI by single-leg standing with heel raised.

The reason why total lengths and RMS amplitude increased may be related to characteristics of ankle joint. While dorsiflexion position in talocrural joint stabilizes ankle joint, plantarflexion makes talocrural joint lose joint stability [3].

The increased total length after instructing to maintain posture as stably as possible indicated less postural stability [4]. Also, increased RMS amplitude shows to fail maintain COP in same position [4].

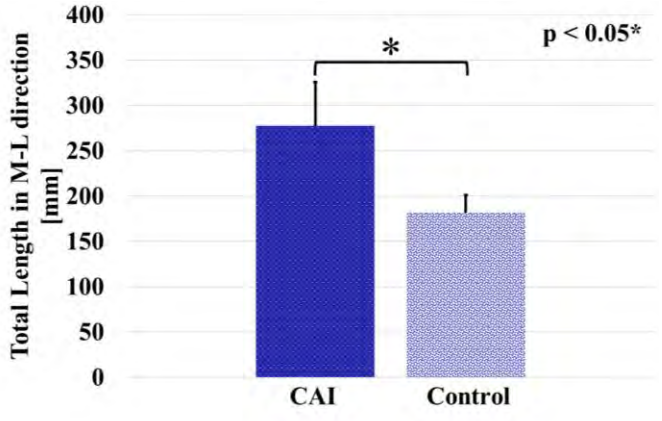

Figure1: Total length in M-L direction during single-leg standing with heel raised up [mm]. M-L, medial-lateral.

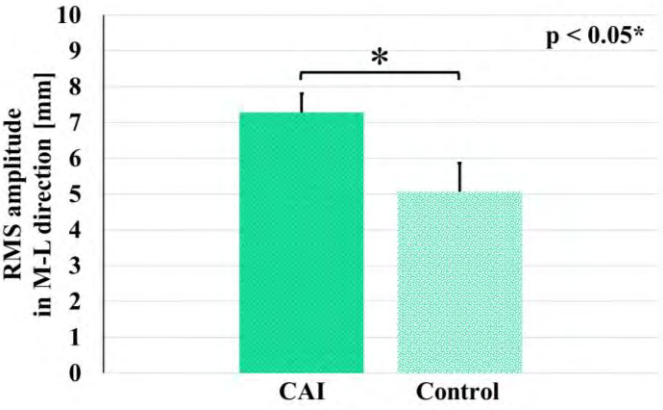

Figure2: RMS amplitude in M-L direction during single-leg standing with heel raised up [mm]. RMS, root-mean-square; M-L, medial-lateral

It is worth mentioning about significant changes of total length and RMS amplitude in only M-L direction. Yota *et al.* found that there was no significant response in total length and RMS amplitude in M-L direction between sprain and control group during single-leg standing without heel raised up. Therefore, single-leg standing with heel raised up may allow to distinguish between CAI and heathy individuals.

CONCLUSIONS

- This study investigated whether single-leg standing with heel raised up can discriminated the individual of chronic ankle instability or healthy.
- Single-leg standing with heel raised up can distinguish individuals of chronic ankle instability by total length and RMS amplitude in M-L direction, in different to previous study.
- Single-leg standing with heel raised up may be effective to evaluate postural stability for chronic ankle instability.

THE EFFECT OF MENTAL FATIGUE ON POSTURAL STABILITY

Amanda Morris and Anita D. Christie

University of Oregon, Eugene, OR, USA
email: amorris8@uoregon.edu

INTRODUCTION

Fatigue is a multidimensional concept that has both physical and psychological components. While neuromuscular fatigue is a transient reduction in the ability of the muscle to produce force or power in response to contractile activity [1], mental fatigue is a psychophysiological state that occurs after or during prolonged periods of cognitive activity [2]. As mental fatigue can negatively affect the ability to simultaneously allocate attention and respond to unexpected stimuli [3], it may impact motor functions such as balance control. This could be especially important in older individuals, as their attentional resources and cognitive processing abilities are more limited than younger adults. However, the effect of mental fatigue on postural stability has not been studied. The purpose of this study was to examine the effect of a mentally fatiguing, sustained attention task on postural stability in young and older women.

METHODS

Thirty-two women (16 young 22.4 ± 3.72 years, 16 older 72.6 ± 6.50 years) participated in this study. Testing was divided into two sessions involving postural perturbations; one mental fatigue session (sustained attentional task) and one control session (scenery video without sound). The order of the protocols across the two visits was randomized across participants.

Perturbations. Hydraulically activated, dual force plates that translated forward and backward were used for postural perturbations. Platform translations were 15 cm at a velocity of 30 cm/s. Trials were randomized and, to account for any learning effect, 20 perturbations (5 forward, 15 backward) were provided in random order at baseline. During both the mental fatigue and control sessions, 5 perturbations (1 forward, 4 backward) occurred at the beginning (1 minute) and end (18 minutes) of the session for a total of 10 perturbations (2 forward, 8 backward) over the 20–minute session. Only backwards perturbation trials were analyzed, forward perturbations were used to avoid an anticipation effect. Force data was sampled at 1kHz then low pass filtered at 10 Hz. Total displacement of center of pressure (COP) and COP velocity in the anterior-posterior direction were used to assess postural stability in response to backward perturbations . . All data were analyzed with custom-written programs using MATLAB software (MathWorks Inc., Natick, MA, USA).

Mental Fatigue Task. During the mental fatigue session, participants were asked to perform the psychomotor vigilance task (PVT; Biotechnology HPC Software Applications Institute) for twenty minutes, which was run using MATLAB. The PVT is based on simple reaction time (RT) to stimuli that are presented at random intervals. Slower reaction times during this task are associated with subjective measures of physical fatigue and decline in energy. Increases in reaction time throughout the protocol indicated the presence of mental fatigue.

Statistical Analyses
Repeated-measures ANOVAs were used to examine the impact of each protocol on each variable. If significance was found, the Bonferroni procedure was used for post-hoc testing. Linear regression was used to determine if there was a significant relationship between percent change in PVT reaction time and percent changes in COP displacement and COP velocity.

RESULTS AND DISCUSSION

Reaction Time. Older women had significantly slower reaction times (325.17 ± 30.90 ms) than young (287.95 ± 29.53 ms) at baseline (p=0.002) (Figure 1). Reaction time significantly increased

over the 20-minute period only for the young women (p=0.001; 287.95 ± 29.5 vs. 320.3 ± 35.05 ms), indicating the presence of mental fatigue (Figure 1).

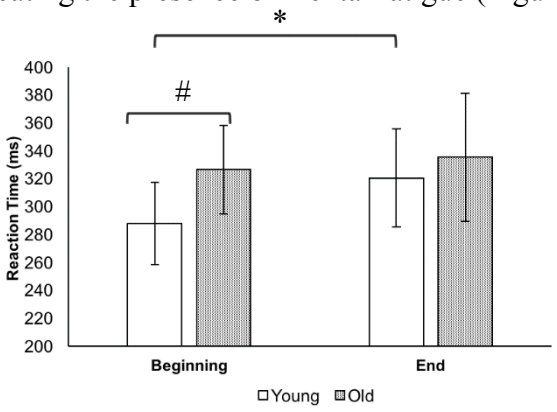

Figure 1. Reaction time from first 5 minutes (Beginning) and last 5 minutes (End) of the PVT. *p=0.001, #p=0.002.

Postural Stability. Older women had significantly larger anterior-posterior COP displacement (p=0.001; 6.89 ± 0.96 cm vs. 5.74 ± 0.96 cm) and significantly faster COP velocity (p=0.04; 41.14 ± 12.29 cm/s vs. 31.51 ± 12.30 cm/s) than young women. Young women had significantly faster COP velocity during the mental fatigue condition (p=0.009; 36.27 ± 16.74 cm/s vs. 26.75 ± 10.68 cm/s) than the control condition

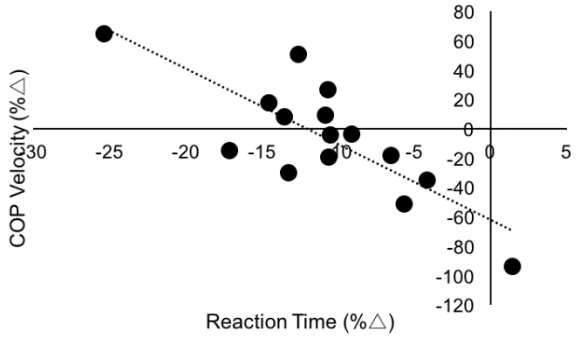

Figure 2. The relationship between percent change in RT and percent change in COP velocity in young women.

Relationship Between Reaction Time and Stability. There was no significant relationship between percent change in reaction time during the PVT and percent change in COP displacement in either the young or older women. Percent change in reaction time during the PVT significantly predicted percent change in COP velocity (r=-0.80, p=0.001) in young women only (Figure 2). The magnitude of this effect was large, explaining 64% of the variance in percent change in COP velocity (p=0.001) in young women only (Figure 2).

CONCLUSIONS

Older women had slower reaction time, larger COP displacement, and faster COP velocity than young women, suggesting that the neuromuscular system in older women may be less efficient in braking the forward movement of the body in response to backward perturbations. Only the young women experienced significant increases in RT and COP velocity during the mental fatigue condition. This could be because the older women were already near their threshold for efficiently allocating attentional resources in response to postural threats and adding a mentally fatiguing, sustained attention task resulted in constraint of the postural response for both safety and to manage the additional attentional demand. This resulted in older women having similar COP displacement and velocity in both conditions. Younger women, however, were still trying to effectively allocate attentional resources to both tasks and maintain RT performance. As young women became mentally fatigued, more attentional resources were redirected to maintaining RT and efficiency of the neuromuscular system's response to postural threats was reduced resulting in increased COP velocity to maintain COP displacements like those seen in the control condition.

While older women did not seem to experience any decrements in performance with mental fatigue, this research can be used to develop intervention strategies to improve attentional efficiency. Cognitive and postural tasks can be practiced simultaneously in to simulate the effect of mental fatigue and improve the ability to efficiently allocate attentional resources and improve the neuromuscular system response to postural perturbation.

INTRODUCTION

People with a transtibial amputation (TTA) can navigate their environments successfully with use of a prosthetic device. The success of the prosthesis is dependent on numerous factors, one of which is the alignment of the prosthetic socket and pylon. Prosthetists alter the alignment of a prosthesis such that the patient has a normal (symmetric) gait pattern, assessed through observation and patient feedback. Misaligned prostheses can cause pressure changes in the socket, increased intact limb loading when standing, and increased asymmetry during walking [1-3]. In particular, anterior and posterior misalignment can increase pressures on the end of the residual limb, which can lead to tissue damage and/or pain [1]. TTA are also at greater risk for secondary conditions such as osteoarthritis [4] and low back pain [5], and this risk may be further elevated by use of a misaligned prosthesis. During sit-to-stand (STS) motions, people with TTA have asymmetric ground reaction forces [6] and greater lateral trunk lean [7] relative to non-amputees, which could be related to a higher risk for low back pain [5]. The purpose of this study was to determine how altering sagittal plane prosthetic alignment affects pain in the residual limb and low back as well as ground reaction force (GRF) symmetry during STS in people with TTA.

METHODS

A prosthetist adjusted the prosthesis of five participants with a unilateral transtibial amputation (1F/4M, 44.8±16.8 yrs, 1.77±0.10 m, 88.7±15.4 kg) by translating the prosthetic foot by 10 mm in the anterior and posterior directions, relative to the prescribed alignment. After each of the three alignment conditions, participants rated pain in their residual limb and back on a Visual Analog Scale (VAS) and performed five self-paced STS trials from a backless chair. Each trial began with hips, knees, and ankles at 90° of flexion and feet hip-width apart. The participants' arms were folded across their chest during the movement. Feet were placed on separate force plates (AMTI) recording at 1200 Hz.

Ground reaction forces (GRFs) were low-pass filtered using a 4th-order Butterworth filter with a cutoff frequency of 10 Hz. We then computed a Symmetry Index (SI) of the peak GRF between the prosthetic and intact limbs for each direction using:

$$SI\ (\%) = \frac{(GRF_{Intact} - GRF_{Prosthetic})}{(GRF_{Intact} + GRF_{Prosthetic})} * 100\%$$

where GRF values were taken at the time of peak vertical GRF within the STS lift phase (0-50%).

We used a single-factor, repeated-measures ANOVA to test for differences in GRF symmetry and pain scores between alignment conditions. Effect sizes were then computed using Cohen's d.

RESULTS AND DISCUSSION

There was no significant main effect for alignment for back ($p = 0.23$) or residual limb pain ($p = 0.18$; Fig. 1). However, there were medium and large effects for pain in the residual limb which increased from prescribed for the anterior ($d = -1.03$) and posterior ($d = -0.59$) alignments. For back pain, there was a trend for decreased pain in the anterior condition compared to prescribed ($d = 0.46$) while it tended to increase in posterior condition compared to prescribed ($d = 0.29$). All participants who scored above the 'No Pain' category had decreased back

pain in either alignment that was not their prescribed alignment. Unlike back pain, the change from the prescribed alignment in residual limb pain was different for every participant (Fig. 1).

The difference in GRF symmetry in the anterior-posterior (A/P) direction across conditions was significant ($F = 5.96$; 2; $p = 0.026$; Fig. 2). The posterior alignment had more symmetric A/P GRFs compared to the prescribed alignment ($d = -0.81$). Differences in GRF symmetry across conditions for the vertical and M/L directions were not significant. However, anterior and posterior alignments had decreased M/L and Vertical GRFs during STS, for both limbs, compared to the prescribed alignment.

These results suggest that using a different alignment than prescribed may reduce the load placed on the intact limb during STS, which may have implications for joint disorders and pain associated with increased intact limb loading [e.g., 4]. While these outcomes may point to more reliance on the prosthetic limb during STS, it is unclear whether TTA can benefit from different alignments as all parameters do not respond to alignment changes in the same way. More work is needed to verify these effects.

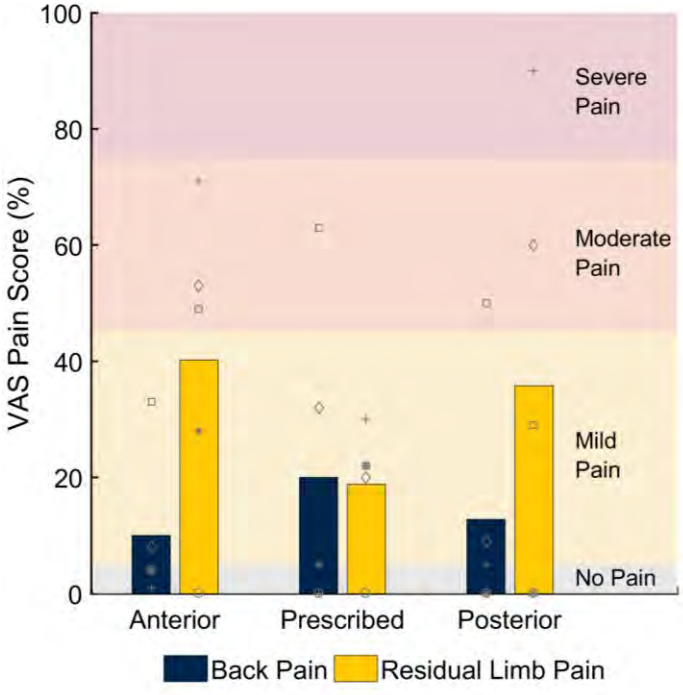

Figure 1: Average VAS scores for back pain and residual limb pain for different alignments (bars). Different gray symbols represent the pain scores for individual participants.

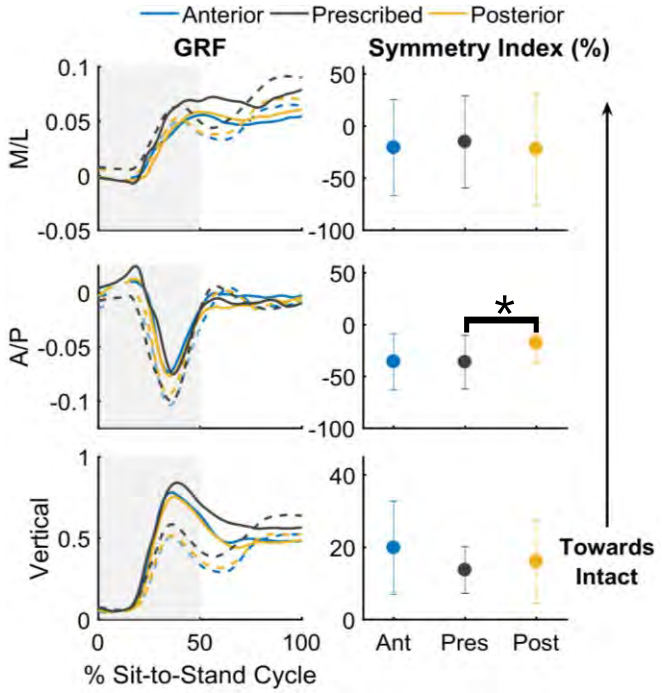

Figure 2: Left: 3D ground reaction forces (GRF) across the sit-to-stand (STS) cycle for all alignment conditions (Anterior (Ant), Prescribed (Pres), Posterior (Post)). Dashed lines represent the prosthetic limb; solid lines represent the intact limb. Right: Average Symmetry Index of peak GRF during the lift off phase (0-50%). Asterisk (*) denotes significance with $\alpha = 0.05$.

CONCLUSIONS

While there was large variation in VAS pain scores and GRF symmetry, decreases in overall GRF and peak GRF asymmetry suggest that STS may require a different alignment from prescribed. Additionally, while changes in back pain across conditions were consistent for all participants, the large variation in residual limb pain suggests that patient feedback alone should not be used in the prosthetic prescription process. Future work will investigate medial/lateral alignment conditions during STS and the effects of alignment on other common tasks.

PROTOCOL FOR REALISTIC VIRTUAL REALITY ENVIRONMENT THAT PERTURBS BALANCE

Caitlin O'Connell, Gustavo Sandri Heidner, J.C. Mizelle, Nicholas Murray, Patrick Rider, Zachary Domire

East Carolina University, Greenville, NC, USA
email: oconnellca17@ecu.edu

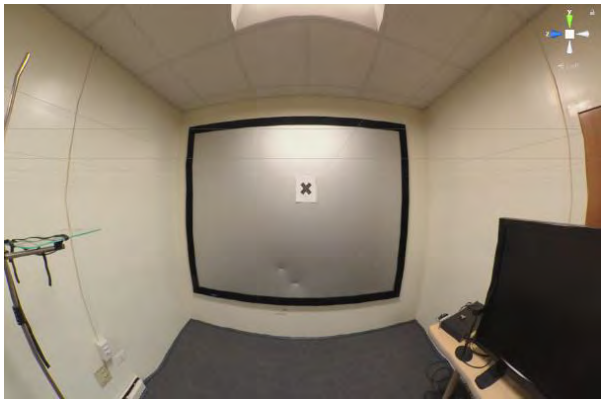
INTRODUCTION

Virtual reality (VR) can be utilized to challenge balance control by manipulating the visual environment. Studies have demonstrated balance perturbations using VR including increased postural sway [1], alterations in center of pressure (COP) displacement [2] and increased COP approximate entropy [3]. Previous research examining the impact of VR on balance have implemented entirely digital scenes, however a more realistic environment, such as a reproduction of an individual's environment may produce greater perturbations to balance. The objective of this study was to establish parameters, specifically amplitude and frequency, of a sinusoidal movement of a realistic VR environment to induce altered balance, as defined by increased sway displacement, velocity and approximate entropy.

METHODS

Twelve young adults (aged 22.1 ± 2.3 years, 2 male) were recruited. Individuals with conditions affecting balance were ineligible. Participants donned a VR headset (Oculus VR, USA) in which a 360° picture of the lab was projected (Figure 1). During data collection, participants were asked to stand still and look at the "X" on the wall in front of them. Prior to introducing balance challenges, a baseline trial was collected while participants wore the VR headset. Balance was challenged by an anterior-posterior sinusoidal movement of the lab within the VR headset. Four different amplitudes of the sinusoidal movement were tested: 1 cm, 5 cm, 10 cm and 20 cm, with each amplitude being presented at two frequencies were tested: 0.5 Hz and 0.25 Hz. The presentation order of sinusoidal amplitude was randomized to account for adaptation effects; and participants were presented first with a movement at 0.5 Hz and then 0.25 Hz within each amplitude. Center of pressure (COP) data was collected for 30s at 1000Hz.

Figure 1: Projection of laboratory environment as seen in VR headset.



COP data was low-pass filtered with a cutoff frequency of 5 Hz. Balance performance was assessed using anterior-posterior COP displacement (root mean square), mean velocity and approximate entropy (length = 2, tolerance window = 0.2 x standard deviation of time series). Paired t-tests (α = 0.05) were performed to determine whether the mean COP displacement, mean velocity and approximate entropies during each sinusoidal movement was greater than during baseline (no movement).

RESULTS AND DISCUSSION

COP mean velocity was significantly greater than baseline when the sinusoidal movement of the VR scene had a frequency of 0.5 Hz and amplitudes of 10 cm (p=0.04) and 20 cm (p=0.007). There were no significant differences when the sinusoidal movement had a frequency of 0.25 Hz or smaller amplitudes (Figure 2).

Sinusoidal movement at 0.5 Hz and 20 cm amplitude was the only condition in which COP approximate

entropy was greater than baseline (p=0.01). Smaller amplitudes and 0.25 Hz frequency did not alter COP approximate entropy compared to baseline standing (Figure 3).

There were no differences in COP displacement between baseline and sinusoidal movement conditions for any of the tested amplitudes or frequencies.

Figure 2: COP mean velocity during varying amplitudes and frequencies of sinusoidal movement of VR environment. Conditions in which the mean velocity was significantly greater than baseline (0 cm, 0 Hz) are denoted (*).

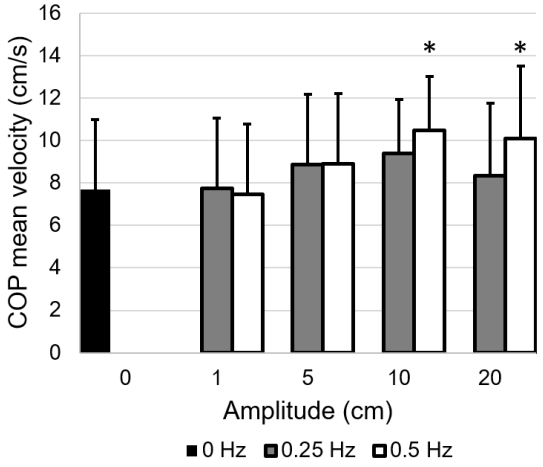


Figure 3: COP approximate entropy during varying amplitudes and frequencies of sinusoidal movement of VR environment. Conditions in which the approximate entropy was significantly greater than baseline (0 cm, 0 Hz) are denoted (*).

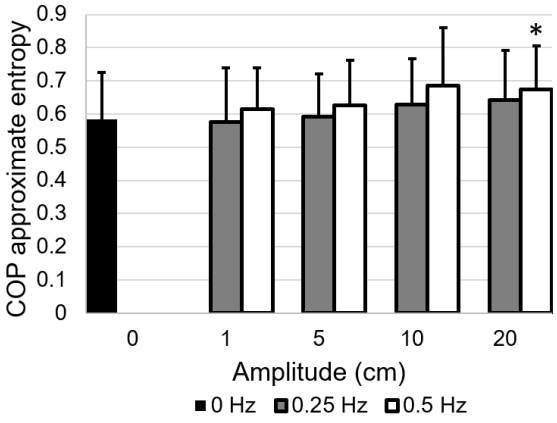

The results suggest that sinusoidal movement of a realistic VR environment produces altered balance compared to baseline standing, but only under specific movement parameters. Specifically, mean velocity and approximate entropy increase under large amplitudes and a frequency of 0.5 Hz. It is likely that the postural control system filters out sinusoidal movement at smaller amplitudes and frequencies so that balance is not altered. Thus, there seems to be a threshold of amplitude (>10cm) and frequency (0.5 Hz) of movement that will induce balance deficits. Interestingly, sway displacement was not impacted by movement of the VR environment. This suggests that the postural control system is able to maintain balance, but must make more adjustments to remain stable, as demonstrated by increased sway velocity and approximate entropy.

One limitation to this study is that a wide range of amplitudes and frequencies were not tested. Future studies should include larger amplitudes (>20 cm) and frequencies (>0.5) to determine if balance deficits increase with amplitude and frequency or if there is a threshold where the postural control system stops responding to the sinusoidal movement. Additionally, future analyses should account for presentation order of amplitude conditions to explore whether there is an adaptation effect when participants are repeatedly exposed to the sinusoidal stimulus.

CONCLUSIONS

This study established parameters of a realistic moving VR environment that perturbs balance. Future directions for this study include comparing response to the moving environment between healthy adults and individuals with impaired balance, such as individuals with concussion.

DIRECTION AND MODALITY SENSITIVITY OF WALKING BALANCE TO VISUAL PERTURBATIONS

INTRODUCTION

Three-dimensional biomechanical walking models suggest that the walking task is passively stable in the sagittal plane direction but unstable in the frontal plane direction [1], indicating that visual information pertaining to frontal plane movement may be more useful for actively controlling balance than information about sagittal plane movement. Previous studies have demonstrated this result for linear visual perturbations; subjects effectively ignore anterioposterior (AP) visual balance perturbations but significantly modify step width in response to mediolateral (ML) perturbations [2].

Since walking is a pendular motion, we hypothesized that pendulum-like visual perturbations (Roll, Pitch) would have greater impact on active balance control compared to linear perturbations, and therefore be more likely to induce step length balance corrections.

It is also unclear how step width adjustments are controlled by the neuromuscular system. Modification of swing leg motion may be an efficient strategy for such control. We hypothesized that variations in hip adduction-abduction would be a significant mechanism for step width adjustment.

To test these hypotheses, we used a virtual reality environment to induce visual perturbations and measured foot placement and muscle activity variability during walking.

METHODS

Nine healthy subjects (aged 22 ± 1.7 yrs., mean ± s.d.) received visual information through a head-mounted display while walking on a large (5x7 ft) instrumented treadmill at a comfortable speed. The display consisted of a virtual dark hallway tiled with randomly placed white rectangles [3] synchronized with the walking speed.

Subjects were exposed to sinusoidal visual perturbations that were categorized as frontal or sagittal plane, linear or pendular modality, and at four amplitudes (Fig. 1). The effect of the perturbations was assessed by measuring variability in foot placement (step length and step width) and variability in root-mean-squared muscle activity (RMS-EMG) recorded from at least 300 steps. Surface EMG was recorded from hip muscles (Adductor Longus, Gracilis, Gluteus Medius) potentially responsible for step width adjustment.

To measure the foot placement sensitivity to the visual perturbations, we calculated the slopes of the step placement variability vs perturbation amplitude trends. Muscle activity sensitivity was calculated as the slope of the RMS-EMG variability vs perturbation amplitude trends.

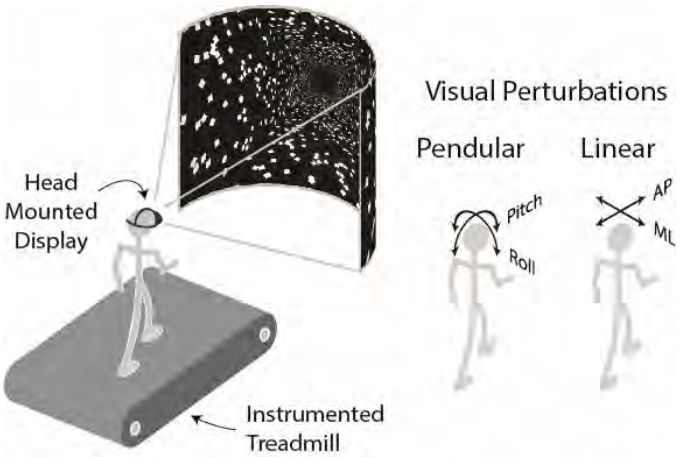

Figure 1: Depiction of experimental setup with instrumented treadmill and head mounted display. Subjects were visually perturbed in either the frontal or sagittal plane and with linear or pendular modality, producing four unique perturbations (Roll, Pitch, Mediolateral (ML), and Anteroposterior (AP).

RESULTS AND DISCUSSION

Results from a two-way ANOCOVA test revealed a significant main effect of perturbation plane on step placement sensitivity (Fig. 2,3). Subjects were 9.3 times more sensitive to frontal than sagittal plane perturbations (P<1.0e-10). This result indicates that greater emphasis is generally placed on side-to-side visual information than front-to-back for controlling walking balance, regardless of the modality of perturbation.

The ANOCOVA also revealed no significant main effect (P=0.54) of perturbation modality (linear vs. pendular), suggesting both perturbation modalities equivalently induced active balance corrections (Fig. 2,3).

Results from a one-way ANCOVA test revealed a significant main effect of Roll perturbation amplitude on RMS-EMG variability (P=7.0e-6). The ANCOVA also revealed no significant main effect (P=0.30) of hip muscle type (Adductor Longus, Gracilis, Gluteus Medius), suggesting that variations in both adductor and abductor activations contribute to active step width adjustment.

CONCLUSIONS

The demonstrated visual sensitivity may be generally explained by needs for maintaining balance during walking, which requires active step width adjustments. These adjustments are controlled by the neuromuscular system through equivalent variations in both hip adduction and abduction muscle activity. The neuromuscular system also appears to rely on sagittal passive balance provided by the limb biomechanics to a significant degree. These findings establish normative balance control behavior and may lead to improvements in clinical assessments for detecting balance impairment.

DECREASED DIVERGENCE OF THE TRUNK MOVEMENT TRAJECTORIES DURING TREADMILL WALKING IS NOT RELATED TO TRUNK FLEXION OF YOUNG SUBJECTS FOLLOWING TREADMILL-DELIVERED DISTURBANCES MIMICING A TRIP

Simisola O. Oludare[1], Nicholas Stergiou[2], Mark D. Grabiner[1]

INTRODUCTION

Trips are a major cause of falls by older adults during walking [1]. Trunk kinematics at recovery step completion following a laboratory-induced trip and following a treadmill-delivered disturbance that mimics a trip discriminates those who fall from those who do not fall following the disturbances [2]. Given their ability to discriminate falls from recoveries in this manner and the demonstrable responsiveness to specific, targeted training, trunk kinematics following a trip appear to qualify as a biomarker for trip-related falls.

Measures of divergence of the trunk movement trajectories during walking have been suggested as estimators of all-cause fall risk of older adults [3,4,5]. These measures, have been associated with retrospectively determined all-cause falls by older adults [6,7] and prospectively determined time to first all-cause fall by older adults [8].

In this study we determined if the movement trajectory of the trunk, measured as the largest Lyapunov exponent (LyE) during unperturbed treadmill walking, could estimate trunk kinematics following increasingly challenging treadmill-delivered disturbances that mimic a trip which discriminate between fallers and non-fallers [2]. LyE reflects the continuous response of a system to disturbances. We expected the largest LyE exponent in the sagittal plane during unperturbed treadmill walking to be positively and significantly correlated to trunk flexion following increasingly challenging treadmill-delivered disturbances that mimic a trip.

METHODS

Following informed consent, eight healthy young adults (6 females, 23.1±2.5 years old, 165.4±10.7 cm, and 60.9±14.1 kg) walked on a microprocessor controlled treadmill for 10 minutes at 2.5 mph before being subjected to eight randomized disturbances from a static upright posture. The disturbance magnitudes reflected treadmill belt motion, under constant acceleration of 14 ms^{-2} to peak velocities of 0.84 m/s, 1.12 m/s, 1.4 m/s, 1.68 m/s, 1.96 m/s, 2.24 m/s, 2.52 m/s and 2.8 m/s.

An eight camera motion capture system operating at 120 Hz tracked the motions of reflective markers placed beneath the left scapula, over the shoe at the heel and 2nd metatarsal phalangeal joints (MTPJ), the acromion processes, the anterior superior iliac spines and on the sacrum at S2.

The time series of the sagittal plane movement trajectory of the trunk, represented by the scapula marker, was used to calculate the largest LyE via the Wolf et al's algorithm and the methods of time delay to reconstruct the state space. Briefly, the state space was constructed by determining the appropriate time delay and embedding dimension via the average mutual information method and the far nearest neighbors methods, respectively [9,10]. Following the state space reconstruction, Wolf et al's algorithm was implemented to compute the divergence of the sagittal plane trajectories in state space. The maximum divergence was determined to be the largest LyE [10] based on 150 consecutive steps.

The recovery response to each perturbation was characterized as the trunk angle at the instant of recovery step completion. Recovery step completion was determined from the markers on the shoe. The trunk angle was calculated using the segment defined from the midpoint of the line between the markers placed over the acromion processes and the midpoint of the line between the

markers placed over the anterior superior iliac spines. For each subject, the computed trunk angles were fit using a second-order polynomial (MATLAB, R2012a) after which each trunk angle at a given disturbance was represented as the point estimate using the subject-specific regression. Correlations and regression analysis (SPSS, V24) were used to describe the relationships between the largest LyE and disturbance-specific point estimates of the trunk angle at recovery step completion

RESULTS AND DISCUSSION

The linearly increasing peak disturbance velocities, intended to increase the difficulty of the recovery, resulted in a quadratic increase (R^2= 0.77, p<0.001) of the trunk angle at recovery step completion (Figure 1).

For the eight participants, the largest LyE of the scapula marker during unperturbed treadmill walking was 0.90±0.57 (range: 0.22-1.86).

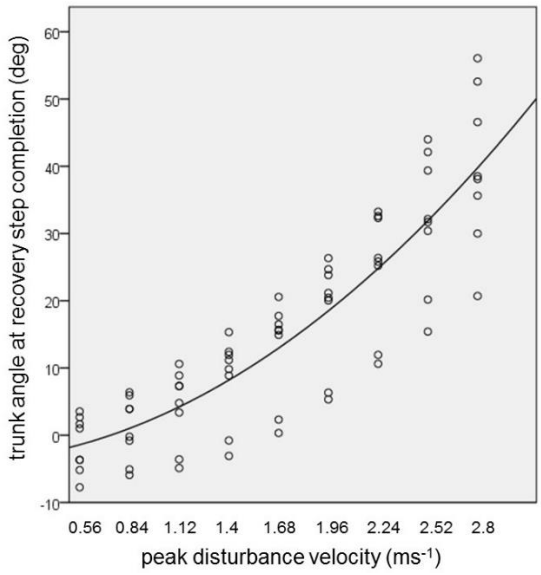

Figure 1: Trunk flexion angle at the instant of recovery step completion following a treadmill-delivered disturbances that mimicked a trip. The disturbance magnitude was manipulated using by increasing the peak velocity of treadmill belt motion. Individual subject data (open circles) and the line of best fit are shown.

Contrary to our expectations, the largest sagittal plane LyE of the scapular marker during unperturbed treadmill walking was not significantly correlated to trunk flexion following the increasingly challenging treadmill-delivered disturbances. The correlations, the values of which ranged from 0.19 to 0.36 (all p>0.38), accounted for a maximum of 13 percent of the shared variance.

The result merits consideration in the context of its representing only a small sample of healthy young subjects who participated in a novel protocol. In light of these limitations, it seems premature to conclude that divergence of sagittal plane trunk movement trajectories during unperturbed treadmill walking is, or is not, a risk factor for trip-related falls by older adults.

CONCLUSIONS

The growth of the population of older adults ensures that the magnitude of the multifaceted problem of falls by older adults will grow proportionately. In our view, replication of the experiment with young subjects and repeating the experiment using older adults merit consideration.

TEST-RETEST RELIABILITY OF THE SENSORY ORGANIZATION TEST AND CENTRAL SENSORIMOTOR INTEGRATION (CSMI) TEST

INTRODUCTION

The collection and integration of information from the vestibular, visual and somatosensory systems are an integral aspect of balance control. Balance dysfunction can arise from damage to sensory systems (e.g. somatosensory decline following lower limb injury) or from central integration issues (e.g. neuromotor impairment following mild traumatic brain injury). Tests such as the Sensory Organization Test (SOT), and the Central Sensorimotor Integration (CSMI) Test [1] have been developed to try to identify contributions to balance dysfunction in patients. Both of these tests collect anterior-posterior sway data under different sensory conditions (e.g. moving surface, moving visual surround, eyes open or closed). One of the key differences between the two tests, is that the surface or visual surround movement during the SOT is dependent upon an individual's sway, and thus the amplitude of surface or visual surround movement is not fixed, while movement of the surface and visual surround in the CSMI is determined by continuous pseudorandom stimuli at fixed peak-to-peak amplitudes of 2° and 4°.

Although the SOT has been recognized as a reliable tool for the assessment of sensory contribution to balance in a number of populations [2,3], one of the recognized limitations is the effect of learning with repeated exposures [4]. Comparatively, there is limited information about the test-retest reliability of the CSMI test, and whether or not the CSMI test is subject to learning effects. In this abstract we present preliminary data on the test-retest reliability of the SOT and CSMI test measures focusing on four comparable conditions across the two tests: 1) surface movement with eyes closed, 2) surface movement with eyes open, 3) visual surround movement, and 4) both surface and visual surround movement. We hypothesize that a) both the SOT and the CSMI will have good to excellent reliability, and b) that the participants will improve on the SOT, but will not improve on the CSMI – suggesting learning effects occur in the SOT but not CSMI test.

METHODS

Participants were 14 healthy volunteers (26.3 ± 2.8 years) recruited from Oregon Health & Science University (OHSU). Exclusion criteria included any history of injury, surgery or medical condition that would impair cognition or motor ability. All participants gave written informed consent, and procedures were approved by the OHSU Institutional Review Board. Participants completed two testing sessions, conducted six-weeks apart –a timeline chosen to reflect a reasonable test-retest interval in a balance intervention program. Participants completed the SOT and the CSMI test in a custom modified SMART Balance Master (Neurocom International Inc.), adapted to collect CSMI test data (Figure 1). For the SOT, participants completed the standard SOT clinical protocol of three 20-s trials per six conditions. For the CSMI test, participants completed randomly ordered trials at amplitudes of 2° and 4°, making eight total trials. Outcome measures were the Equilibrium Score (E, SOT) and the Sensory Weight presented as sensory weight*100 (W, CSMI) per condition.

Figure 1: Custom modified SMART Balance Master

Test-retest reliability was assessed using Intraclass Correlation Coefficients (ICCs) using a 2-way mixed effects model ($ICC_{3,1}$) with absolute agreement. 95% confidence intervals were calculated, and interpretations (<.5=poor; .5-.75=moderate; .75-.9=good; >.9=excellent) were based off Koo & Li [5]. Paired t-tests were also assessed to evaluate any mean differences between testing sessions.

RESULTS AND DISCUSSION

Except for the 2° visual condition, the ICC values for the CSMI were on average higher than the SOT (Table 1). SOT equilibrium score significantly improved in the visual movement condition (mean±SD, E_1=92±3, E_2=94±2, p=.041), and the surface plus visual movement condition, (E_1=64±18, E_2=74±15), p=.001), but no significant changes to performance in the surface movement with eyes open condition (E_1=86±5, E_2=88±6, p=.050) or surface movement with eyes closed condition (E_1=66±14, E_2=72±12, p=.168).

Table 1: ICC values, 95% confidence intervals and interpretation of ICC for each condition tested.

			95% CI		
		$ICC_{3,1}$	Lower	Upper	Interpretation
SOT	S, EC	0.475	-0.46	0.83	Poor
	S, EO	0.733	0.20	0.91	Moderate
	V	0.451	-0.36	0.81	Poor
	S + V	0.867	0.10	0.97	Good
CSMI	S, EC 2°	0.854	0.55	0.95	Good
	S, EC 4°	0.655	0.03	0.89	Moderate
	S, EO 2°	0.557	-0.46	0.86	Moderate
	S, EO 4°	0.878	0.61	0.96	Good
	V 2°	0.392	-0.69	0.80	Poor
	V 4°	0.705	-0.05	0.91	Moderate
	S + V 2°	0.849	0.52	0.95	Good
	S + V 4°	0.882	0.61	0.96	Good

*S = surface movement; V = visual movement; EC = eyes closed; EO = eyes open

The only significant change in performance for the CSMI test was in the 4° visual movement condition, W_1=5±3, W_2=3±1, p=.004. No significant changes in performance occurred in any other condition (2° surface movement, eyes closed condition, W_1=49±8, W_2=50±7, p=.448; 4° surface movement, eyes closed condition, W_1=39±10, W_2=35±4, p=.063; 2° surface movement, eyes open condition, W_1=72±4, W_2=72±5, p=.697; 4° surface movement, eyes open condition, W_1=19±4, W_2=19±3, p=.864; 2° visual movement condition, W_1=10±5, W_2=8±2, p=.178; 2° surface and visual movement condition, W_1=53±7, W_2=54±6, p=.814; 4° surface and visual movement condition, W_1=44±9, W_2=41±7, p=.063).

Our results suggest better test-retest reliability of the CSMI than the SOT for the surface movement with eyes closed condition, while being comparable for surface movement with eyes open, and surface plus visual surround movement. Test-retest reliability was low for the SOT visual condition and the low amplitude CSMI visual movement condition. Repeat test performance improved in the SOT visual movement and surface plus visual movement conditions, while for the CSMI a decrease in the sensory weight occurred in the visual movement condition. Overall reliability of the SOT and CSMI were somewhat lower than expected. This may be an outcome of the repeat trial occurring six weeks following the initial testing block. The general improvement in SOT performance is consistent with a learning effect.

CONCLUSIONS

Test-retest reliability ranged from poor to good for both the SOT and CSMI test, with the CSMI test performing slightly better overall. The observed test-retest changes in performance in healthy young adults provide a benchmark for judging whether rehabilitation interventions are effective in improving balance function in patients.

EFFECT OF SPEED CONTROL ON GLOBAL STABILITY OF A POWERED COMPASS WALKER

Navendu S. Patil, Jonathan B. Dingwell, and Joseph P. Cusumano

The Pennsylvania State University, University Park, PA, USA
Email: nsp129@psu.edu

INTRODUCTION

Identifying the risk of falling is intimately related to characterizing the dynamic stability [1] of neuromuscular control of human walking. However, *global* stability is hard to measure in practice, and data-driven measures of local stability alone may not predict the risk of falling. Conversely, the dynamical systems analysis of simple mechanical models of human walking, which has the issue of stability at its core, can provide crucial insights into the global stability of locomotion in response to external disturbances. We here use a compass walker capable of walking on a level ground using toe-off impulse actuation [2] to study the global stability of its periodic gait. A recent experimental study of humans walking on a treadmill [3] showed that humans primarily regulate their stepping variability by controlling speed rather than by maintaining some constant absolute position on the treadmill. However, the implications of such regulation on global stability have not been examined. For the powered compass walker, we show that a nonlinear state-feedback speed regulator that optimally adjusts the toe-off impulse at each step dramatically enlarges the basin of attraction (BoA) of its periodic gait, i.e., the set of initial "postures" (i.e., states) yielding transient gaits that asymptotically approach a stable periodic motion. Our results thus suggest a functional connection between motor regulation and global stability, and further reinforce the potential importance of speed control as a strategy to regulate intrinsic physiological motor fluctuations in human walking.

METHODS

The step-to-step dynamics is described using the stance leg angle, θ^+, and its time derivative, $\dot{\theta}^+$. The dynamics itself has two phases: In the first, the stance leg swings from a previous heel strike (Fig. 1a), past the vertical, to just before the next heel strike (Fig. 1b) without any energetic cost while the swing leg rotates

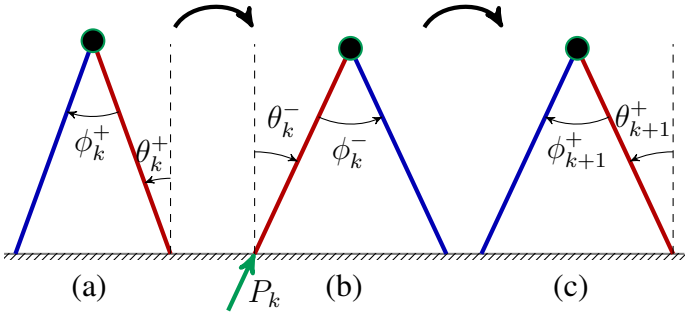

Figure 1: Three snapshots of powered compass walker [2]: (a) just after k^{th}, (b) at $(k+1)^{\text{st}}$, and (c) just after $(k+1)^{\text{st}}$ heel strike. The walker has massless stance (*red*) and swing (*blue*) legs, and a mass at (*black dot*) the hip. At heel strike, $\phi = 2\theta$. The walker's state just after heel strike is $(\theta^+, \dot{\theta}^+)$. The toe-off impulse, P, applied just before the heel strike, allows controlled walking steps on an even ground.

freely, about the hip, past the stance leg. In the second, the toe-off impulse P, applied to the stance foot, compensates for the impending energy loss during the impact of the swing leg with the ground. Finally, the stance and swing legs are switched to prepare for the next walking step (Fig. 1c).

First, we estimated the BoA of the stable fixed point, $(\theta^*, \dot{\theta}^*) \approx (0.30518, -0.31744)$ for a fixed $P^* = 0.1$, by simulating trajectories on a $16501\times$ 1000 grid of initial states in the region where the walker takes at least one step. This region is bounded by two curves, Ω_{low} and Ω_{high} (Fig. 2, top), which we found numerically using a continuation procedure. We restricted our attention to $\theta^+ \in [0.23, 0.56]$. For a given θ^+, $\Omega_{\text{low}}(\theta^+)$ gives the minimum speed for the stance leg to swing past vertical, while $\Omega_{\text{high}}(\theta^+)$ is the maximum speed for a step without falling forward. We simulated trajectories for a maximum of 100 steps and classified a given initial state to lie in the BoA if the distance of states along its trajectory approached the fixed point monotonically for its last 10 steps.

We then imposed our optimal nonlinear speed-

controller that actively sets the toe-off impulse P_k to P_k^{opt} (Eq. 1 below) so as to make the walking speed at the next step, v_{k+1}, as close to the desired speed, $v^* \approx 0.15633$ (of the stable periodic gait), as possible:

$$P_k^{\text{opt}} := \underset{P_k}{\text{argmin}} \left[v_{k+1}(P_k) - v^*\right]^2, \qquad (1)$$

$$v_k := L_k/T_k, \qquad (2)$$

where the step length $L_k := \sin(\theta_k^+) - \sin(\theta_k^-)$, and T_k is the step period. The function $v_{k+1}(P_k)$ is not known explicitly and requires numerical integration of equations of motion and event detection. Thus, the optimization in Eq. (1), if carried out at every walking step, significantly slows down trajectory computation. We addressed this issue by calculating P_k^{opt} offline for several thousand θ_k^-'s in parallel, using MATLAB's `fminbnd` function, and then interpolated the required result as needed during simulations. Furthermore, we simulated the trajectories to a maximum of 50 steps.

RESULTS AND DISCUSSION

The BoA (Fig. 2) of the stable periodic gait of the powered walker with *no active control* is quite thin and has a complicated geometric structure in the state space, with possible "holes" and multiple, disconnected boundaries. Our nonlinear speed-regulator, which pushes the states in each step as close as possible to the *constant-speed GEM* [3] (i.e., the goal-equivalent manifold passing through the operating point on which $v = v^*$), not only regulates the speed of the aforementioned open-loop walker, but also enlarges the BoA 10-fold. Also, the BoA is geometrically much simpler: in the region of the computation it possesses only two disconnected basin boundaries and no holes.

CONCLUSIONS

We have shown that a speed regulator dramatically improves the global stability of the compass walker's periodic gait, as quantified by the area of the set of initial states that can be stabilized (that is, by the size of its BoA). Our results further support [3] the importance of speed-control as a strategy to regulate intrinsic physiological motor fluctuations, and may suggest the future design of assistive devices that would not only regulate walking speed but also reduce fall risk.

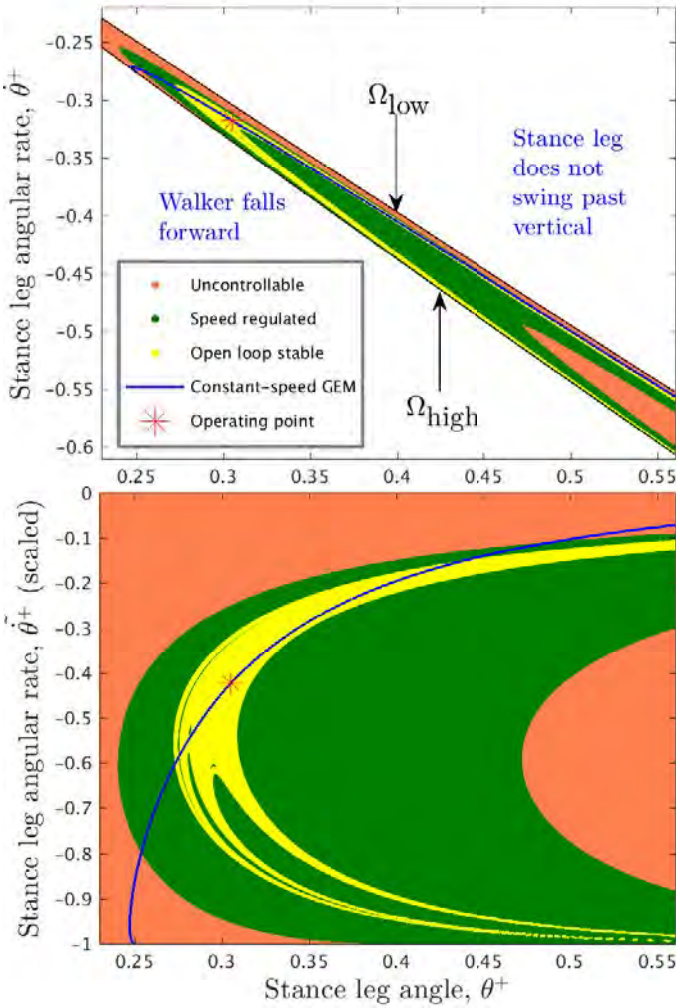

Figure 2: Effect of speed regulation on the basin of attraction (BoA): (*top*) original state space $(\theta^+, \dot{\theta}^+)$; (*bottom*) zoomed-in view using scaled angular velocity $\tilde{\dot{\theta}}^+ := [\dot{\theta}^+ - \Omega_{\text{low}}(\theta^+)]/[\Omega_{\text{low}}(\theta^+) - \Omega_{\text{high}}(\theta^+)]$. Uncontrolled walker has a stable periodic gait at the *operating point* with BoA (yellow) marked *open loop stable*. In contrast, *speed regulated* BoA (green) is ten times bigger than the open-loop BoA, and has a more regular boundary.

INTRODUCTION

Hip fractures in older adults are a big health problem, and more than 90% of hip fractures are due to a fall [1]. While efforts have been made to address this issue, it is still an ongoing problem due to fast growing aging population. As individuals age, they develop an increased risk of falling due to natural changes in the body, activity level, and other characteristics. A simple but effective balance training method that might slow down the progress of age-related changes, or improve one's balance, especially for frail population, should help to reduce incidence of falls and associated injuries in older adults.

A recent study theorized that for every 1% rise in height of COM, there is a 37% increase in the risk of falls [2]. Furthermore, a study has shown that subjects who wore an 8lb cervical halo performed more poorly in sling-legged stance and functional reach tests than a control group who did not wear a halo, suggesting that the halo raised the COM and decreased performance on balance tests [3]. These studies provide an idea that individual's balance may be improved more effectively if trained with the lowered COM.

We conducted balance tests with young adults while lowering the COM with a weighted belt, which could be a useful training tool to improve one's balance.

METHODS

Twenty healthy individuals (mean age 26 (SD = 2.43)) participated in the Limit of Stability (LOS) test. After calculating each participant's center of mass with a reaction board, a weighted belt was fastened ten centimeters below the COM. The SMART Blance Master (Natus, San Carlos, CA, USA) was utilized to quantify changes in each participant's LOS under five weighted belt conditions: 0%, 2%, 4%, 6%, and 8% of the participant's body weight. The order of presentation of weight condition was randomized. In each trial, subjects were asked to move toward each of the four targets (Figure 1).

LOS outcome measures included reaction time, movement velocity, endpoint excursion, maximum excursion, and directional control in 4 cardinal directions (mediolateral and anteroposterior).

A two-factor ANOVA was used to test whether these outcome variables associated with the weighted belt and moving direction.

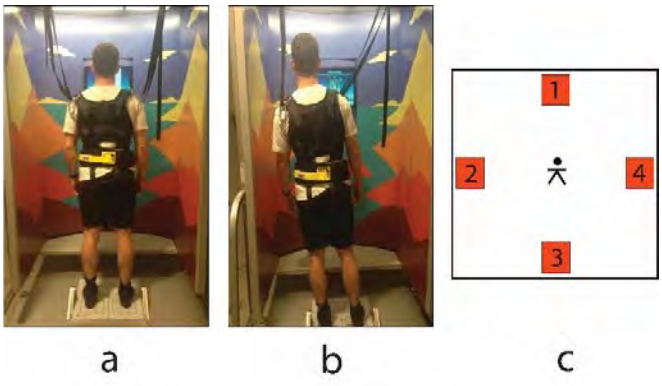

Figure 1: A participant standing with harness (a), moving toward a target on his left (b), and display of targets that participant can monitor during trials.

RESULTS AND DISCUSSION

Surprisingly, none of our outcome variables associated with weighted belt ($p > 0.075$), but all of them associated with moving direction ($p < 0.01$) (Table 1, Figure 2). On average, movement velocity of the COM (degrees per second) and maximum

excursion (maximum displacement as a percentage of maximum LOS distance) were 31% and 18% greater, respectively, in mediolateral than anteroposterior direction (5.4 versus 4.1 °/s; 97.5 versus 82.6 %). There were no interactions between the weighted belt and moving direction ($p > 0.31$).

Biomechanically, postural stability requires that the vertical line passing through the COM locates within the base of support formed by the feet. In theory, postural stability is improved when the height of the COM is decreased. This is, in part, due to a. that a greater angle (perturbation) is required to cause instability and b. a smaller recovery torque is needed to recover balance if the height of the COM is decreased. However, our data from healthy young adults suggest that there is no effect on balance of decreased height of the COM caused by increasing weight of the belt at 10 cm below the COM.

A goal of this study was to examine how balance performance is affected by the lowered COM, and discuss potential benefits of weighted belt as a training strategy to improve balance for individuals at high risk of a fall. Balance is largely affected by neuromuscular responses (i.e., reaction time, muscle strength), which likely decline with age. Therefore, future studies are warranted to confirm our results with older adults.

CENTER OF PRESSURE RESPONSE TO VISUAL PERTURBATIONS IN VIRTUAL REALITY

David Phillips, PhD and Markus Santosa, PhD

Montclair State University, NJ, USA
email: phillipsdav@montclair.edu, web: https://www.montclair.edu/cehs/academics/departments/espe/

INTRODUCTION

The loss of postural control can lead to falls and injury. In older adults the treatment of these injuries incurs direct medical expenses exceeding $31 billion annually. The average hospital bill is estimated at $30,000 [1]. Other than the financial cost, falls are the leading cause of fatal injuries and often lead to loss of independence or a reduced quality of life.

Maintaining balance requires sensory input from the visual, proprioceptive, and vestibular systems. Deficiencies or perturbations in any of these systems may reduce an individual's ability to anticipate or respond to environmental conditions. Inducing perturbations in each system comes with unique challenges. The vestibular system can be stimulated with electrodes behind the ear and ankle proprioception can manipulated through different types of muscle contractions to induce temporary muscle damage or fatigue. Creating visual distortions requires that the entire field of view be manipulated. This can potentially be accomplished by using glasses or by building complex and immersive environments. Glasses are restricted to manipulating incoming visual information and constructing environments requires both space and expense.

Virtual reality (VR) is becoming a popular method to conduct balance training and rehabilitation. Virtual environments do not require physical constructs and the equipment is highly portable. However, VR has not been used to induced visual perturbations to study balance and balance recovery. In previous studies where the physical walls of a room were displaced either anteriorly or posteriorly, subjects leaned in the direction of the displacement [2, 3]. The purpose of this study was to investigate the effects of visual motion (direction and velocity) of corridor walls in VR on the center of pressure. We hypothesized that center of pressure (COP) displacement will be greater after the visual perturbation and that the initial response of the COP will be to move in the direction of the visual displacement.

METHODS

Six subjects (4 males and 2 females) volunteered for the pilot study. Subjects stood barefoot on a Bertec force plate (Bertec Corporation, Columbus, OH) sampling at 1000Hz with custom LabVIEW software (LabVIEW v2017, Austin, Tx) and downsampled to 200Hz. The subjects wore an Oculus Rift VR headset (Oculus VR). The VR environment consisted of a corridor with a width of 16m and a height of 12m (Fig 1) and was developed with Unity3D software (Unity Technologies v2017.2, San Francisco, CA). Subjects stood barefoot with both feet on the force plate facing the computer monitor in the lab and a closed wall of the corridor in VR.

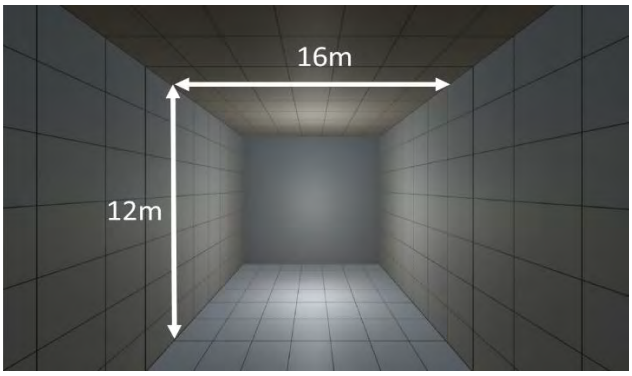

Figure 1: Corridor simulated in VR

The subjects were not aware of when a perturbation would occur. The experimenter initiated a perturbation by pushing a key. Ten seconds of data were collected before the perturbation and 10s after. When the key was pressed the room would displace 3m either anteriorly or posteriorly, at 1m/s, 3m/s, or 5m/s. Three trials were collected for each velocity in the anterior and posterior directions for a total of 18 trials. The 'time zero' (T_0 = 0s, moment the key is pressed) was used to align all trials.

Center of pressure (COP) in the anterior-posterior direction was calculated from ground reaction forces and moments using previous literature [4]. Peak-to-peak displacement was calculated 3s before and after T_0. The peak directional displacement was determined by subtracting the mean COP -3s before T_0 from the peak displacement within +3s of T_0. This indicates both the magnitude of displacement from starting position and the direction of the displacement. This magnitude must be greater than 3SD of the COP position -3s before T_0 to be considered a response (Fig 2).

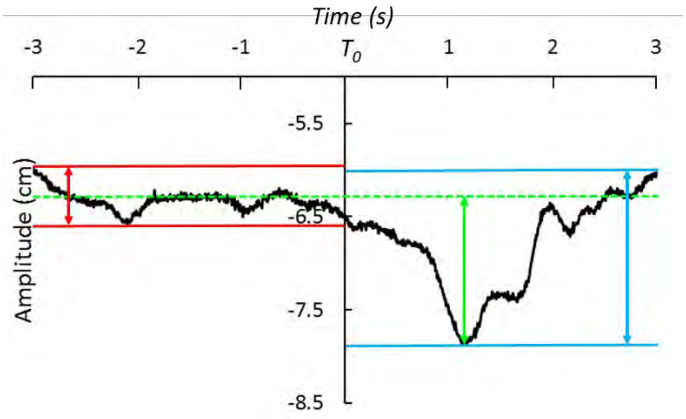

Figure 2: Visual depiction of data analysis of COP in the anterior-posterior direction. Green dashed line is COP mean position prior to perturbation, vertical green line indicates peak COP displacement from mean, blue and red horizontal bars indicate peak-to-peak displacement before and after perturbation.

RESULTS AND DISCUSSION

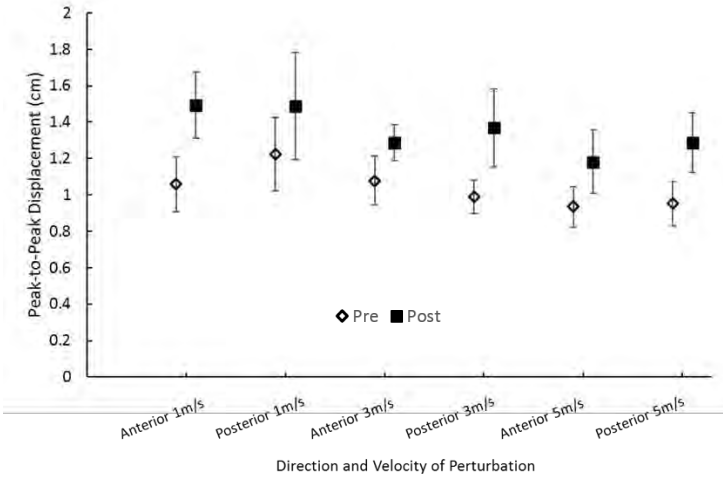

Figure 3: Peak-to-peak COP displacement before and after visual perturbations**.**

In all conditions, the peak-to-peak displacement of the COP after the visual perturbation was greater than the displacement before the perturbation ($p < 0.05$) (Fig 3). Greater displacement is indicative of reduced postural control. Subjects therefore had more difficulty maintaining their balance after the visual perturbation. The magnitude of the peak-to-peak displacement also increased with velocity ($p < 0.05$). The velocity of movement in the visual field likely plays a role in how much postural stability is perturbed.

However, we classified a discrete response to the perturbation as when COP displacement was more than 3 standard deviations from the mean COP position before the perturbation. Only 59% of the trials met this criterion. This may indicate that the visual perturbation was sufficient to require corrective action but it was not sufficient to consistently introduce a response beyond what is normally required to maintain balance. It may be necessary to make the task more challenging in this population by balancing on one foot. Because there were so many trials that did not meet this criterion, we also did not evaluate if subjects' initial COP response was to move in the direction of the perturbation. However, creating visual perturbations in VR may be a useful method to study the role of vision in conditions leading up to falls.

CONCLUSIONS

Creating a visual perturbation in VR increases postural instability but not enough to induce a potential loss of balance in healthy subjects standing on both feet.

LONGITUDNAL ASSOCIATION OF STANDING BALANCE AND NEURODEGENERATIVE BIOMARKERS IN A CONCUSSED ATHLETE: A CASE STUDY

Moira K. Pryhoda, Julie Campbell, Aurelie Ledreux, Kim Gorgens, Lotta Granholm-Bentley, and Bradley S. Davidson

University of Denver, Denver, CO, USA
Email: moira.pryhoda@du.edu

INTRODUCTION

A concussion, or mild traumatic brain injury (mTBI), is a complex sports injury that can possibly lead to long-term disability including chronic traumatic encephalopathy (CTE) and Alzheimer's disease (AD) [1]. Elevated blood biomarker concentrations such as total Tau (t-Tau) are commonly associated with neurodegeneration, and also serve as a strong indicator of secondary injury mechanisms in mTBI [1]. Loss of balance function is a well-known factor in post-concussion syndrome (PCS) that arises from a disruption in sensorimotor integration and may also remain long after the acute phase of recovery is complete [2]. However, it is unclear whether any measures associated with PCS can be used as indicators of concussion severity or long-term consequences including neurodegeneration.

The objective of this case study was to examine whether longitudinal associations exist between various measures of balance and Tau pathology following an acute mTBI through 6 months after injury. These data provide an initial indication of which balance measures are candidates for inclusion in more comprehensive, sensitive, and relevant clinical protocols for mTBI management and could be predictors of long-term neurodegenerative conditions such as CTE or AD.

METHODS

A 20-year-old female student athlete at the University of Denver (DU) with no previous history of concussion was hit on the temporal right side of the head with a volleyball on 11/3/16. She visited the training room that day with a headache. Clinical balance (BESS) and cognitive tests (Immediate Post-Concussion and Cognitive Test; ImPACT) were unimpaired. She returned to the training room on 11/4/16 with elevated symptoms and reported trouble falling asleep the previous night. She was removed from all activity and placed on DU's concussion protocol. She was given full clearance for return to play (RTP) on 11/9/16.

The athlete participated in instrumented standing balance testing (Balance Error Scoring System; BESS) and blood sampling prior to the concussion event (baseline), acutely (within 3 days of concussion), 1 week, 1 month, and 6 months post-concussion (PC). BESS clinical score errors (number of balance errors from 0-10, where 0 is no balance errors and 10 is the greatest number of errors) were recorded simultaneously with force platform data for single, double, and tandem stance on firm and foam surfaces. Center of pressure (COP) total, mediolateral (ML), and anterior-posterior (AP) average velocity, as well as 95% elliptical sway area were calculated for each task. The blood sample was analyzed for t-Tau concentration in plasma, a blood biomarker associated with neurodegeneration. Each biomechanical balance measure and t-Tau across the five data collection time points were plotting on the same axis for visual assessment of simultaneous changes in balance dysfunction and brain neurobiological dysfunction.

RESULTS AND DISCUSSION

t-Tau concentration, a marker of brain health, increased acutely post-concussion (PC) followed by a decrease 1 week PC. t-Tau increased again by 1 month PC and remained elevated as long as 6 months PC. BESS single leg errors, a commonly performed balance test following mTBI was associated with t-Tau concentration for 1 week PC (Fig. 1A). While t-Tau concentration remained elevated up to 6 months PC, BESS clinical score decreased after 1 week PC, which is reflected in prior BESS literature [3].

Among the force platform-based variables, the longitudinal trends of single leg COP total (Fig. 1D) and AP (Fig. 1E) average velocities were the most similar to t-Tau concentration through 6 months PC, indicating possible long-term utility. Double leg stance COP total average velocity, a common biomechanical measure of standing balance, did not follow the longitudinal trend acutely PC (Fig. 1B). However, the long-term trend between 1 week and 6 months PC was associated with t-Tau. If these outcomes hold in larger populations, these may be possible for use long-term associations with brain health after mTBI.

Single leg COP ML average velocity was associated with t-Tau concentration up to 1 week PC (Fig. 1C). 95% elliptical sway area was not associated with t-Tau during any task.

CONCLUSIONS

Total COP velocity during single leg stance provided the best association with t-Tau concentration and has potential to be a sensitive measure that is translational to the clinic and concussion management programs. This case study highlights early data from a large prospective investigation (n=262), which includes additional of clinical domains such as symptoms and neurocognitive function. We will continue to investigate these trends presented here along with additional analyses on functional balance measures during specific movement tasks, which are potentially more applicable as an indicator of readiness for RTP.

VISUOMOTOR ERROR AUGMENTATION AFFECTS MEDIOLATERAL HEAD AND TRUNK STABILIZATION DURING WALKING

Mu Qiao, Jackson T. Richards, and Jason R. Franz

University of North Carolina and North Carolina State University, Chapel Hill, NC, USA
Email: jrfranz@email.unc.edu, web: http://abl.bme.unc.edu

INTRODUCTION

Humans regulate lateral balance in walking through coordinated adjustments between the continuous control of posture (*i.e.*, head and trunk stabilization) and the discrete (step-to-step) control of foot placement (*i.e.*, step width). These corrective adjustments strongly depend on the integration of reliable sensory feedback. Accordingly, walking balance is acutely susceptible to optical flow perturbations designed to elicit the visual perception of lateral imbalance. Specifically, in response to those perturbations, we recently discovered that head and trunk kinematics during walking instinctively synchronize (*i.e.*, entrain) to a broad range of driving frequencies of perceived mediolateral (ML) motion [1]. In that study, we speculated that this entrainment acted to minimize errors between the visual perception of motion and the actual motion of the head and trunk, thereby unifying visual with vestibular and somatosensory feedback. However, we lacked direct evidence that minimizing these 'visual prediction errors' was a control goal for head and trunk stabilization during human walking.

Therefore, we investigated the role of visual prediction errors in governing the control of mediolateral head and trunk position during human walking as a means to explain the acute postural response to optical flow perturbations. Specifically, we used a visuomotor error augmentation paradigm in which optical flow was synchronized to instantaneous head and trunk kinematics recorded via motion capture. We hypothesized that minimization of visual prediction errors, achievable during the task by reducing lateral head and trunk movement, is an important and instinctive feature governing walking balance control. The alternative hypothesis would be that visual feedback overrides other sensory modalities and is itself an independent control parameter in regulating head and trunk position. We also tested the hypotheses that the response to error-augmented optical flow would: (*i*) scale (*i.e.*, increase) with larger feedback gains and (*ii*) exhibit tuning via time-dependent adaptation following prolonged exposure.

METHODS

Twelve subjects participated (8M/4F, age: 24.1±4.7 yrs, body mass: 73.3±13.0 kg; height: 176±9 cm, mean±S.D.). All subjects walked at their preferred walking speed (1.36±0.14 $m \cdot s^{-1}$) on an instrumented split-belt treadmill (Bertec Corp., Columbus, OH) while watching a speed-matched, virtual hallway rear-projected onto a semi-circular screen surrounding the treadmill (1.45 m radius × 2.54 m height, Fig. 1). A 3D motion capture system (Motion Analysis Corp., 100 Hz) recorded the trajectories of markers placed on subjects' pelvis, legs, and 7th cervical (C7) vertebra. In real-time, a Simulink® controller prescribed the mediolateral (ML) position of the virtual hallway for all trials based on the instantaneous ML position of subjects' C7 marker, which we selected as the highest point on the trunk that is not affected by head orientation. In some trials, we introduced errors between the visual perception of self-motion (via optical flow) and actual ML motion of head and trunk using a position gain, *G* (Fig. 1). Across different conditions, *G* took

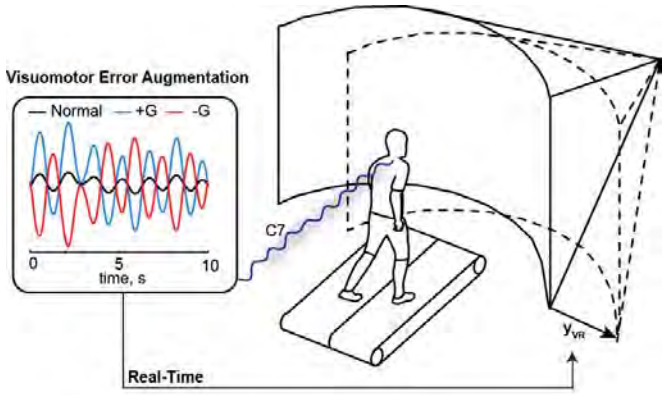

Figure 1. Subjects walked in a virtual environment with visuomotor error augmentation based on instantaneous measurements of their mediolateral (ML) C7 position.

4 values (±2.5 and ±5.0), the largest of which determined in pilot testing to ensure that the virtual hallway remained on the projection screen. Positive/negative values indicate the ML motion of the virtual hallway was in the same/opposite direction of the measured ML C7 motion. Subjects first walked for 1 min with the normal oncoming optical flow (G=0, baseline). Subjects then walked for 10 min with the error-augmented optical flow with one of the four gains. Each of these trials ended with 1 min of walking with the normal oncoming optical flow (G=0, post). Dependent variables included the step-to-step range of ML trunk motion (intra-step measure), and the root mean square (RMS) of ML trunk position (inter-step measure).

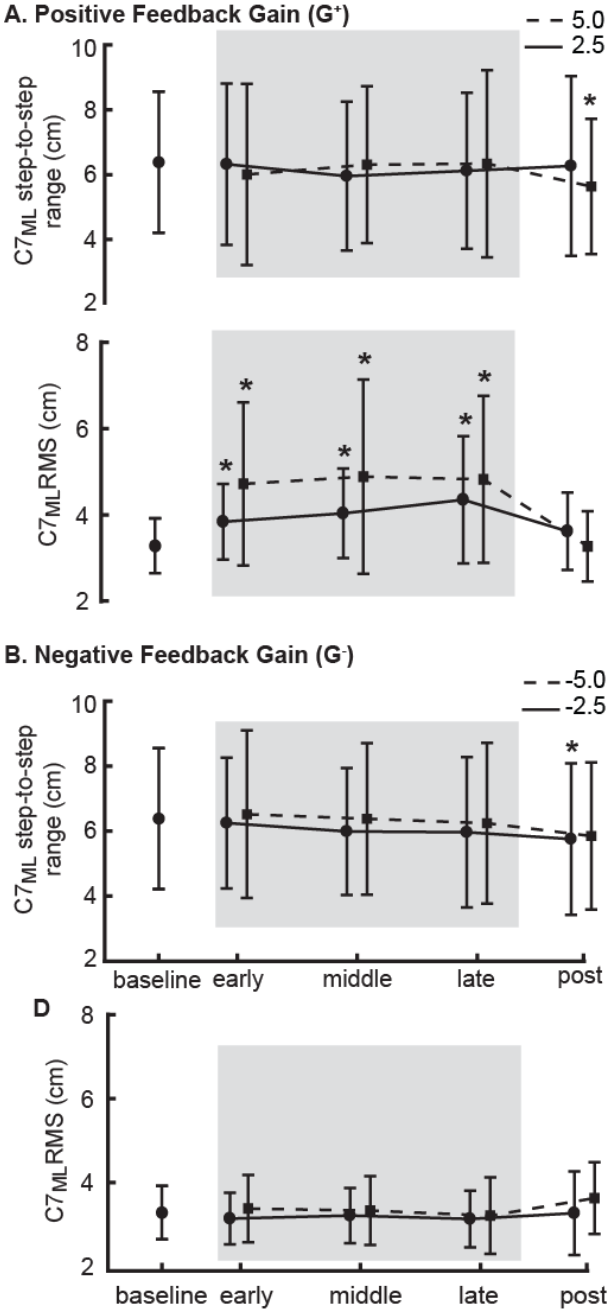

Figure 2. Intra- and inter-step mediolateral trunk motion from all steps across the protocol. Asterisks (*) indicate different from baseline (p<0.05).

RESULTS AND DISCUSSION

In contrast to our hypothesis, neither intra- nor inter-step measures of ML trunk motion amplitude decreased in the presence of error-augmented optical flow (Fig. 2). Rather, larger positive visual prediction errors increased the RMS of ML trunk position – an effect that scaled in proportion to feedback gain amplitude (early vs. baseline, p<0.05, Fig. 2A). These early responses to error-augmented optical flow persisted with prolonged exposure; we found no significant effects of time (i.e., early, middle, late) on step-to-step ML trunk range of motion (G^+: p=0.856, G^-: p=0.124) nor the RMS of ML trunk motion (G^+: p=0.204, G^-: p=0.552) (Fig. 2). Following 'release' of error-augmented optical flow, the RMS of ML trunk position returned to baseline values within one minute. However, despite no apparent effects of time during exposure, the step-to-step trunk range of motion decreased significantly following exposure compared to baseline walking (-12% for G=+5.0, p=0.002, Fig. 2A; -10% for G=-2.5, p=0.002, Fig. 2B). Those after-effects were also accompanied by longer and wider steps, but only following walking with positive feedback gains.

CONCLUSIONS

Subjects did not instinctively minimize errors between the visual perception of movement and actual movement of the head and trunk. Our results are instead more consistent with our alternative hypothesis – that visual feedback can override other sensory modalities and independently compel adjustments in head and trunk position. Our results also allude to a recalibration of head and trunk stabilization toward more tightly regulated postural control following exposure to error-augmented optical flow. Although this study focused on young adults, lasting reductions in ML postural sway evident in our data may have important implications for enhancing the integrity of walking balance control through training, for example in older adults.

EFFECTIVENESS OF SIT TO STAND WORKSTATIONS: A SYSTEMATIC REVIEW

INTRODUCTION

On average, employees spend more than half of the workday in the seated position. Even more, computers are becoming increasingly mainstream in the work place causing workers to spend as much as 10-11 hours sitting throughout the day (Graves, Murphy, Shepherd, Cabot, & Hopkins, 2015). This sedentary behavior has been linked to office workers acquiring negative health conditions including, obesity, insulin resistance, cardiovascular disease, depression and chronic back and neck pain. [1]

In combining the current knowledge on sustained sitting and standing, it is suggested that office workers receive bouts of both sitting and standing time during working hours. A solution to facilitate movement and contest the associated effects of sitting among the office worker population is a sit to stand work station.

The sit to stand workstation can provide office workers with a versatile desk that can adjust the computer screen and keyboard independently of one another in order to fit each individual's ergonomic needs. These stations promote comfort, good health and maintain productivity by giving workers the option to alternate between sitting and standing positions.

Current evidence surrounding sit to stand workstations, is limited. At this point research has not identified significant differences in productivity when using a sit to stand workstation versus the traditional desk environment [2]

The aim of this systematic review was to determine the benefits of sit to stand workstations, both physically and psychologically, on seated workers. This review provides useful knowledge to healthcare professionals regarding ergonomics, health and wellness of employees.

METHODS

Evidence surrounding sit to stand workstations and their ability to reduce physical discomfort and improve cognitive ability was searched over multiple databases. The included databases were CINAHL, PubMed, ScienceDirect, and Google Scholar. Keywords including sit to stand workstation, ergonomics, posture, discomfort, and occupation were divided among two search groups.

Four independent reviewers, broken into two groups, used a combination of search terms in screening the databases. The term sit to stand was used in conjunction with either ergonomics and/or posture, or discomfort and/or occupation. Search limits were peer reviewed, randomized controlled trials published in the English language or translation readily available, articles published within the last 5 years, participants' age range of 18-65 years old, and articles had to focus on the effects of sit to stand workstations on improving workers' physical/psychological well-being.

Articles were excluded if they did not meet the aforementioned criteria. Initial database search led to a peak number of 275 articles. Titles and abstracts of the search results were screened by two independent raters and in case of discrepancy in their inclusion findings, a third rater interfered or raters' consensus was utilized. Titles and abstracts were screened down to 15 articles. Full version of the searched articles were acquired and those without a

full version were excluded. Upon further review, articles that did not meet the criteria based on the study design were excluded. A total of 5 articles met the inclusion criteria.
Two independent reviewers appraised the articles using both the PEDro scale and the risk of bias. Differences in scores led to a third reviewer appraising the article and collaboration to determine an appropriate score.

RESULTS AND DISCUSSION

After critiquing the five RCT's notable trends were identified, including participant demographics, methodological quality of articles, musculoskeletal discomfort, cognitive ability, and productivity.
The mean participant ages for the five articles were 38.4, 38.8, 39.0, 43.2, 46.2, 47.8, and 48.2 with one group having an outlier mean of 22.7. The PEDro scale was used to appraise the strength and quality of the included RCT's. The PEDro scores given to the five articles included within this systematic review were all rated between 5/10 and 7/10. This trend occurred due to a lack of subject blinding, assessor blinding, therapist blinding and the inability to conceal group allocation
The Cochrane Collaboration's Tool for assessing risk of bias (ROB) was used in conjunction with the PEDro to further evaluate the level of bias for each study. The articles were categorized as either unclear or high risk of bias
Measurements of pain and discomfort were discussed within three of the included articles. The most significant areas of reduced pain or discomfort were musculoskeletal which included the low back, shoulders and neck. Cognition was only assessed in one of the included studies, which concluded that the use of sit to stand workstations does not cause a deficit in cognitive ability. Finally, implementation of sit to stand workstations improved or caused no change in work productivity in two of the studies included in this systematic review

CONCLUSIONS

The sit to stand work environment has the ability to decrease musculoskeletal discomfort without compromising productivity and cognitive ability, in the adult office worker population. This systematic review establishes a need for more high quality randomized controlled trials that pay careful attention to methodological quality and risk of bias within the study design.
Employers are encouraged to consider sit to stand workstations because of its affordability and potential benefits to employees.

INTRODUCTION

During uni- and bilateral upright stance the center of pressure (CoP) trajectory reflects the postural control executed to maintain balance. In two recent studies, Ko and colleagues [1,2] observed that skilled sport pistol shooters had lower variability and complexity in their center of pressure movements compared to novices during a shooting-like bilateral stance task. This indicates that extensive practice of stable upright stance reduces the complexity of postural control. However, it is unknown if this alteration in postural control is specific to the nature of the trained task (bilateral standing) or it can be incorporated to other balance task (unilateral). The purpose of the present study was to investigate if the dynamics of postural control during bilateral and unilateral stance differed between elite sport rifle shooters who are exposed to extensive postural control training and healthy non-athletes. We hypothesized that the dynamics of postural control during both bilateral and unilateral stance in elite sport rifle shooters would be characterized by higher predictability, lower rate of trajectory divergence, lower dimensionality, longer time dependency, and lower variability compared to non-athletes.

METHODS

Thirteen skilled sport rifle athletes (mean±SD age: 20.2±4.0 yrs, body mass: 71.0±14.0 kg and body height: 1.74±0.11 m) and eleven non-sport shooters (mean±SD age: 28.1±4.9 yrs, body mass: 71.1±10.5 kg and body height: 175.2±9.0 m) performed 90s of 1) barefooted shoulder wide bilateral stance and 2) unilateral (on each feet) stance on a force plate (AMTI OR6-7) with hands kept akimbo. Anterior-posterior (AP) and mediolateral (ML) CoP trajectories were extracted, filtred using a Daubechies wavelet and down sampled to 100Hz. To assess the dynamics of the postural control, four different nonlinear methods were applied to the CoP trajectories: sample entropy to quantify regularity (input parameters: m=2, r=0.2), the largest Lyapunov exponent (LyE) to quantify rate of trajectory divergence (using Wolf's algorithm and delayed embedding method to reconstruct state space), the correlation dimension (CoD) to quantify dimensionality, and entropic half-life (Ent) to quantify the level of time dependency [3]. Additionally, body sway variability was quantified by the elliptical area of the standard deviation of the CoP trajectories in both directions (elliptical area = pi x SD_{AP} x SD_{ML}). To investigate the effect of group and task on the dependent variables, a two way mixed-design ANOVA was applied. In case of an overall effect of group or task or the interaction, a Holm-Sidak post hoc test was applied. Level of significance was set at 5%.

RESULTS AND DISCUSSION

There was a significant effect of group on SaEn AP ($p<0.001$), SaEn ML ($p<0.001$), LyE ML ($p<0.001$), CoD AP ($p<0.001$), CoD ML ($p<0.001$) and Ent ML ($p=0.005$). While the sport rifle shooters had significantly lower SaEn, LyE and CoD, they had significantly higher Ent compared to the non-athletes (figure 1 and 2). There was a significant effect of task for all extracted variables except CoD ML. In general, the SaEn, LyE and CoD of the CoM were significantly different during bilateral stance compared to unilateral stance. In contrast, the Ent was significantly higher during bilateral stance. There was a significant group-task interaction for SaEn AP ($p<0.001$), SaEn ML ($p=0.003$), LyE ML ($p<0.001$) and Ent ML ($p<0,026$). The post hoc tests revealed that significant group differences were only present during unilateral stance (figure 1 and 2). There was a significant effect of group

($p<0.001$), task ($p<0.001$), and group-task interaction ($p=0.001$) on the body sway variability. The post-hoc test revealed that the sport rifle shooters had lower variability during the unilateral stance tasks (table 1).

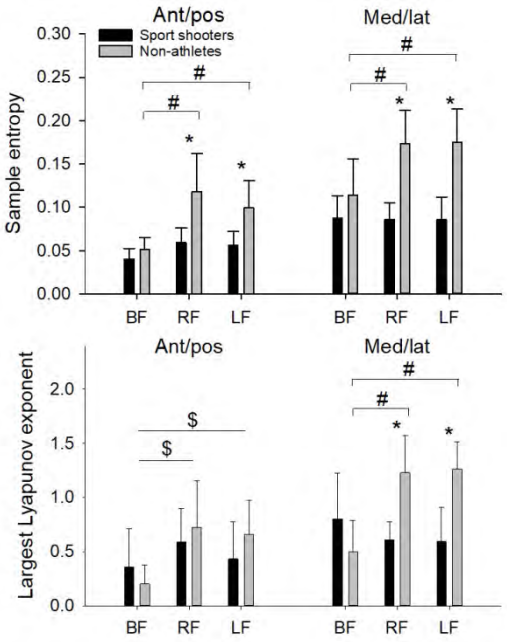

Figure 1: SaEn (top) and LyE (bottom) in anterior/posterior and mediolateral direction for bilateral stance (BS), unilateral (right foot: RF, left foot: LF), *) indicates significant group difference, $ indicates overall significant task difference and # indicates significant task difference within a group.

The raised hypothesis could partly be confirmed as we observed higher predictability, lower rate of divergence, lower dimensionality, longer time dependency, and lower variability in the sport rifle shooters compared to the non-athletes during unilateral stance but not during bilateral stance. Thus, the present study supports previous observations by Ko and colleagues [1,2] suggesting that the postural control in highly skilled sport rifle shooters were characterized by less complexity. Additionally, we observed that the group differences in variability and dynamics only were present during unilateral stance tasks.

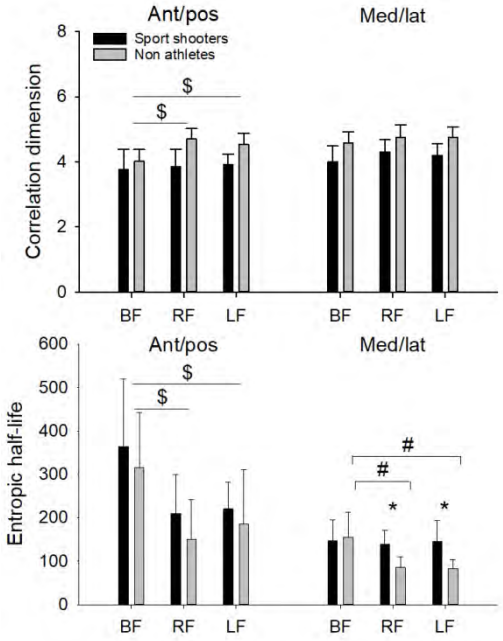

Figure 2: CoD (top) and Ent (bottom) in anterior/posterior and mediolateral direction for bilateral stance (BS), unilateral (right foot: RF, left foot: LF), *) indicates significant group difference, $ indicates overall significant task difference and # indicates significant task difference within a group.

CONCLUSIONS

The present study suggests that extensive training background in maintaining upright quite standing may be associated with altered postural control during unilateral standing task. Thus, sport rifle shooters solved the challenging nature of the unilateral task by use of a less complexed movement pattern compared to the non-athletes.

DYNAMICS OF POSTURAL CONTROL IN INDIVIDUALS WITH LATERAL ANKLE SPRAIN

Peter C. Raffalt, Marios Chrysanthou, Georg N Duda and Alison N Agres

Julius Wolff Institute for Biomechanics and Musculoskeletal Regeneration, Charité – Universitätsmedizin Berlin, Berlin, Germany
email: peter-christian.raffalt@charite.de

INTRODUCTION

The center of pressure (CoP) trajectory reflects the neuromuscular processes executed to maintain postural control. Thus, the dynamics of the CoP trajectory has been related to the development of balance in infants and the superior postural control in elite sport pistol shooters [1,2]. It has previously been suggested that individuals with ankle instability rely more on visual input to maintain postural control during unilateral stance compared to healthy individuals [3]. The present study tested this notion by assessing the dynamics of CoP trajectory in individuals with previous lateral ankle sprain (LAS) and ankle instability, as well as healthy controls during unilateral stance with and without visual input. We hypothesized that the CoP dynamics of individuals with LAS during unilateral stance with no visual feedback would be characterized by lower regularity, higher dimensionality and shorter time dependency compared to healthy controls. In contrast, the characteristics of the CoP dynamics during unilateral stance with visual input were expected not to differ between groups.

METHODS

Sixteen individuals with previous LAS (males/females: 9/7, mean±SD age: 30.9±4.7 yrs, body mass: 73.4±11.9 kg and body height: 176.4±9.5 m) and nine healthy controls (CON) (males/females: 7/2, mean±SD age: 29.3±4.5 yrs, body mass: 72.5±11.3 kg and body height: 178.6±11.5 m) performed 30 seconds of shod unilateral stance (on the affected leg for the LAS individuals and preferred leg for the healthy controls) with 1) eyes open (EO) and 2) eyes closed (EC). Anterior-posterior (AP) and mediolateral (ML) CoP trajectories were extracted from the middle 20 seconds of each trial, filtered using a Daubechies wavelet and down sampled to 100Hz. To assess the dynamics of the postural control, three different nonlinear methods were applied to the CoP trajectories: sample entropy to quantify regularity (input parameters: m=2, r=0.2), the correlation dimension (CoD) to quantify dimensionality (delayed embedding method to reconstruct state space), and entropic half-life (Ent) to quantify the level of time dependency (input parameters: m=2, r=0.2) [4]. To investigate the effect of task (EO vs EC), group (LAS vs CON), and the task-group interaction on the dependent variables, a two way mixed-design ANOVA was applied. In case of an overall effect, a Holm-Sidak post hoc test was applied. Level of significance was set at 5%.

RESULTS AND DISCUSSION

There was a significant effect of task ($p=0.003$) and group ($p=0.028$) on SaEn in the AP direction and a significant interaction ($p=0.019$) on the SaEn in the ML direction. The post hoc test revealed that CON had a significant lower regularity (higher SaEn) compared to LAS for the eyes open task ($p=0.013$, Figure 1). There was a significant effect of task ($p=0.001$) on CoD in the ML direction, indicating that the CoP trajectory during EC had lower dimensionality compared to during EO (Figure 1). There was a significant effect of task ($p=0.001$) on Ent in the AP direction, indicating that the CoP trajectory during EC had shorter time dependency compared to during EO. There was a significant interaction ($p=0.028$) on the Ent in the ML direction. The post hoc test revealed that CON had significantly shorter time dependency ($p=0.024$) during EO compared to LAS.

We could not confirm our hypothesis as we did not observe concomitant group differences in the CoP dynamics during EC and no group differences during EO. Thus, we could not support the previously suggested notion that individuals with ankle instability rely more on visual input during unilateral stance. In contrast, the significantly lower regularity and shorter time dependency in the AP

direction and lower dimensionality in the ML direction during EC compared to EO across groups indicate that the lack of visual information affects the postural control of both groups.

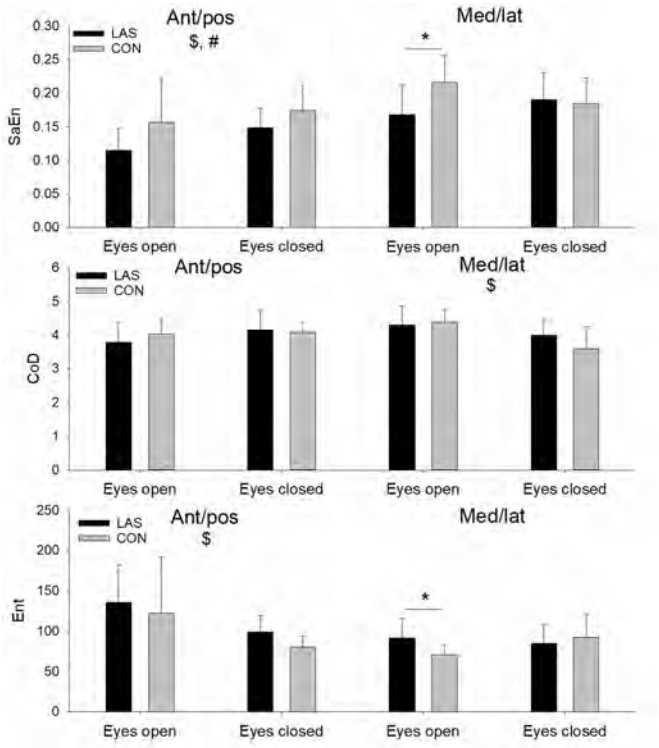

Figure 1: SaEn (top), CoD (middle), and Ent (bottom) in anterior/posterior and mediolateral direction for unilateral stance with eyes open and eyes closed for the CAI and CON group. $) indicates a significant effect of task, #) indicates a significant effect of group, and *) indicates a significant interaction effect and a significant group difference within a task.

The significant effect of visual information for Ent in the AP direction but not in the ML direction suggests that visual feedback plays a more pronounced role for AP postural control.

The higher regularity in the AP direction for the individuals with LAS and in the ML direction during EO, suggest that fewer functional degrees of freedom are available to establish a stable movement pattern [5]. This could be due to impaired motor control in muscles surrounding the ankle joint and increased passive joint laxity, which result in reduced adaptability during unilateral stance.

CONCLUSIONS

The present study did not support the notion that individuals with LAS rely more on visual input during unilateral stance compared to healthy controls. However, higher regularity in the CoP trajectory was observed suggesting that the motor control system of LAS individuals rely on fewer functional degrees of freedom to maintain postural control.

INTRODUCTION

Parametric modeling of human movement provides an insight into the relative contribution of neuromuscular control pathways. Researchers have developed complex dynamical models that describe human movement; therefore, these models usually have many parameters to be estimated. Although different system identification techniques were used to estimate these parameters, the reliability of these estimates received little attention.

Reliable parameter estimates are essential for these models to be useful in clinical and biomechanical applications. With the limited data, usually consisting of gross measurements such as kinematics, estimating many parameters leads to relatively less precise, hence less reliable, estimates. A sensitive parameter selection method [1] reduces parameter variability by selecting only sensitive parameters to be estimated while fixing the remaining parameters to preliminary values. Therefore, we hypothesized this method can provide reliable estimates of the selected sensitive parameters.

METHODS

Ten healthy subjects (Table 1) were recruited for this study. They did not have any history of neck pain lasting more than three days or any neurological motor control impairment. The Michigan State University's IRB approved the test protocol. The subjects signed an informed consent before participating.

The subjects performed a head position tracking task in the horizontal plane (Figure 1) on two visits separated by one day. The subject wore a helmet with

Table 1: Subjects' demographic characteristics.

	Females	**Males**
N	7	3
Height (m)	1.66±0.11	1.78±0.07
Weight (kg)	55.3±11.8	87.7±17.7
Age (years)	22.3±1.2	34.0±11.8

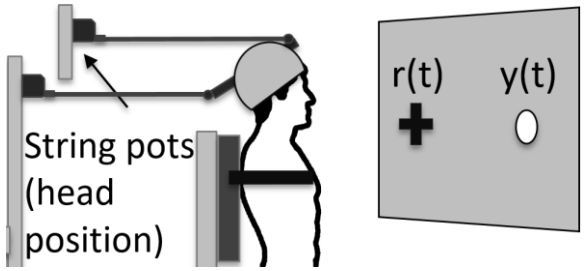

Figure 1: Head position tracking task.

strings attached to two potentiometers (Celesco SP2-50, Chatsworth, CA) to measure the head rotation. Two markers were displayed on a monitor (Samsung SyncMaster SA650; height 27 cm, width 47.5 cm) located 1 m away from the subject: the reference r(t) and the head position y(t) markers. The reference signal consisted of pseudo-random sequence with random step durations (0.3-0.9 s) and amplitudes such that the maximum amplitude was ±4° from the neutral head position. Each subject performed two 15-second practice trials then three 30-second full trials. Data were collected using a data acquisition system (cDAQ-9172, National Instruments, Austin, TX) and sampled at 60 samples per second.

The parametric model describing this task (Figure 2) was augmented from published models of neuromuscular pathways (visual, vestibular, proprioceptive, and intrinsic) [2, 3]. The model parameters were divided into candidate parameters for estimation $\Theta = \{K_{\text{vis}}, K_{\text{vcr}}, K_{\text{ccr}}, \tau, \tau_{1\text{A}}, \tau_{\text{CNS1}}, \tau_{\text{c}}, \tau_{\text{CNS2}}, \tau_{\text{MS1}}, \tau_{\text{MS2}}, B,\ K\}$ and fixed parameters $\Theta_{\text{fixed}} = \{J, T_c\}$. Using the Fisher Information Matrix

(FIM) method for sensitive parameter selection [1], we selected the parameters that have less variability across subjects and visits. Sensitive parameters were estimated using nonlinear least squares while fixing the insensitive parameters to preliminary estimated values. Goodness of fit was measured by Variance Accounted For (VAF).

Between-visit reliability of the selected sensitive parameters was assessed using Intraclass Correlation Coefficients ICC(A, k). The ICCs were classified as poor (<0.40), fair (0.40-0.59), good (0.60-0.74), or excellent (0.75-1.00).

RESULTS AND DISCUSSION

The selected sensitive parameters were $\{K_{\text{vis}}, \tau, \tau_{1A}, \tau_c\}$ that represent visual and vestibular pathways only. Selecting the visual pathway validates the published simplified models that used visual feedback without vestibular and proprioceptive feedbacks (e.g., [3]). Estimates of the sensitive parameters yielded good fit (VAF>78%) (Table 2). By comparison to the case of estimating all 12 parameters (Θ) (VAF>80%), goodness of fit was not sacrificed by estimating only the 4 sensitive parameters.

The ICCs of the sensitive parameter estimates varied between fair and excellent (Table 2). In case of estimating all 12 parameters (Θ), the ICCs of some parameters were negative (e.g., ICC(τ_c)=-0.50). Therefore, estimating many parameters may lead to unreliable parametric models. The FIM method of selecting sensitive model parameters yields more reliable parameters besides providing less parameter variability.

Table 2: Selected sensitive parameters.

	Visit 1	Visit 2	ICC
$K_{\text{vis}}\left[\frac{Nm}{rad}\right]$	388±107	362±74	0.70
$\tau[s]$	0.213±0.027	0.206±0.029	0.81
$\tau_{1A}[s]$	0.077±0.061	0.055±0.038	0.61
$\tau_c[s]$	1.93±1.01	2.17±1.12	0.48
VAF (%)	78.42±7.93	80.33±6.94	-

CONCLUSIONS

The FIM method of selecting sensitive parameters can improve reliability of parametric models, making the parametric models useful for clinical and biomechanical applications.

MEDICINE BALL THROW TO EVALUATE POSTURAL STABILITY IN PERSONS WITH AMPUTATION

Kimberly Rowe, Julianne Stewart, Katherine Sharp, Jenny Anne Maun, and Marilynn Wyatt
Naval Medical Center San Diego, San Diego, CA USA
email: kimberly.l.rowe.ctr@mail.mil

INTRODUCTION

Rehabilitation of service members with lower limb amputation is of utmost importance. The military medical system has worked to impart interdisciplinary rehabilitation methods in order to bring this population to its highest possible level of function [1]. One of the most significant deficits this population struggles with is postural instability [2]. This is important because postural instability poses an increased risk of falling [3]. Many patients have goals to participate in high level activities, and one of the ways to evaluate dynamic postural control during such activities is to monitor the center of pressure total excursion (CoP TE), CoP velocity, and trunk excursion [4]. A chest pass medicine ball throw is one such movement which mimics activities of everyday life, as it requires dynamic postural stability and demands use of both hands.

This study cohort consisted of five subjects, each with a different level of amputation: unilateral transtibial (TTA), bilateral TTA, unilateral transfemoral (TFA), TTA and TFA, and bilateral TFA. CoP TE, CoP velocity, and trunk excursion were identified between limbs within subjects during a chest-pass medicine ball throw. In this study, we considered small CoP and trunk excursion measurements indicators of good postural stability. Therefore, we predict that postural instability increases with the number affected joints.

METHODS

Medicine ball throws were collected using a portable 12 Raptor-E camera setup (Motion Analysis Corp., Santa Rosa, CA, USA), and four portable force plates (Kistler Instrument Corp., Amherst, NY, USA). Target and analog data were processed using Visual 3D (C-Motion Inc., Germantown, MD, USA), and a 4th order, low-pass Butterworth filter with a cutoff frequency of 8 Hz and 50 Hz for kinematic and kinetic data respectively was used. Five retired U.S. Marine Corps service members (age 28.53 ± 1.17 yrs; height 1.76 ± 0.057 m; weight 81.65 ± 16.17 kg) were markered using a full-body, 6 degrees of freedom marker set, with additional markers placed on the 9.07 kg medicine ball for tracking. All participants provided written informed consent prior to the study (CIP #NMCSD-2014.0026).

All subjects were instructed to stand with each foot on two adjacent force plates, bring the ball to their chest, and throw it as far as they could in front of them. The movement was divided into two phases in post-processing: windup and forward throw. A WINDUP event was placed when the ball is closest to the trunk segment in the sagittal plane, and RELEASE was identified at the point of ball release by a custom Visual 3D script.

RESULTS AND DISCUSSION

CoP TE and velocity were calculated between WINDUP and RELEASE (Table 1). These two events marking the beginning and end of the medicine ball throw (Fig. 1).

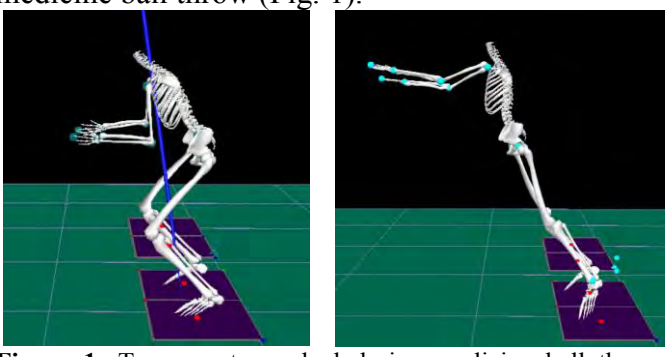

Figure 1: Two events marked during medicine ball throw: WINDUP (left) and RELEASE (right).

Left and right foot CoP trajectories from WINDUP to RELEASE are depicted on respective halves of the graph (Fig. 2), and are represented numerically in Table 1. The time between WINDUP and RELEASE was 0.51 ± 0.04 s, establishing that the CoP

trajectories presented take place over similar amounts of time.

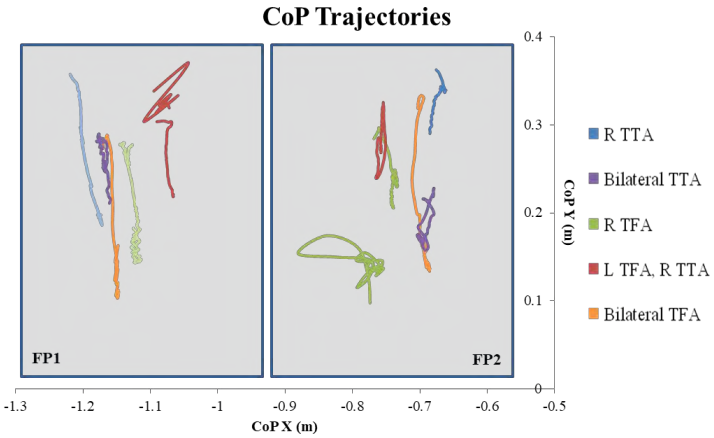

Figure 2: CoP TE for each subject. Data for affected limb(s) are more brightly colored than unaffected limb for comparison purposes. Non-continuous trajectories show a loss of contact between the foot and force plate.

The data follow a trend that CoP TE and velocity increase with the number of major joints amputated and/or number of limbs affected. The Right TTA subject's data does not follow the trend; CoP TE and velocity for the unaffected side was much larger than the affected side. This is likely because this subject spent the entire movement in an athletic position on the toe of his prosthetic foot, and was able to rock back and forth on his intact foot, as confirmed by reference video. It is notable that the two subjects with bilateral, symmetrical amputation (TTA; TFA) exhibit CoP TE and velocity values very close to symmetrical.

In general, subjects with unilateral or asymmetrical amputation demonstrate smaller CoP TE and velocity on their (less involved) intact limb, suggesting greater stability on that side. Gaps in CoP trajectories (Fig. 2) indicate a loss of contact between the foot and the force plate, which may be noteworthy in evaluating stability as well, as losses of contact are present only on affected limbs. Data also show a positive trend of trunk excursion with level of amputation (Table 1). To note: The subject with bilateral TTA has an upper limb injury that requires increased trunk motion for windup and ball release.

CONCLUSIONS

As the population of service members with amputation progresses through rehabilitation, performance of high-level tasks with safety and stability is an important step toward achieving high functional goals. The CoP and trunk excursion trends shown in this subset of subjects support our hypothesis, indicating that use of these measures to evaluate dynamic postural stability during activity is valid. This study and future related work is beneficial because there is limited research regarding postural stability and its role in functional movements for amputee populations. Future work should evaluate larger numbers of subjects, and consider similar variables for other functional movements.

RAMBLING-TREMBLING DECOMPOSITION IS NOT SENSITIVE TO INTENTIONAL POOR BALANCE

Gustavo Sandri Heidner, Caitlin O'Connell, J.C. Mizelle, Patrick Rider, Zachary Domire, Nicholas Murray

East Carolina University, Greenville, NC, USA
email: sandriheidnerg17@students.ecu.edu

INTRODUCTION

An important step in balance testing of concussed patients is the determination of sincerity of effort. Performing poorly intentionally on a balance baseline test, also known as 'sandbagging,' is a practice that can potentially alter the results and compromise the sensitivity to detect the presence of concussion [1]. Rambling-trembling (RT) decomposition of the center of pressure (COP) is a methodology based on the migration of the COP reference point (rambling) and its deviation away from that point (trembling) [2]. Previous research has suggested that rambling (RM) is representative of supraspinal components, more pronounced during voluntary control of balance [3]. Therefore, we have hypothesized that the RM component would be more pronounced in the signal when a participant was sandbagging. The objective of this study was to investigate if RM was a sensitive measurement of balance-test sandbagging in quiet standing by analysis of COP anterior-posterior displacement, and RMS error deviation from the trajectory (RMSe) by implementing RT decomposition.

METHODS

Eleven ($N = 11$) young adults (aged 23.3 ± 4.4 years, 5 males) participated in the study. Individuals with conditions affecting balance were ineligible. Participants performed a balance test that consisted of two vision conditions: eyes open (EO) and eyes closed (EC); and two types of balance conditions: (1) participants were instructed to stand on the force platform naturally (baseline), and (2) to sandbag the test without being detected by the naked eye (poor balance). Sway was assessed by COP displacement in the anterior-posterior direction (COP_{a-p}) and COP spline by the RT method. Rambling was determined as the cubic spline of the zero-time lag points where anterior-posterior force equals zero (Figure 1a,b). The correlation coefficient (r) and the RMSe between the COP_{a-p} trajectory and the RM were used for comparison between conditions.

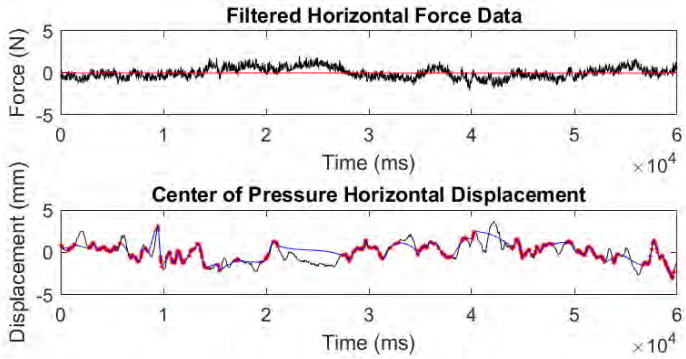

Figure 1a: Example of the RT decomposition analysis of one trial of good balance, with eyes closed. Spline connecting dots represents the rambling component, plotted over the COP_{a-p} displacement.

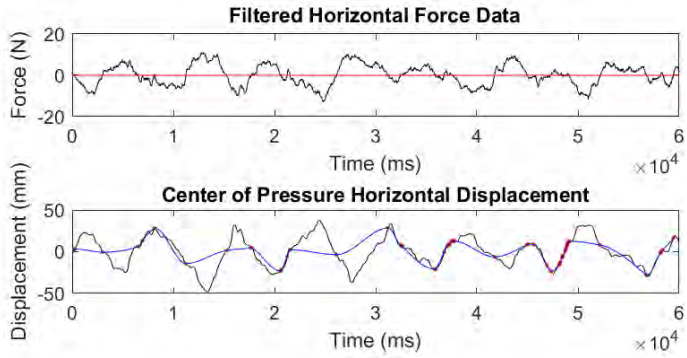

Figure 1b: Example of the RT decomposition analysis of one trial of poor balance, with eyes closed. Spline connecting dots represents the rambling component, plotted over the COP_{a-p} displacement.

COP trajectory data was collected for 60-sec. at 1000 Hz and low-pass filtered with the cut-off frequency of 20 Hz. Two 2-by-2 Factorial ANOVAs were conducted to compare the main effects of type of balance and vision conditions, and the interaction

effect between type of balance and vision conditions on the RT correlation coefficient and on RMSe between COP_{a-p} trajectory and RM spline, respectively. Level of significance was set *a priori* at $\alpha = .05$.

RESULTS AND DISCUSSION

There were no significant main effects of vision condition ($p = .094$) and balance type ($p = .309$) or the interaction between balance type and vision ($p = .701$) on the correlation coefficient (Figure 2).

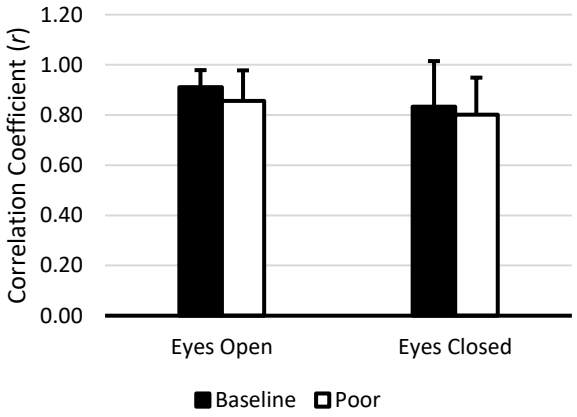

Figure 2: COP mean correlation coefficient during baseline and poor balance, with eyes open and eyes closed.

A significant main effect of vision condition on RMSe was found, $F(1, 10) = 11.61$, $p = .007$, $\eta p^2 = .537$, more specifically, the RMSe of the COP_{a-p} trajectory and the RM spline was lower with eyes open (Figure 3). The main effect of balance type ($p = .280$) and the interaction between balance type and vision condition on the RMSe ($p = .587$) were not significant.

These results suggest removal of visual feedback of balance, i.e. closing your eyes, produce COP_{a-p} alterations that can be detected by RT decomposition analysis if we focus on the RMS error between the COP trajectory and rambling spline, i.e. anterior-posterior COP oscillations induced by superior spinal processes. The correlation coefficients were surprisingly high across all conditions, suggesting that those are not interesting markers for the specific purpose of detecting balance-test sandbagging using RT decomposition.

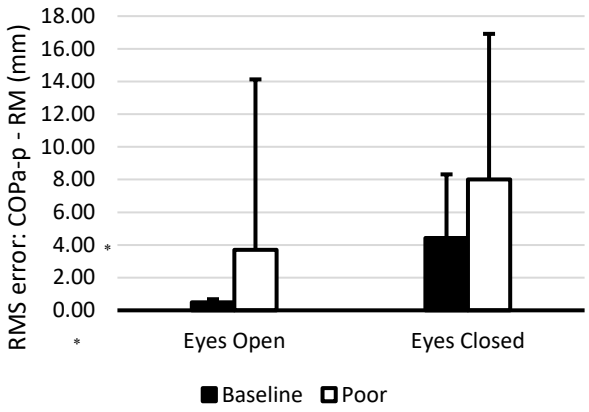

Figure 3: COP_{a-p} mean RMSe during baseline and poor balance, with eyes open and eyes closed. The * denotes greater than Eyes Open.

One limitation to this study is the small sample size in face of the large *SD*s in RMSe. Future studies should target larger sample size to address the large *SD*s, and consider investigating the sensitivity of other balance measures, for instance approximate entropy.

CONCLUSIONS

The correlation coefficient (rambling) and RMSe between the anterior-posterior COP trajectory and rambling spline (trembling) are not good measurements to detect sandbagging of balance tests. Future endeavors should focus on different measures.

A SIMPLE CONTROLLER FOR RUNNING DERIVED FROM STEP-TO-STEP VARIABILITY

[1] Nidhi Seethapathi and [1] Manoj Srinivasan

[1] The Ohio State University, Columbus, OH, USA
email: seethapathi.1@osu.edu, web: www.movement.osu.edu

INTRODUCTION

Constant-speed human running is not exactly periodic. For instance, the body states of the person at mid-flight fluctuate about a mean value. Despite these noise-like deviations, people are able to run without falling down. Here, we examine how these natural fluctuations are controlled using ground reaction forces. As in [1,2], we use step-to-step variability to infer such control. In contrast to [2], which attempted to explain running stability with variants of a spring-mass model, we focus on ground reaction force modulations. We show how classic spring-mass based models of running are incomplete. Our work has implications to mathematical measures of running stability and controllers for running prostheses, exoskeletons and robots.

METHODS

Subjects (N = 8, 5 male, 3 female) ran on a treadmill at 2.5. 2.7 and 2.9 m/s while motion of the hip, motion of the foot and ground reaction forces were collected for a few minutes. Using linear least squares methods similar to those used in [1], we derive a linear model by mining the variability in the data. Using this linear model, we study whether the deviations in control variables like leg force, foot placement, stance duration and leg length during stance are explained by the deviations in the body states at mid-flight. The inputs to the controller and coordinate notation are shown in Figure 1. We implement this derived controller on a simple point mass telescoping leg model by finding the model gains that best match the step-to-step map in the data. We apply these gains to the simple model during stance to control for any perturbations added during flight. We perturb the sideways velocity, fore-aft velocity and vertical position of the model at flight apex, one or two at a time. We obtain the basin of attraction for the model by using a 200 x 200 grid of perturbations and letting the model simulate for 20 steps at each grid point. A fall is defined as when the model's center-of-mass goes below the ground.

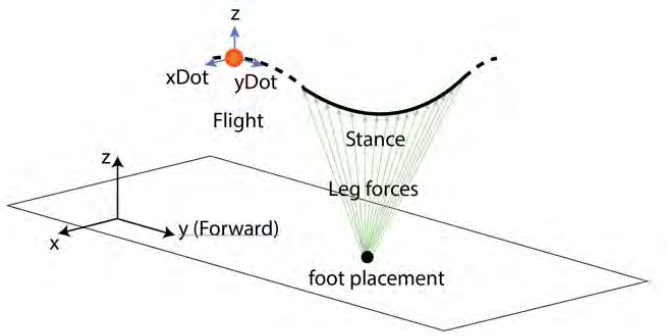

Figure 1. A linear map from flight states to stance controls is inferred.

RESULTS AND DISCUSSION

Experiment Results: The linear model obtained from experimental data found that a sideways velocity perturbation at flight apex is, on average, completely corrected by the sideways impulse during the next step (R^2=0.55). Around 80% of fore-aft velocity deviation at flight apex is corrected by the fore-aft impulse during the next step (R^2=0.35). Impulses can be modulated by modulating leg forces and stance duration. However, we find that stance duration does not play a role in correcting velocity deviations. Stance duration decreases in response to an upward vertical perturbation and increases in response to a downward vertical perturbation at flight apex. The phase-dependent ground reaction force modulation gains are shown in Figure 2. We find that, in response to fore-aft velocity deviations, the negative part of the GRF is modulated more than the positive part. People place their foot in the direction of the velocity perturbation. This foot placement control is more exaggerated in the sideways than in the fore-aft direction. Finally, we find that the landing leg length is changed proportionally in response to a vertical perturbation at flight apex. All gains were independent of running

speed and maintaining horizontal planar position was not found to be a priority for the controller inferred. All experimentally obtained gains are statistically significant with $p<10^{-4}$.

Model Results: The simple point mass telescoping leg model was first simulated with experimentally obtained control gains and some perturbations were applied. These gains were then adjusted to make sure that the step-to-step map for the model matched that from experiment. The adjusted model gains were found to be similar to experimental gains and are shown in Figure 2 below.

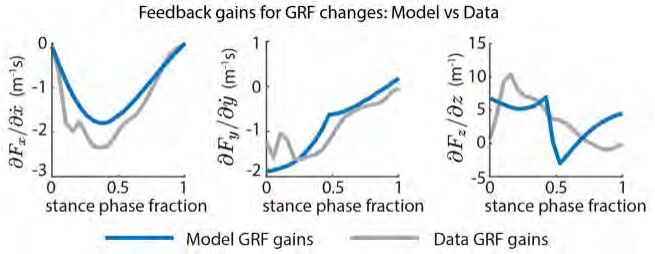

Figure 2: Experimental and model gains for GRF control. The model gains are similar to experimentally-obtained gains.

With the control present, the model has an asymptotically stable running motion. It recovers from fore-aft and sideways velocity perturbations and from vertical position perturbations, as shown in Figure 4. Although not explicit in the model's controller, it discovers a steeper leg angle in response to an upward perturbation. The model's basin of attraction (Figure 3) shows that it recovers from perturbations almost four times larger than the experimental variability size. We find that the basin of attraction is wider for fore-aft than for sideways perturbations. We also find that the model is more robust to upward than to downward perturbations.

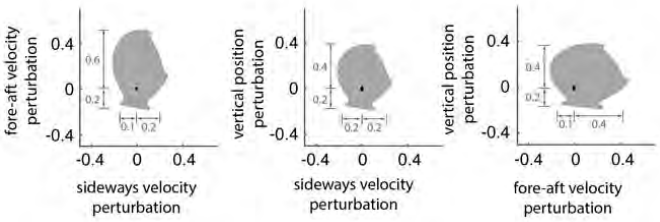

Figure 3: Basin of attractions for the simple model.

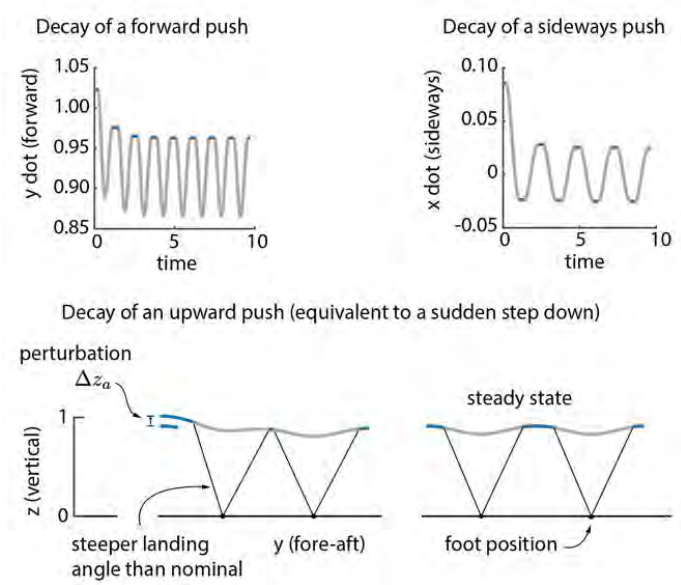

Figure 4: The model is stable to perturbations in fore-aft and sideways velocities and vertical position.

CONCLUSIONS

The control strategies found here are obtained from actual human running data and provide an empirical basis for the running controllers currently in use. The foot placement control found here appears to be qualitative similar to that used by people when walking as found in [1]. Our simple model discovers a steeper leg angle in response to an upward perturbation and this has previously been reported in papers with step-up and step-down perturbations for running birds and humans. An energy-conservative spring cannot explain the control gains observed here. Thus, we find that spring-mass assumptions for running control are insufficient to explain human running stability for even small steady-state perturbations such as those in our experiments. Since our controller is primarily derived from human running data, it can be used to make exoskeletons and prosthetic legs respond to the users in a more natural and seamless manner.

EFFECT OF PROPHYLACTIC ANKLE BRACING ON DYNAMIC BALANCE

Mitchell L. Stephenson and Jason C. Gillette

Iowa State University, Ames, IA, USA
email: mistephe@iastate.edu, web: kin.hs.iastate.edu

INTRODUCTION

Due to the prevalence of ankle injuries in sport and exercise, many athletes choose to wear prophylactic ankle braces in an attempt to prevent injury. Previous research attempted to identify whether lace-up or hinged ankle braces affected dynamic balance in the Star Excursion Balance Test (SEBT) but did not identify any performance changes from the control condition [1].

More recently a new type of ankle brace has become popular: This hybridized design combines rigid sub-structures stabilized against the ankle with compressive strapping. As many manufacturers tout this new semi-rigid design as a technological advancement, the current study was implemented in order to determine if these new braces affect dynamic balance.

METHODS

Twenty physically-active, uninjured recreational athletes (9 females and 11 males; 21.1±1.9 years; 1.67±0.04 m tall; 76.1±14.0 kg) provided informed consent, performed a warm-up, and completed the following as part of a larger study. Four braces were tested: A lace-up and hinged ankle brace were tested to compare to previous research, and two new semi-rigid designs from different manufacturers.

Participants performed a modified SEBT [2] in unbraced and four braced conditions in a counterbalanced order. All participants stood on their right (braced) leg and attempted to reach their left toe as far along guiding vectors as possible. These guiding vectors were marked with tape on the ground, and were oriented anteriorly, posteriolateral to the stance leg at 45°, and posteriomedially at 45° (Figure 1).

Participants performed seven successful repetitions in each direction: six served as practice and the seventh was recorded [3]. An attempt was successful if the participant kept their arms folded across their chest, performed the movement with a smooth continuous motion, did not transfer weight to the reach leg, and kept the stance foot firmly and flatly planted on the ground.

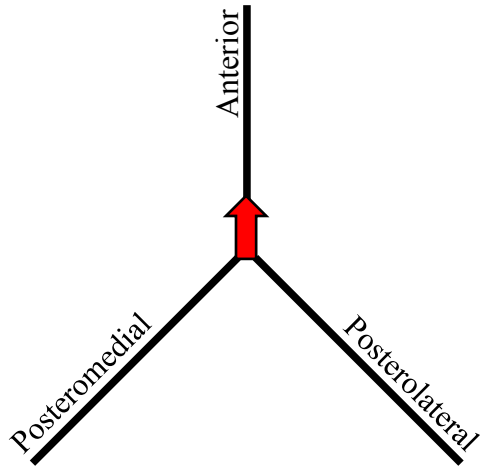

Figure 1: Modified SEBT protocol. Participants stood with their right foot on the red arrow. With their left foot, they attempted to reach their toe as far along the anterior, posterolateral, and posteromedial axes.

Kinematics of retroreflective markers placed on both feet were recorded via 8 Vicon cameras at 160Hz through Vicon Nexus 1.8.2 (Vicon Corp, Oxford, UK). Peak displacement of the left (reach limb) toe marker from the right (stance limb) toe marker (in anterior reaches) or heel marker (in posterior reaches) along the aforementioned axes was calculated and normalized to leg length. A repeated-measures analysis of variance was performed to compare the effect of the braces on the reach distances. An alpha value of 0.05 was utilized to evaluate statistical significance.

RESULTS AND DISCUSSION

No significant main effects were identified for any reach direction ($p > 0.60$). As seen in Table 1 below, participants attained further reach distances in both the posterolateral and posteromedial directions than the anterior direction, but reach distances were similar for all braces and the unbraced condition within each direction.

The lack of significant differences between the braces is similar to previous research [1]. The lace-up and the hinged braces were selected to match the designs in that investigation; as such, a lack of differences was not surprising. But the semi-rigid design is a more recent development in the prophylactic bracing market. Given multiple manufacturers' claims that these braces are more effective than previous models, we expected they may affect dynamic balance. Results indicate this was not the case.

Participants did qualitatively differentiate the perceived effect of certain braces on their performance, indicating in post-performance surveys that the semi-rigid braces were more restrictive than the lace-up brace. Some participants described this restrictiveness as beneficial, providing stability and support which may have facilitated their performance in the modified SEBT. But other participants believed the opposite, suspecting that the restriction may have hindered their range of motion. *Post hoc* exploratory analyses did not identify differing effects on dynamic balance based on these survey results, however.

It is possible that participants' performance was not altered due to the investigation's participant delimitations: Participants were required to be healthy and fit, which may mitigate the effect of a brace. It may be beneficial to investigate these possible effects on athletes with chronic ankle instability. Modern brace designs may affect the dynamic balance of this population, in contrast to the previously-tested lace-up designs [4].

CONCLUSIONS

It appears that prophylactic ankle bracing, independent of the brace's design, may not significantly affect dynamic balance in recreationally-athletic, uninjured populations. Given that athletes have an adequate level of dynamic balance, braces are therefore not likely to hinder balance and increase injury risk. In contrast, individuals within this population that would benefit from enhanced balance should not attempt to rely on ankles braces to augment such performance.

ASSESSMENT OF POSTURAL CONTROL IN MULTIPLE SCLEROSIS: IDENTIFICATION OF CORE OUTCOME VARIABLES

[1]Ruopeng Sun, [2]Salma Musaad, and [1]Jacob J. Sosnoff

[1]University of Illinois at Urbana-Champaign, Department of Kinesiology and Community Health, IL, USA
[2]University of Illinois at Urbana-Champaign, Interdisciplinary Health Sciences Institute at Illinois, IL, USA
email: rusun@illinois.edu

INTRODUCTION

Balance impairment in individuals with multiple sclerosis (MS) is very common and associated with increased risk of falling. Although posturography is the gold standard of balance assessment, the vast number of metrics it yields presents a daunting challenge for clinicians and researchers to properly interpret data and provide actionable insights. Numerous postural sway metrics (i.e. sway path, sway area, sway amplitude, frequency domain measures, and sway entropy, etc.) have been shown to be sensitive to balance impairment in individuals with MS [1]. Yet there is limited data to inform guidelines on the most appropriate postural sway metrics for impairment tracking and fall risk evaluation. This investigation assessed the accuracy and feature importance of various postural sway metrics to differentiate MS individuals as a function of physiological fall risk.

METHODS

This secondary data analysis included 153 participants (50 controls and 103 individuals with MS). Participants were further classified into four subgroups based on individual's physiological fall risk - Physiological Profile Assessment (PPA): controls (n=50, 64.9 ± 4.9 years old, PPA < 1); low-risk MS (n=34, 54.0 ± 13.1 years old, PPA < 1, EDSS: 4.3 ± 1.5); moderate-risk MS (n=27, 58.3 ± 8.3 years old, 1 ≤ PPA < 2, EDSS: 5.3 ± 1.5); high-risk MS (n=42, 56.8 ± 9.7 years old, PPA ≥ 2, EDSS: 6.0 ± 0.9). Participants also completed balance confidence questionnaires (Activities-specific Balance Confidence Scale - ABC, Falls Efficacy Scale – International - FES)

All participants were instructed to stand upright for 30 s on a force platform (Bertec Corp, Columbus, OH) with their feet shoulder width apart, and eyes open, fixating at a target at 2 m away. Forceplate data were sampled at 1000 Hz and low-pass filtered (4th order Butterworth) at 10 Hz. The mediolateral and anteroposterior components of center of pressure (COP) were calculated using standard equations. Twenty common sway metrics (i.e. sway path length, 95% confidence sway ellipse area, mean sway velocity, sway range, root mean squared sway amplitude, sway frequency, sway entropy, etc.) were derived following standard procedure[2,3]. These sway metrics were subsequently used to train a set of random forest (RF) classification algorithms (70-30 training/test split, holdout validation) to predict individuals' fall risk grouping (low, moderate, high). The feature importance from the RF algorithms was used to select the strongest sway metric for fall risk prediction. All COP analysis were performed with MATLAB R2015b (The Mathworks, Inc., Natick, MA, USA), and statistical analyses were performed with Python Scikit-learn [4].

RESULTS AND DISCUSSION

Overall, as shown in Table 1, using sway metrics, the RF classification accuracy was high for discriminating controls from MS individuals (>90%) and discriminating low-risk MS individuals from high-risk individuals (78.9%). Whereas the classification accuracy for discriminating moderate-risk MS individuals from low/high-risk MS individuals were low (≤ 60 %).

Table 1: Classification accuracy based-on sway metrics

Classification Accuracy %	low-risk MS	moderate-risk MS	high-risk MS
controls	90.4	90.0	91.3
low-risk MS		60.0	78.9
moderate-risk MS			52.9

Sway sample entropy, a sway regularity metric, was identified as the strongest feature for classification of low-risk MS individuals from healthy controls. Whereas for all other comparisons, the mediolateral sway range was identified as the strongest predictor for fall risk groupings.

Additionally, when adding the balance confidence scale into the model, the RF algorithm improved its classification accuracy for discriminating controls from MS individuals (≥95%), while decreased its classification accuracy for MS individuals grouping (Table.2).

Table 2: Classification accuracy based-on sway metrics and balance confidence scale

Classification Accuracy %	low-risk MS	moderate-risk MS	high-risk MS
controls	95.2	95.0	95.7
low-risk MS		60.0	73.7
moderate-risk MS			47.1

CONCLUSIONS

Overall, the findings indicate that sample entropy is a sensitive sway metric for differentiating healthy controls and MS individuals without elevated fall risk, whereas mediolateral sway range can be used as a hallmark for increased fall risk in moderate to high-risk MS individuals. Self-reported balance confidence can improve the fall risk classification accuracy between healthy controls and MS individuals, but does not add value toward fall risk classification among MS individuals. These findings may set the foundation for the development of guidelines for accurate assessment of balance impairment in individuals with MS.

Reliability of A Novel, Clinically-Oriented Approach to Quantify Ankle Proprioception

[1]Rachel H. Teater, [2]Scott M. Monfort, [3]Kim E. Bigelow, [1,4]Ajit M.W. Chaudhari

[1]The Ohio State University, Columbus, OH, USA; [2]Montana State University, Bozeman, MT, USA;
[3]University of Dayton, Dayton, OH, USA; [4]Perfect Practice, Inc.
email: rachelteater21@gmail.com, web: http://u.osu.edu/osusportsbiomechanics

INTRODUCTION

Proprioception is an essential component of balance and postural control, as it provides information relating to the sense of movement (kinesthesia), the position of joints (joint position sense), velocity of muscular contraction, and the force associated with muscular contractions. Proprioception is at risk of deterioration with factors such as aging, peripheral neuropathy, osteoarthritis, and ligament injury [1]. Being able to measure proprioception in the clinic is important as rehabilitation in patients with decreased proprioception may mitigate declines in their functional stability [2].

Proprioception is often evaluated using a Biodex isokinetic dynamometer or custom-built devices. These methods have cost, space, ease-of-use, and portability barriers that impede the ability of clinicians to measure proprioception in populations that are at risk of having deficits. Because of these challenges, mobile device applications have increasingly been investigated as an alternative method of measuring human movement and proprioception. CoreX Therapy (Perfect Practice, Inc.) is an iOS app that has previously demonstrated utility for quantifying core stability through the measurement of pelvic tilt [3]. Recent research has investigated using this application as a clinically-relevant tool for measuring ankle joint position sense (JPS), a component of proprioception [4], but the reliability of this novel tool has not been established.

The purpose of this study was to establish the reliability of the CoreX Therapy app as a tool for assessing ankle proprioception in the clinic. Number of trials and post-processing considerations were examined to determine the most reliable protocol for clinical implementation.

METHODS

Forty-five healthy participants (16 females, 29.3 ± 7.8 yrs, 1.76 ± 0.10 m, 76.0 ± 15.7 kg) were recruited at the 2017 Annual Meeting of the American Society of Biomechanics at the University of Colorado Boulder in August 2017. Data were collected by a number of undergraduate, graduate, and faculty researchers, to demonstrate the approach's ease of use.

Figure 1: Ankle joint position sense assessment using CoreX Therapy iPod application.

Each participant's ankle JPS was evaluated using the CoreX Therapy application. Participants' more unstable ankle (self-reported) was tested. If neither ankle was reported to be unstable, the ankle of the dominant leg was tested. An iPod was strapped to participants foot, as they lay supine on a table (Figure 1). Each participant performed ten trials of active ankle repositioning. For each trial, the participant started with their sole perpendicular to the ground then actively plantarflexed their foot until they reached the target angle of 15 degrees and were instructed to stop by the researcher. The participant held this position for 5 seconds to learn the angle. The participant then repeated the movement and indicated when they thought they had reached the target angle once again. The researcher recorded the

error from target angle of the participant's ankle for each trial.

Intraclass correlation coefficients (ICCs) were used to assess the trial-to-trial reliability of participants' absolute error in active joint reposition sense. To determine how the reliability changed with the available number of trials, an iterative analysis was performed. ICCs were calculated considering the first five through all ten trials. The reliability of each number of trials was assessed with and without the most and least accurate trials included.

RESULTS AND DISCUSSION

The ICCs for five through ten trials are shown below in Figure 2. The reliability of using the CoreX Therapy app as a measure of ankle active JPS generally increased with increasing number of trials included. The reliability was always greater with the most and least accurate trial excluded. When analyzing only the first five and six trials and not excluding the most and least accurate trials, the test had poor reliability (ICC(1, k) < 0.50). All other scenarios resulted in moderate reliability. The most reliable measure of JPS was achieved by collecting ten trials then excluding the most and least accurate trial with an ICC(1, k) of 0.741.

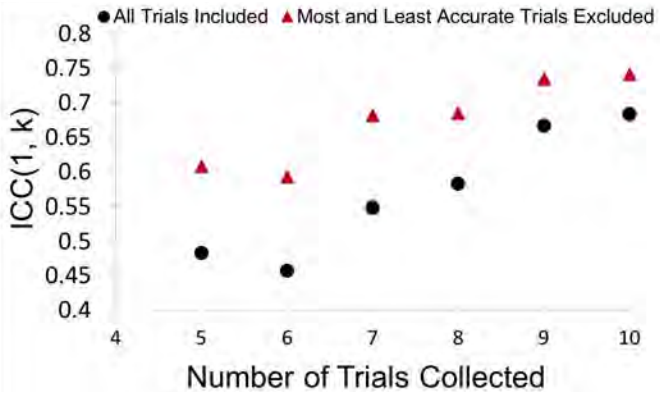

Figure 2: ICCs for the absolute error of five through ten trials of active ankle reposition tests.

This tool reduces the barriers to widespread clinical assessment of proprioception as it is low-cost and easy to operate. Materials necessary only include an iPod and a way of securing the iPod to the patient's foot, such as a Velcro strap. Widespread clinical assessment of proprioception can lead to increased implementation of rehabilitative interventions for patients who have impaired proprioception. Additionally, this tool provides improved ability for researchers to directly test relationships between ankle proprioception and other variables of interest rather than inferring proprioception from indirect measures such as nerve conduction velocity or self-reports.

CONCLUSIONS

The CoreX Therapy app is a moderately reliable tool that can be used to evaluate ankle JPS and proprioception by both clinicians and researchers. The low cost, high portability, and simplicity of this method allows proprioception assessment to be easily implemented in clinical settings. For best reliability, ten trials of active joint position sense should be collected and the most and least accurate trial should be excluded before determining the average absolute error.

DYNAMIC STABILITY DURING WALKING IN CHILDREN WITH AND WITHOUT CEREBRAL PALSY: A PILOT STUDY

[1] James B. Tracy, [1] Drew A. Petersen, [1] Jamie Pigman, [2] Benjamin C. Conner, [3] Christopher M. Modlesky, [1,4] Freeman Miller, [1] Curtis L. Johnson, [1] Jeremy R. Crenshaw

email: crenshaw@udel.edu, web: http://sites.udel.edu/kaap/crenshaw-lab/

INTRODUCTION

Cerebral palsy (CP) is associated with a high risk and rate of falling, 55% of which occur during walking [1]. Gait abnormalities associated with CP include a "stiff" knee during swing, knee hyperextension (i.e. recurvatum) or excessive flexion (i.e. crouch) in stance, limited dorsiflexion (i.e. equinus), leg crossing in swing (i.e. scissoring), intoeing, internal hip rotation, and excessive hip adduction [2]. These abnormalities likely alter the trajectory of the whole-body center of mass (COM) during gait and foot placement in a way that increases the risk of falling forward or to the side.

Previous analyses of gait stability in children with CP demonstrate that it is dependent on speed and direction. By evaluating step placement relative to a "foot placement estimator", one study suggested that those with CP are *more unstable* anteriorly, especially at fast speeds and when stepping with the more affected limb [3]. By evaluating the inclination angle between the COM and center of pressure, another study suggested that children with CP are *more stable* anteriorly, likely achieved through slower speeds as a protective means against falling [4]. Both studies, however, noted lateral instability in children with CP compared to typically developing (TD) counterparts [3, 4]. These results align with other studies that determined that children with CP have larger mediolateral COM excursions and velocities relative to the center of pressure [5, 6].

The "margin of stability" (MOS) represents the distance between the edge of the base of support and the vertical projection of the extrapolated center of mass (xCOM), which is determined by the position and velocity of the whole-body COM [7]. The MOS has distinct advantages in that it is a dynamic measure (i.e. it accounts for velocity), and it can be evaluated at distinct time points in the gait cycle. In addition, the magnitude of the MOS is proportional to the impulse needed to change stability states, so it has explicit biomechanical meaning [7].

The purpose of this study was to compare the anterior and lateral MOS of children with and without CP. We hypothesized that (1) children with CP would be less stable than TD children, (2) group differences would be greater when bearing weight with the non-dominant limb, and (3) group differences would be greater at fast speeds than at preferred speeds.

METHODS

A group of 5 children with CP (3 boys and 2 girls, mean = 8.4 (standard deviation = 2.2) years old, 4 GMFCS level I, 1 GMFCS level II) were age-matched with 5 TD children (3 boys and 2 girls, 8.4 (2.2) years old).

Using motion capture technology (Qualisys, Göteborg, Sweden, 120 Hz) and a full-body marker set, the overground gait of all participants were recorded at preferred and fast speeds.

The MOS [7] was calculated as follows:

- The anterior MOS was evaluated immediately before foot strike as the anterior distance between the trailing stance toe and the xCOM. This measure represents the maximum anterior instability that the child allowed.
- The anterior MOS at mid-swing was evaluated as the anterior distance between the stance toe and the xCOM. This measure represents the state of stability when a trip is likely to occur.
- The minimum lateral MOS was evaluated as the minimum lateral distance between the stance toe and the xCOM during stance. This measure is proportional to the minimum impulse needed to induce frontal plane instability.

The average of each measure over two complete gait cycles was calculated for each participant. Mixed factorial ANOVA's were used to evaluate the effects and interactions of GROUP (CP or TD), LIMB (dominant or non-dominant, as per reported kicking preference), and SPEED (preferred or fast) (SPSS, IBM Corp, New York, USA). Given the small sample size, results were interpreted using effect sizes (large: $f = 0.40$, medium: $f = 0.25$, small: $f = 0.10$).

RESULTS AND DISCUSSION

Gait Speed

A large effect of commanded SPEED ($f = 3.39$, $p < 0.001$) indicated that participants walked faster when instructed to do so (Table 1). Small main effects and interaction containing GROUP ($f < 0.07$, $p > 0.86$) suggested that children with CP did not walk slower than TD children.

Anterior Margin of Stability before Foot-Strike

There were medium-to-large effects of LIMB ($f = 0.35$, $p = 0.357$) and SPEED ($f = 3.44$, $p < 0.001$) on anterior stability, such that faster speeds were more unstable and participants allowed themselves to be more unstable when pushing off of their dominant limb (Table 1). All other main effects and interactions were weak ($f < 0.23$, $p > 0.53$).

Anterior Margin of Stability at Mid-Swing

There was a medium effect of SPEED x LIMB x GROUP ($f = 0.33$, $p = 0.381$). In post-hoc comparisons, only small between-group differences were observed (Cohen's $d < 0.24$, $p > 0.72$).

Minimum Lateral Margin of Stability

There was a large SPEED x LIMB x GROUP effect ($f = 0.41$, $p = 0.285$). At fast speeds, as well as when bearing weight on the non-dominant limb at preferred speeds, children with CP were more stable than TD children (Cohen's $d = 0.78 – 2.00$, $p = 0.015 – 0.17$, Table 1).

CONCLUSIONS

This high-functioning group of children with CP exhibited a more conservative lateral stability strategy, especially on the non-dominant limb and at fast speeds. Despite a worse response to anterior perturbations (*in review)*, no group differences in anterior stability during walking were observed. This discrepancy could increase the risk of falling should an anterior perturbation, such as a trip, occur during walking.

INTRODUCTION

Chiropractic is the third-largest health care profession in the United States. As of 2012, based on data from the National Health Interview Survey, approximately 8.4% of U.S. adults (19.1 million) had seen a chiropractor within the past 12 months, and 24% (54.6 million) during their lifetime. [1]

While the therapeutic method most commonly associated with chiropractic is spinal manipulation, also known as manual "adjustment", there has here has been limited investigation into the mechanical characteristics of how chiropractors perform adjustments. More knowledge of how chiropractors *do* perform manual adjustments could contribute to a more ambitious effort of determining how they *should* perform them. Most chiropractic care involves performance of "high-velocity, low-amplitude" thrusts (HVLA), which is considered to be physically demanding. Improper technique is thought to contribute to injury in chiropractic practitioners; documented common complaints include pain in the low back, neck, shoulders, hands, and wrists. [2,3] Furthermore, the educational process is largely dependent on instructors' subjective assessments of students' performance; objective measurement methods and educational standards is an emerging area of investigation.

One of the more commonly-known chiropractic methods is the side-posture adjustment (SPA). The aim of the present study, using a single chiropractor (Doctor of Chiropractic, or DC), was to develop a protocol to track postural angles and angular velocities during the performance of SPAs.

METHODS

All procedures were approved by our institution's IRB. An email was sent to students in the DC program who had recently completed a 3rd-level technique class, had an established clinical file, and were known to have no contraindications to receiving HVLA chiropractic care. Potential participants were included if an SPA of the lumbar spine was deemed appropriate the day of data collection; they were to be excluded if HVLA was deemed inappropriate for any reason, or if their health & examination records were not available. The first 10 students who responded were examined and included in the study.

One chiropractor, with 23 years of practice and teaching experience, was outfitted with MyoMotion inertial measurement unit (IMU) sensors (Noraxon, Scottsdale Arizona, USA), on the back of her head, overlying the C7 and T12 vertebra and upper sacrum, on the lateral aspects of both upper arms, and on the distal thighs. System calibration was done before each adjustment, using the manufacturer's proprietary system, with the doctor standing still in an upright neutral posture for approximately 30 seconds. She then performed a Gonstead-style lumbar SPA on each patient.

The first author examined motion recordings to identify the moment of maximum execution of each adjustment thrust. Data were exported to an algorithm developed in Excel by the fourth and fifth authors and analyzed for a period from one-half second before to one-half second after the thrust. We have thus far limited our analyses to spinal motions, specifically maximum values of angular measurements and rates of change for flexion-extension, lateral bending, and rotation of the cervical, thoracic, and lumbar regions.

RESULTS AND DISCUSSION

Data collection was successful for all trials, though the SPA was repeated on one trial in which the chiropractor felt that her first attempt was not optimally executed.

Relative to neutral calibration, the DC's spinal regions were flexed during the entirety of set-up and thrust. The cervical region also remained in right lateral bending and rotation; the lumbar spine was mostly in slight left rotation. Otherwise, the patterns of thoracic lateral bending and rotation and lumbar lateral bending were small in magnitude and clustered around the calibrated zero position.

The general patterns of all motions were consistent, trial-to-trial, though peak angles varied in their magnitudes and in when they occurred relative to the thrusts. Figure 1 presents cervical flexion-extension as an example of one regional motion pattern.

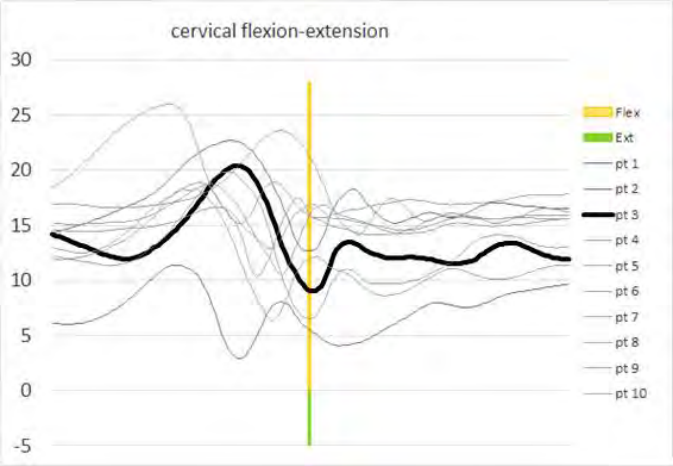

Figure 1: Cervical flexion-extension motion patterns around time of peak thrusts in side-posture adjustments (SPAs). The bold line highlights one pattern felt to be typical; those for other patients are sequentially similar, though they differ in magnitudes, and in timing of peak motions relative to the moment of peak thrust (vertical line).

Around the times of peak thrust, angular velocities during acceleration for the cervical, thoracic, and lumbar regions were, on average, 111.8, 73.5, and 38.7 degrees per second (deg/s), respectively; one period of cervical flexion reached 137.3 deg/s. Angular velocities in the frontal plane for the cervical, thoracic, and lumbar regions were, on average, 83.5, 66.5, and 48.6 deg/s, respectively; one period of thoracic lateral bending reached 140.3 deg/s. Angular velocities during transverse plane rotation for the cervical, thoracic, and lumbar regions were, on average, 124.7, 61.7, and 32.1 deg/s, respectively; the fastest was during one period of cervical rotation, at 205.8 deg/s.

The motion capture system and our data analysis method both worked well. Our patient recruitment was successful, but this was a small study and may not work for an expanded version. The patients were relatively young and healthy, and the findings could be different for older patients and those with pain, stiffness, or degeneration. The study also involved only one chiropractor, who may or may not be typical.

CONCLUSIONS

The methods appear to be feasible for identifying similarities and differences in motion patterns. Future studies will include additional chiropractors and should draw patients from other populations. These efforts may contribute to chiropractic student education and the understanding of occupational injuries of chiropractors.

INTRODUCTION

Falls are a major health and economic burden in the United States. Peoples over the age of 65 contribute to over 80% of all fall related deaths in the United States [1], and within this older population, fall-related injuries account for approximately $19 billion in annual medical costs [2]. Falls are also a major hazard in occupational settings, and represent another robustly studied area of fall research. Occupational injuries related to slips, trips, and falls resulted in a direct cost of over $16 billion in the United States. The process of an unexpected slip is divided into four distinct phases (environment, initiation, detection, and recovery) [3]. Researchers have commonly classified slips in a severity range based on the magnitude of this heel slip distance, as well as the velocity of the heel slip [4-6]. Though, more recent work has attempted to quantify the slip response as a fall or recovery through the use of a force criterion in the fall arrest harness system [7]. The kinetic analysis during slip events has generally focused its attention on the GRFs and the corrective joint moments during the slip response [4-6, 8-10]. These responses have been reported to be scaled to the severity of the slip, but have yet to be analyzed between groups of fallers and non-fallers. Thus the purpose of this study was to examine lead leg slip recovery parameters between those classified as a fall, or recover during an unexpected slip.

METHODS AND PROCEDURES

This study was conducted in a case-controlled design, with 32 healthy adults (16 male, 16 female; age: 21.66 ± 3.156; height: 170.24cm ± 13.86; weight: 74.62kg ± 16.60), who had no history of musculoskeletal, orthopedic, neurological, or vestibular abnormalities. An 8 camera Vicon Nexus (Oxford, UK) 3D motion capture system was used to collect and analyze kinematic and kinetic gait data. A lower body plug-in gait model from the Helen–Hayes marker system was used for the participant configuration and the kinematic data was sampled at 100 Hz and collected using the Vicon Nexus software. Variables of interest are mean sagittal moments about the ankle, knee, and hip, during stance phase (ANKm, KNEm, HIPm). Peak moments (ANK_PFp/DFp, KNE_Ep/Fp, HIP_Ep/Fp), and time to peak moments (ANK_PFttp/DFttp, KNE_Ettp/Fttp, HIP_Ettp/Fttp). A back-pack type fall arrest system with a movable trolley was used to prevent any undesired falls. Glycerol mixed with water in the ratio of 75% glycerol and 25% water was used as the slippery agent [3]. During the slip trials, glycerol was applied and evenly distributed on a force plate for contact of the leading left leg. Participants were strapped to a harness and performed multiple gait trials until normal self-selected pace walking with appropriate foot positioning onto the force plate was achieved. Participants turned away and listened to music on noise cancellation head phones for about 1 minute between each of these normal gait trials. One trial was then chosen to be the unexpected slip (US) and the contaminant was applied. Each slip trial was classified based on a force criterion using a digital crane scale inline with the overhead harness system. The slip was classified as a fall if the peak body weight measured by the scale exceeded 30% of body weight during the slip, and confirmed with visual inspection. After classification, recovery kinetics were analyzed, using independent samples t-tests between falls and recovers.

RESULTS AND DISSCUSSION

For the slip recovery measures, we have evidence of significant differences for the average ankle moment ($t(30) = 2.878$, $p = 0.007$), peak knee extension moment ($t(30) = -2.125$, $p = 0.042$), and knee extension time to peak moment ($t(30) = 2.051$, $p = 0.049$). Our results suggest a decreased average ankle moment over stance phase, likely due to the fall eliminating the progression into toe-off and the propulsion phase of gait. Our data also suggest an increased knee extension peak for fallers, but a decreased knee extension time to peak. Previous research has shown that after a slip has been initiated, a series of corrective responses attempt to rescue the fall and maintain locomotion. The primary response identified during a slip is an increased flexion knee moment, and extension moment about the hip [6]. This is followed by a secondary response consisting of a knee extension moment and hip flexion moment. These portions on average, represented approximately 190ms to 350ms after heel contact. Our findings also observed a peak knee flexion moment at approximately 200ms (201.8 in recoveries vs 198.7 in falls), however our data further suggest that a greater, premature knee extension peak similar to the previously observed secondary response may contribute to a fall as opposed to a recovery.

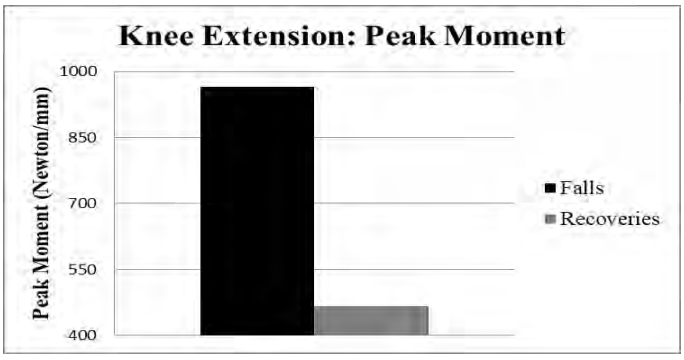

Figure 1: Peak knee extension moments between those who fell, and those who recovered.

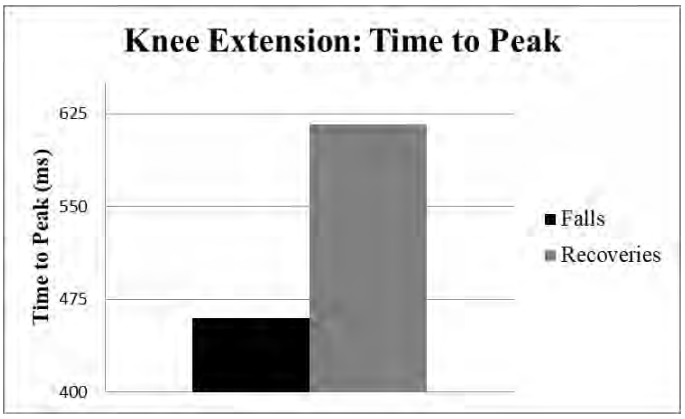

Figure 2: Time to peak knee extension moments between those who fell, and those who recovered.

CONCLUSION

The findings of this study suggest that differences in knee extension during the secondary response of slip recovery may contribute to the likelihood of a slip induced fall. These temporal differences could be due to co-contraction responses at the knee during slip responses, or different muscle synergy underpinnings within the slip recovery response.

RELATIONSHIP BETWEEN MUSCLE ACTIVATION AND POSTURAL STABILITY IN PERSONS WITH MULTIPLE SCLEROSIS

[1] Silvia Zanini, [1]Derek Tolbert, and [1] Bradley J Bowser

[1] South Dakota State University, Brookings, SD, USA

INTRODUCTION

Multiple sclerosis (MS) is a chronic neurological disease that affects millions of people worldwide and may significantly affect activities of daily living [1,2]. Peersons with MS (PwMS) often exhibit poor postural control [3], likely contributing to the high rate of falls in this population. For example, 56% of PwMS in one study fell at least once in a three-month period [4].

Surface electromyography (EMG) records the summed electrical activity of the individual motor unit action potentials. These data give insight into the magnitude of muscle activation as well as the temporal characteristics of the muscular activation. Postural stability can be assessed by tracking the center of pressure (COP) on a force plate. By combining EMG and COP data, we can determine which muscles are most active during quiet standing and how muscle activation differs between PwMS who exhibit varying degrees of postural stability.

Thus, the aim of this study was to determine the relationship between muscle activation and postural stability in MS patients. We hypothesized that there will be positive correlations between postural sway and muscular activity in the lower extremities.

METHODS

Thirteen patients with a physician's diagnosis of MS and an expanded disability status score (EDSS) ≤ 6.5 participated in the study (age 5.7±9.4, mass 78.1±20.6, height 1.68±0.1, EDSS score 3.65±2.1). Participants who experienced an MS flare-up or had a change in medication during the 3 months prior to enrollment were excluded from the study.

Following a light warm up (3-minutes of walking), participants performed 5 trials of a sit-to-stand-to-sit movement. With arms folded across the chest, participants stood up from a chair at a self-selected speed, stood quietly for 10 seconds, then sat back down. A 90-120 second rest period was given between trials. Muscle activation and postural stability were assessed during the middle 5 seconds of the quiet standing phase.

After prepping the skin, surface EMG electrodes were placed bi-laterally on the following muscles: vastus medialis, vastus lateralis, tibialis anterior, medial and lateral gastrocnemius, and medial soleus. EMG data was captured at 2000Hz. A 2nd-order recursive high-pass filter (20Hz) followed by a 2nd-oder recursive low-pass filter (500Hz) was applied to the EMG data to remove any DC bias. The EMG signals were then filtered using a moving-root mean square (RMS) filter with a 101ms window. The mean and max RMS values from the 5s window were then calculated from the filtered EMG signals. Both meanRMS and maxRMS values were scaled to the maxRMS of the entire sit-to-stand-to-sit movement.

Ground reaction forces were collected at 1000 Hz. Participants stood with their feet on separate adjacent force platforms (figure 1). After filtering the force data (50Hz 4th-order recursive low-pass), Net COP data was calculated from both force plates using the methods described by Chung et al. [5]. Finally,

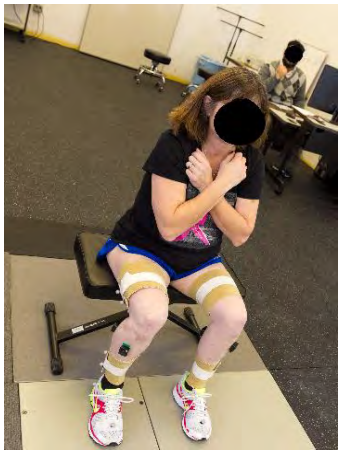

Figure 1: Participant starting position.

absolute path length and peak sway velocity were calculated in the anterior- posterior and medial-lateral directions. All variables of interest were averaged across the 5 movement trials.

Pearson correlation coefficients were calculated to determine the relationships between postural sway variables and the mean and maxRMS of each muscle.

RESULTS AND DISCUSSION

Results from the correlation analysis are shown in Table 1. Several significant correlations were found between the postural variables and the muscle activation.

	Max	0.34	0.35	0.40	0.38

*p <0.05; **p<0.01; s: stronger limb; w: weaker limb; VL: vastus lateralis; VM:vastus medialis; TA: tibialis anterior; Lat G:lateral gastrocnemius; MedG: medial gastrocnemius; MedS: medial soleus.

As hypothesized, several significant positive correlations between muscle activation and measures of postural stability were identified. Both the mean and maxRMS of the vastus medialis of the weaker limb displayed significant correlations with each of the stability measures. In addition, the maxRMS of both the strong and weak gastrocnemius (both medial and lateral head) were found to be significantly related to several of the postural stability variables. These findings are consistent with other studies where the muscle activity of the vastus medialis of the weaker limb was reported to be greater ie. patients with Osteoarthritis [6] or Stroke [7]. This confirms our results, and shows that the VM in the affected leg is highly involved in stability. Similar to patients who have experienced a stroke, persons with MS displayed increased sway [7]. One may speculate that the greater maxRMS suggests that participants compensate for muscle weakness by increasing muscle activity of the muscles that will help maintain control of their body. Because it is energetically costly, this mechanism may lead to fatigue, a common symptom of MS.

CONCLUSIONS

Several significant correlations were found between the postural sway variables and muscle activation. Out of those, the vastus medialis of the weaker limb and the gastrocnemius of both limbs appears to demonstrate the strongest correlations to postural stability. Because of the small sample size, more research is needed to confirm and these findings.

DEVELOPMENT OF A MUSCULOSKELETAL FINITE ELEMENT ANALYSIS METHOD FOR DYNAMIC BONE STRESS ANALYSIS OF PROXIMAL FEMUR

[1] Kazuhiko Adachi, [1]Nungna Wi and [2]Mitsuaki Noda

[1] Department of Mechanical Engineering, Chubu University, Kasugai, Aichi, Japan
[2]Orthopedics, Nishi Hospital, Kobe, Hyogo, Japan
email: kazuhiko@isc.chubu.ac.jp

INTRODUCTION

Proximal femur fractures due to osteoporosis are one of the serious health issues in aging societies. The fractures happen as a result of an accidental fall that would not usually cause the fracture for younger people. In stable fractures, osteosynthesis with pin / screw / plate type fixations, such as Hansson pin (Stryker) and Dual SC Screw (KiSCO), is widely used for femoral neck fracture treatment in Japan. Unfortunately, some complications such as secondary fractures may occur during postoperative rehabilitation period. In order to reveal the potential cause of the postoperative fracture from the viewpoint of the biomechanics, authors had already performed the dynamic stress analysis of the treated proximal femur based on finite element (FE) analysis. The final goal of our study is to establish the reliable postoperative bone fracture risk assessment method in response to the daily activity including mainly walking. The aim of this study is to propose a novel musculoskeletal finite element (MS-FE) analysis method for proximal femur biomechanics.

METHODS

This study was approved by the Ethical Review Board of the Konan Hospital. Patient was provided with a written informed consent. A new patient-specific 3D left hip joint FE model was constructed from the CT images of an elderly female volunteer. The model consists of the pelvis, proximal femur, cartilage, and Dual SC Screw (DSCS). The fracture surface was modeled an inclined surface with an angle 50 degrees as Pauwels type II classification [1]. The model was meshed into 4-noded tetrahedral elements and then assembled as multi bodies shown in Fig.1. The mechanical properties, Young's modulus and Poisson's ratio, were shown in Table 1 which obtained from the literature [2]. The mass densities both cortical and cancellous bone were calculated from their Young's modulus by using the expression shown in the literature [3]. All materials were assumed to be homogeneous, isotropic, and linear elastic feature. Each muscle was modeled in a straight line element. The dynamic muscle loading, joint reaction force and boundary conditions were applied to the model for simulating a gait motion.

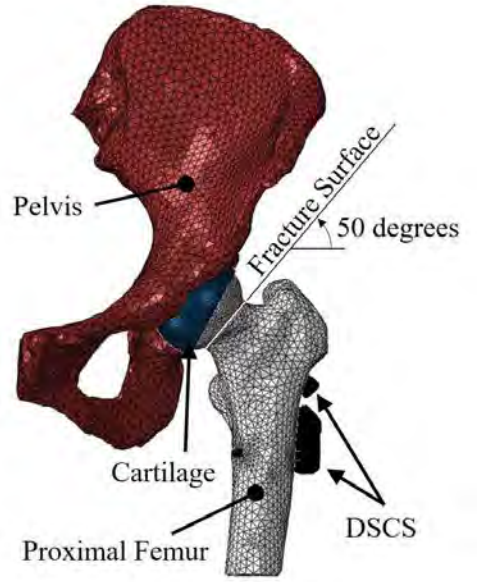

Figure 1: Three dimensional left hip joint FE model; DSCS treated model.

Table 1: Material properties.

	Young's modulus MPa	**Poisson's ratio**	**Mass density** kg/m^3
Cortical bone	13,300	0.3	1,141
Cancellous bone			
Head	440	0.3	138.8
Neck	320	0.3	120.1
Distal	150	0.3	85.1
Pelvis	13,300	0.3	1,141
Cartilage	10	0.4	100
Implant	110,000	0.3	4,620

Direction and magnitude of the loads varies in response to the gait motion. The time dependent loading forces; hip contact, gluteus medius, gluteus maximus, tensor fasciae latae and adductor, acting around the hip joint was obtained by inverse dynamic analysis of a human gait using in-house lower-limb musculoskeletal (MS) model. These loading and boundary conditions for simulating the gait motion are the major technical advantages of the proposed MS-FE analysis comparing with the conventional static FE analysis. Time varying stress distribution during the gait was evaluated by using dynamic explicit method via ABAQUS.

RESULTS AND DISCUSSION

Obtained stress distributions shown in Fig.2. The figure successfully demonstrated the detailed time varying cortical bone stress distribution and the excessive local stress concentration. The stress distribution fields indicate significant increase of the stresses around the proximal lateral insertion holes for DSCS treatment model comparing with the intact model. Maximum stress values are good agreement with previous static FE analysis [4]. It is indicated that the proposed method is feasible to support the better pre- and postoperative clinical decisions, which is the main contribution of this study.

CONCLUSIONS

In this study, we proposed a novel MS-FE analysis method for proximal femur biomechanics. The dynamic loading and boundary conditions for simulating the gait motion are the major technical advantages of the proposed method. The simulation results successfully demonstrated the detailed time dependent stress distribution and excessive local stress concentration that is the potential cause of sub-trochanteric fractures during postoperative rehabilitation period. It is proved that the proposed method is effective to assess the postoperative fracture risk of the osteosynthesis with implants.

INTRODUCTION

Bone can be described as a multi-level composite arranged in a hierarchical form. At the macrostructure scale, bone is grouped into two types: cortical bone (also known as compact bone or dense bone) and trabecular bone (known as cancellous bone or spongy bone) [1]. Generally, cortical bone surrounds trabecular bone. While cortical bone has a porosity of five to fifteen percent, trabecular bone has a porosity that varies from forty to more than ninety percent [1]. Because cortical bone has low porosity, continuum based finite element methods have been used for most FE modelling. Similarly, homogenized continuum methods have been used for trabecular bone. Recent FE approaches have meshed the trabecular architecture (i.e., non-homogenized) using continuum elements, however, these meshes are difficult to produce, may require detail CT or MRI imaging, and are costly to solve. The proposed paper studies a representation of the trabecular micro-architecture using beam elements. The proposed approach may permit lower meshing and computational cost while capturing the behavior sought with detailed trabecular models. Further, the proposed approach readily admits stochastic analysis incorporating both porosity level and other inputs and model outputs.

METHODS

Trabecular bone consists of a three-dimensional network structure mainly composed of rod-shaped and plate-shaped fundamental units named "trabeculae." In this work, the trabeculae were modelled as beam elements.

The method assumed randomly oriented beams over a cubic trabecular bone specimen with 4 mm sides. The beams were created algorithmically so that beam properties could be applied stochastically, Fig. (1).

The algorithm is general to apply a stochastic approach to all beam properties. However, in this article, stochastic properties included length and orientation while the cross section was assumed to be a square shape with a side length ranges between (0.07 – 0.25) mm. For both methods, the beam element type was a 2–node linear beam element (B31). Abaqus (V. 6.16, Simulia Ltd) was used as an FE solver.

Boundary conditions were consistently applied on the "cube surfapce" nodes of the beam structure to attain successful axial and shear loadings on the specimen. For axial loading, these constraints were placed on two parallel faces of the specimen. All degrees of freedom were fixed for nodes of one face and a small displacement was perpendicularly imposed on the nodes of the opposite face. For shear loading, the constraints were placed on four orthogonal faces of the specimen in opposing pairs. All degrees of freedom were fixed for nodes of the lower left edge of the specimen. A small displacement was imposed on the nodes of each face and parallel to the face; such that pure shear is consistently applied to the specimen. Apparent stress was calculated by dividing the applied force by the apparent area of the relevant face. Apparent strain was obtained by calculating the ratio of resulting displacement of the moving nodes to the original side length of the specimen (i.e., change in length over length) figure (1). Apparent moduli were computed from apparent stress and apparent strain. Apparent densities were calculated by obtaining the ratio of the beams' mass to the volume of the unit cube.

The Individual FE model created in this study exhibited the apparent mechanical properties listed in Table (1). The model demonstrated effective moduli and apparent density within published ranges of trabecular bone [1, 2]. Anisotropic material moduli were extracted and the three normal-normal stress-strain relationships are presented here.

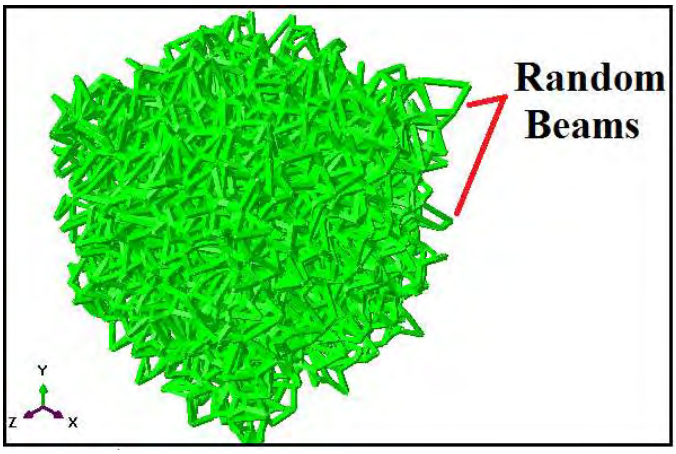

Figure 1: Trabecular bone (representative model).

RESULTS AND DISCUSSION

The Individual FE models created in this study exhibited the mechanical properties listed in Table (1). Each model demonstrated effective moduli within published ranges of trabecular bone [1]. The similarity on average of the three elastic constants suggests a lack of bias in the random algorithm, though bias could be intentionally introduced. The difference among the elastic constants within a single model exhibits anisotropy consistent with the localized trabecular architecture. The apparent densities of the current models were also within the published ranges [1, 2]. In the models, apparent density strongly correlates with the elastic moduli as would be expected in cancellous bone. Cancellous bone preferred directionality can be introduced into the stochastic model by controlling the parameters such that they are not fully random. Rather, they should follow some stochastic process with a distribution of properties that result the preferred anisotropy on average. For example, the beam elements can have a distribution of orientations centered on a preferred orientation. The apparent densities of the FE models are dependent on the number of beams and on their cross sections which were dissimilar between the models. Future models will emphasize cross sections and lengths that are consistent with the nominal (and stochastic) geometry of physical trabecular architecture.

Table 1: Young moduli, Apparent density, Beam section area and Anisotropy ratio.

	Random FE Model Mean (SD)	**Bartel, D.L. [1]**
Exx (MPa)	256.7343 (±57.6553)	237
Eyy (MPa)	258.1053 (±59.9611)	309
Ezz (MPa)	257.4531 (±61.6275)	823
App. Den. (g/cm3)	0.8782 (±0.1295)	0.09 ~ 1
Ab (mm2)	0.1665 x 0.1665 (±0.06 x 0.06)	-
Anisotropy Ratio	1.2075 (±0.2067)	-

CONCLUSIONS

The stochastically driven beam element approach may prove useful for efficiently modeling trabecular bone, structural open cell foams, grid stiffened core composites, and other structures. The need for efficiencies in meshing and computation are particularly relevant for current areas of interest to the composites and medical communities including the modeling of mechanical fasteners and bonding, damage evolution, and the modeling of aging. The proposed paper may provide a detailed description of the methodology in future research.

A COMPREHENSIVE TESTING SUITE FOR MECHANICAL CHARACTERIZATION OF ARTICULAR CARTILAGE WITH DOCUMENTED REPEATABILITY

Snehal K. Chokhandre and Ahmet Erdemir

Dept. of Biomedical Eng., Lerner Research Institute, Cleveland Clinic, Cleveland, OH 44195, USA
email: chokhas@ccf.org, web: https://simtk.org/projects/openknee

INTRODUCTION

Reliable mechanical characterization of cartilage is essential for finite element (FE) analysis that can provide a predictive platform to improve treatments options and to identify prevention strategies targeting cartilage pathologies. The literature on cartilage material characterization is vast and diverse with large variations in documented mechanical response of the tissue. There is also a lack of specimen-specific cartilage characterization to determine the extent and need for specimen-specific information [1]. An important limitation of the testing results is associated with the reproducibility and fidelity of the experimental procedures that are often not very well documented or addressed. The repeatability of the experimental procedures and subsequently the usefulness of obtained material properties are paramount for dependable analysis.

The goals of this study were to develop a testing suite for extensive characterization of articular cartilage from a human knee specimen and to provide cartilage mechanical response with quantified repeatability. This comprehensive testing suite and accompanying data sets encompass various testing types conducted on samples from multiple locations of cartilage within the knee.

METHODS

Specimen and samples: Cartilage samples were obtained from a cadaver left knee of a 25 years old female Caucasian donor with a body mass index of 22.8. One compression sample (5 mm diameter, full cartilage thickness) and one tensile sample (5 mm length by 1 mm width, close to superficial region) were taken from the load bearing regions of patella, patellar groove, medial and lateral femoral condyle, and medial and lateral tibial plateau (a total of 12 samples).

Mechanical testing: The six compression samples were tested under unconfined (UC) and confined conditions (CC). Each test was repeated three times. Including the repeatability tests for six tensile (T) samples, a total of 54 tests were conducted. All tests were performed at room temperature and the samples were immersed in phosphate buffered saline (PBS) during the entire test. Sample thicknesses were measured using an optical thickness measurement system designed in house.

Testing protocol included: (i) A 10 g initial load applied to either establish contact (compression) or to find reference length (tensile), (ii) ramp load-unload to 15% strain at 20%/s strain rate, (iii) 1000 preconditioning cycles between 10-15% strain at 2 Hz, (iv) ramp load-unload to 15% strain at 20%/s strain rate followed by a full unload, (v) 10 g force applied to establish contact or find reference length. (vi) stress-relaxation test at 5-10-15% target strains at 20%/s strain rate with a 30 minutes wait after each step.

For convenience, the displacement at 10 g force was used as reference. Nonetheless, a 300 micron offset was adapted before the preconditioning and stress relaxation stages of testing to capture the full range of loading and deformation included the unloaded state.

Analysis: For the 18 repeatability sets (6 confined compression, 6 unconfined compression, and 6 tension), average instantaneous (AIM) and equilibrium moduli (AEM) were calculated by the mean of the full range moduli at the three strain levels. Coefficient of variation (COV) was calculated for each of these sets to assess variability within the set.

RESULTS AND DISCUSSION

For all the unconfined compression test sets the COV was < 10% except for the lateral femur (COV, AIM: 31.37%; COV, AEM: 23.41%). For the tension test sets the COV was < 6% for all sets. For the confined compression test sets the COV ranged from 1.5% - 31.46% with most sets with COV < 15%. The larger discrepancies in repeatability of confined compression tests may be due to the challenges associated with misalignment of sample in the confined compression test chamber or its position relative to the moving indentor head. Non-uniformities of the dissected samples may have also resulted in non-uniform deformation of the sample during confined compression. The equilibrium moduli values for compression tests (0.205 - 0.63 MPa) were within the range reported in literature [2, 3] indicating these results are within the envelope of previously reported values.

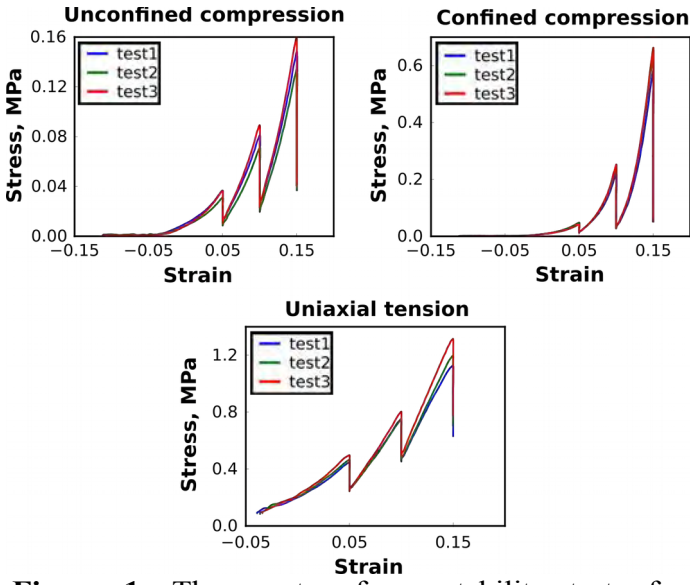

Figure 1: Three sets of repeatability tests for samples taken from the patella cartilage.

The results of these repeatability tests were encouraging (Fig. 1). As per our knowledge this is the first study to document experimental repeatability for cartilage mechanical characterization in a comprehensive manner, including multiple test types. The inter-sample variability (e.g., 4.85 – 26.18 MPa AEM for tensile tests) supports that there exists a large range of location dependent properties for cartilage within the specimen [4]. This is significant when location dependent intervention is required. A further in-depth analysis of this data set will be conducted to capture overall experimental repeatability to understand its relevance to compare regions and different knees. Availability of this extent of specimen-specific material information, may allow a better understanding of its need.

The primary motivation behind this study was to obtain repeatable and reliable cartilage material properties to support specimen-specific finite element model development of the knee. This is a part of the Open Knee(s) project (https://simtk.org/projects/openknee). However, the utility of this testing suite, including the accompanying data and the repeatability assessment may have a significant impact on dependable cartilage characterization methods. This study will be extended to other tissues of the knee and to additional knee specimens. Our approach and documentation will likely be helpful in developing testing standards for soft tissue characterization.

Temporal response of muscle-bone deformities at the shoulder following brachial plexus birth injury

[1] Nikhil Dixit, [1,2] Jacqueline H. Cole, and [1]Katherine Saul

INTRODUCTION

Brachial plexus birth injury (BPBI) is a traumatic perinatal neuromuscular injury causing muscle paralysis, shoulder contracture, and deformed growth of the scapula and humerus [1-3]. The resulting lifelong impairment greatly limits critical activities of daily living, such as eating and bathing. Almost nothing is known about the timing and mechanisms of changes in underlying bone and muscle structure following nerve injury occurring at birth to provide a foundation for clinical decision-making. As a result, there is currently no consensus on optimal timing or approach for therapy after injury [4], leading to inconsistent clinical outcomes. When the brachial plexus is injured in children outside of the neonatal period, there is limited contracture compared to BPBI, providing a unique opportunity to explore why the same injury in a similar period of rapid musculoskeletal growth avoids marked deformity.

Understanding the timing and mechanism of deformity initiation is essential for developing treatments that prevent bone and postural deformities from developing, rather than correcting deformity after formation. The objective of this work is to identify whether deformity is initiated first in muscle or bone by examining gross bone and muscle structure and contracture, and to explore how tissue response to injury depends on timing of injury.

METHODS

The study protocol was approved by the NC State IACUC. We used an existing rat model of BPBI developed in our group [5]. Because contracture and bone deformity are known to depend clinically on whether the nerve injury is proximal or distal to the dorsal root ganglion [6], we explored these effects in models of both injuries. Nerve injuries were created under isoflurane anesthesia using standard aseptic technique [7]. For preganglionic neurectomy, the C5 and C6 nerve roots were excised proximal to the dorsal root ganglion, partially preserving afferent innervation and muscle spindle function [8], which produces nerve damage without marked postural shoulder contracture. For postganglionic neurectomy, the C5 and C6 nerve roots were excised distal to the dorsal root ganglion, resulting in nerve damage and associated increases in shoulder contracture.

The progression of shoulder deformity after neonatal injury was examined by intervention at postnatal day 4 (P4), and progression was examined using 3 timepoints (2, 4, and 5 weeks post injury). The effect of injury timing (neonatal vs. postnatal) was examined by using a 4-week postnatal injury age (P4wks). Rats were provided water and rat chow *ad libitum* and sacrificed at the respective timepoints via CO_2 asphyxiation. To assess changes in muscle and bone structure and deformity, we measured passive external rotation range of motion (ROM) to analyze shoulder contracture ($n_{preganglionic} = 16$, $n_{postganglionic} = 22$) [5], glenoid inclination angle using micro-computed tomography, and optimal muscle fiber length of biceps long head (BICLong) using a laser diffraction technique (P4 postganglionic: $n_{2wks} = 1$, $n_{4wks} = 4$ for glenoid inclination angle and 1 for BICLong fiber length, $n_{5wks} = 1$; P4 preganglionic: $n_{4wks} = 1$; P4wks: $n_{postganglionic} = 1$; $n_{preganglionic} = 1$) [7]. Due to challenges in the preganglionic procedure, we looked only at the 4-week post-injury timepoint. Measures in the affected limb were compared relative to those in the contralateral unaffected limb.

RESULTS AND DISCUSSION

Our analyses of muscle and bone structure in rats following P4 pre- and postganglionic neurectomy support early changes to muscle and bone when

nerve injury is inflicted in the neonatal period (Figure 1, P4). Range of motion at 4 weeks post-neurectomy indicated more contracture in the postganglionic group compared to preganglionic group, consistent with previous studies [6]. Glenoid inclination measured at 2, 4, and 5 weeks tended to be more declined in the affected shoulder, with deformity values increasing with time for the postganglionic group. Biceps long head in the affected limb tended to be shorter than the contralateral limb at the same timepoints for postganglionic injury.

In contrast, analyses of bone and muscle following postganglionic neurectomy at P4wks showed that limited deformity to bone and muscle was observed when neurectomy occurred postnatally. Minimal changes to glenoid inclination and muscle length were observed at 2 and 4 weeks post-neurectomy (Figure 1, P4wks). Our results in rats are consistent with another study of the elbow following postganglionic injury in mice [9]. In that study, elbow contracture following postganglionic neurectomy at P4wks (n=17) was nearly absent, with no contractures more than 10°, and significantly lower ($p<0.001$) than in mice with neonatal postganglionic injury (n=42) [9], with elbow contractures up to 40°.

CONCLUSIONS

Our preliminary work shows gross alterations in both muscle and bone by 4 weeks after neonatal injury in rats (~1 year in infants [7]), suggesting early tissue changes at odds with the wait-and-see approach in clinical practice [5]. The observed bone and muscle deformities due to a neonatal injury become more severe over time. However, severe deformities do not occur when the injury occurs postnatally. This study provides new information about the effect of time progression and timing of BPBI.

The current work is limited by a small sample size and limited time points for preganglionic injury; data collection is ongoing. Further, the current work identifies structural changes alone; ongoing work examines the underlying changes in metabolism, microstructure, and mechanics to explicate the observed macrostructural changes.

INTRODUCTION

Accurate modeling of trabecular architecture in computational simulations is essential when evaluating joint replacement components and pathologic bone disease. Although significant advancements have been made in micro finite element (FE) modeling of trabecular bone, models are generally limited to small cores, due to the computational expense of these high-resolution models. As such, FE modeling whole bones that maintain trabecular architecture are seldom utilized and are limited to models that oversimplify the boundary conditions [1].

The reduction in computational resources provided by meshless methods has the potential to overcome these shortcomings. This allows for whole bone modeling while maintaining trabecular architecture and complex boundary conditions. In order to evaluate if meshless methods are comparable to micro-FE models that have been extensively validated, comparative analysis is necessary.

The objectives of this study were to: i) compare the apparent modulus of trabecular bone using μFE and meshless models, ii) evaluate if models derived from different μ-CT spatial resolutions affect model apparent modulus, and iii) compare FE element type to meshless models.

METHODS

Two separate micro-CT scans (Nikon XT H 225 ST, Nikon Metrology, NV, 95 kVp, 64 μA, 3141 projections, 1000 ms exposure) at 32 μm and 64 μm spatial resolutions were acquired for 14 cadaveric scapulae (7 male; 7 female; mean age 67 ± 8 years). The raw DICOM images were filtered to remove high frequency noise (Gaussian filter: $\sigma = 1.25$, support = 2). Virtual bone cores were extracted from the glenoid vault, medial to the subchondral bone, maintaining the recommended 2:1 aspect ratio [2]. Custom code was used to generate finite element models (FEMs) with 8-node hexahedral elements (HEX8) at both 32 μm and 64 μm. Stereolithography (STL) models were created to maintain the bone volume fraction (BV/TV) of each HEX8 model (BV/TV=0.24±0.10). These STLs were used to generate 10-node tetrahedral (TET10) FEMs and are the direct input to the meshless software (Simsolid, Simsolid Corporation). A homogeneous tissue modulus of 20 GPa was applied to all models. All FEMs and meshless models were constrained with identical boundary conditions and compressed to 0.5% apparent strain. The apparent modulus of each model was calculated and compared.

RESULTS AND DISCUSSION

The "gold standard" apparent modulus in this study is provided by the HEX8 32 μm FEMs. Across the volume fraction range of cores tested, the meshless models generated from 64 μm scans most accurately matched the E_{app} of the HEX8 32 μm FEMs (Table 1). The TET10 32 μm FEMs and Meshless 32 μm were generated from the same STLs, but interestingly the Meshless 64 μm models were a closer match over the volume fraction range of cores tested (Table 1).

The Meshless 32 μm models tended to over-estimate E_{app}, while the Meshless 64 μm models under

estimated E_{app} (Figure 1). This was most pronounced at the extreme bone volume fractions (0.40 < BV/TV < 0.20). There was no significant difference (p=0.633; Kruskal-Wallis One-Way ANOVA, Sigmaplot 11.0, Systat Software Inc., San Jose, CA, USA) between the apparent modulus of any of the models tested (Figure 1): however, due to the large variability in apparent modulus due to large variations in BV/TV, significant differences may have occurred with a larger sample size, or cores that had less variation in BV/TV.

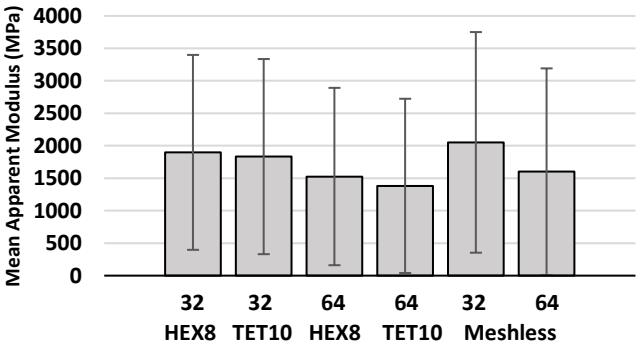

Figure 1: Mean apparent modulus for 14 trabecular cores with different modeling parameters. HEX8 refers to 8-node hexahedral µFEMs, TET10 to 10-node tetrahedral µFEMs, Meshless to meshless models, and 32 and 64 to models derived from 32 µm or 64 µm spatial resolution µ-CT scans. There was no significant difference between model types (p=0.633)

Inherently, at lower resolution (64 µm) and lower BV/TV (< 0.20), STL generation loses trabecular connectivity [3]. This has a marked effect on E_{app}. It is therefore recommended that for lower BV/TV bone, higher resolution scans be acquired to provide optimal trabecular architecture during model generation. This is necessary in both µFEMs and meshless models, but is perhaps less necessary in meshless models, as was shown by the ability of the lower resolution (64 µm) meshless model to closely match the E_{app} of the HEX8 32 µm "gold standard" µFEMs.

Future comparisons of whole bone meshless models to empirical bone testing has the potential to validate meshless methods for use in accurately replicating the non-linear and complex boundary conditions native to *in-vivo* and *in-vitro* joints, as well as joint replacement component loading.

CONCLUSIONS

This study compared to apparent modulus of trabecular cores among hexahedral and tetrahedral finite element, and meshless models. The results suggest that meshless methods can accurately model the mechanical properties of trabecular bone. This is important because meshless methods significantly reduce computational resources, allowing for whole bone models to be generated with trabecular architecture. This allows for complex boundary conditions to be implemented and non-linear models to be evaluated. This has the potential to significantly improve understanding of joint replacement components and pathologic bone disease.

INTRODUCTION

Osteopenia (low bone mass) and the disease of osteoporosis are of concern for a significant population in the U.S. including 50% of adults >50 years of age and 30% of postmenopausal women [1]. Hip fractures, which increase exponentially with age and occur disproportionally in women [2], account for the majority of the disability and financial burden associated with osteoporosis [3], and often lead to premature death.

Estimates of bone mineral density (BMD) are an important factor in the identification of fracture risk, however provide no insight into identifying modifiable causal factors. To date, physical activity with low and high impact forces continues to be the primary behavioral modifier for the prevention of osteoporotic fractures [4]. Unfortunately, a well-defined relationship between physical activity and hip BMD has not been determined. We hypothesize that cumulative estimates of dynamic skeletal loading in the free-living environment could provide a biomarker for tracking and prescribing physical activity changes in high risk patients.

METHODS

Sixty nine post-menopausal women (age: 61.3±7.4 years, BMI: 25.9±4.3 kg/m^2) were included in this study. Exclusion criteria included: current use of prescribed medication which could result in BMD changes, assistive device use while walking, any amputations or orthotics use, a history of hip surgery or hip or knee joint replacement on the non-dominant side. The study protocol was approved by the Mayo Clinic IRB and written informed consent was obtained prior to subject participation.

Under laboratory conditions, participants performed a minimum of 5 bare-foot walking trials at each of three self-selected walking speeds categories (slow, normal and fast) to simultaneously collect bilateral ankle acceleration (ActiGraph GT3X+, ActiGraph LLC, USA; 100 Hz) and ground reaction forces (GRFs) using five floor-embedded force plates (3 AMTI, USA and 2 Kistler Instruments, Switzerland; 600 Hz). Linear regression and cross-validation techniques yielded a model to predict bodyweight normalized vertical GRFs (1) with low average mean absolute error (6.8±5.5%) and low root-mean-square error (0.087±0.006) suggesting strong predictive qualities [5].

$$\mathrm{GRFbw} = 0.1118(Az) + 0.7865 \qquad (1).$$

where Az is the peak vertical component of ankle acceleration identified during foot-strike on the laboratory force plates.

All participants received DXA scans (Lunar iDEXA, GE Medical Systems, USA) to measure total hip BMD on the non-dominant side and wore the Actigraph activity monitors on both ankles for 7 days in their free-living environments. Steps taken in the free-living environment were detected from ankle acceleration data using our previously developed and validated step detection algorithm [5] in MATLAB 2016b (Mathworks, USA). Peak vertical GRF, in units of body weight (GRFbw), was calculated for each step using equation (1). A bone density index (BDI), an index of cumulative loading, for each day was determined as the cumulative sum of the peak vertical GRF estimated for each detected step [7]:

$$\mathrm{BDI} = [\textstyle\sum_{i=1}^{n}(\beta.GRF_i)^m]^{1/2m} \qquad (2)$$

where β is the ratio of the individual subject's

bodyweight (BW) to the cohort's mean BW and n is the daily step count. The exponent m weights the relative importance of force magnitude and loading cycles and was set to a value of 6 [6]. Mean BDI ($\overline{BDI}$) was calculated across the 7 days of activity monitoring for each participant.

Mean BDI, age, BMI and mean step count were entered into stepwise multiple regression to identify the significant predictors of BMD and estimate the strength of the relationship among these variables.

RESULTS AND DISCUSSION

All participants successfully completed 7 days of activity monitoring resulting in the capture of over 7 million steps, producing a population representative range of peak accelerations from detected steps (Fig.1).

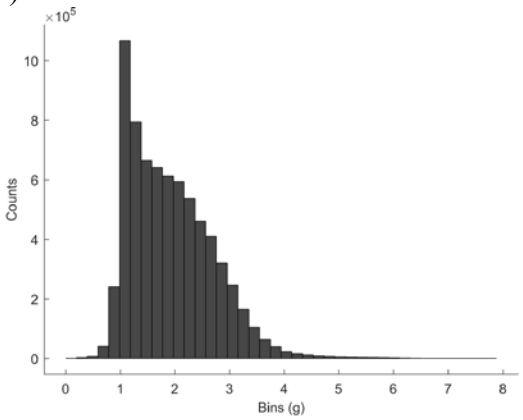

Figure 1: Histogram of peak acceleration (g) values identified at each detected step throughout 7 days of activity monitoring.

The mean±SD daily step count across participants estimated was 14485 (4334), which is in line with ActiGraph algorithms producing mean estimates of 10565±4313 and 15792±5284 using default and "Low Frequency Extension" settings, respectively.

Of the four factors entered, stepwise linear regression revealed $\overline{BDI}$ and age to be significant predictors of BMD ($F_{2,66}$=12.60, $p < 0.001$) (Fig. 2).

$$\text{BMD} = 0.312(\overline{BDI}) - 0.005(age) + 0.533 \quad (3)$$

With a standardized beta of 0.392 ($p < 0.05$) mean BDI was the strongest predictor of BMD, accounting for 19.5% of the variance in BMD. Age accounted for an additional 8.2% of the variance in BMD, with a beta of -0.29 ($p < 0.05$). Overall, the multiple regression model explains 27.6% of the variance in BMD (R = 0.526), suggesting a stronger relationship than previous studies using simple linear regression (R = 0.437) [7,9].

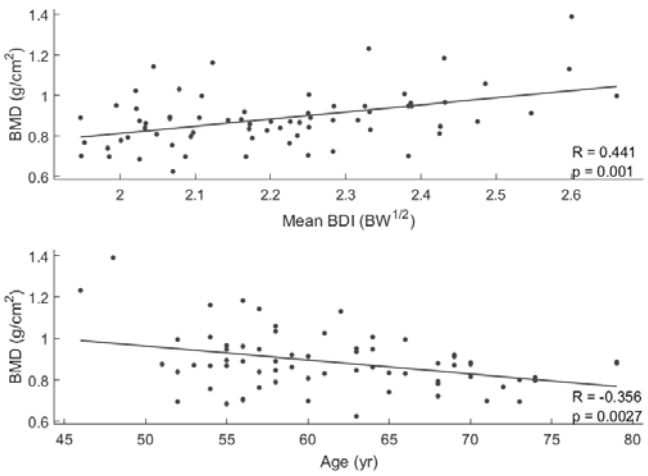

Figure 2: Partial regression plots highlighting the significant linear relationships among mean bone density index (BDI) and age with bone mineral density (BMD) in the free-living environment.

CONCLUSIONS

These results provide evidence to support the use of cumulative dynamic loading estimates captured through daily PA observation as a biomarker of total hip BMD. Future PA interventions can leverage this relationship to improve outcomes in postmenopausal women at high risk of hip fracture.

email: kiriyama@cc.kogakuin.ac.jp

INTRODUCTION

The bone remodeling mechanism requires an adequate mechanical load surrounding the bone. The loading condition *in-vivo* could be different individually, therefore the individual structure of the trabecular bone could be affected by the load *in-vivo*. Especially, the trabecular bone in the vertebral body shows the optimized configuration against the magnitude and direction of the mechanical loads *in-vivo* [1]. This means that it could be possible to estimate the loading condition by evaluation of the configuration on the trabecular bone. In this study, we've developed an estimation method of the loading condition *in-vivo*. We evaluated the bone configuration based on the analysis of stress distribution by using the finite element model of the trabecular bone constructed from MDCT.

METHODS

We estimated the mechanical load *in-vivo* from the trabecular bone as the following two procedure: (1) Modeling process to extract the trabecular bone from MDCT and calculate the value of the yield stress as shown in Fig. 1, (2) Estimation process to decide the three dimensional load applied to the trabecular bone (Fig. 2).

The IRB of the institute approved all methodological procedures and the subject gave an informed written consent prior to participation.

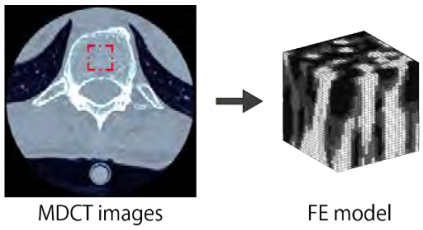

Figure 1: Extraction procedure of analysis region

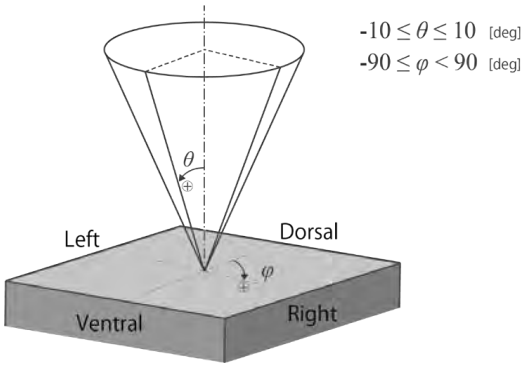

Figure 2: *in-vivo* load direction of the estimation procedure

(1) Modeling process: we extracted the trabecular bone in the vertebral body from MDCT, and constructed the finite element model. Subject was a 75-year-old female, who was diagnosed osteoporosis. We took the MDCT images of the L1 vertebra. We used a phantom in the measurement to compensate CT value and convert it to bone mineral density (BMD). And then, the BMD values were converted to Young's modulus based on the literature by Kayak et al. [2] as the following equation,

$$E = \begin{cases} 0.001 & (\rho = 0.0) \\ 33900\rho^2 & (0.0 < \rho \le 0.27) \\ 5307\rho + 469 & (0.27 < \rho < 0.6) \\ 10200\rho^{2.01} & (0.6 \le \rho) \end{cases} \quad (1)$$

where E is Young's modulus [MPa], ρ is BMD [g/cm^3].

This conversion from BMD to Young's modulus was applied to a rectangular region (10.14 × 10.14 × 10.20 [mm^3]) in the center of the vertebral body.

(2) Estimation process of the loads; Because the trabecular bone should not be destroyed in daily life, we assumed that the maximum limitation of the bone was the yield stress σ_y of the cancellous bone. By using the BMD ρ, we calculated the magnitude of the load *in-vivo*. The yield stress σ_y was calculated based on the following equation by Keyak [2].

$$\sigma_y = \begin{cases} 137\rho^{1.88} & (\rho < 0.317) \\ 114\rho^{1.72} & (0.317 \leq \rho) \end{cases} \quad (2)$$

Simultaneously, we assumed that the cancellous bone in the vertebral body was remodeled to withstand loading condition *in-vivo* and the configuration was optimized to reduce the stress against a specific loading direction. Hence, we applied a load of 300 N to the fem model of the trabecular bone. In finite element analysis, the load was applied to the top surface on the bone model (Fig. 1). In this study, the surface was modeled as a rigid plane, and the load was assumed as a plane load. The various loading direction were evaluated as shown in Fig. 2. The direction of the load was decided by two parameters of θ and φ. Here θ is inclined against the vertical downward direction, and φ is the axial rotated angle around the model as Fig. 2.

RESULTS AND DISCUSSION

Previous to the *in-vivo* load estimation, we evaluated the estimation process. We calculated the direction when we applied loads to the uniform inclined beam of 0, 5, 10 [deg.]. As the results, the process has an error of ±1 [deg.] in both the inclination and rotation angles.

We obtained the median value of the yield stress in each element of 2.96 [MPa]. These value is regarded as the mechanical load per unit area applied to the cancellous bone in the vertebral body.

Figure 3 shows the typical stress distribution when adequate (a) or inadequate directions of the loads(b) were applied to the trabecular model. Even when the same magnitudes of the loads were applied to the model, different direction of the loads showed the different patterns of stress distribution and adequate direction of the load should be able to reduce the averaged von Mises stress over the model.

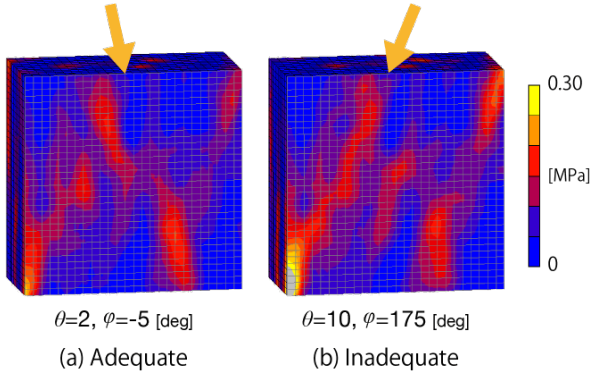

Figure 3: Typical stress distribution

From our estimation, we obtained the load direction of θ =2, ϕ =-5 [deg.]. This direction is slightly inclined from vertical direction, i.e. the posterior to the anterior.

Since the healthy L1 vertebra is usually extended, the loading direction should be inclined from ventral to dorsal relatively. However, our estimation was opposite to it. Considering our estimation method with an error of 1 [deg.] about the direction, the subject could show kyphotic posture as a patient of spine osteoporosis, and the result of the direction could be acceptable enough.

Our limitation was that we didn't investigate the subject or X-ray images. Also, we just estimated the loading condition applied to the cancellous bone. However, our method has a possibility to expect an individual loading condition, and it could be useful to estimate the bone remodeling *in-vivo*.

CONCLUSIONS

In this study, we showed the estimation method of mechanical load *in-vivo* consisted of (1) modeling process to extract the trabecular bone, (2) estimation process to decide the load applied to the trabecular bone. This method could estimate individual loading condition *in-vivo*.

INTRODUCTION

Subchondral bone is the thin layer of cortical bone found at the ends of long bones and underlies articular surface that provides an interface transmitting loads between the articular cartilage and trabecular bone. Changes in subchondral properties enable identification of differences in joint loading conditions in comparative biology, and in biomedical studies of the etiology of joint diseases such as osteoarthritis (OA). Previous studies have examined the subchondral bone apparent density and used it to infer differences in joint load orientation and magnitude in humans [1,2] and primates [3]. However, considerable uncertainty remains to determine how and where the osteological changes occurs due to habitual loading; and the choice of analytical methods also greatly influence the results.

The primary goal of this study is to test whether subchondral thickness responds to experimentally induced differences in knee postures, and exercise.

METHODS

We included 15 juvenile sheep ($\bar{x} = 60\ d$) divided into three group: (i) incline treadmill exercise (15% grade; n=3), (ii) flat treadmill exercise (0% grade; n=3), and (iii) control (n=3). Sheep were housed at the University of Illinois Sheep and Beef Cattle facility. All the procedures were approved by the UIUC IACUC. Sheep from groups (i) and (ii) were first trained to walk on a motorized treadmill (Star Trac 4000HR, Star Trac, Irvine, CA) at moderate walking speeds and were exercised twice daily at 1.12m/s for 20 min/bout for 60 days. The duration of exercise has been shown a significant osteogenic response in sheep and other mammals [3, 4]. The control sheep were not exercised. All sheep were housed in a large indoor pen and were able to move freely. Access to food and water was not limited.

Three-dimensional (3D) limb kinematic data were measured with a 6-camera Qualisys (qualisys.com) motion capture system at 160Hz. Kinematic data were collected for group (i) and (ii) only, since control group was not trained to walk on treadmill. Reflective markers were placed on standard hindlimb landmarks (Fig. 1). Joint angles were measured at mid-stance (the hoof is beneath the hip) when peak loads are experienced. All subjects were euthanized humanely, limbs were dissected, muscles and ligaments were removed, and their limb bones segments were frozen.

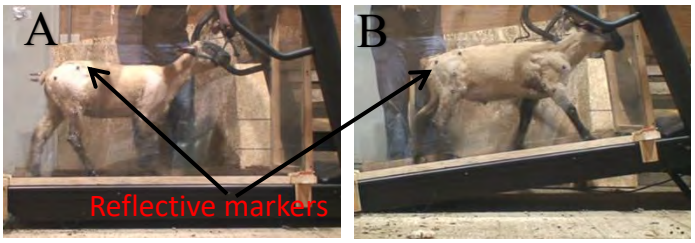

Figure 1. Sheep walking on treadmill: (a) Flat, and (b) Incline (10° grade)

Subchondral bone thickness measurement was evaluated on the medial femoral condyle (MFC). Femora were microCT scanned at 50µm voxel size using a Siemens Inveon microCT scanner (siemens.com/inveon). Noise was removed using MATLAB (MathWorks Natick, MA, USA), and 3D representations created using AMIRA (v 6.4, Thermo Fisher Scientific, MA, USA). Each specimen was resliced through the long axis of the MFC to obtain images along the axis of the joint. Thickness data were obtained using the BoneJ plugin from imageJ. The thickness values were then extracted by fitting a contour line to the joint

surface. The coordinate values were plotted in 3D surface plot in MATLAB by putting the thickness as a color matrix. Differences between groups were assessed using nonparametric Mann-Whitney U tests. All statistics were calculated in Minitab (v.16, Minitab, Inc. PA, USA), with a type one error rate of α=0.05.

RESULTS

Exercised sheep experienced around 3600 more loading cycles per day than did non-exercised sheep. On the incline walking, sheep used significantly more flexed knees (n=10; $p < 0.0001$) postures at mid-stance than on flat treadmills (Fig. 2). The difference of mean knee joint angle was 8° between these two groups. A similar pattern of difference is observed when comparing the position of subchondral bone thickness between the groups of sheep. The position of the maximum subchondral thickness moved more posteriorly for the Inclined group compared to Flat group (Fig. 3). The mean angular positions difference between the Flat and Inclined groups was 10° (n=3, p=0.08). The difference is close to our kinematically measure angular difference. The angular difference between Flat and Control, and Inclined and Control groups was 5° (n=3, p=0.38) and -4° (n=3, p=0.66) respectively. Average of peak subchondral thickness were 1.77 mm, 1.58mm, and 1.38mm, respectively, for flat, inclined, and control group.

DISCUSSION

The main goal of this study was to test whether the patterns of subchondral bone thickness could be used to infer differences in joint posture. Overall, there is good correspondence between thickness-based measurement and kinematic results, suggesting that the selected characteristics can be used to infer differences in joint posture. As expected, we observed higher subchondral thickness in exercised group compared to control group. However, more subjects experiment is required to make statistically strong conclusion on maximum thickness.

This study has direct application to questions of behavioral inference in anthropology, paleontology, and for clinical debates concerning the bony changes that precede osteoarthritis. For example, the relationship between the spatial patterns of subchondral bone thickness and kinematic measurement should permit the reconstruction of habitual posture used by extinct hominins and other primates, particularly for those in museum collections.

INTRODUCTION

In 2017, new cancer cases were estimated to be 1,688,780 in the United States [1]. Spinal metastases are expected to occur in up to one-third of all cancer patients [2]. A metastatic disease reduces the structural integrity of the spine leading to vertebral fracture which can lead to pain and neurologic manifestations that significantly affects the quality of life. Unfortunately, there is no objective method to assess fracture risk in patient with metastatic disease in the spine. To target this problem, we have developed a non-invasive and quantitative technique that integrates quantitative computed tomography (QCT) imaging and finite element analysis (FEA). This method (QCT/FEA) estimates vertebral fracture loads in vertebral bodies with metastatic lesions, and has the ability to evaluate vertebral fracture properties based on various tumor characteristics (shape, size, and location). While tumor size has been considered as the most important risk factor for vertebral pathologic fractures, the effect of tumor location within vertebral bodies has not been previously addressed appropriately. A main goal of this pilot study was to assess the effect of lesion size and location within vertebral bodies on vertebral fracture strength using QCT/FEA.

METHODS

Three cadaveric spines were obtained and the L3 vertebral bodies were dissected. The L3 vertebrae were intact and did not present any lesions. The specimens were potted in PMMA and CT scan imaging was then performed. Specimens were mechanically tested in compression to fracture to measure the fracture properties. The QCT/FEA process is shown in **Fig. 1**; first, QCT images (**Fig. 1A**) are segmented to obtain a 3D model (**Fig. 1B**); then, the volume of the vertebra is meshed using voxel elements (**Fig. 1C**), and material properties, Young's modulus, are assigned to each element based on the specific grey values of the CT image determined by the Hounsfield units (HU) (**Fig. 1D**). Boundary conditions mimicking the experimental process, as well as a failure criterion, are then applied to the models (**Fig. 1E**), with a final analysis of predicted fracture properties outcomes (**Fig. 1F**).

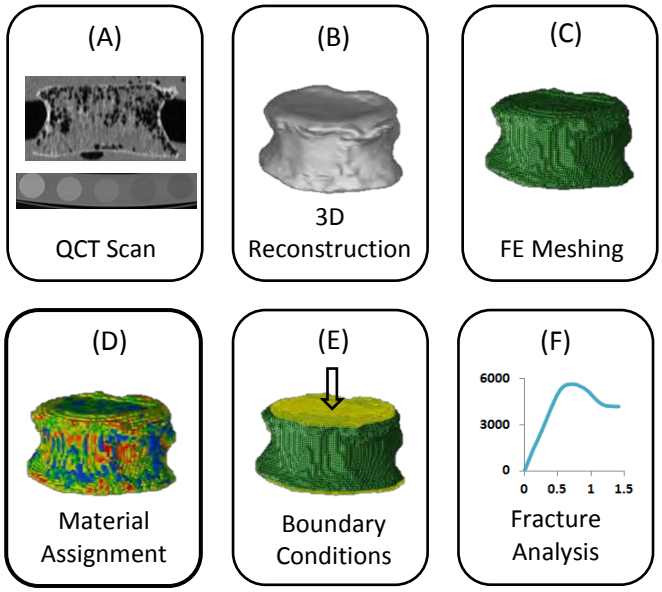

Figure 1. Overview of QCT/FEA process

For each intact vertebral body, thirteen QCT/FEA model scenarios were created; **1)** intact (with no virtual lesion), **2)** virtual spherical osteolytic lesion at the center, **3)** in the anterior, and **4)** at the pedicle of the vertebral body. The lesion sizes consisted of 1.5, 5, 12, and 24 % of the total vertebral volume **Figure 2** shows a QCT/FEA model of a vertebral body with a spherical lesion at the center. PMMA was also modeled and included in the simulations to mimic the experimental testing setup. Colors represent varying material properties.

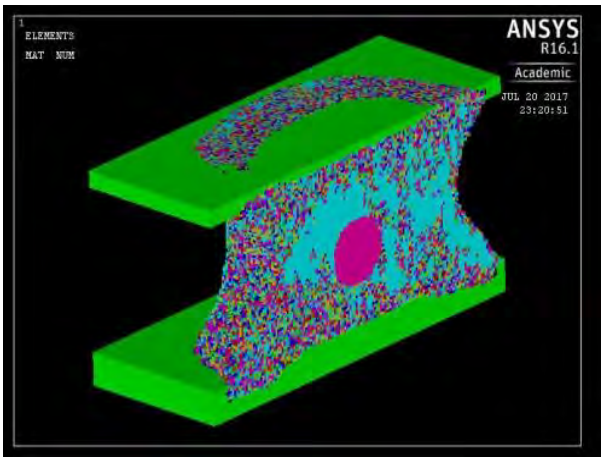

Figure 2. QCT/FEA model of a vertebral body with a simulated lytic lesion at the center.

RESULTS AND DISCUSSION

Experimentally measured vertebral fracture forces showed close agreement with their respective QCT/FEA-estimated outcomes) **Fig. 3A** (R^2=0.94)).

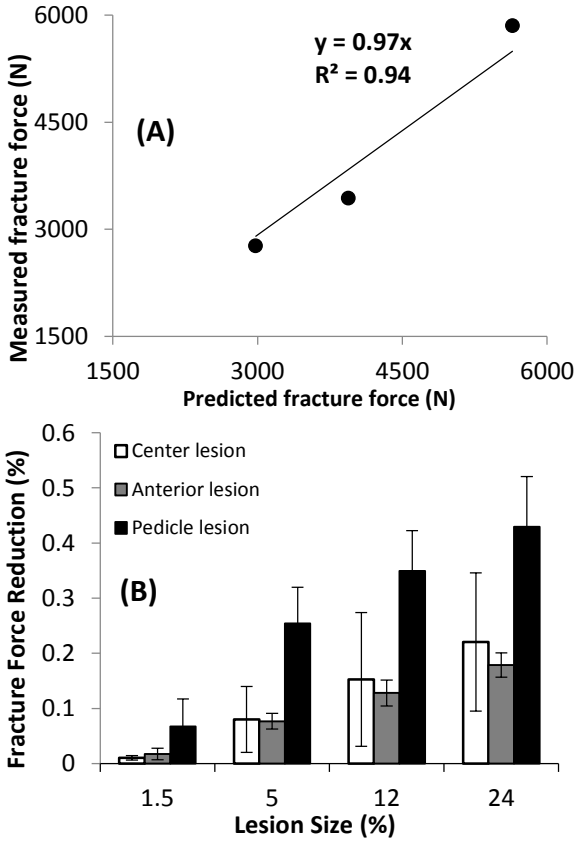

Figure 3. (A) Experimentally measured fracture force vs QCT/FEA predicted fracture force in intact specimens; (B) fracture force reduction with lesion size at three different locations.

QCT/FEA results showed that the effect of a lesion size of about 5% of the total vertebral volume, in the pedicle region, reduced the fracture load by more than 20%. This reduction was considerably lower when the lesion was located at either the center or anterior side of the vertebral body (**Fig. 3B**). Although with increasing lesion size the fracture load decreased dramatically, a lesion at the pedicle showed the largest decrease in the load bearing capacity of the vertebrae, up-to 50% when the lesion size was 24% of the total volume.

CONCLUSIONS

Osteolytic lesion size has been considered as one of the most significant risk factors leading to vertebral fracture [3]. Tumor location is also an important risk factor. When considering tumor location, a vertebra is divided in three locations; 1) the body, irrespective of the location of a lesion within the body; 2) the pedicles and 3) the posterior elements [3]. Interestingly, the location of the lesions within the vertebral body has not been highlighted sufficiently in previous studies. The results of the current study suggest that the destruction of bony tissue in the pedicle of a vertebral body by a lytic lesion can have significant negative effects in the load bearing capacity of the vertebrae when compared to a lesion size with same volume either at the anterior or at the center of the vertebral body. Our results highlight the importance of location inside vertebral bodies as a risk factor for vertebral fracture.

Strain rate dependent responses of the engineered and native cartilage

Alireza Seifzadeh[1]
[1]Biomedical Engineering, Islamic Azad University Khomeinishahr branch, Khomeinishahr, Isfahan Iran
Email: seifzadeh@iaukhsh.ac.ir

INTRODUCTION

To gain insights into the osteoarthritis initiation and progress, the study of changes in the material properties of tissue engineered cartilage and functional consequences after implantation that accounts for tissue associated non-linearities, as well as intrinsic viscous effects, fiber reorientation and dispersion at higher strains (~20%) is inevitable. It is, however, anticipated that knowledge of the stress-strain state of both cartilage collagen and in chondrocytes under repeated cartilage deformation will aid the understanding of how osteoarthritis begins and progresses. Prediction of changes in the material properties of soft hydrated tissue engineered, its behavior under loading, and associated consequences after implantation, is challenging. Therefore, using a model that accounts for tissue non-linearities at higher strains (~20%), is inevitable. In this work, Fibrillar stiffness and transient compressive stiffness of cartilage at various strain rates of both native and implanted ovine cartilage in biphasic construct in vitro and implanted into sheep for 3 and 9 months, were determined. Stiffening of both solid matrix and collagen fibers of cartilage in higher strains and strain rates were modeled.

METHODS

The indentation data for 10 native cartilage samples harvested from knee joints of 6-9 month old sheep as well as 10 engineered cartilage samples (at various times from implantation) on calcium polyphosphate (CPP) scaffolds were analyzed and compared to determine changes in material properties [1]. To determine material properties of both the native and engineered samples, the non-linear biphasic fiber-reinforced poro-hyper-visco-elastic (BFPHVE) model proposed by Seifzadeh et. al. [2], along with the coupled FE-optimization proposed by Seifzadeh et. al. [3] were performed using experimental indentation data for extracted cartilage samples at different growth stages (i.e., time periods after implantation) and different loadings. The transient and equilibrium stiffness, for both solid matrix and collagen fibers were determined for both native and engineered cartilage for strain rates ranging from zero to 20% s^{-1}.

RESULTS

Figure 1 shows the computed transient compressive stiffness in the radial direction for a 3 month native specimen (N-3) for different strain rates, and for two values of solid matrix shear modulus, 0.254 MPa to 0.370 MPa. Figure 1 shows that the stiffness increased more with an increase in solid matrix shear modulus values at the higher strain rates than the lower ones. As seen in the figure 2, the collagen fibers stiffen rapidly initially followed by a soft region at low and intermediate stretches. Only a small force is needed to achieve significant extension in the intermediate strains. Finally, there is a sharp increase in collagen fiber stiffness at higher stretches, the magnitude of which strongly depends on the value of the collagen stiffness κ_1.

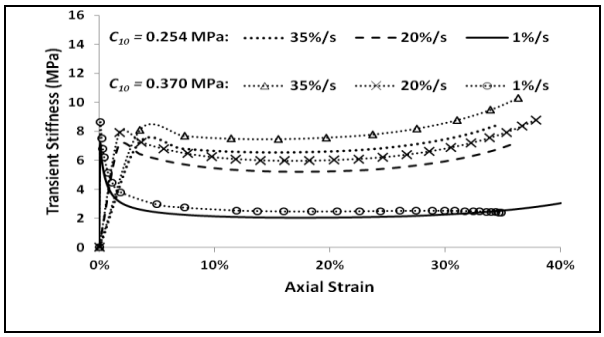

Figure 1: Transient compressive stiffness of cartilage

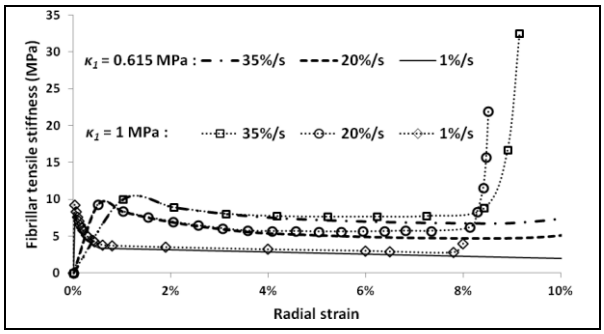

Figure 2: Fibrillar stiffness for a native sample

DISCUSSION / CONCLUSIONS

The strain rate dependent responses of the engineered and native cartilage in unconfined compression were investigated using a constitutive model that captures the response of cartilage over the whole experimental time and incorporates all included non-linearities. It was found that the non-linear BFPHVE is useful for modeling the transient and equilibrium responses of cartilage in tension and compression and dynamic tests to diagnose and evaluate cartilage quality. Osteoarthritis results in simultaneous changes in the solid matrix and collagen quality and interaction of these constituents impairs both the dynamic and static properties of cartilage. This study can be used to gain insights into the damage process in cartilage and determine load bearing.

EXPERIMENTAL MEASUREMENT OF THE CUTTING FORCES GENERATED DURING A ROBOT-DRIVEN GLENOID REAMING PROCEDURE

[1,2,3] Mayank Sharma [1,2,3] Louis M. Ferreira and [1] O. Remus Tutunea-Fatan

[1] Western University, London, ON, CANADA
[2] Roth|McFarlane Hand and Upper Limb Centre, London, ON, CANADA
[3] Lawson Health Research Institute, St. Joseph's Health Care Center, London, ON, CANADA
email: msharm@uwo.ca

INTRODUCTION

Total shoulder arthroplasty (TSA) aims to surgically restore the lost functionality of a degenerated shoulder joint. TSA involves implantation of a prosthesis on the glenoid bone for which the native bone must be resurfaced to ensure its optimal contact with the mating implant surface. Due to significant natural variability in the anatomy of the glenoid among patients, pre-operative planning, surgical technique, and skill play a significant role in a surgeon's ability to successfully place the glenoid implant in a suitable position [1].

To determine if the reaming process has been performed to an adequate depth, a virtual simulator with augmented-feedback was developed to mimic the TSA procedure for surgical training purposes. One of the core features of the intended simulator is to convey appropriate reaming force levels to the user to tune his/her surgical decisions based on the feedback. The generation of the appropriate reaming force levels is strongly dependent on the adequate calibration of the bone removal model, which in turn depends on experimental data collected with varying levels of bone densities.

METHODS

An electric surgical reamer (DePuy Synthes, West Chester, USA) was retrofitted to a light-weight robot (Kuka Robotics, Augsburg, Germany) (Fig. 1). The robot was programmed to apply preset levels of reaming thrust force (36 N) corresponding to an experienced surgeon's reaming practice. Five synthetic bone specimens (Sawbones, Vashon Island, USA) each of densities 0.16 g/cm^3, 0.24 g/cm^3 and 0.32 g/cm^3 - replicating different human cancellous bone - were reamed to a 5 mm depth.

Figure 1: Experimental setup of the KUKA robot retrofitted with a Synthes glenoid reamer and an optical tracker.

Labview (National Instruments, Austin, USA) was used in conjunction with a 6 degrees-of-freedom load cell to collect and filter the load data during reaming. An optical tracker (Northern Digital Inc, Waterloo, Canada) was used to evaluate the linear motion of the reamer relative to the specimen. Peak force, reaming speed, and force as a function of displacement (stiffness) were evaluated. One-way ANOVA followed by Tukey's post-hoc were performed to assess differences between various specimen density groups.

RESULTS AND DISCUSSION

An increase in the peak force was noted as the specimen density increased (Fig. 2). The 0.16 g/cm^3, 0.24 g/cm^3 and 0.32 g/cm^3 samples exhibited a mean peak force (MPF) of 16.45 ± 0.79 N, 26.15 ± 2.69 N, and 34.51 ± 1.23 N, respectively. Peak force increased significantly with material density ($p < 0.001$)

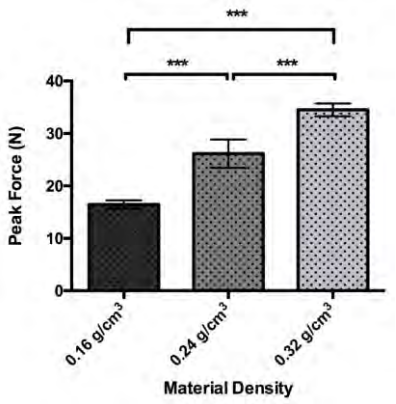

Figure 2: MPF recorded during reaming Sawbone specimens of various densities (*** $p < 0.001$).

For a given thrust force, reaming through a denser material should result in a slower reamer translation. In accordance, the average speed of the reamer through 5 mm specimen depth was recorded as 2.87 ± 0.30 mm/s, 1.95 ± 0.23 mm/s, and 1.29 ± 0.11 mm/s for the 0.16 g/cm^3, 0.24 g/cm^3 and 0.32 g/cm^3 specimens, respectively (Fig. 3). The decrease in reamer speed with increasing material density was significant ($p < 0.001$).

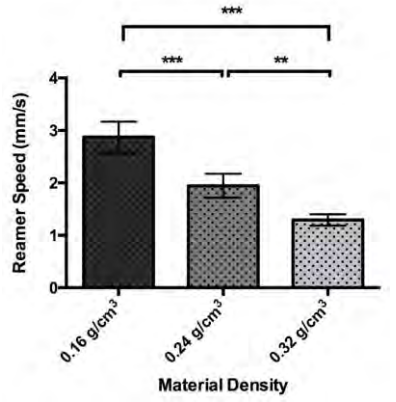

Figure 3: Average speed of the reamer while reaming Sawbone specimens of various densities (*** $p<0.001$, ** $p<0.01$).

Reaming force as a function of displacement was also evaluated (Fig. 4). This dependence could be related to the stiffness of the medium used in the simulator. For the five samples of each density tested, the average force-displacement rate was 3.72 ± 0.88 N/mm, 6.25 ± 0.73 N/mm, and 8.50 ± 0.41 N/mm for the 0.16 g/cm^3, 0.24 g/cm^3 and 0.32 g/cm^3 specimens, respectively. As expected, the perceived stiffness of the reamed material was directly proportional with its density ($p<0.001$). This implies that while advancing into the material, the reaming force will increase faster for denser specimens.

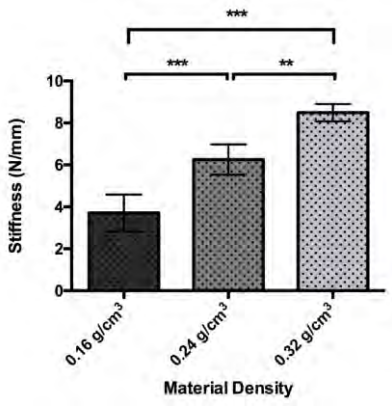

Figure 4: Average stiffness while reaming Sawbone specimens of various densities (*** $p<0.001$, ** $p<0.01$).

CONCLUSIONS

The results obtained suggest that greater reaming forces are required in cortical bone when compared to the cancellous bone (former has a higher density than the latter). Future tests will be conducted on human glenoid samples to verify this hypothesis.

LOCAL THICKNESS OF THE HUMAN SKULL AFFECTS PATTERNS OF CRANIAL FRACTURE

[1,2] Paul Snyder, [2] Steven Rundell, [3] Todd Fenton, [1] Roger Haut, and [1] Feng Wei

[1] Orthopaedic Biomechanics Laboratories, Michigan State University, East Lansing, MI, USA
[2] Explico Engineering Company, Novi, MI, USA
[3] Department of Anthropology, Michigan State University, East Lansing, MI, USA
email: weifeng@msu.edu, web: http://www.obl.msu.edu/

INTRODUCTION

Differences in skull thickness of more than 300% have been documented in the adult human population [1]. While the effects of global skull thickness on cranial fracture tolerance have been investigated in the literature, computational models have yet to demonstrate the variability of cranial fracture patterns that are observed experimentally under the same mechanical inputs [2, 3]. Such variability may be explained in part, among several factors, by differences in the local thickness distribution of the skulls. It was hypothesized that variations in fracture patterns arising from the same mechanical input would present in areas of reduced skull thickness on a specimen-by-specimen basis.

METHODS

Blunt impacts were administered to the parietal bone of eighteen unembalmed, adult male human crania. Prior to impact, each specimen underwent a high-resolution computed tomography (CT) scan (GE 750HD; 120 kVp; 125 mAs; 0.625-mm slice thickness; 0.49-mm pixels; 512x512 matrix). Sample preparation involved removal of the scalp on the ipsilateral side of impact, with the exception of an island of scalp at the location of impact. Specimens were secured between the third and sixth cervical vertebrae to a horizontal mounting plate (located on the x-y plane) that allowed translation in the x- and y-directions as well as rotation about the z-axis during impact. A positioning collar with breakaway tethers was affixed around the neck to suspend the head in an upright posture.

A custom-built pneumatic striker applied fracture-initiating impacts to the temporoparietal region. Three different aluminum impactor geometries were tested: a flat 1-inch diameter implement ("hammer" n = 7), a flat 3-inch diameter implement ("brick" n = 5), and a cylindrical curved 2.5-inch diameter implement ("bat" n = 6). Mass of the impact trolley ranged from 6.048 to 9.593 kg, and impact velocities ranged from 4.968 to 6.280 m/s. Slightly increased velocities were used to ensure fracture initiation in the "brick" and "bat" impacts. Forensic anthropologists hand-diagrammed the resulting fracture patterns post-impact.

Three-dimensional models of each skull were generated from the CT data using thresholding and segmentation operations in Mimics (Materialise NV; Leuven, Belgium). Wrapping operations were performed to eliminate cavities in the diploë layer, allowing a consistent thickness measurement between the cortical layers. Heat map thickness analyses were then scaled and overlaid onto the corresponding fracture diagrams to evaluate the effects of local skull thickness distribution on fracture pattern presentation arising from three different impacting implements.

RESULTS AND DISCUSSION

Local thickness maps from specimens showing typical fracture patterns of each implement were closely overlaid with their corresponding fracture diagrams (Fig. 1). "Hammer" specimens tended to exhibit a focal fracture pattern consistent with the implement's 1-inch diameter at the point of impact. Typically, secondary fracturing propagated anteriorly into the areas of reduced thickness. The thickest "hammer" specimen (17-3757) did not experience focal fracture at the point of impact but fractured remotely in an area of reduced thickness near the external auditory meatus. One of the thinnest "hammer" specimens (17-2071) experienced a diffuse pattern of fracture in the temporoparietal region of reduced thickness. No

"hammer" specimens fractured superiorly towards areas of increased thickness.

"Brick" specimens tended to exhibit diffuse fracture patterns in the temporoparietal region. The outline of the diffuse area of fracture tracked along transition regions of reduced thickness to regions of increased thickness. One specimen (17-2035) experienced linear type fractures near the point of impact anteriorly towards regions of reduced thickness in the sphenoid. The thickest specimen (16-3817) fractured remotely in the sphenoid region in an area of reduced thickness.

"Bat" specimens tended to exhibit the widest variety and span of diffuse and linear fractures. "Bat" impacts were the only to travel anteriorly into the frontal bone (16-3803, 17-2067, 17-2081), as well as the only to experience significant superior propagation towards the sagittal suture (17-2118). While "bat" specimens 16-3803 and 17-2081 experienced more focal fracture near the point of impact with anterior linear fracture propagation, specimens 17-2067, 17-3758, and 17-2118 experienced more diffuse fracture in the area of impact, and 17-4813 experienced more remote linear fracture. In general, "bat" fracture occurred in relative regions of reduced thickness.

CONCLUSIONS

Fractures tend to occur in, and propagate through, regions of reduced thickness. While "hammer" impacts are likely to exhibit focal fracture near the point of impact, "brick" and "bat" impacts are likely to exhibit more diffuse fracture patterns that track along locally thin areas of the skull.

In general, the results of the current study have confirmed the hypothesis. Intrinsic skull properties, specifically thickness distribution, play an important role in the patterns of cranial fracture. These findings are important when determining the cause of a skull fracture in a forensic setting.

Relating Gait and Bone Growth in Rat Tibia

INTRODUCTION

Material and mechanical properties of bone are optimized via modeling during growth – when mass and size increase significantly – in order to sustain the loading cycles from everyday movement [1, 2]. However, the mechanisms of this optimization are not clear. Using rats as a model system for bone development, the aim of this study was to understand how rodent bone morphology, apparent density, and bone volume fraction respond to the everyday movements during growth, and if they are related to changes in joint kinematics and gait dynamics.

METHODS

Data was collected from 5 healthy female Sprague-Dawley rats beginning at the age of 7 weeks. All protocols were approved by the IACUC at UIUC. Computed tomography data and gait biomechanics data was collected at seven time points: weekly from age 8 weeks to 12 weeks, 14 weeks, and 20 weeks.

The hindlimbs were scanned using in vivo microCT with a resolution of 35.8 μm. The right hindlimb was segmented semi-automatically using Amira 5.6. The apparent density along the length of the bone was calculated by Hounsfield unit to apparent density conversion using hydroxyapatite phantoms placed within the scan field of view [3]. The length of the bone and transverse cross-sectional area were calculated using custom Matlab code.

Next, rat gait analysis was performed. A custom walkway was developed with an in-ground force plate to record ground reaction forces (GRF). Each rat was trained to walk on the walkway before collecting the data. Kinematics of the hindlimb during walking were measured using two high-speed cameras (Fig 1). Key anatomical landmarks were marked with a non-toxic permanent marker. Each rat was placed upon the walkway and marker positions and the GRF were collected at 240 Hz frequency when the right foot hit the force plate correctly. The knee marker position was estimated in 3D by measuring the length of the femur and the tibia to minimize skin movement error [4].

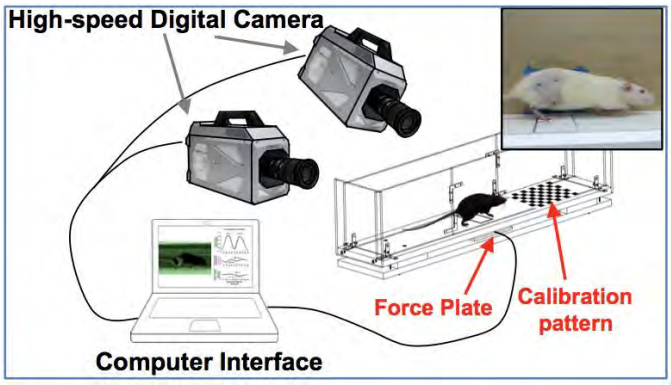

Figure 1: Schematic of rat walkway platform for gait data.

RESULTS AND DISCUSSION

Ground reaction forces and hip, knee, and ankle joint angles were obtained at each time point along one gait cycle. Peak GRF and joint angles at the time of the peak GRF were averaged at each time point (Fig. 2). Mean peak GRF increased during growth, but the rate of increase decreased over time. At 11 weeks, the GRF increased and remained relatively constant until it increased again at 20 weeks ($p<0.05$). The joint angles decreased at ten weeks after which they again remained constant beyond ten weeks of age (Fig. 2).

As expected, tibia bone length followed a power law increase with age and converged by the end of the experiment (93% of skeletal maturity). The proximal portion had a larger cross-sectional area, but smaller

apparent density compared to the middle and distal regions of the bone over time (Fig. 3).

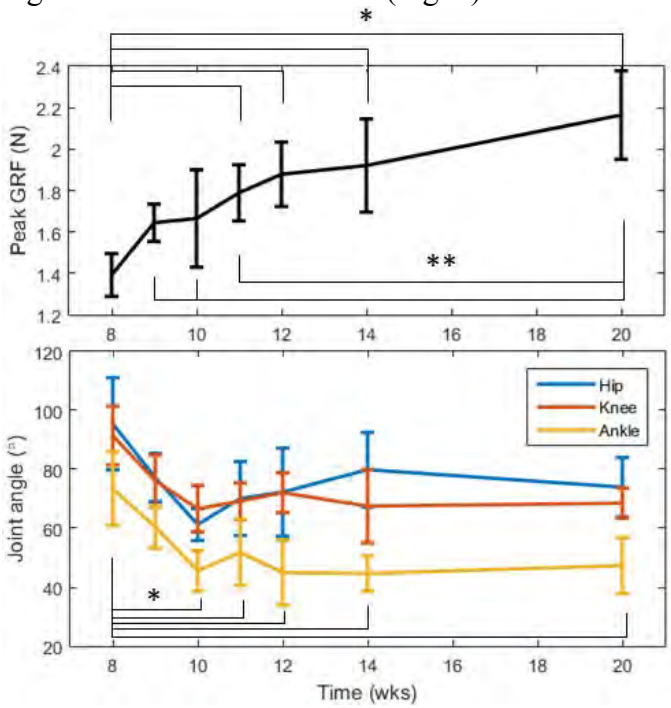

Figure 2: Mean peak ground reaction forces and standard deviations, and Hip, knee, and ankle joint angle trajectories when peak GRF at each age.

Proximal CSA kept increasing, whereas distal and middle CSA did not change over time. However, density in all three regions increased and then converged at the end of experiment similar to the trend observed in bone volume fraction.

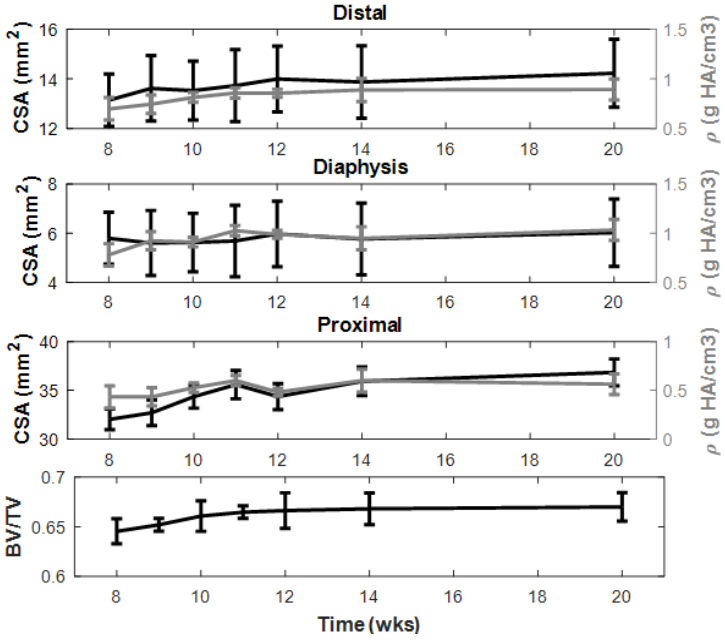

Figure 3: Cross-sectional area and apparent density of distal, middle, and proximal ends, and bone volume fraction at each age.

The peak ground reaction forces correlated with respect to body mass over time when rats walked naturally during growth. To generate the ground reaction forces, each joint angle decreased until week 10 and then converged. This trend was also observed from the proximal CSA, the apparent density of whole regions of the bone, and the bone volume fraction, but one week shifted. The shift may represent the time bone needs to undergo bone modeling in response to the change in motion.

The proximal end had a larger CSA and lower apparent density because it has more trabecular bone. Unchanged CSA and increased density at the distal and middle ends imply that the distal and middle regions of the bone are getting denser and stronger than other regions during growth. Generally, the ankle joint has higher moments and force during walking and this loading condition may initiate the need to increase the strength of the distal tibia.

At the age of 20 weeks, rodents are almost mature in terms of CSA, apparent density, and bone volume fraction that are about to converge, even though ground reaction forces keep increasing over time.

CONCLUSIONS

This study shows how bone properties change during the growth period and that those properties are related to gait strategy. The specific role of muscle forces during growth remains to be understood, and is the subject of future work.

TENDON ALLOGRAFT PROCESSING AND RECONSTITUTION INCREASES FLEXURAL STIFFNESS

[1] Andrew Thoreson, [2] Chun Bi and [1] Chunfeng Zhao

INTRODUCTION

Tendon grafts play a critical role in functional recovery of Zone II tendon repairs and have been sourced from both intrasynovial and extrasynovial sites. Intrasynovial tendon (e.g. flexor digitorum profundus (FDP) tendon) is a preferred source because of its smooth surface, low friction; however, its supply is limited. Extrasynovial tendon is readily available and is often sourced as an allograft for tendon repair. Clinical outcomes of graft repair will be partly dependent on mechanical properties of the processed graft.

Differences in mechanical properties between intrasynovial and extrasynovial tendon have been previously documented [1, 2]. However, mechanical characterization of tendon allograft has largely been limited to compressive, tensile and frictional properties. While these properties are relevant to the functional performance of tendon, its flexural stiffness will also affect performance, a parameter which has been largely neglected in prior studies. The tendon's ability to bend will impact the gliding resistance as the tendon traverses through the pulley of a flexing digit. Each mechanical property could be completely independent of the others, requiring a more robust characterization to appreciate in vivo performance of the graft.

The objective of this study was to first develop an approach to quantify the flexural modulus of tendon, then determine how this property differs between extrasynovial and intrasynovial tendon, between regions within intrasynovial tendon, and between the freshly harvested and rehydrated lyophilized conditions. We hypothesized that extrasynovial and intrasynovial tendon have different flexural moduli and lyophilization would increase flexural moduli of both fibrocartilaginous and non-fibrocartilaginous regions.

METHODS

A custom-fabricated apparatus was designed based on the 3-point bend test methods traditionally used for evaluating flexural properties of materials [3]. The device consisted of a recessed well that retained a room temperature saline bath, two vertical 3.2-mm-diameter pins that served as simple supports for the tendon and a mechanical actuator instrumented with a load cell and linear potentiometer that extended into the saline bath with another vertical 3.2-mm pin to load the tendon (Fig 1). The tendon was flexed in the horizontal plane to negate the effects of gravity. The span between pins was set to 12.5 mm.

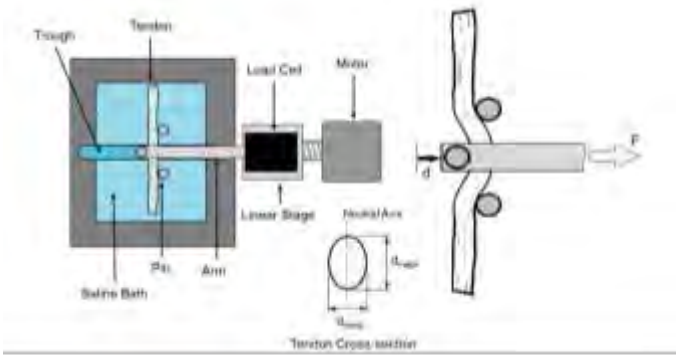

Figure 1: Schematic of custom apparatus to test tendon flexural modulus in a saline bath.

Twenty hind paws were harvested from 10 adult mongrel dogs which were sacrificed for other Institutional Animal Care and Use Committee approved studies. Second digit flexor digitorum profundus (FDP) intrasynovial tendons and peroneus longus (PL) extrasynovial tendons were harvested. Intrasynovial and extrasynovial tendons were each randomly divided into two groups of ten

tendons each, one to be tested as harvested and the other to be processed as allografts.

Allografts were processed starting with 5 cycles of liquid nitrogen immersion and thawing in 37°C saline (0.9%), lyophilization for 12 hours (Benchtop Manifold Freeze Dryer, Millrock Technology, Kingston, NY). and rehydration in saline solution (0.9%) at 4°C for twenty-four hours. The middle 20 mm was cut from each PL tendon or tendon allograft and 40-mm FDP tendon/allograft samples were cut that included fibrocartilaginous (fc) and non-fibrocartilaginous (nfc) regions. The major and minor diameters of each tendon cross-section were measured with a digital caliper.

Tendons were placed on the device and at a constant rate of 0.05 mm/s for 2 mm for two cycles. Data from the 2nd cycle was used for property calculations as the first cycle was applied to stabilize the tendon. Flexural modulus (E) was calculated using classic mechanical equations for beam deflection (Eq 1), assuming tendon cross-section was elliptical, where F is the force loading the tendon, L is the span, d is the tendon deflection, and a and b are the major and minor tendon diameters, respectively.

$$E = \frac{FL^3}{12ab^3\pi d} \qquad \text{(Eq 1)}$$

Student's t-tests were performed to compare the flexural modulus between groups. A p value of 0.05 or less was considered statistically significant.

RESULTS AND DISCUSSION

Lyophilization and rehydration significantly increased flexural modulus of PL tendon and FDP tendon in both the fibrocartilage and non-fibrocartilage regions ($P<0.001$ for all). Flexural modulus was significantly different between fibrocartilaginous and non-fibrocartilaginous regions in fresh tendon, and this difference remained significant after lyophilization ($P < 0.001$ for both comparisons) (Fig. 2).

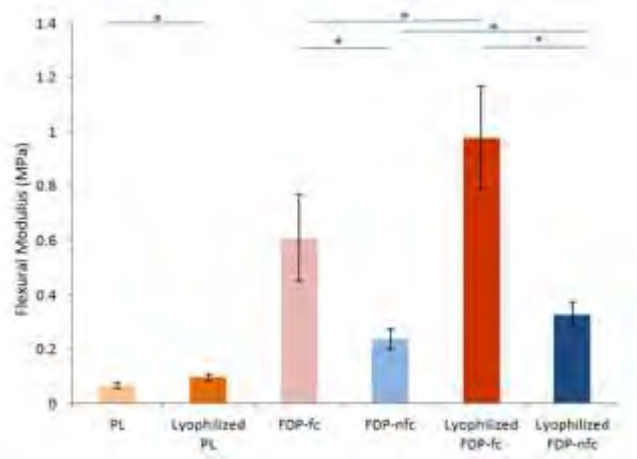

Figure 2: Mean flexural modulus of different tendon types and preparation. Bars connect groups that are significantly different.

Gliding resistance and longitudinal stiffness represent only two relevant properties of tendon. This new characterization shows yet another manner in which graft processing technique can alter mechanical properties of the tendon and potentially affect clinical outcomes.

CONCLUSIONS

Lyophilization and reconstitution of tendon allografts can alter flexural properties compared to the native state. This may increase tendon gliding and wear on the tendon surface. Methods to reconstitute allografts without increasing stiffness should be investigated further.

DEVELOPMENT OF PELVIS MODEL FOR BIOMECHANICAL EVALUATION OF MINIMALLY INVASIVE ACETABULAR RECONSTRUCTION

[1] Sean M Tutton, [1]David M King, [1]D Ian English, [1]William B Lea,
[1]John C Neilson, [2]Randolph M Setser, [2]Sebastian Schafer, [1,3]Mei Wang

INTRODUCTION

Bone is the third most common site for cancer metastases behind the lung and liver, while pelvis is the second most common site of bone metastasis (second to the spine). Goals of the reconstruction are to achieve full weight-bearing post-op and to provide durable construct to last expected lifetime of patient. Harrington established guidelines for treatment of type III and IV lesions [1]. Image-guided minimally invasive percutaneous acetabular stabilization using augmented screws combined with thermal ablation is newer treatment approach that avoids the morbidity of open surgical reconstruction and allows patients undergo earlier chemotherapy and radiation [2]. However, there is a lack of suitable model for biomechanical evaluations of these minimally invasive fixation procedures. The standard 4th-generation composite hemipelvis model was almost twice as stiff as that of the cadaver specimens.

The purpose of this study was to develop a composite model of hemipelvis with metastatic acetabular lesions that mimic the biomechanical properties of human cadaver, and a surrogate soft tissue torso to perform percutaneous augmented screw fixation. Composite model contained a defect in the acetabulum partially involving the medial and superior acetabular walls consistent with a Harrington type III.

METHODS

The CT images of a patient with Harrington III bone defect in the medial and superior acetabulum were selected. Based on these images, prototypes of composite hemipelvis were developed for this study in collaboration with Pacific Research Laboratories (Vashon, WA). In addition, a surrogate soft tissue torso with skin from waist to upper thigh was custom-made (Fig.1). The torso surrogate was used to house the sawbone hemi-pelvis and to be strapped onto the patient table of an angiography system for the percutaneous stabilization procedures. The torso was designed for repeated utilization, with a Velcro opening on the side for the insertion and removal of composite hemipelvis.

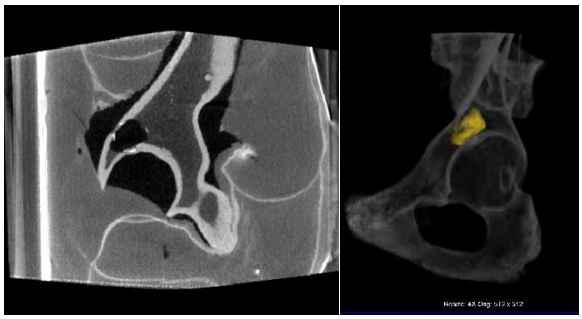

Figure 1: Fluro-image of hemipelvis model inside foam torso (left) and CT-scan of the model (right).

To characterize the biomechanical behaviors of the prototypes, compressive force up to 1200N and then load to failure tests were conducted with the hemi-pelvis being in a configuration that mimic single-leg mid stance phase of a gait. Servo hydraulic loading frame (MTS Landmark 370, Eden Prairie, MN) was used to apply axial load through a 4th-generation composite femur (proximal half) at a rate of 0.1mm/s for both tests. The hip was positioned with 15-degree flexion and 10-degree adduction [3]. Lateral shift of 5cm from the sagittal midline was also added to the loading point when mounting the pelvis to the actuator. This was to simulate lateral displacement of the pelvis as the center of gravity moves closer to the stance leg. Two marker triads from a motion tracking system (Optotrak Certus, NDI, Waterloo, Canada) were each placed on the pubic tubercle and anterior margin of the iliac crest to track movement of the hemipelvis and deformation in response to loading. Marker triads data and axial force and displacement

data from MTS built-in sensors were synchronized and collected at 100Hz.

From the non-destructive test, compressive stiffness was obtained from the linear portion of the load-displacement plot, while maximum deformation under 1200N was identified from the motion tracking data. Mechanical yield strength, ultimate strength, and stiffness were obtained from the load-to-failure test. After finalizing the model, four samples of the selected hemipelvis prototype were fabricated for mechanical evaluation. Mechanical variables of these samples were compared to the previously published data from cadaver testing where was available [4].

Figure 2: Configuration for axial compression test.

RESULTS

After two rounds of modification (tuning elastic module of the cortical shell and altering cortical thickness) and testing, the finalized model was a composite model consisted of cortical shell made of 20pcf rigid foam with thickness varying between 1-2 mm, and cancellous core made of 8pcf rigid foam. The volume of superior lateral acetabular wall defect was 13ml (Fig.1).

Results of axial compression tests showed that the mean stiffness of the hemipelvis was 730±141N/mm, 12% lower than the 832±62N/mm obtained from cadaver hemipelvis from healthy elderly donors [4]. The mean yield strength and ultimate strength was 2400±432N and 2758±230N respectively. The mean corresponding yield and ultimate deformations were 4.3±1.2mm and 6.2±0.9mm respectively. At 1200N compression, the deformation across the acetabular area was relatively small, with the mean rotational deformations ranged from 0.12 to 0.17 degree around the three axes, and the mean axial deformation of 0.59mm.

DISCUSSION

A composite model of hemipelvis with simulated metastatic acetabular lesion was developed based on previously treated patient scans. Biomechanical testing of the model in a single-leg loading configuration showed that its stiffness, at 730N/mm, was more comparable to the cadaver specimens (at 832N/mm) than the standard 4th-generation composite model (at 1448±54N/mm). The 12% reduction over the intact cadaver specimens in stiffness also supports its suitability as an acetabular lesion model. There is no previous data on compressive strength on cadaver pelvis except under high-speed impact loading, but the yield and ultimate strengths of the current model, at 3-4 times of bodyweight, represents good estimations for patients in this population.

CONCLUSIONS

The composite sawbone Harrington III hemipelvis developed in this study provides a reasonable model to be used for comparative studies of minimally invasive technique of percutaneous acetabuloplasty and screw fixations for metastatic lesions of the acetabular area.

EFFECT OF SURFACES WITH DIFFERENT STIFFNESS ON BODY KINEMATICS WHILE ROLLING

[1] Rahul Agrawal [2] Mahdi Hassan and [1] Nils Hakansson

[1] Wichita State University, KS, USA

[2]University of Nebraska at Omaha, Omaha, NE, USA

email: nils.hakansson@wichita.edu, web: http://www.wichita.edu/thisis/home/?u=bme

INTRODUCTION

Rolling is an activity that most people perform repeatedly on a daily basis without knowing. This complicated movement requires the coordinated motion of body segments, i.e., trunk and upper and lower extremities [1]. Rolling and repositioning in bed serves to improve comfort, circulation, sleep quality, and prevent pressure sores. People who cannot roll or have difficulty rolling may receive training from a physical therapist based on a standard or norm. To date, no standard or norm exists. Previous research on autonomous rolling kinematics has been limited to rolling on an exercise mat [1-2] or firm surface [3]. Thus, rolling on surfaces with different stiffness could provide further insight into understanding the biomechanics of rolling and offer new training options. The goal of this research is to determine the body kinematics when rolling from the supine position to the side-lying position on three surfaces with different stiffness (i.e., a stiff surface, exercise mat, and a mattress) under two rolling conditions to mimic independent rolling and assisted rolling by a caregiver: (1) arms free to move naturally and (2) arms crossed over the chest (constrained arms), respectively. The objective of this study was to determine the effect of rolling surface stiffness and arm conditions on the body kinematics as defined by the body segment (shoulder vs. pelvis) that initiates and concludes the roll.

METHODS

Data were collected from 18 participants (12 males and 6 females; mean weight 76.3 ± 13.9 kg; mean height 173.6 ± 7.6 cm; mean age 24.6 ± 3.4 yrs.) who were not limited in their ability to roll after receiving informed consent as defined by the WSU Institutional Review Board. Participants were instructed to roll to their right from the supine to a side-lying position on three different surfaces (stiff floor, 2-inch exercise mat, 8-inch memory foam mattress) using two types of rolling conditions: arms free to move naturally and arms crossed over the chest, to mimic autonomous and caregiver assisted rolling respectively. Five trials were collected for each type of rolling for a total of 30 trials per participant.

The data collection order was randomized by surface and by arm condition within each surface. Shoulder and pelvis kinematics were recorded at 50 Hz using an eleven-camera, high-resolution motion analysis system (Motion Analysis Corp., Santa Rosa, CA) and reflective spherical markers positioned on the left and right acromia and anterior superior iliac spine (ASIS). Shoulder and pelvis angles were calculated from the inverse tangent of the horizontal and vertical components of the vector formed from the right to left shoulder (AB) and the right to left ASIS (CD) markers, respectively (Figure 1). Initiation and cessation of the rolling motion was based on the shoulder and pelvis angular velocities [3].

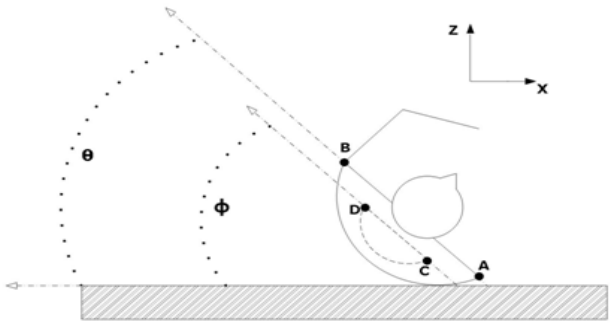

Figure 1: Shoulder (θ) and pelvis (ϕ) angles.

The dependent variables studied are listed in Table 1. Friedman's nonparametric tests for repeated measures were used to test for differences in the initiating and ending segment for each surface and rolling condition. Two-way repeated-measures ANOVA (α=0.05) tests were performed to examine the effect of rolling surface stiffness and arm

condition had on shoulder and pelvis kinematics during the rolling motion. When significant main effects were identified, *post hoc* pairwise t-tests with Bonferroni correction (p = 0.05/n where n is 5) were performed.

RESULTS AND DISCUSSION

No significant difference was observed for the segment (shoulder or pelvis) that initiated or concluded the roll, the timing of the peak angular velocity of the shoulders, the peak angular velocity of shoulders, or the duration of the roll. There was a significant interaction between conditions and surfaces for both the timing of the peak angular velocity of the pelvis (p=0.034) and the magnitude of the peak angular velocity of the pelvis (p=0.006). The rolling condition had a significant ($p<0.001$) effect on the pelvis peak angular velocity. Across all rolling combinations, the shoulder initiated 61.3% and ended 50.5% and the pelvis initiated 37.8 % and ended 45.1 % of the rolls.

An important finding of this study was neither the constraint imposed on the arms nor the rolling surface stiffness affected the majority of dependent variables that were examined. This information could be useful to a therapist teaching a patient to roll. The consistency of the initiating and concluding segments across conditions and surfaces supports the motor control theory that a movement is planned prior to initiation [4]. The mean peak angular velocity for the arms-uncrossed condition appears to be higher, yet there was not a significant difference in the duration of the roll, indicating that the average angular velocity was similar for all rolling conditions. This characteristic is consistent with previous research that upper extremity and torso rotation is smooth and steady [2-5]. The decrease in peak pelvis angular velocity when rolling on a compliant surface with arms crossed suggests that subjects generated less peak kinetic energy with the pelvis segment. The increase in peak angular velocities of shoulder with arm uncrossed condition could be associated with an increase in momentum generated by arms to assist in rolling on compliant surface.

CONCLUSIONS

The application of motion constraints that do not alter segment coordination patterns could facilitate future biomechanical analyses of human rolling. To this end, we found that constraining the arms surface stiffness did not affect most rolling kinematic measures. This result provides confidence that future research work on rolling, for example the creation of a musculoskeletal simulation of rolling, can be performed with constrained arms and on varying surface stiffness's without altering the basic rolling movement.

DIFFERENCES IN MECHANICAL ENERGY OF HUMAN ROLLING ON DIFFERENT SURFACES

[1] Rahul Agrawal, [2] Mahdi Hassan and [1] Nils A. Hakansson

[1,3]Wichita State University, Wichita, KS, USA
[2]University of Nebraska at Omaha, Omaha, NE, USA
email: nils.hakansson@wichita.edu, web: http://www.wichita.edu/thisis/home/?u=bme

INTRODUCTION

Rolling is a milestone in human development. Rolling serves to improve comfort and prevent ischemic-associated injuries to the tissues (i.e., pressure sores), facilitate a healthy quality of sleep, and reduce the potential for long-term health complications. Previous research provides some knowledge on how people roll on a firm surface [1-3]. A goal of our research is to determine fundamental characteristics of rolling and evaluate whether environmental factors (e.g., rolling surface) or movement constraints (e.g., crossing the arms over the chest as employed in an assisted roll) changes the rolling motion. This information would be useful to a therapist working to evaluate or train a patient's rolling. The objective of the study was to determine mechanical energy requirements of the body when rolling from the supine position to the side-lying position on surfaces with three different stiffness: a) firm surface, b) exercise mat, and c) mattress under two rolling conditions: (1) constrained arms (arms crossed over the chest) and (2) arms uncrossed (arms free to move naturally).

METHODS

Written informed consent, as defined by the Wichita State University Institutional Review Board, was obtained from 18 healthy participants (12 males and 6 females; mean weight 76.3 ± 13.9 kg; mean height 173.6 ± 7.6 cm; mean age 24.6 ± 3.4 yrs) prior to their participation in the study. Subjects were instructed to cross their arms over their chest, to prevent the effects of varying arm motions from influencing the results [4].

The data collection order was randomized by surface order and by arm condition within surface. Whole body kinematics were recorded at 50 Hz using an eleven-camera, high-resolution motion analysis system (Motion Analysis Corp., Santa Rosa, CA). The eleven cameras recorded the three-dimensional positions of reflective spherical markers positioned on the body. Twenty-two retro-reflective markers were placed on bony landmarks to define different body segments.

Participants were instructed to lay supine and roll to their right to a right side-lying position in a controlled and comfortable manner under two different conditions: (1) arms crossed, and (2) arms uncrossed, as shown in (Figure 1). Subjects were asked to roll under these two conditions five times on three different surfaces (stiff floor, exercise mat, and memory foam mattress).

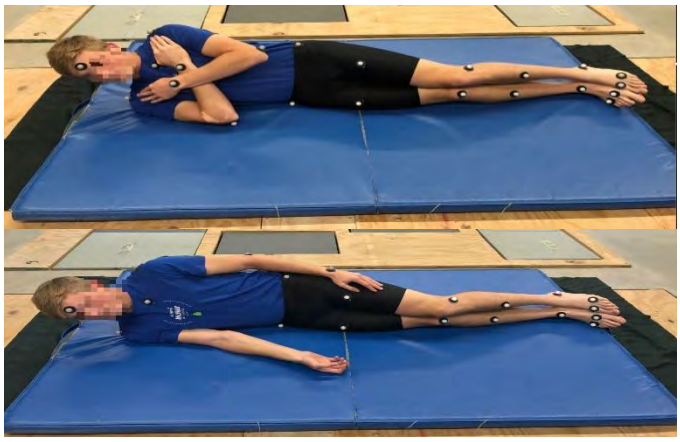

Figure 1: Rolling with arms crossed (upper figure) and arms uncrossed (lower figure).

The marker position x, y, z data were imported into a musculoskeletal simulation software (OpenSim version 3.3) [5] to calculate the body kinematics, including linear (v) and angular (ω) velocities and individual body segment center of mass positions. The total mechanical energy is the sum of potential energy (Ep) and kinetic energy (Ek), which were calculated as:

$$Ep = mgh$$

$$Ek = \frac{1}{2}mv^2 + \frac{1}{2}I\omega^2$$

where m is the mass of the body segment, g is the gravitational acceleration, h is the height of the segment COM in the lab reference frame, *v* is the velocity of the segment COM, I is the mass moment of inertia of the segments, and ω is the angular velocity of the segment. Total energy (Etot) was calculated by summing all positive increments in Ep and Ek [6].

RESULTS AND DISCUSSION

The mean total mechanical energy (E_{tot}) measures across all subjects for arms-crossed rolling on three different surfaces including hard surface, exercise mat, and mattress were 78.4 ± 21.6J, 77.1 ± 20.7J, and 77.7 ± 22.2J, respectively. Similarly, for the arms-uncrossed condition on three different surfaces including hard surface, exercise mat, and mattress, E_{tot} measures were 91.3 ± 23.8J, 88.8 ± 24.0J, and 87.9 ± 26.3J, respectively (Figure 2). There was a significant difference observed for main effects of rolling conditions (p<0.01) for total mechanical energy. No statistically significant difference was observed between the rolling conditions and the surfaces (p=0.403) or in the main effects of the surfaces (p=0.053) for total mechanical energy. For the mean total mechanical energy, potential energy comprised about 90% and kinetic energy comprises 10%, which is consistent for all surfaces and rolling conditions.

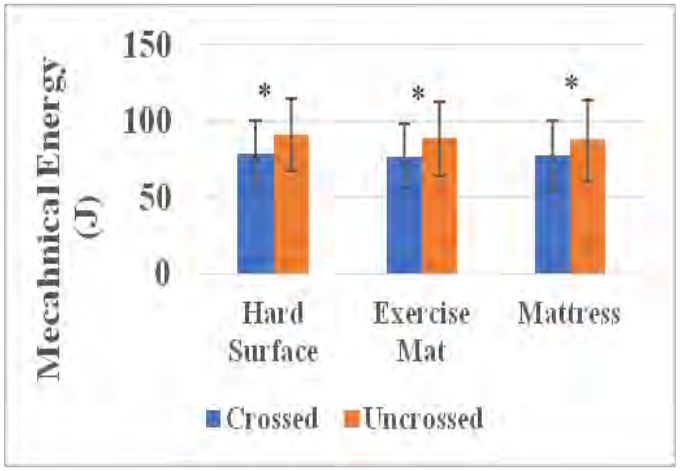

Figure 2: Mean body total mechanical energy across condition and surfaces. Asterisks indicate significant differences between rolling conditions.

Potential energy comprised the majority of energy generated to roll for surfaces and conditions tested [7]. This energy represented the energy required to raise the body center of mass. Kinetic energy is comprised of two components: translational energy and rotational energy. Across all trials, the mean translational kinetic energy was 99% and rotational kinetic energy was 1%, which was consistent for the two rolling conditions and three different surfaces. Constraining the arms over the chest reduces the energy demands to roll from the supine to side-lying position. This finding is very important from the perspective of healthcare workers who reposition individuals with immobility in bed. Since crossing the arms of the patient may reduce the energy required by healthcare providers to roll a patient, which in turn may reduce their risk of low back injury.

CONCLUSIONS

This study provided insight about the mechanical energy requirements of the body when rolling on different surfaces with arms crossed and arms-uncrossed conditions. The arm segments were the major contributor to the difference observed in the mechanical energy. This information will further help to simplify the musculoskeletal models and simulations in order to understand energy absorbed by the compliant surface during rolling. Rolling on the compliant surface is more difficult as some amount energy is being absorbed by the surface, leading to more requirement of energy as input to roll.

INTRODUCTION

Surgical procedures always involve an element of risk and even a minor error can lead to serious complications. Recent data suggests that over 200 million surgeries are performed annually worldwide and about 3 to 22% of these surgeries involve some sort of complications. Surgical errors can be caused by both technical errors and cognitive errors which may happen to even an experienced surgeon. However, resident surgeons are more prone to surgical errors as they start their surgical career with less experience and skills [1]. In order to reduce errors and accelerate the learning experience of surgeons, we propose a method that can identify, model and prevent surgical errors by using biomechanical motion analysis and a high-fidelity 3-D surgery simulator.

Our work targets a complex, common, and high-risk surgery for stress urinary incontinence called the midurethral sling (MUS) procedure. The procedure involves using a sharp steel trocar to place a mesh underneath the urethra to control its mobility. For this surgery, the surgeon has to guide the sharp steel trocar blindly past the bladder, bowel and some major blood vessels that require the surgeon to have distinct surgical skills (bimanual dexterity, ability to envision a blind 3-D space, strong knowledge on the complex anatomy of the periurethral and perivesical spaces etc.) [2].

Surgical errors occurring during trocar passage procedure could be described and therefore predicted and/or prevented by discrete changes in the kinematics of the surgeon's shoulder, arm, hand and the spatio-temporal characteristics of the trocar [3]. The main goal of this study is to create a high fidelity 3-D pelvic simulator to study the kinematics of on particular high-risk step of the MUS surgery.

METHODS

The first step in this work is to create a high fidelity 3-D model of the pelvic anatomy. The Virtual Pelvic Surgery model (VPS) was developed from segmentation of high resolution magnetic resonance images (MRI) of a 57-year-old female patient with stress urinary incontinence. Structures of pelvic anatomy including bone, muscle, blood vessels, bladder, uterus, urethra, vaginal wall, and skin were segmented from MRI using 3D Slicer (www.slicer.org). The 3-D geometries were post-processed using MeshLab (http://www.meshlab.net/) and Artec Studio (www.artec3d.com). Post-processing of 3-D geometries included reduction of artifacts and noise, and decimation to reduce the file sizes. Finally, all individual geometries were combined to form the complete 3-D virtual pelvis model.

The VPS was then used to construct a physical pelvic model. All the structures of the pelvic anatomy were 3-D printed using a Dimension bst1200es series 3D printer. Individual physical structures are assembled and encased to construct the complete 3-D physical pelvis model.

The next step will be to use biomechanical motion analysis (www.vicon.com) to measure surgeon shoulder, hand, and arm kinematics, as well as the kinematics of the surgical instrument during simulated trocar passages. The kinematics of the most common surgical errors (injury of the bladder, urethra, bowel, or external iliac vessels) will be analyzed using this procedure.

RESULTS AND DISCUSSION

High resolution T2 MR Image sequences were used to segment the bowel, urethra, vaginal wall, ureter,

levator muscle and rectus abdominus muscles. Muscles such as obturator, quad, vastus, adductor, tensor fasciae latae, sartorius, iliopsoas, rectus femoris, piriformis, pectineus, gracillis, semimembranus and semitendinosus were more clearly visible from out-phase MR image sequences. In-Phase MR image sequences were used to segment the skin (with fat layer), part of bowel and urethra. Major blood vessels (external iliac vein and artery, femoral vein and artery), fascia and bowel were segmented from the Water MR Image sequences. Femur, pelvic bone, bladder, rectum and uterus were segmented from all five sequences (T2, In-Phase, Out-Phase, Water and Fiesta) and merged to finalize these geometries.

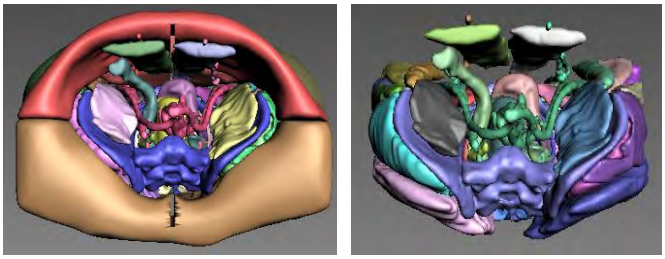

Figure 1: Pelvic Model (after post-processing)

High resolution Out-Phase MR image sequences have been used to extract the peritoneum membrane to provide us with a proper indicator of surgeon's performance. In ideal cases, it is expected that the surgeon will maintain minimum distance between the trocar and peritoneum membrane while performing this surgery.

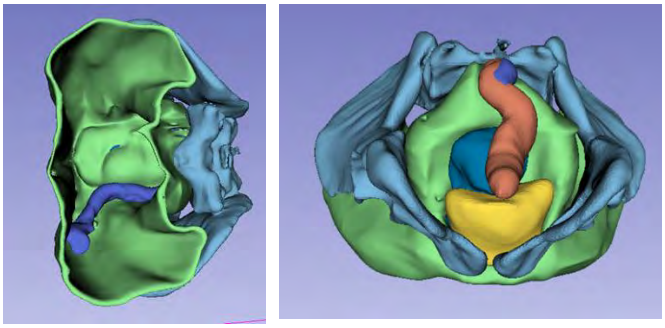

Figure 2: Pelvic Model with Peritoneum

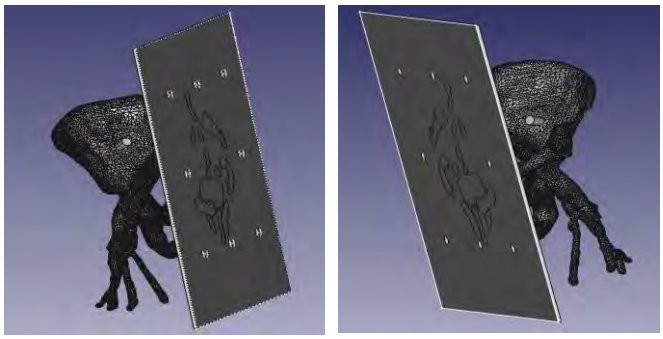

Figure 3: Virtual CAD model with mid-plates

During the procedure, the trocar will never cross through the mid-plane of the pelvic anatomy. This novel model includes two thin plates (3mm thickness) in the middle to attach the soft tissues and blood vessels from both sides, and two mid-pates have been mounted on each other using 8 small posts (3mm radius for each of them). After post-processing, small posts and pockets (5mm radius) have been created on individual geometries using FreeCAD (www.freecad.com) to attach them on the physical model based on correct anatomical orientation.

CONCLUSIONS

The aim of this research project is to create a realistic anatomical platform on which surgical trainees can practice their skills and get effective feedback on their overall surgical errors through kinematic analysis.

INFLUENCE OF INCREASED FORWARD TRUNK FLEXION DURING STAIR ASCENT ON THE AVERAGE RATE OF PATELLOFEMORAL JOINT STRESS DEVELOPMENT

[1]Lee T. Atkins, [1]Cevan Smithson, [1]Daniel Grimes, [1]Nancy Heuer

[1]Angelo State University, San Angelo, TX, USA
email: lee.atkins@angelo.edu

INTRODUCTION

Patellofemoral pain (PFP) is a common yet complex, multifactorial condition that affects women more frequently than men [1]. One theory assumes that increased patellofemoral joint (PFJ) stress is a contributing factor to PFP onset and exacerbation [2]. In particular, a recent study reported that the average rate of patellofemoral joint (PFJ) loading was significantly and positively associated with the rate of change in PFP ($r=0.42$, $p=0.02$) [3]. Thus, it has been recommended that clinicians utilize treatments that minimize the average rate of PFJ loading during provocative functional tasks for patients with PFP.

Stair ambulation has been identified as an activity that evokes symptoms for persons with PFP [4]. Furthermore, it has been reported that while running a 7° increase in forward trunk flexion was associated with a reduction in peak PFJ stress ($p<0.01$) [5]. Although feasible, it is not known if the same strategy (i.e. increased forward trunk flexion) causes a decrease in the average rate of PFJ stress development during stair ambulation. Therefore the purpose of this study was to test the hypothesis that increasing forward trunk flexion during stair ascent would cause a decrease in the average rate of PFJ stress development.

METHODS

Twenty female subjects (age: 23.4 ± 2.5 yr; height: 164.4 ± 7.9 cm; mass: 63.0 ± 12.2 kg) participated in this study. To be included subjects must have been free of lower limb and low back pain at the time of testing and must have reported no prior lower limb or low back surgery.

Each subject performed 5 trials of stair ascent (tread height: 12 cm, tread depth: 26.5 cm) using their self-selected (SS) and a forward flexed trunk posture (FLX) for a total of 10 trials. The velocity of each trial was controlled by having subjects step to the beat of a metronome (96 steps/min). Sagittal trunk and knee kinematics (200 Hz) and ground reaction force (2000 Hz) data were collected using an 8 camera Vicon motion capture system and Bertec forceplate (embedded in the first step of the staircase) respectively. Patellofemoral joint stress was estimated using a previously described PFJ model [5]. Subject-specific model inputs included sagittal knee angle and moment data obtained during the stance phase of each trial. Additional model inputs, not specific to subjects, were calculated using data from previous studies and included quadriceps lever arm length, quadriceps muscle force, PFJ contact area, and a constant that described the ratio of the quadriceps force to patellofemoral joint reaction force (PFJRF) as a function of knee flexion angle [6, 7, 8].

The primary dependent variable was the average rate of PFJ stress development. Secondary dependent variables included the average rate of change of the PFJRF, PFJ contact area, knee extensor moment, and knee flexion angle. All dependent variables were calculated during the time from initial contact to the point of peak PFJ stress. Paired t-tests were used to evaluate for differences in dependent variables between conditions.

RESULTS AND DISCUSSION

The average sagittal plane trunk angle was significantly greater during the FLX condition ($p<0.01$, 45.4 ± 22.4°) compared to the SS condition (14.6 ± 8.3°). Additionally a concomitant decrease in the average rate of PFJ stress development was observed during the FLX condition ($p<0.01$, 51.0 ± 16.3 MPa/sec) compared to the SS condition (33.2 ± 15.5 MPa/sec) (Figure 1).

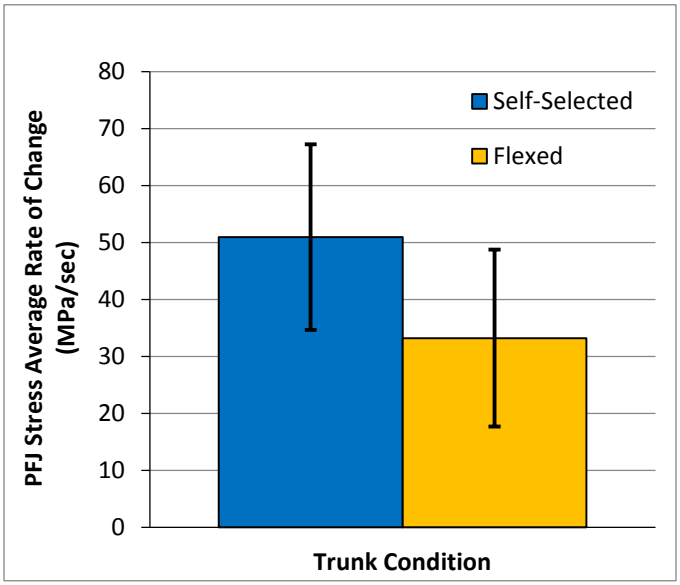

Figure 1. Average rate of change in patellofemoral (PFJ) stress during the self-selected and forward flexed trunk conditions. Error bars represent one standard deviation.

The observed decrease in average rate of PFJ stress development was the result of a significant decrease in the average rate of PFJRF development ($p<0.01$) from the FLX to the SS condition (Table 1) as the average rate of change in PFJ contact area was similar for both conditions ($p=0.48$) (Table 1). Furthermore, the observed decrease in average rate of PFJRF development was caused by a decrease in the average rate of change in knee extension moment ($p<0.01$) from the SS to FLX condition (Table 1). The knee flexion angle did not contribute to the change in PFJRF rate as the knee extended at a more rapid rate during the SS condition compared to the FLX condition ($p<0.01$) (Table 1).

CONCLUSIONS

Findings from this study indicate that increasing forward trunk flexion during stair ascent is effective for minimizing the average rate of PFJ stress development. Clinicians should consider teaching patients with PFP to utilize increased forward trunk flexion during stair ascent as this may be effective for minimizing symptom exacerbation. However, additional studies are needed to confirm these findings in PFP patients. Additionally, the effects of increasing forward trunk flexion on PFP should be examined as well.

INTRODUCTION

There are more than 146,000 roofers in the United States of America, and that number is expected to increase to more than 162,000 by 2026 [1]. Roofers are required to bend and twist their bodies repetitively in a kneeling, crouching, stooping or crawling position for 75% of their work time, and when combined with excessive loading, these postures may contribute to the development of musculoskeletal disorders (MSDs) [2]. From 2013 to 2016, the occurrence of MSDs in the roofing industry has more than doubled from 340 to 850 reported cases per year [2], resulting in a median of 10 days away from work in 2016 [3].

The lower back is largely affected by MSDs in the roofing industry, evidenced by a greater back injury rate among roofers than the average construction sector [2]. Workers who experienced back pain in more physically demanding work settings and in awkward postures were 300% more likely to retire prematurely than those involved in less physically challenging work [4]. The goal of the current study is to investigate whether the roof pitch and task performed during simulated shingle installation significantly influences trunk joint angles.

METHODS

Eight male subjects (age: 27.6 ± 5.9 years, height: 181.0 ± 6.6 cm, weight: 89.5 ± 9.8 kg) participated in the National Institute for Occupational Safety and Health's (NIOSH) Institutional Review Board (IRB) approved study after providing informed consent.

Three dimensional kinematic data were collected using a 14-camera motion capture system (Vicon, Oxford, England), sampled at 100 Hz, using spherical skin-surface reflective markers placed on body segments using clusters, as well as bony anatomical landmarks. Subjects were asked to simulate roof shingle installation five times at three randomly ordered roof pitch angles (0°, 15°, and 30°) for a total of 15 trials. The subjects used their dominant hand during trials (all but one were right-handed), and the nail gun was not loaded or powered.

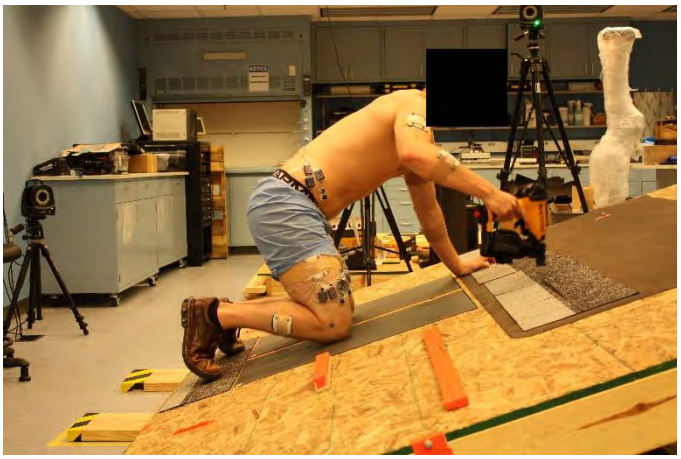

Figure 1: Subject using a nail gun to simulate affixing roof shingles at a 15° pitch.

Kinematic data were modeled to obtain six degree of freedom trunk joint angles (flexion/extension, left/right lateral bending, left/right axial rotation) using commercially available biomechanics analysis software (Visual 3D, C-Motion, Germantown, MD, USA). The simulated roof shingle installation was analyzed in four sequential phases: (1) beginning from an upright kneeling posture, picking up and placing the shingles, (2) picking up and positioning a nail gun, (3) using the nail gun to affix the shingles (Fig. 1), and (4) returning the nail gun to its original position, going back to an upright kneeling posture. For each trial, the maximum angle for each degree of freedom was found within each phase. Two-way repeated measures analysis of variance tests were performed to determine statistical significance ($p<0.05$) between different phases and

roof pitch angles, using the Greenhouse-Geisser correction when sphericity was violated.

RESULTS AND DISCUSSION

Statistical significance was found for the following main effects: (1) flexion pitch and phase ($p \leq 0.001$), (2) left lateral bending phase ($p \leq 0.001$), (3) right lateral bending pitch ($p=0.003$) and phase ($p \leq 0.001$), (4) left axial rotation phase ($p \leq 0.001$), and (5) right axial rotation phase ($p=0.011$). Significant differences were also seen in the interaction effect between pitch and phase for right lateral bending ($p \leq 0.001$), right axial rotation ($p=0.016$), and left axial rotation ($p \leq 0.001$). Pairwise comparisons between different pitch angles and phases for each kinematic variable produced significant results (Table 1 & 2). One interesting result is that as the pitch angle of the roof increased, the maximum flexion angle of the roofer's trunk decreased (0°: 81.1°±6.3°; 15°: 68.1°±4.7°; 30°: 61.1°±5.7°). Our results suggest that trunk posture is influenced by differences in roof pitch and shingle installation tasks.

CONCLUSIONS

Postural changes in the trunk induced by different roof pitch angles and roof shingle installation phases suggest the necessity of wearable interventions. Devices such as knee pads and knee savers may reduce joint angles in the trunk; however, there are no such devices currently designed exclusively for roofing work. Future studies will examine the effects of such devices.

RELATIONSHIP BETWEEN MEDIAL LONGITUDINAL ARCH ANGLE AND FIRST RAY MOTION DURING WALKING

Christopher Casillas, Linnea Zavala, and James Becker

Montana State University, Bozeman, MT
email: james.becker4@montana.edu; web: http://www.montana.edu/biomechanics

INTRODUCTION

Abnormal motion of the first ray has been associated with several foot disorders, including metatarsalgia, hallucis valgus, and hallucis rigidus [1]. In clinical settings, static measurements of first ray mobility are commonly used to assess risk for these disorders. However, static measurements of the first ray do not seem to fully represent the motion of the first ray during walking [2]. Thus, the use of both static and dynamic measurements of first ray motion are important to gain a further understanding of the relationship between foot disorders and first ray motion.

A "gold standard" method for assessing dynamic motion of the first ray requires the use of detailed foot models and three-dimensional motion capture, options which are not available in most clinical settings. However, in clinical settings it is feasible to use two-dimensional video analysis to quantify the medial longitudinal arch (MLA) angle. The MLA encompasses the structures composing the first ray and could potentially be a simplified method of assessing first ray motion. A relationship between MLA and first ray motion would provide clinicians a practical option for describing first ray motion.

Therefore, the aim of this study was to explore the relationship between first ray motion and MLA. We specifically examined the relationship between both static measures of MLA taken during quiet standing and dynamic measures of MLA during gait, and dynamic first ray motion. We hypothesized that a strong relationship exists between MLA angle and the mobility of the first ray.

METHODS

All participants provided IRB-approved informed consent. Participants consisted of 10 physically active individuals (sex: 5 M, 5 F; age: 21.8 ± 3.0 years; mass: 71.4 ± 9.9 kg; height: 1.74 ± 0.90 meters). All participants were free from any lower extremity injuries at the time of testing. A 12-camera motion capture system (Motion Analysis) was used to record foot kinematics 200 Hz. Participants completed a static trial of quiet standing with feet shoulder width apart followed by three walking trials for both left and right feet. The subjects were asked to walk at a self-selected walking speed. Stance phase was determined using an AMTI force plate sampling at 1200 Hz.

A multi-segment foot model was used to calculate sagittal plane movement of the first metatarsal relative to the midfoot [3]. MLA angle was determined by calculating angle between the medial heel, navicular, and first metatarsal head marker. For the quiet standing trial, mean MLA across the trial was calculated. For the walking trials range of motion (ROM), peak, and minimum angles for MLA during stance phase were calculated. First ray motion was quantified as ROM across the walking trials. The three trials from each foot were averaged with the average value being used for the regression analysis (n = 20 trials).

Linear regressions were used to analyze the relationship between first ray motion and peak, minimum, ROM, peak, and static MLA angles.

RESULTS AND DISCUSSION

Average first ray ROM across all subjects during the walking trials was 7.8 (± 2.5°). The results from the multiple regressions varied among the different measures of MLA. The first ray and MLA share components; therefore, it was hypothesized that the MLA angle would move in tandem with the first ray. However, there was no relationship between first ray ROM and MLA angle ROM ($R^2 = 0.05$, $p = 0.36$, Figure 1). There was a statistically significant but weak relationship between first ray ROM and

peak MLA angles ($R^2 = 0.21$, $p = 0.04$, Figure 1). A similar significant but weak relationship existed between first ray ROM and minimum MLA angle ($R^2 = 0.29$, $p = 0.01$, Figure 2). The static measurement of MLA angle unexpectedly had the strongest relationship with first ray ROM. ($R^2 = 0.41$, $p = 0.002$, Figure 2).

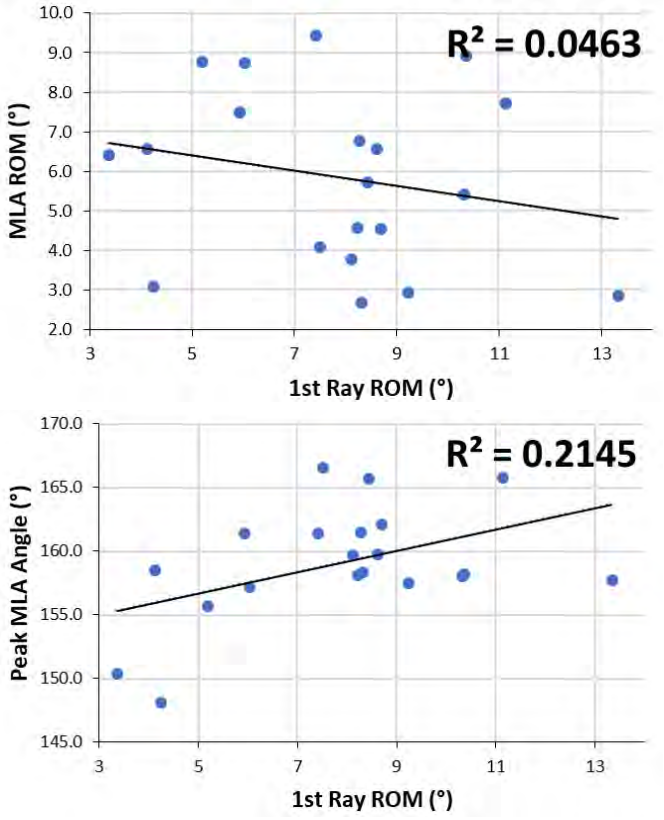

Figure 1. Relationship between first ray ROM and MLA ROM during stance phase (top) and peak MLA angle during stance phase (bottom).

The results were unexpected, as previous literature has shown that static first ray measures do not accurately reflect dynamic first ray motion [2]. As such, it was hypothesized that dynamic measurements of MLA angle would have a stronger relationship to the dynamic motion of the first ray. However, dynamic measures only had weak relation to first ray motion compared to the moderate relation between static MLA angle and first ray motion. This might indicate that during dynamic task MLA and first ray motion are quantifying different aspects of foot function. Further research is necessary to determine the relationship between MLA and the first ray using both static and dynamic measures.

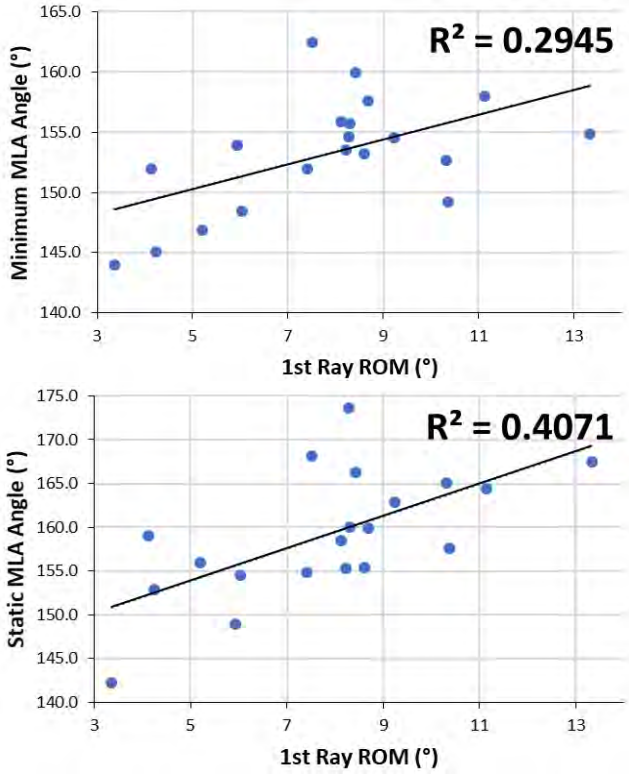

Figure 2. Relationship between first ray ROM and minimum MLA angle during stance phase (top) and static MLA during quiet standing (bottom).

In interpreting our results, it is important to note that our measurement of MLA angle was different from what is commonly used in clinical settings in two ways. First, three-dimensional motion capture was utilized instead of two-dimensional video, and secondly, the marker on the first metatarsal head was placed on the distal dorsal aspect of the metatarsal instead of the distal medial aspect. While previous studies have quantified MLA using similar marker placements [3], it is not clear whether marker placement influenced the relationships examined in the current study.

CONCLUSIONS

Static measures of MLA angle during quiet standing are able to predict movement of the first ray during gait better than dynamic measures of MLA. Static measures may be clinically useful for quantifying potential abnormalities in first ray motion

MOVING OUT OF THE LABORATORY AND IN TO THE REAL WORLD: USING INERTIAL MEASUREMENT UNITS TO ASSESS LONG-TERM RECOVERY AFTER TOTAL KNEE ARTHROPLASTY

[1] Ryan M. Chapman, [2]Wayne E. Moschetti, and [1]Douglas W. Van Citters

[1] Dartmouth College, Thayer School of Engineering, Hanover, NH, USA
[2] Dartmouth Hitchcock Medical Center, Department of Orthopaedics, Lebanon, NH, USA

INTRODUCTION

Maximum knee range of motion (ROM) is typically the metric cited when attempting to establish dysfunction prior to total knee arthroplasty (TKA) and recovery following TKA [1, 2]. However, this measure is traditionally captured at discrete time points (e.g. 1-week pre- or 6-weeks post-TKA) in ideal settings (e.g. clinic or laboratory) while performing idealized movements (e.g. passive ROM via goniometry). This idealized measurement technique may not accurately represent knee function during activities of daily living (ADL). Moreover, simply because an individual can achieve a large ROM, does not mean they will actively utilize that ROM during ADL. As such, a novel method for continuously monitoring long-term knee function was developed and validated using inertial measurement units (IMUs). Then, a prospective study was completed to evaluate long-term knee function before and after TKA and the results compared to a cohort of healthy individuals.

METHODS

Two distinct IMU sensors (Fig. 1) were affixed to the thigh (superior to lateral epicondyle) and shank (inferomedial to tibial tuberosity), respectively. Relative motion between the two IMUs was utilized to calculate knee flexion continuously.

This method was validated in a laboratory via comparison to optical motion capture (MOCAP) with two subjects during repeated walking trials on a treadmill at 1.5, 2.0, and 2.5 MPH.

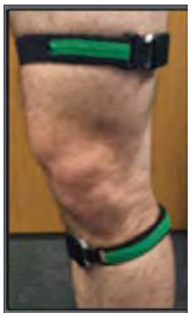

Fig 1. IMU placement for knee ROM

Following validation and IRB approval, 17 patients (10M, 65±6 years) undergoing TKA wore the sensors on the affected leg for 1-week pre-TKA, 6 weeks immediately post-TKA, and 1 week at 1 year post-TKA. Additionally, 10 control subjects (5M, 50±18 years) wore sensors on the dominant leg for 1 week. Subjects donned/doffed the IMUs upon waking/prior to sleeping each day for the duration of their required participation in the study. Daily average and maximum knee flexion were computed. Additionally, knee flexion during periods of gait was averaged across strides each day and normalized as a percentage of the gait cycle. IMU-based metrics were averaged weekly and weekly average metrics were averaged across subjects. Finally, patient reported outcome measures (PROMs) and clinical maximum ROM were captured from all subjects at all time points.

RESULTS AND DISCUSSION

Validation via comparison to optical MOCAP showed good agreement between MOCAP and IMU-based measures with average error of 1° for all both subjects at all walking speeds (Fig. 2).

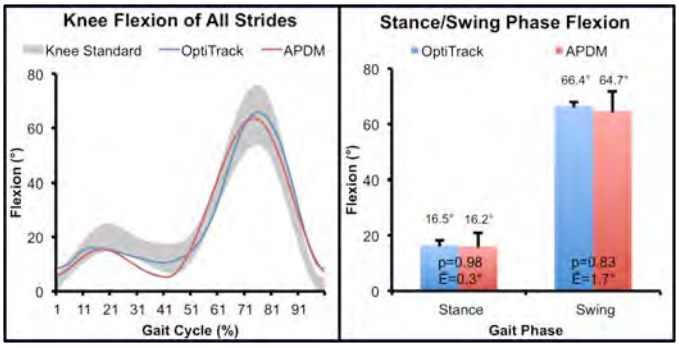

Fig 2. Validation of IMU-based ROM algorithm via comparison with optical MOCAP.

Subject demographics are contained in Table 1. Only one significant difference was noted between cohorts with respect to age ($p<0.05$). Average

flexion (Fig. 3) was increased during post-TKA weeks 2/3 and subsequently decreased thereafter. Maximum flexion (Fig. 4) was not significantly different between cohorts at any time point. When assessing flexion during stance phase (Fig. 5), patients were reduced below controls pre-TKA and during post-TKA weeks 1 and 2. However, from post-TKA week 3 onward controls and patients were indistinguishable with steady improvement for patients week after week. In contrast knee flexion during swing phase of gait (Fig. 6) was reduced for patients pre-TKA and during all six immediate post-TKA weeks. However, when analyzed at one-year post-TKA patients and controls were equal.

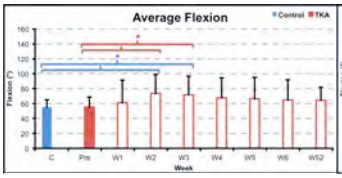

Fig 3. Average flexion

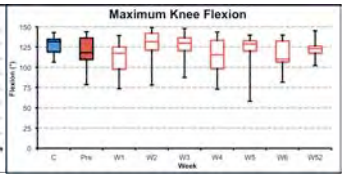

Fig 4. Maximum flexion

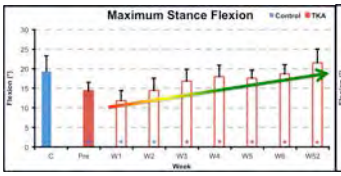

Fig 5. Maximum stance flexion

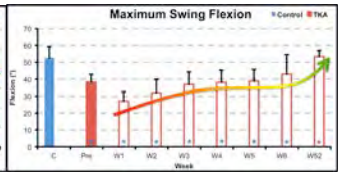

Fig 6. Maximum swing flexion

Despite many advances in orthopaedics (e.g. patient specific implants), pre- and post-operative monitoring has remained homogenous. As such, we developed and validated a novel IMU-based method for continuously (8-12 hours/day) monitoring long-duration (weeks at a time) knee ROM before and after TKA. The method was validated with average error of 1°.

In more detail, we found average flexion rose and subsequently fell and is likely not useful for assessing function following TKA. Our results with respect to maximum knee flexion are well aligned with previous work indicating pre-TKA maximum flexion is the greatest predictor of post-TKA maximum flexion. Specifically, we noted maximum flexion was not significantly different between cohorts at any time. As such, maximum knee flexion is likely not well suited for assessing knee function following TKA. Despite the limited utility of average and maximum flexion, we found significant improvements in stance and swing flexion following TKA. More specifically, given the relatively short time to recovery for stance flexion we believe this can be used to assess basic gait function. In addition, because swing flexion needed one year to fully recover we believe this metric can be used to quantify gait quality post-TKA.

CONCLUSIONS

Our method provides far more clarity on expected pre- and post-TKA knee biomechanics in real-world environments. More specifically, the method allows extension beyond well-controlled laboratory studies while maintaining the precision and accuracy afforded by those methods. Additionally, this study further elucidates what metrics are critical to monitor before and after TKA. Clinical ROM is often used as the metric to assess function, however our work highlights that knee flexion during both phases of gait are more sensitive for capturing knee function before and after surgical intervention.

INTRODUCTION

Shoulder arthroplasty (SA) is the fastest growing arthroplasty procedure in the United States (US). However, because the total volume of SA procedures is significantly less than that of total knee (TKA) and hip arthroplasty (THA), little is known about the typical recovery process after surgical intervention. Generally, clinicians utilize maximum shoulder elevation to measure recovery. Unfortunately, this metric is typically captured at discrete time points (e.g. 1-week pre-SA, 6-weeks post-SA) in controlled settings (e.g. clinic) while performing prescribed movements (e.g. passive ROM via goniometry). These idealized measures may not represent 'real-world' shoulder function during activities of daily living (ADL). Moreover, an individual that can achieve a large shoulder range of motion (ROM) may not actively utilize the entirety of such ROM during ADLs. As such, a novel method for continuously monitoring long-term shoulder function was developed and validated using inertial measurement units (IMUs). A prospective study was then undertaken to evaluate long-term shoulder function before and after total shoulder arthroplasty (TSA), before and after reverse shoulder arthroplasty (RSA), and the results compared to a cohort of healthy individuals.

METHODS

Two IMU sensors were rigidly attached to the sternum (xyphoid process) and humerus (deltoid tuberosity), respectively. Relative motion between the two IMUs was used to continuously calculate shoulder elevation. This method was validated in a laboratory via comparison to optical motion capture (MOCAP) with two subjects during repeated upper extremity movements including forward flexion, abduction, external rotation at 0° abduction, and external rotation at 90° abduction.

Following validation and IRB approval, 10 patients (7M, 70±7 years) undergoing TSA and 10 patients undergoing RSA (1M, 82±5 years) wore the sensors on the affected arm for 1 week pre-SA, 6 weeks beginning at 3 months post-SA, and 1 week at 1 year post-SA (at time of submission, all RSA patients have not returned for one year follow up and are thus omitted from analyses). Additionally, 10 control subjects (4M, 69±20 years) wore sensors on the dominant arm for 1 week. Subjects donned & doffed the IMUs upon waking & prior to sleeping each day, respectively, for the duration of their required study participation. Average and maximum shoulder elevations were computed daily. Additionally, shoulder elevation was broken in to 5° angle bins and the percentage of each day spent in each angle bin (e.g. 0-5°, 5-10°, etc.) was computed. Each IMU-based metric was averaged weekly and weekly average metrics were averaged across subjects. Finally, patient reported outcome measures (PROMs) and clinical maximum ROM were captured from all subjects at all time points.

RESULTS AND DISCUSSION

Validation via comparison to optical MOCAP showed good agreement between MOCAP and IMU-based measures (R^2=0.98) with average error of 1.4° for all aforementioned movements (Fig. 1).

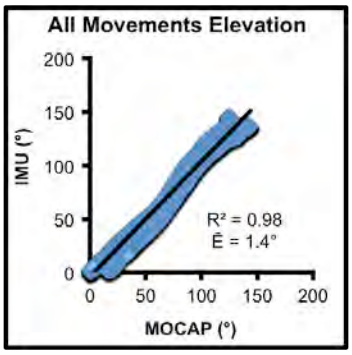

Fig 1. Validation of IMU-based ROM algorithm via comparison with optical MOCAP.

Average elevation (Fig 2) was equal between controls and TSA patients at all times. For the RSA cohort, average elevation was greater than controls at weeks 1 and 3 but was equal at all other times. Maximum elevation (Fig 3) was significantly reduced for TSA patients compared to control subjects during the preoperative week as well as week 1 but was equal thereafter. The RSA cohort showed reduced maximum elevation at all times.

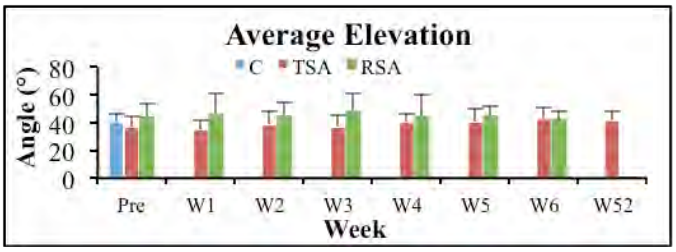

Fig 2. Average elevation

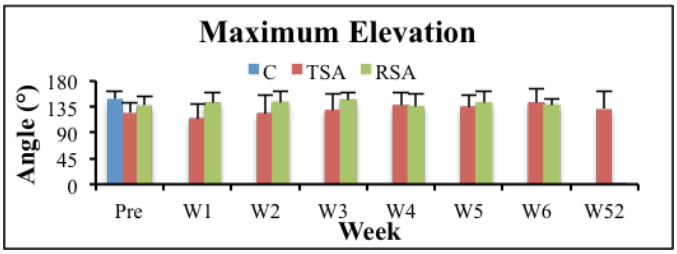

Fig 3. Maximum elevation

Binned elevation showed percentage of day spent below (Figure 4) and above 90° elevation (Figure 5) were similar between cohorts preoperatively. Following surgery, TSA patients showed a consistent decrease in the percentage of the day spent between 0-30° and a corresponding increase in the percentage of day spent between 90-180°. Interestingly, the RSA cohort showed decreasing percent of the day in 0-30° during post-RSA weeks 1-3 and corresponding increases in percent over 90° of elevation but that trend reversed in weeks 4-6.

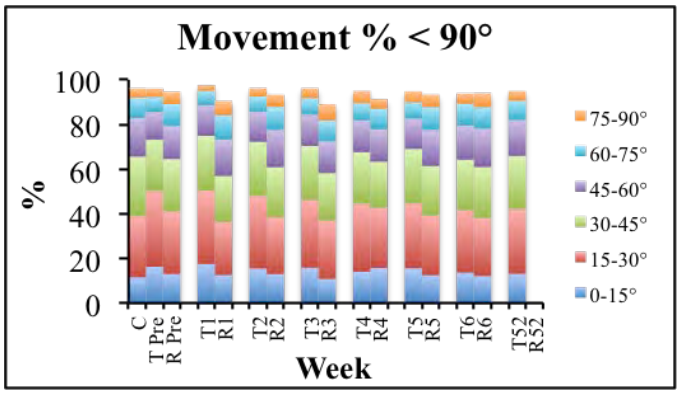

Figure 4. Movement percent < 90°

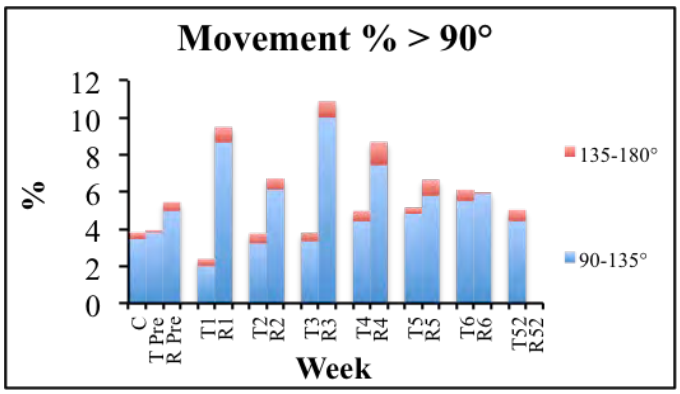

Figure 5. Movement percent > 90°

Although significant improvements have been made in orthopaedics, pre- and post-operative patient monitoring continues to lag. Accordingly, we developed a novel IMU-based method for capturing continuous (8-12 hours) long duration (weeks at a time) shoulder ROM before and after TSA and RSA, respectively. The method was validated with average error of 1.4°.

Through our prospective study, we found that patients undergoing TSA showed steady improvement with respect to movement percentage spent above 90°. In contrast, this study did not elucidate a suitable metric for assessing post-RSA function.

CONCLUSION

Our method provides more nuanced information on our expectations about shoulder function before and after shoulder arthroplasty. Our IMU-based method allows clinicians, patients, and scientists alike the opportunity to capture high-precision biomechanics information outside of the well-controlled laboratory and clinical environments.

INDIVIDUALS WITH MULTIPLE SCLEROSIS EXHIBIT MORE REGULAR CENTER OF MASS ACCELERATIONS AFTER PHYSICAL THERAPY

INTRODUCTION

Multiple sclerosis (MS) is a progressive, demyelinating disease that affects both the sensory and motor pathways, which disrupts an individual's balance and can also affect mobility [1]. There is a prevailing consensus that neurologic health is associated with a gait pattern that exhibits an optimal amount of variability and that alterations to this variability may serve as a biomarker for disease [2]. Recent investigations have displayed that individuals with MS often have uncharacteristic gait variability [3]. However, it is currently unknown if this uncharacteristic variability can be changed after undergoing a therapeutic exercise intervention and if this change is related to improved mobility.

Therefore, the purpose of this investigation was to explore the influence of a therapeutic exercise intervention upon the variability of the center of mass (COM) accelerations of individuals with MS during a walking task. Secondarily, we evaluated how changes in the spatiotemporal kinematics and walking endurance were related to the changes in COM variability after the intervention. We hypothesized that the COM variability would become more similar to that of a healthy population following the intervention and that these changes would be related to the improved spatiotemporal kinematics and walking endurance.

METHODS

Fifteen individuals (7 female; mean age: 54.8 ± 9) with relapsing-remitting or secondary progressive MS were enrolled in this study. Additionally, 15 healthy, age-matched adults (10 female; mean age: 53.5 ± 7 years) were enrolled and acted as a healthy control group for the gait variables. All experimental procedures were reviewed and approved by the UNMC Institutional Review Board. All subjects provided written informed consent before participating in the experimental procedures.

The subjects with MS completed the experimental procedures before and after the therapeutic intervention and the healthy control subjects completed all outcome measures once. All subjects completed a 6-minute walk test in a hallway ~40 m long. Accelerations of the COM were measured using a tri-axial accelerometer (Delsys Inc., Natick, MA) that was positioned over the L2 vertebra and attached to a neoprene belt. The subjects completed two self-paced walking trials where the spatiotemporal kinematics of gait were measured with a digital mat (GAITRite®, CIR Systems Inc., Sparta, NJ). The spatiotemporal kinematic variables of interest were velocity (m/s), step width (m), step length (m), and cadence (steps/minute).

The unfiltered resultant accelerometer signal was used to evaluate the changes in the gait variability. Standard deviation (SD) was used to quantify the amount of variability present in the acceleration signal. Sample entropy (SampEn) was also calculated to quantify the regularity of the time dependent changes in the resultant accelerometer time series [4]. More regular time dependent changes in the accelerometer time series will have a SampEn closer to zero, while completely irregular time dependent changes will have a SampEn that approaches infinity.

The total physical therapy intervention period was six weeks with the therapy being performed twice a day for five consecutive days each week. Each therapy session consisted of 15 minutes of strength and flexibility exercises, 15 minutes of postural balance exercises, and 15 minutes of treadmill walking.

RESULTS AND DISCUSSION

Thirteen subjects completed the entire six weeks of the therapeutic program. Before the therapeutic intervention, the accelerometer time series for the individuals with MS had a lower SD ($p=0.008$) and a higher SampEn ($p<0.001$) than the healthy control group. Hence, indicating that the individuals with MS had less overall variability and less regular time dependent changes in the accelerations than the healthy control group (Figure 1A & B). After the therapeutic program, there was an increase in SD ($p=0.008$) and decrease in SampEn ($p=0.01$) for the group with MS. These results implied that the amount of variability of the acceleration time series increased and the time dependent changes became more regular for the individuals with MS after the intervention. However, the individuals with MS still had a lower SD ($p=0.05$) and higher SampEn ($p=0.02$) post-intervention than the healthy control group.

After the therapeutic exercise program, there was an improvement in the distance walked during the 6-minute walk (Pre: 298.8 ± 23m; Post: 318.0 ± 24m; $p = 0.04$); however, the improvement did not match the healthy control subjects ($ps<0.001$). Additionally, after the intervention, the individuals with MS improved their walking velocity (Pre: 0.83 ± 0.06 m/s; Post: 0.90 ± 0.06 m/s; $p = 0.05$) and step lengths (Pre: 0.51 ± 0.02m; Post: 0.54 ± 0.02m; $p=0.03$). Even though velocity was still different between the groups post-intervention (Control: 1.17 ± 0.02 m/s; $p<0.001$), the step lengths of the subjects with MS normalized to those of the healthy individuals (Control: 0.58 ± 0.01 m; $p=0.11$).

There was a negative correlation between the percent change in SampEn and the percent change in the distance walking during the 6-minute walk test ($r=-0.64$; $p=0.02$). This indicates that the subjects who had a greater improvement in the distance walked after the therapeutic intervention also tended to exhibited a greater improvement in the regularity of the COM accelerations. There was a negative correlation between the percent change in SampEn and the percent change in the walking velocity ($r=-0.56$; $p=0.05$), indicating that subjects who exhibited greater improvements in walking speed after the therapeutic intervention also tended to have a greater improvement in the regularity of the COM accelerations.

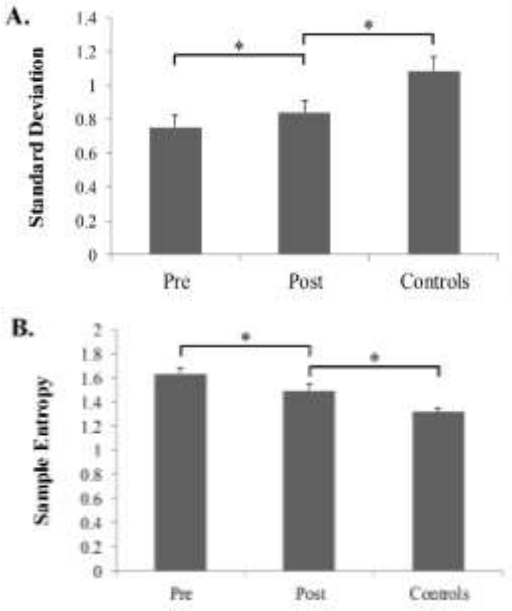

Figure 1: The SD **(A)** and SampEn **(B)** of the resultant accelerations during the 6-minute walk test before and after the therapeutic intervention and for the healthy control group.

CONCLUSIONS

Altogether, these outcomes indicate that after a six week high-frequency therapeutic exercise program, individuals with MS not only exhibited improved walking speeds, step lengths, and walking endurance but also displayed more normal amounts of COM variability and more regular COM accelerations during walking. These improvements in COM accelerations were related to the improvements in walking velocity and endurance. Altogether these results suggest that therapeutic exercise may improve the ability of individuals with MS to control their gait.

INERTIAL LOADING OF THE PEDIATRIC HEAD EXCEEDS NECK INJURY TOLERANCE PRIOR TO HEAD INJURY TOLERANCE

INTRODUCTION

Shaken Baby Syndrome (SBS) has been thought to occur as a result of inertial loading of the head resulting in retinal hemorrhaging, cerebral hemorrhaging, and encephalopathy with little or no sign of external trauma. Recent findings suggest that inertial loading alone is not sufficient to cause these symptoms and that cervical trauma will precede head injury [1,2].

The objective of the current study was to evaluate pediatric neck and head injury potential during purely inertial loading of the head. Both real-world and empirically derived data from automobile collisions provides valuable information related to pediatric injury patterns during pure inertial loading of the head, which is similar to violent shaking. Specifically, frontal collision events involving forward-facing children provide a biomechanical environment analogous to violent shaking. Thus, publicly available full-scale vehicle collision tests and laboratory sled test data from the National Highway Traffic Safety Administration (NHTSA) were analyzed.

The objective of the current study was to evaluate pediatric neck and head injury potential during purely inertial loading of the head. Given the anatomical and biomechanical properties of the pediatric cervical spine, we hypothesized that inertial loading of the pediatric head provides a greater risk of injury to the cervical spine when compared with closed-head injury.

METHODS

Each of the tests considered in the current study involved Hybrid III, 3-year-old anthropometric test devices (ATDs) seated in age-appropriate, forward-facing child restraint systems. The full-scale crash tests utilized in the current study were conducted in accordance with NHTSA's New Car Assessment Program (NCAP), an ongoing program that evaluates new automobiles for occupant safety. Specifically, the NCAP tests involve rigid frontal barrier impacts at barrier equivalent speeds of 35 mph. The laboratory sled testing utilized in the current study was conducted in accordance with FMVSS No. 213. Specifically, the tests consisted of 30 mph deceleration sled tests. 131 New Car Assessment Program (NCAP) test reports were reviewed in addition to 32 sled tests.

Head Injury Criterion 15 (HIC_{15}), and upper neck peak tension force measurements from the reviewed technical reports were documented for each of the ATDs (n=234). The collected values were then evaluated in the context of published and accepted Injury Assessment Reference Values (IARVs) for the Hybrid III, 3 year-old ATD. The IARVs for HIC_{15} and upper neck peak tension force were 570 and 1,430 N for the 3 year-old ATD. The percentage of data points that exceeded either IARV was calculated. Additionally, HIC_{15} was plotted against peak neck tension in order to investigate the presence of a correlation and to graphically depict each data point in relation to the IARVs.

RESULTS AND DISCUSSION

A total of 190 individual data points were obtained from 131 NCAP full-scale vehicle crash tests. The average HIC_{15} was 480.9 (SD = 164.9). The average upper neck peak tension force was 1933.1 N (SD = 275.3). Of these tests, 161 (96%) exceed the upper neck peak tension IARV and 37 (22%) surpassed the HIC_{15} IARV (Figure 1).

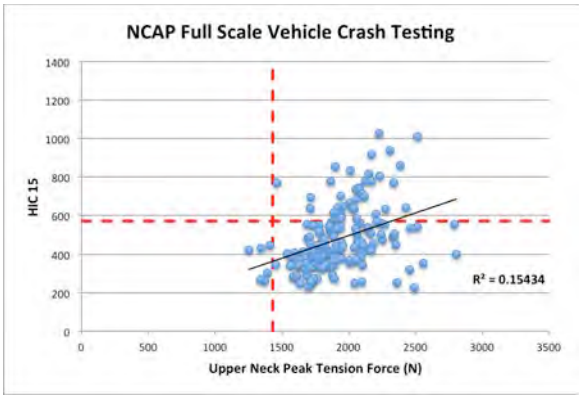

Figure 1: NCAP full-scale vehicle crash testing of the Hybrid III, 3 year-old ATD compared to head and neck IARVs.

A total of 38 separate occupant data points were obtained from 32 laboratory sled test runs. The average HIC_{15} was 306.9 (SD = 120.5). The average upper neck peak tension force was 1723.2 N (SD = 337.7). Of the 33 data points garnered from the laboratory sled testing reports, 27 (82%) exceeded the upper neck peak tension IARV while only 1 test (3%) surpassed the HIC_{15} IARV (Figure 2).

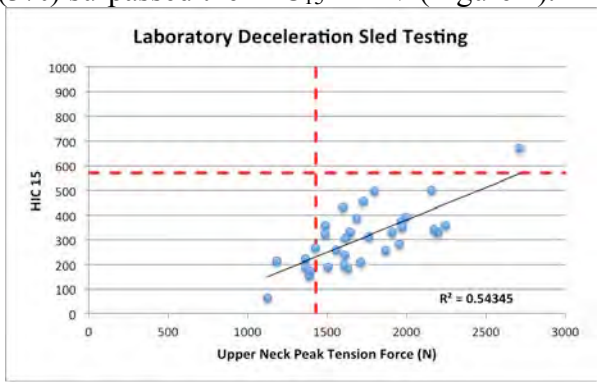

Figure 2: Laboratory deceleration sled testing of the Hybrid III, 3 year-old ATD compared to the head and neck IARVs.

The objective of this study was to investigate the injury potential associated with the pediatric neck and head during pure inertial loading. ATDs in the current study were subjected to injurious levels of neck tension, yet HIC_{15} values tended to remain below the IARV. These findings support the original hypothesis that inertial loading of the head provides a greater risk of injury to the cervical spine when compared with closed-head injury. At minimum, these data indicate a clear coupling of head and neck injury risk for the pediatric population in the absence of head impact.

In the current study, ATDs that underwent full-scale NCAP crash testing were subjected to mean peak head accelerations of 740 m/s^2 (SD = 213). Similarly, ATDs that were tested in laboratory sled tests measured average peak head accelerations of 602 m/s^2 (SD = 142.2). For comparison, previous studies involving young pediatric biofidelic surrogates have reported head accelerations associated with a shaking event to range between 90 m/s^2 and 272 m/s^2 [1,4]. Consequently, frontal collisions occurring at speeds in the range of 30 to 35 mph result in more severe inertial loading conditions to the head and neck than violent, maximum-effort shaking by an adult. Regardless of the magnitude of the inertial forces involved, the findings indicate that an infant's neck is the most vulnerable anatomical structure under these loading conditions. It is only after the ATDs surpassed injury tolerance thresholds for the cervical spine that they even began to measure injurious head accelerations.

CONCLUSIONS

The findings indicate that the pediatric neck is the most vulnerable structure under inertial loading conditions. It is only after the ATDs surpassed injury tolerance thresholds for the cervical spine that they experienced injurious head accelerations. These data support the hypothesis that inertial loading of the head provides a greater risk of injury to the cervical spine when compared with closed-head injury. The results indicate that the traditional triad of symptoms associated with infant shaking should be revised to include the presence of neck injury in cases of suspected shaking.

INTRODUCTION

Human gait can change as a function of age and disease. The onset of knee osteoarthritis (OA) is associated with muscle weakness and knee instability, and results in a decreased knee range of motion compared to healthy controls [1]. Advanced cases of OA require a total knee arthroplasty (TKA) in attempt to relieve pain and improve function; however, suboptimal outcomes are very common. Patients often report knee instability and walking abnormalities, such as reduced range of motion in the knee joint and irregular muscle co-activation [2].

While previous studies have investigated a large number of gait variables (e.g., speed, joint kinematics, torques, etc.), insight into gait changes following surgery may be complex and challenged by the number of comparisons that are necessary to compare these gait changes between different populations. Conversely, Ivanenko et al. introduced the idea that human locomotion can be represented by a footpath trajectory, which they defined as the path that the foot travels over one gait cycle with respect to the hip forms an elongated ellipse [3]. Their investigation demonstrated that this footpath trajectory changes in different walking conditions, indicating different neuromuscular control strategies. Given recent work that has suggested the importance of neuromuscular control in patient function following TKA (e.g.[4]), parameters of this footpath could characterize patient function with fewer parameters than what is generated from a more traditional motion analysis.

The purposes of this study were to determine if there are differences in the footpath ellipse during gait before and after TKA and to determine if characteristics of the footpath ellipse were related to a patient's function.

METHODS

Twenty-two subjects (7 male, 15 female, age=60.6±6.8 years, height=1.66±0.86 m, mass=92.9±16.5 kg) provided IRB approved written informed consent to participate. Each completed the Knee Injury and Osteoarthritis Outcome Score (KOOS) [5], the 6 Minute Walk (6MW) Test [6], and motion analysis at three different time periods: pre-operatively, 6-months post-surgery, and 24-months post-surgery. Markers were applied to subjects following the modified point-cluster technique [7]. Motion capture data were collected at 150 Hz using 10 Vicon MX-F40 cameras (Vicon; Oxford, UK) and filtered using a fourth-order Butterworth filter at 6 Hz. Subjects completed multiple (at least 3) walking trials at self-selected speed.

Vicon software and custom MATLAB code were used to process gait trials. Footpath trajectory was calculated by extracting the locations of the marker on the 5th metatarsal with respect to the marker on the greater trochanter and plotting the horizontal location versus vertical location throughout the gait cycle. The resulting trajectory data were normalized according to subject height and evaluated according to length (maximum toe excursion), and angle (with respect to the horizontal). The area of the ellipse was calculated with numerical trapezoidal integration (Fig 1).

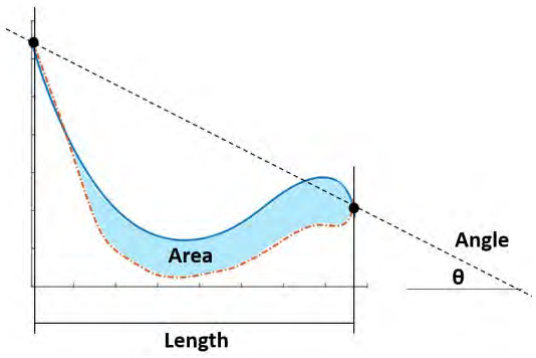

Figure 1: Representative footpath and characteristics

A repeated measures analysis variance was used to determine differences in these characteristics at the different time points, with post-hoc tests performed as appropriate. Spearman's rho was used to identify how the footpath characteristics were related to Activity of Daily Living (ADL) and Quality of Life (QOL) KOOS sub-scales. Pearson's correlations were used to relate footpath characteristics to the 6MW distances.

RESULTS AND DISCUSSION

The angle, length, and area of the footpath were different across the 3 time points ($p=0.03$, $p=0.007$, $p=0.002$, respectively). Despite non-significant post-hoc tests for all measures, average ellipse angles pre-operatively trended towards being larger (9.91±2.07°) than angles both at 6 months (7.99±1.15°) and 24 months (7.23±0.65°) after surgery. Additionally, average non-dimensional ellipse lengths at 6 months post-operatively trended towards being larger (0.42 ±0.11) than lengths before (0.36 ±0.16) and 24 months after surgery (0.41 ±0.11). Average non-dimensional ellipse areas at 6 months post-op also trended towards being larger (0.39 ±0.11) than before (0.33±0.17) and 24 months (0.38 ± 0.027) after surgery.

Changes in the 6MW test were associated with some characteristics of the footpath. 6MW distance was greater 6 months post-operatively (449.7±79.6m) than before surgery (400.4±87.7m, $p=0.001$). This distance at 24 months after surgery (467.0±75.1m) was not significantly different than at 6 months post-operation ($p=0.504$). Longer ellipse lengths and areas were significantly associated with a greater 6MW distance pre-operatively ($r=0.640$, $p=0.001$; $r=0.623$, $p=0.001$) and at 6 months after surgery ($r=0.537$, $p=0.008$; $r=0.494$, $p=0.016$). However, this relationship was not significant at 24 months post-operatively ($r=0.323$, $p=0.143$; $r=0.276$, $p=0.214$). Pre-operatively, longer ellipse length was related to a better KOOS ADL sub-scale score ($\rho=0.440$; $p=0.035$). There were no significant relationships to KOOS sub-scales in either category at 6-months and 24-months post-operatively.

CONCLUSIONS

This exploratory study suggests that the length and area of the path of the toe relative to the hip may be related to patient function before and 6 months after TKA. Future work should investigate this footpath trajectory in healthy older and younger adults and relate characteristics of the footpath to more traditional gait analysis variable to clarity its clinical utility.

EFFECTS SEMITENDINOSUS TENDON STIFFNESS ON ISOKINETIC FORCE AND TORQUE: IMPLICATIONS FOR ACL REPAIR

Zachary J Domire, Clara Amat Fernandez, Anthony S Kulas

East Carolina University, Greenville, NC, USA
email: domirez@ecu.edu

INTRODUCTION

The Semitendinosus Tendon (ST) regenerates following harvest for an ACL reconstruction. While there is evidence that the tendon physically regenerates, little is known about the quality of this regeneration. Evidence from elastography studies conducted in our lab [1] has shown that tendon stiffness is highly reduced following ACL reconstruction. Having information about the quality of the regenerated tendon is crucial as the stiffness of a tendon can have a large effect on muscle force output under dynamic situations [2]. As the hamstrings are protective of the ACL, any reductions in muscle function from this change in stiffness would potentially increase the risk for re-injury. Furthermore, changes in knee joint loading could contribute to an increased risk for the development of osteoarthritis.

The purpose of this study was to investigate the functional consequences of the change in the ST stiffness due to harvest for ACL reconstruction using a computer simulation model of an isokinetic strength test.

METHODS

Isokinetic, concentric knee flexion was simulated at 60º/sec using a custom MATLAB program (MathWorks, Natick, MA). The simulation model included the semitendinosus as a separate muscle and the other hamstrings grouped into a single muscle with respective force-length and force-velocity properties. Maximum active state was assumed throughout the entire motion. The simulation used was similar to past simulations [3]. Model parameters for the simulation are presented in Table 1. These parameters seem reasonable based upon comparison with measurements from various cadaver studies [4].

Simulations were performed with the model representing the healthy state, with a 65% decrease in ST tendon stiffness. This value is consistent with experimental findings measured using ultrasound elastography [1].

Net hamstrings moment and isolated ST force were calculated to assess functional outcomes of tendon compliance.

Table 1: Model parameters

Model parameter	Semitendinosus	Other Hamstrings
Optimal Fiber Length (cm)	17.8	17.8
Spread of the force-length curve	0.56	0.56
Maximum isometric force (N)	1100	3900
Resting tendon length (cm)	26.3	26.3
Tendon stiffness (N/m)	73333	260000
Maximum shortening velocity (optimal fiber lengths per second)	5.2	5.2
Force-velocity curvature	2.439	2.439
Pennation Angle (°)	10	15

RESULTS AND DISCUSSION

The overall effect of ST tendon stiffness on knee flexor moment was relatively modest (Figure 1). The peak knee flexor moment decreased from 140.8 Nm to 139.3 Nm. There was also a shift in the joint angle where the peak occurred from 33.8° to 26.1°.

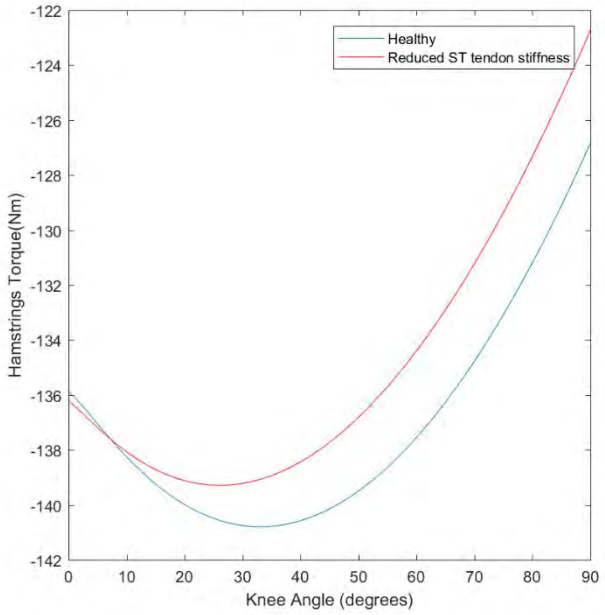

Figure 1: Net hamstrings isokinetic torque plotted vs. knee angle for healthy and reduced stiffness conditions.

The effect of reduced tendon stiffness was more apparent when looking at isolated ST muscle force (Figure 2). The reduction in peak ST force was only 12 N. However, the pattern of force production across the range of motion was highly altered. The angle of peak force shifted from 28.3° to 1.4°. Additionally, the force was significantly lower throughout most of the range of motion.

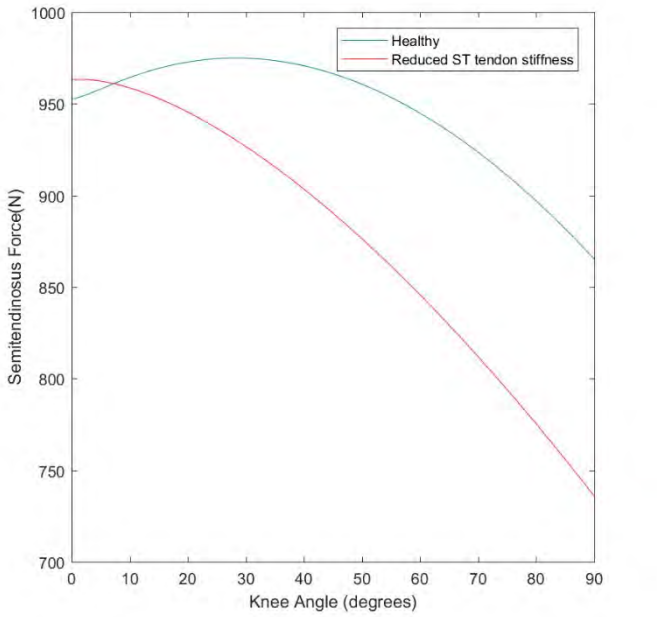

Figure 2: Net semitendinosus isokinetic force plotted vs. knee angle for healthy and reduced stiffness conditions.

CONCLUSIONS

While the change in total torque is relatively small. This would result in any deficits from reduced tendon stiffness being very difficult to measure with strength testing.

The pattern of ST force across the range of motion is highly altered. This is a result of the increased tendon stretch shifting the fiber force length relationship. While this change is likely to produce negligible effects on movement performance, the change in loading pattern could alter cartilage loading. Additional research is needed to examine the possible effects on the progression of osteoarthritis.

ANTICIPATORY NECK MUSCLE ACTIVITY IN AUTOMATIC AND MANUAL EMERGENCY BRAKING

[1] Ethan C. Douglas, [1]Valentina Graci, [1]Thomas Seacrist, [2]Jason Kerrigan, [3]Julie Mansfield, [3]John Bolte, [4]Rini Sherony, [4]Jason J. Hallman, and [1]Kristy B. Arbogast.

INTRODUCTION

Up to 80% of automobile crashes are preceded by pre-crash maneuvers such as emergency braking [1]. Braking may influence passenger kinematics and lead to less optimal positioning at the moment of impact. As the automotive field moves to more active safety technologies, the method by which braking is achieved is changing – from driver-applied manual braking to vehicle-triggered automatic braking. Previous research has investigated head and sternum kinematics and muscle activity during automated braking; however, only adult drivers were examined, and muscle activity prior to the maneuver was not reported [2]. Anticipatory cervical muscle activation has been found to alter the kinematic response of the head to impulsive loading [3], and it could decrease muscle strain and whiplash injury risk in simulated rear impacts [4]. Thus, it is important to understand how varied muscular activation strategies prior to and during braking maneuvers influence occupant kinematics. Therefore, we examined the effect of anticipatory neck muscle activity on head kinematics for pediatric and adult rear seat passengers in automatic emergency braking (AEB) and manual emergency braking (MEB) via closed-course testing.

METHODS

18 male participants age 10 – 33 (17.1 ±5.6) years old were restrained in a lap/shoulder belt in the rear right passenger seat of a modern 4-door sedan. The pre-crash maneuvers were performed at the Transportation Research Center Inc. (East Liberty, Ohio) by a professional driver. For MEB an average deceleration of ~1 g was achieved by the driver pressing the brake pedal with maximum effort while the vehicle was moving at 50 km/h with cruise control. The AEB was triggered by the vehicle radar detecting a 3D Soft Car (Dynamic Research, Inc.) while travelling at 50 km/h with cruise control, achieving an average deceleration of ~0.8g. Vehicle dynamics were collected with an Inertial and GPS Navigation system (Oxford RT 3003, 200Hz Oxford Technical Solutions Ltd.), kinematics were collected with an eight-camera 3D motion capture system (Optitrack 200Hz, NaturalPoint, Inc.), and muscle activity was collected with surface electromyography (EMG) sensors (2000 Hz Delsys, Inc.). Photo reflective markers were placed on the participant's head and sternum, while EMG sensors were placed bilaterally on the participant's sternocleidomastoid. Participants were instructed to initially sit relaxed with their hands on their lap as a starting position, and then to react naturally during the maneuver. Muscle activity was normalized to a 5 second static trial in which participants were instructed to sit in the vehicle with their initial position as described above. Pre-maneuver muscle activity and during-maneuver activity are defined for AEB in the below graph (Fig. 1). The EMG activity for the MEB maneuver was quantified in the same way.

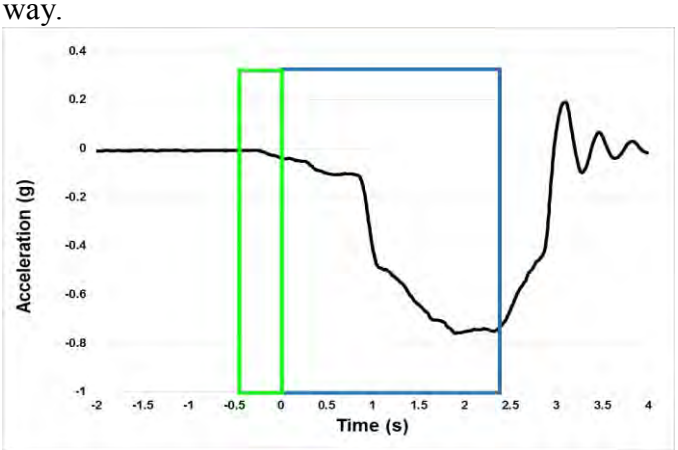

Figure 1: Graph of vehicle acceleration (g) over time for the AEB maneuver. Pre-maneuver EMG activity was collected for 0.5 seconds before the onset of the maneuver (green box), while during-maneuver EMG

activity was collected from onset of the maneuver until the end of steady-state braking (blue box).

A repeated measure 2-way ANOVA was performed to understand the differences in pre and during maneuver muscle activities between AEB and MEB. Tukey's post hoc test was performed to analyze significant main effects. Product-moment correlation tests were performed to understand the relationship between occupant age and muscle activity pre- and during-maneuvers, and, the relationship between head kinematics and pre-maneuver muscle activity in both AEB and MEB.

RESULTS AND DISCUSSION

Paired t-tests found no significant differences between right and left sternocleidomastoid, therefore the average of the two sides is presented. A significant main effect was found between pre-maneuver and during-maneuver muscle activity. In AEB, sternocleidomastoid muscle activity during the maneuver (1.97 ±1.78) was significantly greater than pre-maneuver muscle activity (p=0.048, 1.48 ± 1.07). In AEB, pre-maneuver sternocleidomastoid muscle activity had a moderate negative correlation with head excursion (r = -0.67, p=0.001, Fig. 2).

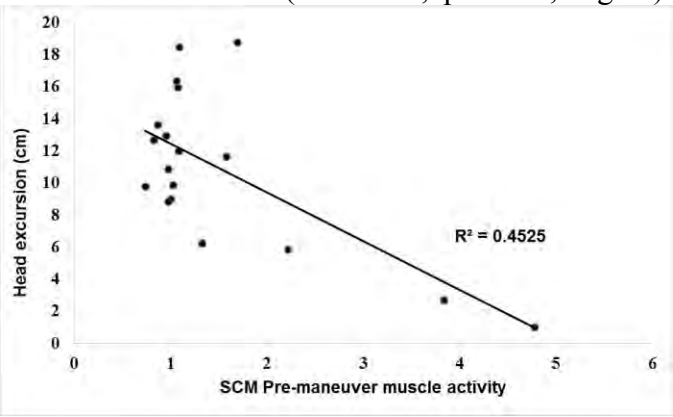

Figure 2: Scatterplot of head excursion (cm) versus sternocleidomastoid (SCM) pre-maneuver muscle activity during automatic emergency braking (AEB).

For MEB, during-maneuver sternocleidomastoid muscle activity (11.34 ±19.92) was significantly greater than pre-maneuver activity (p=0.022, 1.43 ±0.97), but there were no significant correlations between sternocleidomastoid muscle activity and head excursion. Age had no effect on muscle activity in both MEB (p=0.650) and AEB (p=0.440). Lastly, there were no significant differences between AEB and MEB in the pre-maneuver activity (p=0.719), while MEB during-maneuver activity was significantly greater than AEB during-maneuver activity (p=0.046)

During-maneuver muscle activity was greater than pre-maneuver activity for both MEB and AEB, indicating increased muscle activation to resist the forward acceleration. However, despite no significant differences in pre-maneuver muscle activity between AEB and MEB, greater anticipatory muscle activity in AEB was related to reduced head excursion, while no such relationship was found for MEB. Participants experienced a lower acceleration and a longer time to maximum acceleration during the AEB maneuver than the MEB maneuver, and thus their sternocleidomastoid muscles may have been better able to resist the forward motion of the head. Safety countermeasures such as auditory warning systems have been found to increase muscle activity before an impact and reduce important kinematic variables such as head excursion and head acceleration [4]. Given that pre-maneuver muscle activity correlated with reduced head excursion in AEB, these countermeasures could potentially be useful in optimizing occupant position during pre-crash maneuvers such as automatic emergency braking.

CONCLUSION

For AEB test conditions, pre-maneuver anticipatory muscle activation in the sternocleidomastoid muscles was associated with greater muscle activation during the maneuver and reduced head excursion. Similar observations were not seen in MEB test conditions. Active safety technology could alert participants to impending maneuvers, reducing the amount the occupant is out of position prior to an impact. Future work should investigate the effect of anticipatory muscle response on kinematics in a variety of pre-crash maneuvers, and examine other muscle groups that control occupant kinematics.

INTRODUCTION

Arthroscopic hip preservation is one of the fast-growing fields in orthopaedic surgery. One of its frequent applications is the treatment of symptomatic femoral acetabular impingement (FAI). To gain access to the joint to visualize the morphology and perform joint preserving procedures, a capsulotomy must be performed. Two of the most commonly used approaches are interportal capsulotomy and T-capsulotomy. Interportal capsulotomy allows good viewing of the central compartment, including the labrum, acetabular rim, and articular cartilage. T-capsulotomy, with additional incision perpendicular to the interportal capsulotomy, allows the viewing of the peripheral compartment such as the proximal femoral head-neck junction. The necessity of capsular repair after arthroscopic procedure has been debated. The decision to leave the capsulotomy open, or perform a complete or partial repair, is typically made depending on factors such as patient age, BMI, gender, and degree of chondral damage [1].

Quantitative studies into biomechanical effects of capsulotomy are limited. Wuers et al. compared the joint stability after 4-cm vs. 6-cm interportal capsulotomy and found increased motions with the larger sized procedure, but repair effectively restore the joint motion to the intact level [2]. The purpose of this study was to determine the biomechanical impacts of two common capsulotomy procedures on the stability of the hip joint during external rotation, and to evaluate the effects of partial and full capsular closures on the restoration of hip joint stability.

METHODS

Eight fresh-frozen cadaveric specimens of hemi-pelvis with proximal femur attached were procured from musculoskeletally normal donors (mean age 59.4 yrs). Mechanical tests were conducted on an axial-torsion servo hydraulic testing system (MTS Landmark 370, Eden Prairie, MN). The pelvis was secured at the iliac wings using bolts and dental cement and mounted onto the MTS base with ASIS and the pubic symphysis were aligned in the same frontal plane for an upright alignment. The end of the proximal femur was bolted to a pair of angle plates and mounted to the MTS actuator in neutral position. Torque in the external rotation direction was applied under load-control with maximum torque limited to 5Nm for the intact capsular condition and 3Nm for the operated conditions. Five cycles at a rate of 2deg/sec for loading and 5deg/sec for unloading were completed in each trial, with the last cycle used for data analysis and the first four cycles for pre-conditioning. Two marker triads from a motion analysis system (Optotrak Certus, NDI, Waterloo, Canada) were fixed on the proximal femur and the superior pubic ramus to track the relative hip joint motion while the torsional load was applied (Fig.1). Two additional markers were attached to the MTS actuator to synchronize data from the MTS and motion analysis systems. Data from both systems were sampled at the rate of 100Hz.

Each specimen was sequentially tested in five capsular conditions: 1) intact, 2) 4-cm interportal capsulotomy, 3) T-capsulotomy, 4) partial repair (3-stitch suture closure of T-branch), 5) full repair (additional 4-stitich suture closure of interportal cut). All repairs were made with FiberWire#2 sutures (Arthrex, Naples FL). For each specimen, data from four capsule-operated conditions were normalized with respect to their intact condition. Three outcome variables were compared: 1) range of motion (ROM) of the hip joint at 3Nm, 2) neutral zone motion (NZ), a metric for joint laxity determined by amount of motion prior to rapid stiffening point on the load-displacement plot, and 3) structural stiffness and

structural stiffness obtained from the linear region of the MTS load-displacement plot for each condition. Analysis of variance (ANOVA) was performed on the normalized data with post-hoc comparisons using Dunnett's method. All tests were completed using statistical software JMP (v.13, SAS Institute, Cary NC), with level of significance set at 0.05.

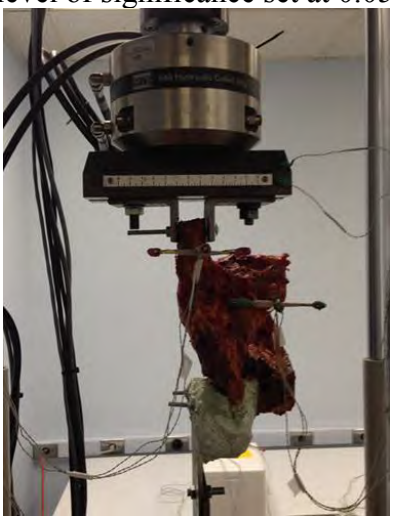

Figure 1: Experimental setup of a hemipelvis.

RESULTS

The mean ROM at 3Nm external rotation torque was 15.0±4.2 degrees for the intact capsular. The mean normalized increase over the intact was 134±20% and 149±25% for interportal and T-capsulotomy respectively, and 145±23% and 138±22% for partial and full repairs respectively (Fig.2). There were no statistically significant differences between any of the four operated groups, while mean ROMs of all four operated groups presented were significantly higher than the intact group ($p<0.006$).

The mean NZ result was 6.8±3.9 degrees for the intact group. The mean normalized NZ increase over the specimen's intact stage was 162±26% and 186±31% for interportal and T-capsulotomy respectively, and 179±30% and 151±32% for partial and full repairs respectively (Fig.3). Comparisons of the means found that the increases in the interportal capsulotomy stage and full repair stage did not reach the level of statistical significance ($p=0.18$ and $p=0.12$ respectively), while mean increases for T-capsulotomy and partial repair were ($p=0.02$) over the intact stage.

The mean stiffness obtained from the MTS load-displacement plot were similar among the five capsular conditions. The differences of the four operated stages were within 6% of the intact stage without reaching statistical significance.

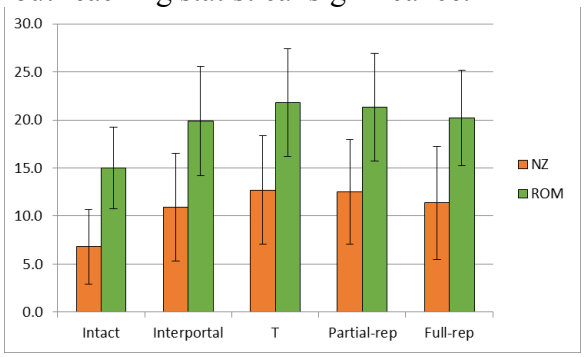

Figure 2: Mean (sd) NZ and ROM (unit:degree)

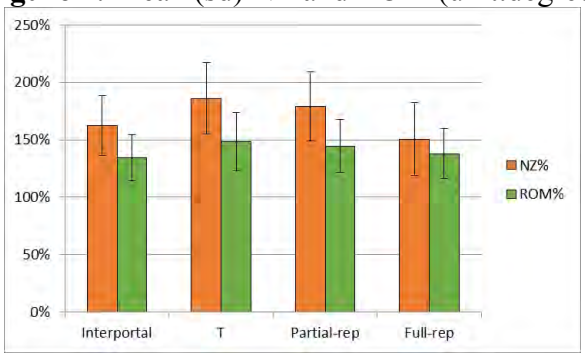

Figure 3: Mean (sd) normalized NZ and ROM

DISCUSSION

Results from this study show that capsulotomy affects joint laxity, as measured by NZ, the most, and only full repair of the capsule can restore it close to intact level. Once the hip as loaded beyond the laxity zone, the joint with all capsular altered conditions responded similarly to the intact joint under external rotation loading, as demonstrated by insignificant changes (<6%) in construct stiffness among all tested conditions.

Limitation of the study includes the sequential testing protocol designed to optimize the use of cadaver specimens. The true effect of the repair of interportal capsulotomy was hampered by the creation of T-capsulotomy.

An Upper-Extremity Function Dual-task to Identify Cognitive Status of Older Adults

INTRODUCTION

The need to coordinate concurrent motor and cognitive tasks (e.g., "dual tasks") occurs constantly in our daily life. Dual tasks place demands on attentional resources, and reflect increasing cognitive challenge for older adults and those with cognitive impairment. Understandably, performing dual-task actions is accompanied with a decline in performance when compared to single task performance (e.g., dual task "cost"). As this decline becomes more evident with increasing age, and with cognitive decline, researchers have tried to find meaningful associations between the state of cognition in older adults and how it is reflected in their dual-task performance.

Our objective, in this study, was to develop a novel dual-task cognitive function test incorporating a validated upper-extremity function (UEF) motor test [1], which was simultaneously performed with counting backwards as a cognitive challenge. Unlike gait, UEF is an uncommon motor activity and during its performance possible skill learning may evolve. Further, counting backward was selected, since it involved working memory and its rhythmic structure would interfere with repetitive elbow flexion.

METHODS

Older adults (≥65 years of age) were recruited and stratified into three clinically confirmed groups: 1) cognitively healthy (CH), 2) mild amnestic cognitive impairment (MCI, presumed due to Alzheimer's disease), and 3) early dementia due to Alzheimer's disease (AD) according to National Institute of Aging – Alzheimer's Association (NIA-AA) criteria. According to our previously validated UEF method [1], wearable motion sensors (tri-axial gyroscope sensors, sample frequency = 100 Hz, BioSensics LLC, Cambridge, MA) were employed to measure forearm and upper-arm motion, and ultimately the relative elbow angular velocity. Participants completed four trials of dual-task UEF: NDT1: Normal-paced elbow flexion while counting backwards by one; NDT2: Normal-paced elbow flexion while counting backwards by three; FDT1: Fast-paced elbow flexion while counting backwards by one; and, FDT2: Fast-paced elbow flexion while counting backwards by three. Normal-paced and fast-paced trials were performed for 60s and 20s, respectively. In addition to the number of flexions, using the coefficient of variation, we computed the variability of the following UEF parameters for each trial: 1) speed (elbow angular velocity range that is the maximum minus minimum speed); 2) range of motion (elbow flexion range); 3) rise time (the required time to reach the maximum angular velocity), 4) semi-period (time distance between two consecutive maximum angular velocity).

Separate multivariable ANOVA models were used to assess differences in UEF parameters between the three groups. Age, body mass index (BMI), and gender were considered as covariates in these analyses. In case a significant difference was observed among the groups, we performed multiple comparisons correcting for family-wise error rates using Tukey's test.

Using the same procedure explained previously [2], within each dual-task condition a logistic regression model was developed to predict cognitive status via the selected demographic and UEF parameters. For all models, area under curve (AUC) was estimated using receiver operator characteristic (ROC) curves. All analyses were done using JMP (Version 11, SAS Institute Inc., Cary, NC, USA), and statistical significance was concluded when $p < 0.05$.

RESULTS AND DISCUSSION

A total of 30 participants were recruited, 10 in each group (CH: age=86.3±2.9, MCI: age=87.2±3.0, and AD: age=86.5±5.3; 40% male in each group).

Results from ANOVA models for UEF dual-tasks demonstrated that in all trials the number of flexion, semi-period and rise time variability were significantly different among the groups (Table 1). Also, range of motion (ROM) variability was significantly different between the groups within both normal-paced trials. Speed variability was non-significant among the groups in all trials except NDT1.

Multiple comparisons within NDT1 trial showed that all parameters could differentiate between CH and AD groups (Table 1). However, not all UEF parameters were different between MCI and AD or CH and MCI. Results suggest that rise time and semi-period variability differed more noticeably between MCI and AD groups. On the other hand, the number of flexions, especially within the FDT2 was the only parameter that was different between CH and MCI individuals.

Based on the ANOVA results and the procedure explained in [2], number of flexions, ROM, semi-period and rise time variability were chosen as the independent variables of the logistic models. Also, we incorporated sex, age, and BMI in these models. Using these models, MCI and AD group assignment was predicted. The receiver operating characteristic area under curve of these predictions were shown in Fig. 1.

While the performance of all logistic models are satisfactory, slight differences between the trials can be observed. Within fast-paced dual task trials, counting backwards by three led to a superior dual-task function compared to counting backwards by one. Also, all models showed better performance to identify AD compared to MCI group. As expected, similar trends were observed in the ANOVA results (Table 1).

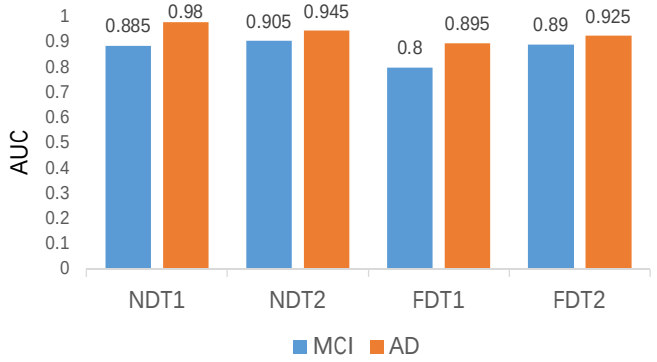

Figure 1: Area under curve (AUC) in predicting MCI and AD group assignment

CONCLUSIONS

Accurate, objective, and rapid cognition screening strategies are needed for use in research and clinical settings. Although several previous studies have reported associations between dual-task gait and cognitive assessment, we propose a new gait-free method that can be implemented more easily in clinical settings, especially for older adults with mobility problems. The reported method has high screening potential, and could be likewise employed to measure change over time. Our preliminary findings should be further explored in a larger clinical study.

MUSCLE AND JOINT CONTACT FORCES WHILE ROWING ON AN ADAPTED ERGOMETER

[1] Ying Fang and [1] Karen L. Troy

[1] Worcester Polytechnic Institute, Worcester, MA, USA
Email: yfang3@wpi.edu

INTRODUCTION

Individuals with spinal cord injury (SCI) experience rapid and profound bone loss in the legs, which is partly attributed to mechanical disuse [1]. Functional electrical stimulation (FES) on an adapted ergometer is used by SCI population to improve musculoskeletal health. During the activity, knee extensors and flexors are stimulated to help SCI rowers to accomplish a smooth rowing movement [2]. Muscle contraction and reaction force at the foot initiate joint loading, which potentially prevents bone loss. Adaptations made to the ergometer constrain rower's trunk movement and knee range of motion (ROM), which affect rowing biomechanics in a manner that hasn't been well established. Quantifying joint loading in FES rowing is a key step to making it more effective for the prevention of bone loss. As a first step, we developed a rowing musculoskeletal model based on able-bodied rowers, and calculated joint contact and muscle forces during able-bodied rowing on an adapted ergometer. We also examined factors that affect knee loading.

METHODS

10 male and 10 female able-bodied subjects with no rowing experience participated in this study (age: 26.5±3.8, height: 1.7±0.1 m, mass: 70.0±14.8 kg). They rowed on an adapted ergometer (Concept2, model D. Morrisville, VT) at 40 strokes per minute, with a knee ROM from 45° to 135°. Kinematics were collected using a motion capture system (100 Hz; Vicon Motion Analysis Inc., UK), and the force under the right foot was collected using a six-axis force sensor (1000 Hz; MC3A-1000lb, AMTI, Watertown, MA). Data were used as the basis for calculating muscle force versus time curves using OPENSIM (3.3, SimTK, Standford, CA).

To accomplish this, a generic lower body rowing model (**Figure 1**) was developed by constraining the subtalar joint and metatarsophalangeal joint, increasing the range of knee, hip, and ankle angles, and adjusting the path of the knee muscles in an existing model [3]. The generic model was then scaled by weight, and by the marker positions of each subject to generate subject-specific models (total error: 1.5±0.6%, RMS error: 2.9±0.9%). Marker trajectories were applied to the model to replicate the kinematics, and measured foot force was added to the right foot. We assumed that subjects generated symmetrical forces at their feet, therefore measured foot force was also applied to the left foot. The force beyond the hip joint (seat force, hand pulling force) was applied at the pelvis as a reaction force. We ran the residual reduction algorithm (RRA) considering pelvis force and foot force at both feet, to get updated kinematics and model. The maximum residual forces and moments were acceptable (Fx: -11.6±7.2 N, Fy: 8.2±12.3 N, Fz: 7.0±15.2 N, Mx, My, Mz: <1 Nm). Muscle forces were calculated by static optimization.

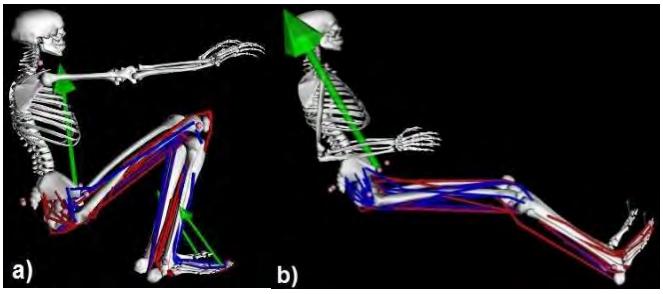

Figure 1: Musculoskeletal model of an able-bodied rower at the start (a) and end (b) of a rowing cycle. Green arrows indicate external forces applied at both feet and at the pelvis.

Summed forces were calculated for hip extensors and flexors, knee extensors and flexors, and ankle plantarflexors and dorsiflexors. Mean foot reaction force during the driving phase and resultant joint contact forces (JCF) were calculated. Peak forces were calculated on the mean of 4 rowing cycles for all variables. Joint contribution (%) was calculated by dividing the joint extensor muscle force by the total of hip, knee, and ankle extensor muscle forces.

We observed two patterns in the foot reaction force curves (**Figure 2**). Subjects were categorized based on the presence (pattern 1) or absence (pattern 2) of a second peak during the drive phase. All variables was compared between the two patterns using

independent t-tests. Correlation between knee JCF and other variables was tested for all subjects (IBM SPSS Statistics 22, Chicago, IL).

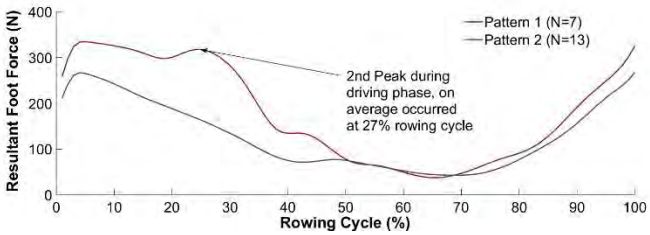

Figure 2: Average foot force curves showing two patterns. Both had a peak at the very beginning of the drive, but pattern 1 also showed a 2nd peak.

RESULTS AND DISCUSSION

Rowers with pattern 1 (N=7) generated significantly higher mean foot force during the driving phase than rowers with pattern 2 (N=13). Joint contact and muscle forces were significantly higher in rowers with pattern 1, except for knee muscle forces (**Table 1**). Knee JCF was positively correlated with mean foot force during driving phase, and was negatively correlated with ankle joint contribution (**Figure 3**).

Table 1: External foot force, joint contact force (JCF), summed muscle force, and joint contribution of subjects with two patterns (mean ± standard deviation). *p<0.05, and **p<0.01.

	Pattern 1	Pattern 2
Peak Foot Force (N/kg)	3.9±1.0	4.2±0.7
Mean Foot Force (N/kg)	3.3±0.4	2.6±0.4**
Hip JCF (N)	3755±1172	2392±876**
Knee JCF (N)	3429±706	1994±851**
Ankle JCF (N)	2408±255	1622±410**
Hip Extensor (N)	2839±868	1917±635*
Hip Flexor (N)	1784±583	973±431**
Knee Extensor (N)	2546±956	1741±861
Knee Flexor (N)	1883±694	1366±574
Ankle Plantarflexor (N)	1717±309	1433±353
Ankle Dorsiflexor (N)	1294±367	547±345**
Hip Contribution (%)	39.8±8.0	37.5±4.9
Knee Contribution (%)	35.4±9.5	33.6±5.8
Ankle Contribution (%)	24.8±5.6	28.8±2.9**

It's not surprising that both groups have similar knee muscle forces, since the knee is the main power generator during rowing. We found that the more one relies on the ankle joint, the lower the knee loading. And, people with pattern 2 had significantly higher ankle contribution, which led to lower knee and hip contributions. They also had lower ankle muscle force, indicating the higher ankle contribution may be the result of weaker or less active proximal joints. People who were able to engage relatively more proximal muscles generated higher mean force at the foot, and also had higher knee loading (**Figure 4**).

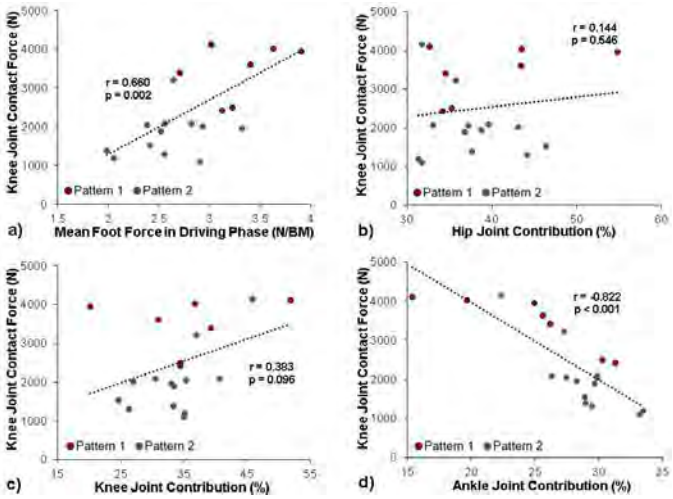

Figure 3: Correlation between knee contact force and mean foot force, and between knee contact force and joint contributions.

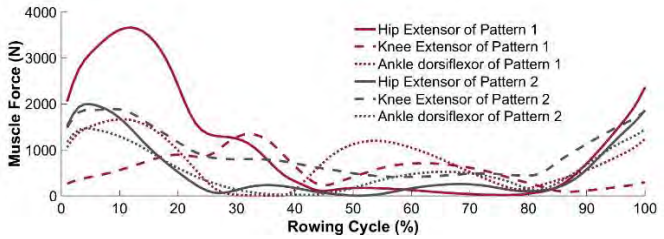

Figure 4: Joint extensor muscle force curves of two subjects with two pattern. Hip extensor muscle was much higher in rower with pattern 1 than pattern 2.

CONCLUSIONS

Knee contact force was affected by external foot reaction force and joint contribution. Relying more on hip and knee joints, and less on the ankles, may increase knee loading. For SCI rowers, stimulating hip extensors muscles during rowing may potentially benefit to bone health.

How Does Ergometer Setup and Rowing Speed Affect Biomechanics during Rowing on an Adapted Ergometer Designed for People with Spinal Cord Injury

[1] Ying Fang and [1] Karen L. Troy

[1] Worcester Polytechnic Institute, Worcester, MA, USA
Email: yfang3@wpi.edu

INTRODUCTION

Functional electrical stimulation assisted rowing (FES-rowing) is used in spinal cord injury (SCI) rehabilitation to improve musculoskeletal and cardiovascular health [1]. A primary goal is to mechanically load the bones in the legs as a means of preventing disuse osteoporosis. In FES-rowing, a normal rowing ergometer is adapted to ensure the safety of SCI users. Specifically, two stoppers are added on the seat rail to limit the seat movement, which prevents knee hyperextension; a seat backrest is added and the user wears a seatbelt with shoulder straps for stabilization; and a knee stabilizer is placed between the legs during rowing to prevent knees from separating apart (**Figure 1a**).

The amount of force that is delivered to bone is a major determinant of whether a given exercise is beneficial or harmful. Recent data show that SCI rowers generate only 20% of the foot force produced during able-bodied (AB) rowing [2,3]. The low loads (0.22–0.25 body weight (BW)) may be attributed to less muscle engagement by SCI users, and/or to the altered rowing mechanics, which can be affected by different setup on the adapted ergometer. If an optimized setup exists to passively maximize loading, SCI rowers could benefit from it. Therefore, our **purpose** was to investigate the effect of rowing speed, knee range of motion (ROM), and seat position on lower extremity loading when AB users row on an adapted ergometer.

METHODS

Ten male and ten female subjects with no rowing experience participated in this study (age: 26.5±3.8, height: 1.7±0.1 m, mass: 70.0±14.8 kg). Upon arrival to the lab, subjects practiced rowing on the adapted ergometer after receiving instructions on basic technique. A researcher set the stopper location based on subject's knee angle. The front stopper was adjusted such that the angle was 45°, 70°, or 95°; and the rear stopper was adjusted such that the angle was 115°, 135°, 140°, or 165°. In this way, knee ROM and seat position could be independently adjusted. Each subject rowed for 90 to 120 seconds at each of the 12 conditions, which included 3 speeds (25, 35, and 40 strokes per minute (SPM)), 3 knee ROM (70°, 90°, and 120°), and 3 seat positions (forward, middle, and rear) (Table 1). Data were collected for 30 s starting at 30 s into the bout of rowing.

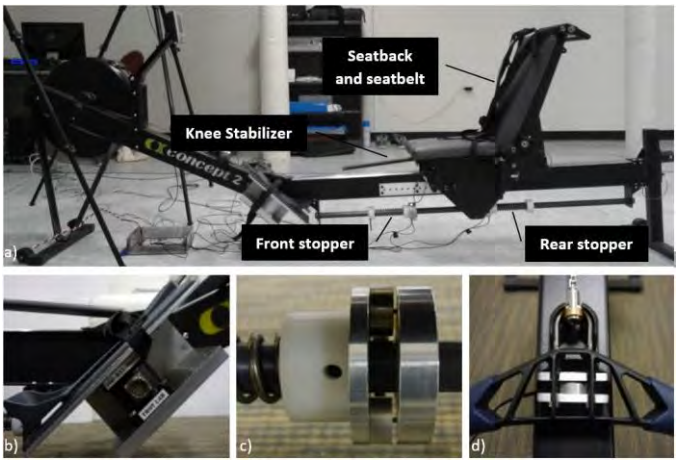

Figure 1: Instrumentation and experimental setup with a) adapted rowing ergometer, b) six-axis force sensor, c) two single load cells on the stopper, and d) one single load cell on the handle.

An adapted rowing ergometer (Concept2, model D. Morrisville, VT) was used for the rowing test (Figure 1a). A ten-camera motion capture system (100 Hz; Vicon Motion Analysis Inc., UK) was used to collect kinematics data. A six-axis force sensor (1000 Hz; MC3A-1000lb, AMTI, Watertown, MA) was mounted under the right foot stretcher of the ergometer (**Figure 1b**). Single-axis load cells (Phidgets Inc., Alberta, Canada) were mounted at the stoppers (**Figure 1c**) and the handle (**Figure 1d**) to measure the hand pulling force and the impact force between the seat and stoppers.

The raw kinematics and force data were filtered using a low-pass 4th order Butterworth filter with zero lag at a cutoff frequency of 1 Hz. Joint angles, moments, and forces were calculated based on ISB recommendations and a recursive Newton-Euler

approach [4,5]. Peak forces and moments were calculated by averaging the peaks of at least five rowing cycles, which began at the start of pulling. All analyses were done using customized code in Matlab (MathWorks, Natick, MA). Three repeated measures analyses of variance were used to examine the each of the three factors (speed, ROM, position). If a main effect was significant, post hoc analysis was performed using pairwise t-tests with Bonferroni adjustments. An alpha level of 0.05 was set as a priori (IBS SPSS Statistics 22, Chicago, IL).

RESULTS AND DISCUSSION

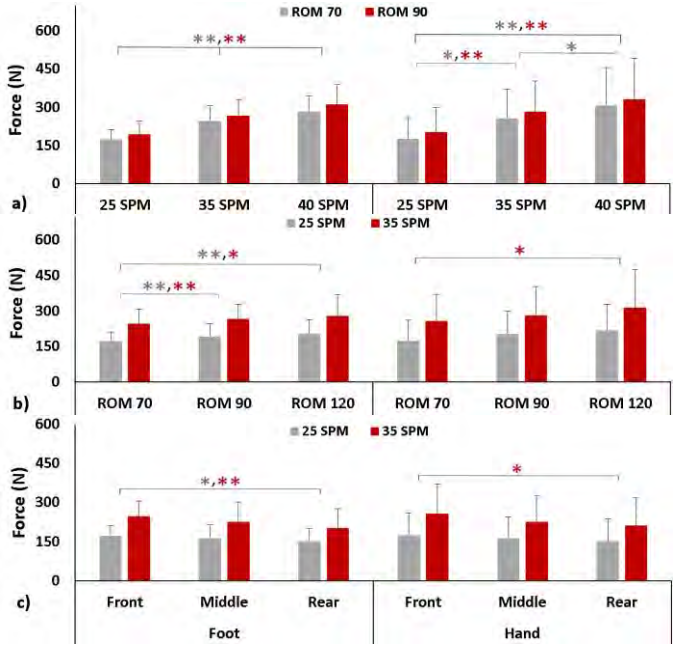

Figure 2: Resultant foot reaction forces and hand forces at different a) rowing speed, b) knee ROM, and 3) seat position. *p<0.05, and **p<0.01.

There was no sex effect in any variable. Peak foot reaction force reached 0.45 BW, and rowing setup could change loading by 0.23 BW. Rowing at higher speeds generated significantly larger foot force, hand force, and peak extension moments at the hip, knee, and ankle. Rowing with larger knee ROM led to significantly larger foot force, and peak extension moments at the knee and hip. Rowing with a forward seat position caused significantly larger foot force, and peak extension moment at ankle and knee (**Table 1**, **Figure 2**).

We observed two patterns in the foot force versus time curve among all subjects. One pattern showed continuously large force throughout the first 30% of the cycle (n=7), while another showed a peak at the beginning of the rowing cycle (n=13) (**Figure 3**). Further analyses indicated that the use of hip extensor muscles may contribute to lasting force generation at the foot (pattern 1).

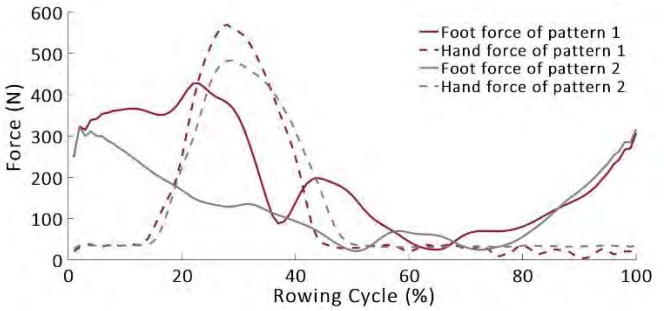

Figure 3: Resultant foot force and hand force curves of two subjects, who showed different patterns in the foot force curve.

CONCLUSIONS

Ergometer setup has a large effect on lower extremity loading. However, even with the optimal setting, foot force was 50% less than rowing on non-adapted ergometers [6]. The added seat back and seatbelt constrained trunk extension, which may be the factor that limits foot force production. This knowledge can be transferred to the SCI population to further improve the FES-rowing program.

THE EFFECT OF TRANSITIONING FROM A REARFOOT STRIKE TO A NON-REARFOOT STRIKE ON RUNNING IMPULSES PER STEP

Gregory Freisinger, Nathaniel Schlosser, Daniel Watson, Erin Miller, Donald Goss

United States Military Academy, West Point, NY, USA
Email: Gregory.freisinger@usma.edu; Web: http://www.usma.edu/cme/

INTRODUCTION

Over 19 million people consistently run as a form of exercise in the United States alone. Annually, approximately 50% of these runners will experience an injury detrimental to performance [1]. A recent approach to mitigating running injuries is modification of a runner's foot strike pattern (FSP).

Transitioning runners from a rearfoot strike (RFS) to a non-rearfoot strike (NRFS) pattern has been shown to influence several factors related to running injuries, to include a reduction in average vertical loading rate (AVLR) [2]. This idea is well established, but there are likely other factors influencing running related injuries, such as running cadence and different impulses during each stance phase.

The purpose of this study was to analyze the effect of a transitional NRFS running program on the magnitude of impulse per step. We hypothesized that impulse per step will decrease in the vertical, anterior, and posterior directions following the running program due to increased cadence. We hypothesized that medial and lateral impulses will remain unchanged after the treatment protocol.

METHODS

Twenty-seven runners recovering from lower extremity injuries at the United States Military Academy were recruited to participate in this study after providing IRB approved consent. All participants had previous running experience (14 males, 13 females; mean age: 25.3 ± 9.9 yrs; mean height: 172.1 ± 10.3 cm; mean weight 73.0 ± 12.0 kg).

Participants met each of the following six inclusion criteria: 1) previously a RFS runner; 2) recovering from a lower extremity injury; 3) able to walk pain free for 2 miles; 4) dorsiflexion range of motion of at least 80% symmetry; 5) capable of performing 20 unassisted single leg heel raises; 6) able to perform a single leg hop for distance with at least 80% symmetry. The participants were clinically diagnosed and recovering from lower extremity injuries including, but not limited to: patellofemoral pain syndrome, lower leg stress injury, lower leg fracture, plantar fasciitis, and anterior cruciate ligament reconstruction.

The running transition program began with a private 30 minute training session to initiate transition from a RFS to a NRFS running pattern. Training focused on soft landing off of the heel, a cadence of approximately 180 steps/minute, forward trunk lean, and strict adherence to a gradual walk to run progression. Participants met with their study assigned medical provider once a week post-training for the first 4 weeks, then again at weeks 6, 8, and 10 during which the training focuses were reinforced.

Initial and 10 week assessments were conducted before and after the 10-week training program. Assessments consisted of subjects running on an instrumented treadmill at a self-selected pace for five minutes. Speed was kept constant for both evaluations. Two-dimensional video was collected at 240 Hz [Casio, EX-ZR200; Tokyo, Japan] in the sagittal plane to confirm FSP. Ground reaction force data was collected via the instrumented treadmill [Bertec; Columbus, OH] at 1000 Hz, low-pass Butterworth filtered at 35 Hz, and normalized to bodyweight.

Impulse was then calculated in vertical, anterior, posterior, medial, and lateral directions based on ground reaction forces for five stance phases on each foot. The ensemble averages of left and right impulse values were calculated for use in further analysis. Cadence in steps per minute was also determined based on ground reaction force data.

Subjective measures of running ability were taken initially and at 10 weeks. Metrics used were the PSFS (Patient Specific Functional Scale) and SANE (Single Assessment Numeric Evaluation) which assess functional running ability and self-reported normalcy of the injured body part, respectively.

Paired t-tests with a significance level of alpha = 0.05 were used to identify differences between the initial and 10 week assessments for the impulse, cadence, PSFS, and SANE measures.

RESULTS AND DISCUSSION

All subjects successfully transitioned from a RFS to NRFS pattern based on high speed video data. Cadence increased from 168.7 ± 8.2 steps/min to 173.6 ± 7.5 steps/min following the treatment ($p<0.01$). PSFS and SANE scores also increased significantly after 10 weeks ($p<0.01$) (Table 1).

In accordance with our hypotheses, vertical impulse per step decreased by 2.1% following the protocol ($p<0.05$); while medial impulse failed to demonstrate a change after 10 weeks ($p=0.14$) (Table 1).

Anterior and posterior impulse per step both showed significant changes; however contrary to the hypothesis, they increased following the training protocol. Anterior impulse per step grew by 8.7% ($p<0.05$), while posterior impulse increased by 8.5% ($p<0.001$). Additionally, lateral impulse grew by 79.7% ($p<0.01$), which conflicts with the original hypothesis. These changes are displayed in Table 1 and Figure 1.

These results indicate that the transition from RFS to NRFS alter not only loading rate, as has been previously reported, but also impulse per step. The reduction in vertical impulse may be offset over a given distance due to the significant increase in cadence, while by the same logic the increase in anterior, posterior and lateral impulses may be magnified.

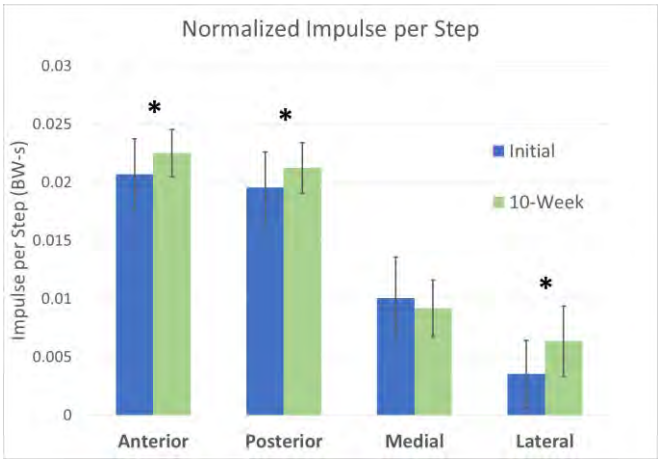

Figure 1. Changes normalized impulse per step after 10 week NRFS program. Asterisks indicate statistically significant changes ($p<0.05$).

CONCLUSIONS

The 10 week NRFS program increased the subjective functional running ability of participants, indicated by higher PSFS and SANE scores. Impulses in the medial direction were unaffected by this protocol. Vertical impulse per step decreased as hypothesized, while anterior, posterior, and lateral impulses all increased per step.

Further research is required to determine the specific characteristics of the ground reaction force leading to these changes in impulse. Long-term effects of altered impulses following transition to NRFS pattern and the effect on overall runner health are also unknown.

EFFECTS OF PROSTHETIC SOCKET SUSPENSION ON KNEE PROPRIOCEPTION AND DYNAMIC BALANCE IN TRANSTIBIAL AMPUTEES

Fan Gao
University of Kentucky, Lexington, KY, USA
Email: fan.gao@uky.edu

INTRODUCTION

Prosthetic socket suspension offers a critical means to intimately integrate the prosthetic device with the human body. Though several studies highlighted the benefits of using vacuum assisted socket system (VASS), the outcomes have been shown only marginal and/or amputee dependent. The limited scientific evidence fails to justify its clinical necessity. To further extend our knowledge base on the effectiveness of VASS, studies addressing aspects closely related to amputee's functional performance when using VASS are strongly needed. In this study, we systematically evaluated and compared three prosthetic socket suspensions: 1) locking-pin; 2) suction; 3) VASS. It was hypothesized that VASS will improve knee proprioception and dynamic balance when compared to other suspensions.

METHODS

Participants

Unilateral transtibial amputees, who have amputations due to either trauma or PVD for more than a year without neuromuscular disorders and can walk independently (K level ≥ 2, 15 male and 1 female; mean (std); age: 63.4 (7.9) yrs; body mass: 85.5 (22.4) kg; body height: 1.77 (0.10) m), participated in the study. With one-way expulsion valve and/or vacuum pump, we were able to obtain two other types of suspension (i.e. suction and VASS) for five participants who were originally using locking-pin suspension. Participants were placed in three groups according to the suspension types used: 1) locking pin (n = 10); 2) suction (n = 9); 3) VASS (n = 7).

Instrumentation

A custom electrical goniometer (Bourns AMS22U non-contacting analog rotary position sensor, linearity: 0.5%; supply voltage: 5VDC) was used to measure knee joint position. A custom LabVIEW GUI was used for data acquisition and signals were collected via an NI PCIe6363 data acquisition card at a rate of 100 Hz (National Instrument, Inc., Austin, TX, USA). A three-dimensional wireless IMU sensor (YEI Technology, 3-Space Sensor Wireless 2.4 GHz) was used to register the acceleration (at a range of ±2 g) of the center of mass of the body during treadmill walking. The signal was streamed to a desktop PC at a rate of 100 Hz. A NordicTrack™ treadmill was used for walking trial. For the five participants who originally used locking-pin suspension, a battery-powered air-pump (vacuum level up to 25 inHg) was used to convert the test suction socket to VASS.

Knee position sense

A custom electrical goniometer was used to measure knee joint position. Knee position sense was tested with and without weight bearing across joint positions ranging from 5 to 25 degrees with 5 degrees of increment. The matching errors were calculated using root mean squared error (RMSE) over a window size of 100 samples.

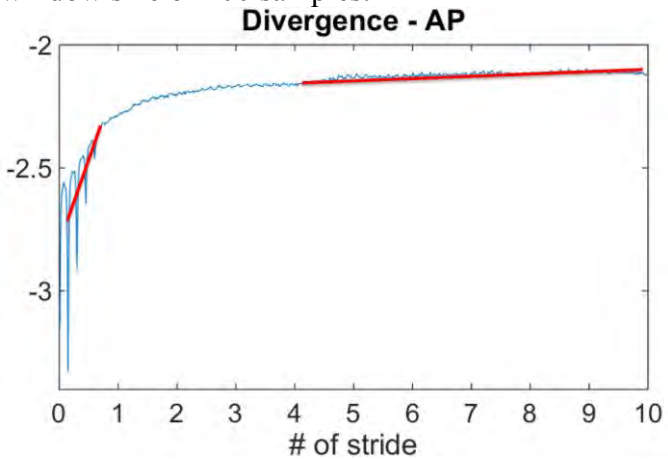

Figure 1: Sample divergence curve as a function of number of strides.

Dynamic balance

Participants walked on a treadmill at their self-selected speed with a tri-axial accelerometer attached

to the lower back for three 3-min walking sessions with break in between. Local dynamic stability (LDS) was estimated using Lyapunov exponents in mediolateral, anteroposterior and vertical directions. Data were processed in MATLAB (Mathworks, Inc. MA).

Statistics

One-way ANOVA with repeated measures was conducted with alpha level set at 0.05.

RESULTS AND DISCUSSION

Knee joint proprioception

The performance of knee joint proprioception was assessed using joint target position matching error. The matching errors of knee joint position are 2.02±0.57 deg, 2.20±0.60 deg and 2.02±0.68 deg (mean±SE) for locking-pin, suction and VASS respectively and there is no statistical difference between suspensions (P=0.97). The matching errors of knee joint position are 2.63±0.44 deg and 1.53±0.35 deg for non-weight-bearing and weight-bearing respectively (P=0.004). Target position shows significant effect and the matching errors are 1.50±0.32 deg, 2.78±0.46 deg, 2.50±0.37 deg, 1.74±0.33 deg and 1.87±0.66 deg for target positions of 5, 10, 15, 20 and 25 degrees respectively (P= 0.004). In addition, sound side shows slightly better performance than affected side (1.82±0.29 deg v.s. 2.35±0.52 deg) though the difference does not reach significant level.

Dynamic balance

No significant effect is revealed on long term LLE. The short term local dynamic stability in the anteroposterior direction are 0.38±.04, 0.52±0.04 and 0.44±0.04 (mean±SE) for locking-pin, suction and VASS respectively. The effect of suspension shows statistical significance (P=0.047) only in the AP direction and the AP short-term LLE of locking-pin is significantly less than that of suction (P=0.036).

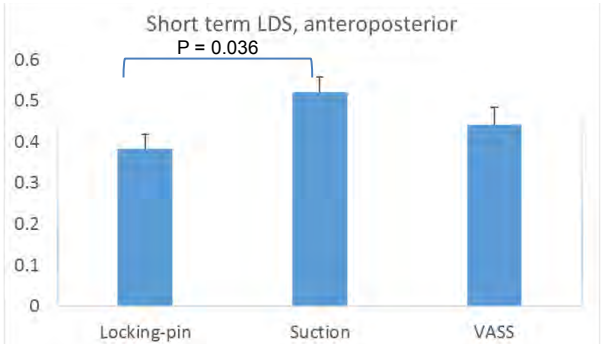

Figure 2: Short term LDS in anteroposterior direction.

The outcome of this study indicates that prosthetic socket suspension does not influence knee joint sense and locking-pin is superior to other means particularly suction in dynamic stability. The study is limited by a relatively small sample size and the fact that some of the participants have not used other suspensions (i.e suction or VASS) before. Further study with larger sample size and suction/VASS suspension of original users is needed.

CONCLUSIONS

Socket suspension does not appear to influence knee joint sense and locking-pin is superior to other means particularly suction in local dynamic stability. The benefits of using VASS are hence not supported by this study.

DEVELOPMENT OF A CHARGED OPF HYDROGEL-SCAFFOLD SYSTEM FOR THE TREATMENT OF VERTEBRAL FAILURE IN METASTATIC SPINES

[1]Hugo Giambini, [2]Asghar Rezaei, [1]A. Lee Miller II, [1,2]Xifeng Liu, [1,2]Michael J. Yaszemski, [1,2]Lichun Lu.

email: lu.lichun@mayo.edu

INTRODUCTION

Multiple pathologies affect vertebral bodies in the spine, including tumors and fractures, reducing spinal stability and increasing the risk for additional vertebral or nervous tissue injury [1]. There were about 1.6 million new cancer cases estimated in the U.S. in 2017 [2]. Up-to one third of all cancer cases will eventually develop secondary bone metastasis, usually to the spine. Vertebral body injury has historically been treated with corpectomy of the affected body and adjacent intervertebral discs. The defect can then be replaced with autografts, allografts, or a variety of fixed and expandable titanium or polymeric cages. However, these approaches have been either associated with complications such as pseudoarthrosis, graft collapse, kyphotic deformity, and graft extrusion; or require both an anterior and a posterior surgical exposure, or the modulus is much higher compared to natural bone, leading to injury of adjacent vertebral bodies. To overcome these shortcomings, we developed a novel biodegradable polymeric hydrogel scaffold to replace the missing vertebral body and intervertebral discs. These scaffolds could potentially enable a less invasive posterior-only surgical approach.

METHODS

Oligo poly(ethylene glycol) fumarate (OPF) was synthesized using fumaryl chloride and polyethylene glycol (PEG) with average molecular weight of 2,000 Da. Gel permeation chromatography (GPC) was then performed to evaluate its molecular weight. The synthesized OPF was used to fabricate scaffolds of 8mm in internal diameter. Briefly, a solution containing OPF, and Bis-acylphosphine oxide (BAPO, photoinitiator) were combined into a flask, vortexed, and placed into a mold in a UV oven. After 2h, the scaffolds were removed from the oven and placed in a laminar flow fume hood at room temperature overnight to fully dry. The effect of negative charge on swelling of the scaffolds was studied by physically infiltrating sodium methacrylate (SMA) into the network. The cross-linked OPF scaffolds were soaked for 8h in ddH_2O containing 0.5% SMA. The expansion rate was evaluated on the final scaffolds containing charge by immersing them in phosphate buffered saline (PBS) solution at 37 °C. Mass, length and diameter were measured at serial time points from 0-100 min. Compressive force-displacement curves for OPF cages before and after swelling were obtained and the stiffness was calculated from the linear portion of the curve.

RESULTS AND DISCUSSION

A sample image of the expanded and charged scaffold is shown in **Fig 1**. The expanded scaffolds were malleable while presenting consistent diameter along its length. Average cross-sectional area (CSA) of the dry and expanded scaffolds were 20.6 (2.4) and 107.1 (3.5) mm^2, respectively. There was a significant radial and longitudinal expansion over time of the scaffold when immersed in the PBS solution. Scaffolds showed a significant increase in their length, wall thickness, internal diameter (ID) , volume, and mass during the first 20 min. All measurements tended to plateua after the initial 20 minutes. **Fig. 2** shows the ratios (based on initial dimension) for the ID, length, and wall thickness. Average stiffness outcomes of the dry and expanded scaffold were 109 N/mm and 0.25 N/mm, respectively. It can be clearly observed that expansion of the hydrogel scaffold reduced the mechanical properties significantly. As a proof of

concept and to mimick the potential *in vivo* application where a vertebral body, containing a defect, and the adjacent intervertebral discs are removed, we conducted a simplified *in vitro* study. Briefly, a metal mold with two metal rods, mimicking vertebral bodies, was manufactured. A gap distance was set to create an artificial defect, mimicking vertebra and disc removal, and the mold was immersed in PBS. The dry OPF cages were then inserted into the defect and allowed to expand. Once expanded inside the defect and between the rods (mimicking adjacent vertebrae), polymethyl methacrylate (PMMA) was injected inside the lumen of the scaffold to allow for mechanical stability. The OPF scaffold, acting as a containment system, allowed for PMMA to cross-link inside the lumen without leaking and preventing potential damage to adjacent tissues (**Fig. 3**).

Figure 1: The expanded hydrogel scaffold is malleable and shows consistent longitudinal morphology.

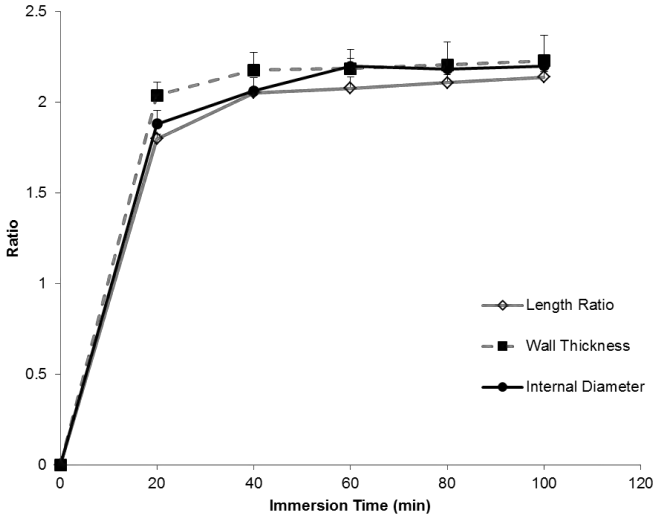

Figure 2: Length, wall thickness and internal diameter changes over time. All measurements tended to plateau after approximately 20 minutes of immersion, reaching a 2-fold change in values.

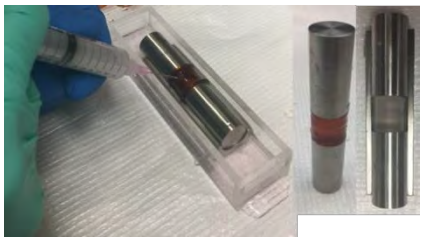

Figure 3: In-situ swelling and injection. A mold consisting of metal rods and a liquid container were used to mimic a lesion. Swelling of the OPF and injection of PMMA allowed for rigidity and stability of the construct.

CONCLUSIONS

The spine is a load-bearing structure and vertebral fragility and vertebral body collapse due to metastatic disease significantly decreases the patient's quality of life. Longtime survival in some cancer types, as well as the existing demographic shift toward an elderly population, places a significant importance in trying to develop new treatment strategies that can not only minimize the likelihood of vertebral failure and adjacent tissue injury, but also minimize surgical intervention and reduce the cost of treatment.

The developed OPF polymeric hydrogel scaffold plays a key role in this process. Its' cost is cheap, could potentially be delivered via a posterior-only surgical procedure, which is much less invasive compared to the combined anterior and posterior approaches, and, upon augmentation, would provide the necessary structural stability to the spine. Because vertebral geomery varies along the length of the spine, the scaffolds could potentially be developed in different sizes to accommodate these various morphological differences.

ESTABLISHING NORMS FOR WEIGHT-BEARING HIP ROTATION RANGE OF MOTION

Heather Gulgin, Lindsey Remski, Brittany Sugg, Josie Freybler, Alexis Van Dusen
Dalton Payton, Jake Sommers

Grand Valley State University, Allendale, MI, USA
email: gulginh@gvsu.edu

INTRODUCTION

Range of motion (ROM) is typically measured in a non-weight-bearing (NWB) status, however we participate in most activities of daily living (ADL's) and sport activities in a weight-bearing (WB) status. Thus, the primary purpose of this study was to establish normative values for WB hip rotation ROM. The secondary purpose was to compare WB hip rotation ROM values for younger (age 18-35 years) and older (age 36-55 years) adults.

METHODS

135 participants were separated into two different age categories: 18-35 (20.7 ± 3.3 yrs., 173.4 ± 9.7 cm, 74.3 ± 18.4 kg, 24.2 ± 3.9 BMI) and 36-55 (45.2 ± 6.0 yrs., 173.0 ± 9.7 cm, 76.8 ± 19.9 kg, 25.4 ±4.8 BMI) and had hip internal and external rotation measured on the Functional Footprint® device (Figure 1-2). Statistical analysis was completed using SPSS version 24 (IBM Corp, Raleigh, NC). The average of three trials for each measure were entered for data analysis. A One-way ANOVA tested for significant differences ($p < 0.05$) between the two groups for internal and external rotation. Additionally, to test for any side-to-side differences within each age category, separate paired t-tests were conducted for internal and external rotation.

RESULTS & DISCUSSION

Participant background information is reported in Table 1. Average internal and external WB ROM for right and left sides are reported by group in Table 2. There was no significant difference between hip internal or external rotation between the two groups. When examining side-to-side differences between right and left sides for internal rotation, there was no significant difference in younger group ($p = 0.089$), but there was a significant difference for the older group ($p = 0.006$). For external rotation, there was a significant side-to-side difference (Table 2) for both younger group ($p = 0.002$) and older group ($p = 0.003$). While statistically significant the differences were generally 2-4°, which would not be considered clinically significant (< 5 degrees). Most of the existing literature on hip rotation ROM has been measured actively or passively, but measured in a NWB condition. Sports occur with athletes in load-bearing or weight-bearing condition. Thus, it is important to determine normative values for WB ROM. One previous study [1] did examine hip rotation in a load-bearing condition, but it was not a full WB condition. For internal rotation, they found average values of 22.6 ± 2.7 and 21.1 ± 2.1 for right and left sides respectively and the current study found internal rotation values ranging from 19.8-21.2 (right) and 22.6-22.7 (left) depending on age category. For external rotation, Aefsky [1] found average values of 27.8 ± 2.1 and 25.8 ± 1.7 for right and left respectively and our current study found values ranging from 41.5 (right) and 37.2-38.7 (left). While the internal rotation values were similar between studies, it appears our values for external rotation were quite higher than Aefsky [1]. This could be due to the difference in position of pelvis being slightly tilted in frontal plane for Aefsky [1] measurements. In comparison to other literature on active, prone hip rotation ROM measures, our study found lower internal and external rotation than Simoneau [2], but we found similar values for internal rotation and slightly higher external rotation than Ellenbecker [3].

CONCLUSION

Normative values for healthy adults were established and may be used to compare to actual hip rotation range of motion used in various sports.

HOW FEMORAL VERSION CHANGES JOINT LOADING IN PATIENTS WITH DEVELOPMENTAL DYSPLASIA OF THE HIP

Michael D. Harris, Ke Song, Brecca M.M. Gaffney

Washington University School of Medicine, St Louis, MO, USA
email: harrismi@wustl.edu

INTRODUCTION

Femoral version (FV) describes torsional changes in shape between the proximal and distal femur (**Fig 1**). FV deformities are found in several disorders (e.g. cerebral palsy, FAI) and may detrimentally affect hip joint mechanics [1]. FV is also an important surgical consideration in total hip arthroplasty and derotational osteotomies when correcting lower extremity alignment [2].

Development dysplasia of the hip (DDH) is a major etiologic factor in hip osteoarthritis, and is diagnosed primarily using measures of acetabular geometry [3]. However, there is growing interest in the role of femoral deformities in damage within DDH [4], but their mechanical influence in this population is unknown. Accordingly, the objective of this study was to compare how FV variation alters hip joint reaction forces (JRFs) and muscle forces during gait in patients with DDH.

METHODS

Joint angles and ground reaction forces during gait were used from nine previously reported patients with DDH (6F, 26.4±7.2 y/o, 22.7±3.1 BMI) [5]. A baseline model with 23 degrees of freedom and 96 musculotendon actuators was modified in OpenSim (v3.3) by adding subject-specific pelvis geometries, hip joint center locations, and pelvis muscle attachments using CT-based reconstructions as described previously [5,6].

To simulate variations in FV, the femurs of each patient were divided into proximal and distal sections 1 cm inferior to the lesser trochanter. Next, a rotation-only joint was created at the junction of the femur sections. The joint was rotated to create three models per patient: Neutral (15° anteversion [7], matching native OpenSim geometry), ANTE (35° anteversion), and RETRO (7° anteversion), based on FV reports from patients with DDH [4] and an internal DDH database (**Fig 1**). After

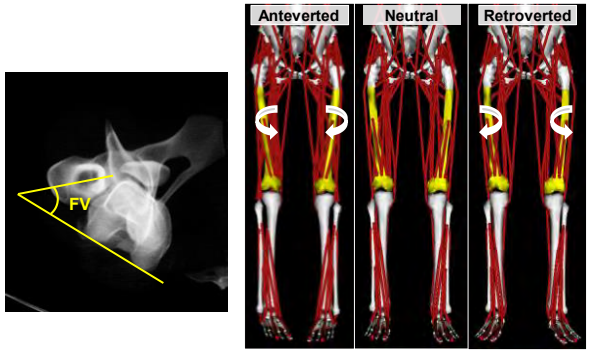

Figure 1: *Left* - FV is the angle between the femoral neck and posterior condyles. *Right* – FV variation was simulated by rotating the distal femur (yellow) relative to proximal femur.

rotation, the custom joint was locked and muscle forces during a full gait cycle were calculated using residual reduction analysis (maintaining original kinematics) and static optimization. JRFs were calculated for each subject's symptomatic hip and presented in a pelvic coordinate frame to reflect the direction and magnitude relevant to the acetabulum.

JRFs and forces for muscles spanning the hip were normalized to bodyweight (BW), peak resultant JRF times during early and late stance (JRF1, JRF2) were identified, and JRFs and muscle forces at those times were reported. Resultant JRF; anteroposterior (AP), superoinferior (SI) and mediolateral (ML) JRF components; and muscle forces in Neutral, ANTE, and RETRO were compared across models using repeated measures ANOVA with Bonferroni correction (initial α=0.05).

RESULTS AND DISCUSSION

Compared to Neutral, ANTE femurs resulted in significantly smaller ML JRFs at JRF1 (p=0.002), with smaller forces in the posterior gluteus medius (p=0.02), but larger forces in the long head of biceps-femoris (**Fig 2, Table 1**). At JRF2, ANTE caused larger AP JRFs (p=0.004) with larger forces in the anterior gluteus minimus and tensor fascia latae (TFL), but a smaller rectus femoris force.

RETRO femurs caused larger ML JRFs at JRF1 (p=0.01) and larger posterior gluteus medius forces compared to Neutral (**Fig 2, Table 1**). At JRF2, RETRO SI and resultant JRFs were smaller than Neutral (p=0.02, 0.01, respectively). Anterior gluteus medius, anterior gluteus minimus, and TFL forces were smaller at JRF2 in RETRO versus Neutral, but rectus femoris forces were larger.

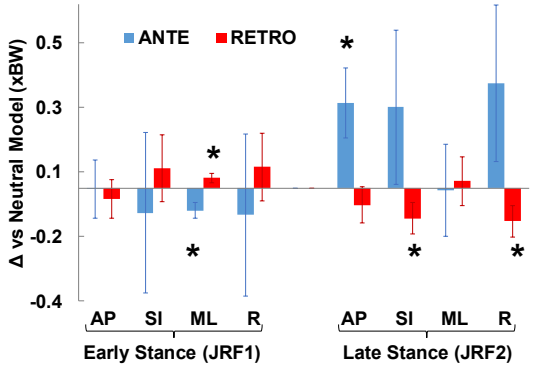

Figure 2: Mean and 95% CI JRF differences (Δ) of ANTE and RETRO models versus Neutral. * indicate p<0.05.

In addition to the statistically significant changes, resultant JRFs in late stance were 40% higher in ANTE models compared to Neutral (p=0.09). Anteversion is more common in DDH [4], and the increased anterior JRFs, and increased superior JRFs, in ANTE cases may contribute to patterns of damage on the superoanterior acetabulum where bony support is lacking and the labrum experiences greater than normal loading [6]. While the magnitude of changes caused by ANTE were much greater than RETRO, it is interesting that each caused an equal number of significant changes to JRFs and muscle forces given the relatively small FV change applied to the RETRO models. Thus, either type of deformity may have important mechanical ramifications on joint loading, with their impact being greatest in late stance.

ANTE increased the role of TFL on pelvis stabilization in late stance. Muscles in these models were not weakened, and the patients did not walk with grossly abnormal patterns. However, if TFL and other abductors were weak, (as found in some DDH patients), the increased demand from anteversion could reasonably lead to the Trendelburg gait and lateral pain some patients manifest. Changes in abductor demand were also evident in the anterior gluteus minimus, which had altered forces in ANTE and RETRO, despite not being directly affected by the FV rotation. Finally, the effect on rectus femoris was opposite TFL, with its activity diminished in ANTE and enlarged in RETRO. While rectus femoris makes a large contribution to hip flexion during transition from stance to swing, in cases of RETRO it may also assist with stabilization to compensate for the mechanically disadvantaged TFL during late stance.

CONCLUSIONS

This study represents the first reported combination of pelvic and femoral bony abnormalities (pelvic shape, lateralized hip joint center, and FV) for investigating musculoskeletal biomechanics in patients with DDH. ANTE and RETRO both caused significant changes to JRFs and muscle forces and may help explain patterns of intra-articular damage found in DDH. The femoral junction was chosen at a location commonly used for rotational correction surgery [8]. However, the location of FV deformities in DDH is not well known and is a topic of our ongoing work. Future work will investigate the effect of changes to proximal FV (i.e. head/neck or inter-trochanteric) and femur neck-shaft angles.

DETERMINING CERVICAL DISC INJURY POTENTIAL IN MOTOR VEHICLE COLLISIONS

Rami Hashish, Omid Komari, Manon Limousis-Gayda

National Biomechanics Institute, Los Angeles, CA, USA
email: rhashish@nationalbi.com, web: https://nationalbi.com/

INTRODUCTION

More than 6 million motor vehicle collisions (MVCs) occur annually in the United States, resulting in 3.9 million injures and $23 billion of medical expenses. The most common type of MVC is a rear-end, whilst 65 percent of all claimed injuries following low speed MVCs are to the cervical intervertebral discs. Despite such a high prevalence, the potential and mechanism for cervical intervertebral disc injuries in response to low-speed rear-end MVCs is frequently debated in medicolegal circumstances. Accordingly, biomechanics experts are commonly tasked to provide professional opinion with regards to whether an incident was sufficient in severity to cause the medically diagnosed injuries. In order to connect said injuries to the subject incident, experts should rely on valid and reliable methods and criterions. Thus, the purpose of this paper is to provide a qualitative analysis of the current biomechanical approach to evaluating the potential for cervical intervertebral disc injuries in low-speed rear-rend MVCs.

METHODS

Research papers examining rear-end MVCs between 1960 and 2018 were analyzed. For the purpose of this analysis, a low-speed MVC was operationally defined as when the bullet (i.e. impacting) vehicle was traveling between one and 25 mph at impact. Ultimately, 300 peer-reviewed manuscripts were appraised, 20 of which included a biomechanical analysis of injury. A qualitative analysis of these 20 papers was conducted to evaluate the current biomechanical approach for determining cervical intervertebral disc injury potential in low speed rear-end MVCs.

RESULTS AND DISCUSSION

The current biomechanical approach to determine injury potential in a low-speed rear-end MVC is as follows:[1]

1. Accident reconstruction experts determine the magnitude and direction of impact forces at the time of the accident. This step is commonly conducted using computational tools and software such as the EDSMAC4 or GATB models.

Table 1: Injury criteria methods and issues.

Injury criteria	Based on	Method	Issue(s)
Nij (Neck Protection Criterion)	Function of the dynamic loads at the occipital condyles.	Concept of linear combination of axial loads and bending moments initially developed on pigs for frontal crashes.	Relies on pig's skeletal structure for frontal impacts. Risk curves show injury risk greater than zero when Nij equals zero.
NIC (Neck Injury Criterion)	Relative acceleration and velocity of the occipital condyles v. 1st thoracic vertebra.	Assuming relationship between pressure changes inside spinal canal and injury based on animal tests.	The first 150 ms are the only reasonable values obtained during tests, only enabling evaluation of the retraction phase.

2. Biomechanics expert relate the findings as determined from the accident reconstruction to the forces experienced by the occupant(s).
3. Biomechanics experts compare the magnitude of forces experienced by the occupant(s) to research-established injury tolerances and / or criteria, such as Nij or NIC (Table 1).

There appears to be (at least) three issues / flaws to this approach.

Firstly, relating tolerance limits to human injury is not considered externally valid. Tolerance limits have largely been ascertained through an analysis of cadaveric responses and / or tests conducted in healthy youth subjects. Therefore, comparisons of these findings across populations of different ages, genders, sizes, BMIs, and/or pre-existing injuries / conditions (e.g. elderly or obese populations) can lead to an over (or under) estimation of injury tolerance.

Secondly, a simple comparison of force magnitude does not (fully) take into consideration the viscoelastic characteristics of human tissue / intervertebral discs. The crash pulse duration during rear-end impacts is approximately 80-120 milseconds.[2] The resulting occupant kinematic profile is characterized by approximately 350-500 milliseconds of total movement, with only a fraction of that movement being composed of the initial rearward thrust. Research papers examining tolerance limits for the cervical spine, however, have commonly applied loads to cadaveric interverbal discs for time durations ranging from 300 milliseconds to 1 second. Because intervertebral discs are viscoelastic – i.e. they demonstrate time dependent resistance to strain – the loading rate affects the potential for tearing and / or protrusion of the disc(s). Therefore, the tolerance to injury as determined from research may theoretically overestimate the threshold to injury during a rear-end impact.

Thirdly, injury criterions have commonly been developed using cadavers, dummies and / or animals such as piglets used as human surrogates.[3] The inherent issue with using human surrogates is their inability to mimic how humans respond to impact. Accordingly, such data may not accurately reflect intrinsic human responses (such as muscle tensing / contractions that may occur during anticipated MVCs).

CONCLUSION

There are a variety of parameters that affect injury potential, including, past medical history, weight, age, gender, and the magnitude, duration, location and direction of applied forces. However, the current biomechanical approach to determine injury potential in low-speed rear-end MVCs appears to be relegated to a comparison between the magnitude of experienced forces to injury tolerance metrics. This is despite such tolerance metrics may overestimate the force required to cause injury. It is thus encouraged that future biomechanical analyses consider other parameters – such as loading rate, passive / active muscle contraction, and pre-existing condition – when making conclusions regarding injury potential. Simulation technologies and computational models based on response data obtained from laboratory studies could also help improve the validity of the conclusions made by experts. Further research is also encouraged to determine new neck injury criteria and tolerance limits of cervical discs injuries that consider these parameters.

SINGLE LEG LAND PROVIDES UNIQUE INSIGHT INTO LANDING MECHANICS IN FEMALE ATHLETES POST-ACL/R

INTRODUCTION

Over 200,000 athletes sustain anterior cruciate ligament (ACL) injuries every year, half of which require surgery and/or rehabilitation. Athletes who have undergone ACL reconstruction (ACL/R) surgery are 15 times more likely to re-injure themselves within the first year of surgery and 5 times more likely to re-injure themselves within 24 months of surgery [1]. Previous research has highlighted the importance of limb symmetry during clinical testing for return to participation clearance in athletes post-ACL/R, but because re-injury rates remain high, biomechanical testing is now recommended as an additional method of detecting limb asymmetries [2].

Biomechanical tasks that include double-leg jump landings, such as the drop vertical jump, have been used most often in return to participation protocols [3]. The outcome measures from this task identify compensatory techniques that athletes often develop during the course of rehabilitation, offering valuable information about their landing strategies. However, these outcomes provide limited insight about individual limb capabilities. The single leg land is a task that is understudied but may be useful for identifying key information about individual limb characteristics that is not available through evaluation of the drop vertical jump. Outcome measures from the single leg land have previously been reported, but limited research has compared outcomes between the two tasks [4]. This comparison may be useful in understanding the effectiveness of the single leg land for identification of individual limb capabilities that are not detected using the drop vertical jump.

Therefore, the purpose of this case series is to compare outcome measures between the single leg land and drop vertical jump in athletes post-ACL/R. By evaluating the outcomes from these tasks, we may gain insight into the potential usefulness of the single leg land to identify information about individual limb capabilities in injured athletes.

METHODS

Return to participation testing in three collegiate female soccer players post-ACL/R (Age: 21 ± 1 year; Time post-surgery: 30 ± 7 weeks) was conducted using a combination of clinical and biomechanical testing. Clinical testing consisted of isometric strength, y-balance, and single leg hop testing. For biomechanical testing, individuals were assessed using three dimensional kinematics and kinetics. Individuals performed five repetitions of the single leg land where they stood on an 8" box in single limb support, dropped onto one foot, and held for approximately 2-3 seconds. Individuals also performed five repetitions of the drop vertical jump where they stood on a 12" box in double limb support, dropped onto both feet simultaneously, immediately performed a maximum vertical jump, and landed on both feet simultaneously again. Kinematic and kinetic data were then used to compare symmetry across subjects, and the symmetry index (SI) was defined:

$$SI = \frac{Uninvolved\ Limb - Involved\ Limb}{Uninvolved\ Limb} \times 100\%,$$

where an increase in SI represents greater asymmetry. Limb symmetry for peak vertical ground reaction force (vGRF), peak knee flexion angle, and peak internal knee extensor moment were compared across tasks as these outcomes have been identified as biomechanical risk factors for re-injury [2].

RESULTS AND DISCUSSION

As expected at an average of 30 weeks post-surgery, individuals passed all clinical tests (Table 1), demonstrating limb symmetry during this aspect of return to participation testing. However, limb asymmetries were evident in the outcomes from the biomechanical tasks (Fig. 1). For the single leg land, the average SI for individuals was increased for the peak knee flexion angle (11.3%) and peak knee extensor moment (23.2%). For the drop vertical jump, the average SI for individuals was increased for the peak vGRF (1st land: 21.9%, 2nd land: 26.0%) and peak knee extensor moment (1st land: 25.7%, 2nd land: 34.4%).

The outcomes from both biomechanical tasks revealed increased limb asymmetries for the peak knee extensor moment. However, the contributing factors to these asymmetries varied between tasks. During the drop vertical jump, while the peak knee flexion angles were nearly symmetrical, the peak vGRF values were asymmetrical during both landings, indicating that individuals shifted their weight to one side. Because ground reaction forces are used to calculate joint moments, it is likely that the increased joint moment asymmetries during the drop vertical jump were due to asymmetric weight distribution. Therefore, these drop vertical jump outcomes reflect how athletes functionally use their involved and uninvolved sides simultaneously. However, during the single leg land, individuals are required to land with all of their weight on a single limb, reflecting the capacity of the limb to absorb landing forces. The outcomes from this task resulted in symmetrical landing forces (peak vGRF SI: 7.45%) and asymmetrical peak knee flexion angles. This highlights a key difference in what the outcomes from these tasks can provide: the increased joint moment asymmetry during the single leg land could not be due to weight shifting to the opposite limb, but instead was likely due to a difference in landing strategies between limbs, suggesting different limb capabilities.

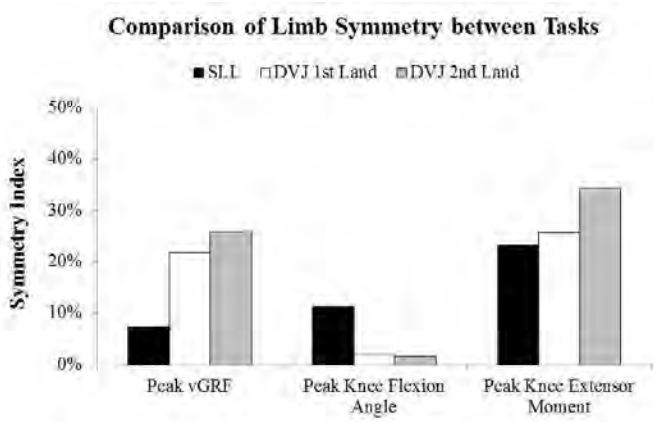

Figure 1: Average limb symmetry indices for athletes during the single leg land (SLL) and both landings of the drop vertical jump (DVJ).

To further understand the athletes' landing strategies, quadriceps strength symmetry was examined, as this has previously been reported as a predictor of knee flexion angle and extensor moment symmetry [5]. Interestingly, individuals demonstrated symmetric quadriceps strength but were asymmetric in peak knee flexion angle and extensor moment. This suggests that although muscle strength has been restored post-surgery, athletes may have neuromuscular deficits that are affecting individual limb capabilities [6].

In summary, the results from this case series highlight the usefulness of the single leg land for identification of individual limb capabilities in injured athletes. By understanding the value of this task, a more comprehensive return to participation protocol can be developed to help reduce the risk of re-injury in athletes post-ACL/R.

MECHANICAL CHARACTERIZATION AND BIOMECHANICAL COMPUTAIONAL MODELING OF SHORT BOWEL SYNDROME

[1] Department of Surgery, Stanford University, Palo Alto, CA, USA
email: hh2@stanford.edu

INTRODUCTION

Intestinal failure (IF) is a rare multifactorial clinical condition that results in patients' inability to sustain normal growth and nutritional and hydration status. Short bowel syndrome (SBS) is the most common cause of IF which is a devastating condition owing to loss of significant intestinal length thereby affecting the organ's ability to absorb nutrients. The incidence of SBS is approximately 25 per 100,000 live births per year in the US [1]. SBS is a congenital or acquired condition affecting the small intestine, hallmarked by loss of intestinal absorptive capacity with resultant malabsorption, dehydration, and malnutrition. This is due to the loss of absorptive surface area, as the human intestinal tract requires a massive surface area to effectively absorb nutrients to support a growing and living organism. Current treatment strategies for SBS involve parenteral nutrition and small bowel transplantation; various transit slowing and bowel lengthening procedures have been employed in highly selected subpopulations [2]. However, these therapies have shown limited success and are associated with high rates of sepsis, intestinal failure-associated liver disease, and mortality [2].

Intestinal lengthening by distraction enterogenesis from use of mechanical forces has been studied as a potential treatment for SBS. [3]. Our previous studies have shown successful lengthening of jejunum using self-expanding springs in rats and pigs for both metal and biodegradable springs [4,5]. However, mechanisms that generate lengthening remains poorly understood from a biomechanical perspective. Main aim of this study was to determine the mechanism behind intestine lengthening as well as optimizing spring implementation and characterization to have maximum intestine lengthening using both finite element modeling and experimental approach.

METHODS

Experimental method: female juvenile (age 4 to 6 weeks) Yucatan pigs (S&S Farms), weighing at least 5kg were used for all experiments. Animals were kept alive for 1-2 weeks on a normal solid food diet prior to sacrification. Immediately after euthanizing the animal, a laparotomy was performed to remove 10-20cm segment of small intestine. Specimen was rinsed with saline to remove intestinal content and the specimen was placed in phosphate buffered saline (PBS) on ice. Segments of freshly harvested porcine small intestine were stored in PBS prior to uniaxial tensile testing. Cylindrical intestinal tract was cut open, and longitudinal cuts were made to obtain the Elastic Modulus of the small intestine in the longitudinal direction. Tensile tests were performed using an Instron type 5565 (Fig. 1A), with a 1kN load cell to measure the Elastic Modulus. Specimens were clamped using special custom-made anti-slip grips to counteract any slipping (Fig. 1B). A pre-load of 2N is then applied at a displacement of 0 mm to eliminate slack within the sample.

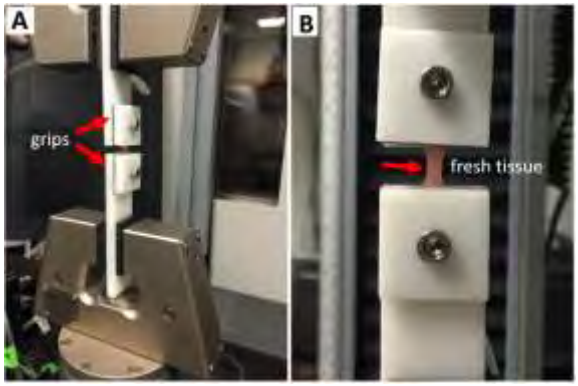

Figure 1: Tensile test performed using an Instron type 5565 with anti-slip grips.

Computational method: To study mechanics involved in the intestinal tract lengthening, finite

element analysis (FEA) was used. Three-dimensional models were created using ABAQUS (D. S. Simulia) where initial geometry was matched to geometry of real intestinal tracts which was a hollow cylinder and for nonlinear material behavior, new-hooking model was taken.

RESULTS AND DISCUSSION

For every specimen ($n = 12, length = 22.6 \pm 6\ mm, width = 7.2 \pm 0.7 mm$), tensile test with rate of 0.4 mm/min was performed and a force-displacement curve was obtained (Fig. 2A). From this, once a linear line was fit to the data, stress was calculated by dividing the force by the undeformed cross-sectional area (width × thickness) of the specimen and strain was calculated by dividing the displacement of the specimen by the initial length (ΔL/L). Finally, Young's modulus (E) was characterized by dividing the stress by strain, $E = 1.54 \pm 0.26$ (MPa) (Fig. 2B).

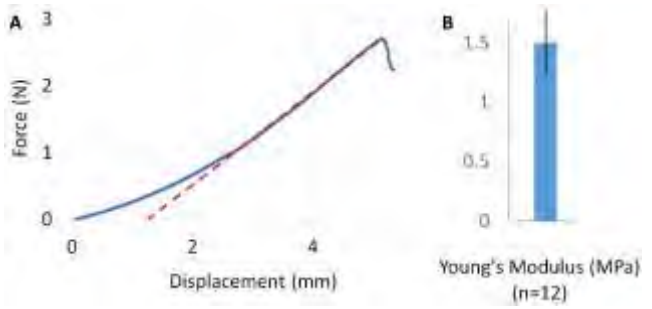

Figure 2: Mechanical testing of intestinal tissue: (A) Representative force-displacement plot, dashed-red line shows the linear fit. (B) Average Young's module of specimens, $E = 1.54 \pm 0.26$ (MPa).

As previously mentioned in introduction section, an effective way to apply mechanical force is use of self-expanding springs for successful lengthening of jejunum but with variable intestinal sizes, it is critical to determine safe, translatable spring characteristics in differently sized animal models before clinical use. To this goal, finite element modeling was used where models in different size in radius and thickness was made (Fig. 3A) and mechanical forces was applied at both ends of the cylindrical hollows with fixed boundary condition for midline. In different models (size was changed while other features of models kept unchanged), scaled forces based on the cross-sectional area predicted same lengthening ratio (Fig. 3B). Further investigation proved robustness of model in prediction for lengthening ratio when different range of material properties was chosen.

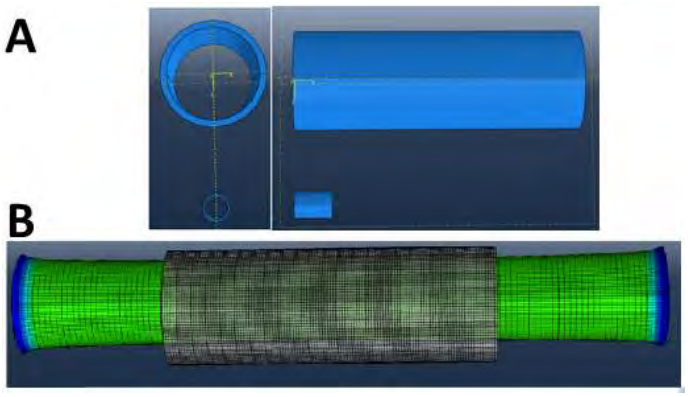

Figure 3: Computational model for intestinal lengthening due to applied mechanical force: model results confirm cross-sectional area as an appropriate parameter for force scaling for variable intestinal sizes.

CONCLUSIONS

Experimental results provided required material properties of intestinal tract while computational models suggests cross-sectional area as a proper parameter to rescale the required mechanical force in variable intestinal sizes. However future work will include additional complications (tissue growth and tissue lengthening due to growth in response to stress experienced by tissue) for the further investigations.

AN INVESTIGATION OF BUCKLING COMPLICATIONS IN SPINAL ANESTHESIA ADMINISTRATION PROCEDURES

[1] Tessa C. Hulburt, [2]Jessica M. Booth, [2]Peter Pan, [1]Philip J. Brown

[1] Biomedical Engineering, Wake Forest Baptist Health
[2] Anesthesiology, Wake Forest Baptist Health
Email: thulburt@wakehealth.edu

INTRODUCTION

In an effort to reduce the most common complication of spinal anesthesia administration procedures, post-dural puncture headaches (PDPH), small diameter spinal anesthesia needles are used. Though effective in reducing PDPH prevalence, the use of small diameter needles has increased complications due to needle buckling [1]. While a mechanical evaluation of needle deviation during advancement as well as a clinical understanding of needle fracture have been documented, buckling behavior is not well understood [1,2]. Therefore, it is clinically relevant to quantify changes that occur from uninterrupted needle insertion, axial loading during barrier contact and buckling. Furthermore, due to the large variety of spinal needles used clinically, it is appropriate to compare performance of different needle types in their ability to resist buckling. The goal of this study was to quantify the buckling behavior of spinal anesthesia needles with respect to the relative contribution of needle brand, gauge (G), and tissue depth.

METHODS

A repeatable spinal anesthesia administration procedure and buckling complication was simulated using a novel test fixture (**Figure 1**). The needle shaft was clamped to advance it through a ballistics gelatin tissue surrogate to a barrier using a servohydraulic Landmark material testing machine [MTS, Eden Prairie, MN]. This setup simulated Euler buckling in an elastic medium with fixed-pinned boundary conditions to match needle advancement in a clinical setting. Needles were tested in 50mm and 70mm tissue depths to represent average and obese bodyweights, respectively [3]. Varying gauges of needles manufactured by four different companies were selected for testing (see **Figure 3**). Four phases of buckling were analyzed (**Figure 2**): uninterrupted needle insertion into the gelatin tissue surrogate, axial loading of the needle once the barrier was met, critical buckling point (X_2 in **Figure 2**) and the buckling region where buckling continues as the needle is further advanced into the tissue. An analysis of variance (α=0.05; β=0.8) was conducted to compare results.

Figure 1. Test fixture diagram. 1) Force applied by MTS. 2) Needle grip that simulates physician's grip. 3) Ballistics gelatin tissue surrogate. 4) Needle. 5) Barrier.

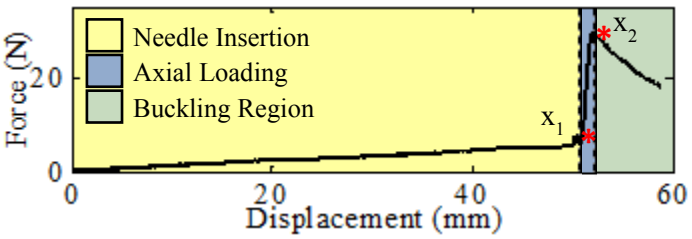

Figure 2. F-D plot of a buckling test defining four buckling phases

RESULTS AND DISCUSSION

F-D data showed consistent results within different needle testing groups, verifying reproducibility. Needle deformation occurred closer to the barrier, suggesting minimal lateral movement at the needle

hub. This is likely due to lateral support from the gelatin on the needle. Therefore, we propose that buckling is better detected from axial force or displacement.

Critical buckling loads (CBL) collected at different tissue depths did not vary significantly for most needle types. CBL is the force at the critical buckling point. It was observed that the force increased linearly as the needle was advanced (see **Figure 2**) due to friction created by the tissue surrogate on the needle. When performing this procedure, it is possible that increased resistance from barrier contact could feel like expected proportional resistance increase as the needle is further inserted into the tissue, especially for larger tissue depths. **Table 1** compares the force change when a barrier is met (ΔF) at the two tissue depths. Smaller ΔF were found for all same gauge needles at the larger tissue depth, supporting our theory that buckling is more challenging to detect at larger tissue depths due to the smaller ΔF, rather than from CBL alone.

Table 1. ΔF (N) = CBL – Force at x_1

	22G	27G
50mm	23.54 ± 0.63	7.700 ± 0.01
70mm	21.18 ± 0.65	5.737 ± 0.16

Analyses of axial loading and buckling regions found large stiffness and minimal energy values during axial loading and large energy values during continued buckling. These results indicate that buckling is better detected with axial force feedback, rather than displacement due to the needle's limited ability to displace axially. Due to the minimal energy that is able to be absorbed when loaded axially, needles are prone to buckling. Therefore, the needle will fail under much smaller loading than the material ultimate failure load. While the needle will buckle easily, far more energy is required to fracture the needle as indicated by the large buckling region energy results.

When analyzing different needle types, larger diameter needles produced overall larger CBL. Differences in CBL for different brand needles of a single gauge were far less than CBL differences between needle gauges (**Figure 3**). Statistically significant variations were found between CBL from all same-brand-different-gauge and different-brand 22G and 24G needles, but not for all different-brand 25G and 27G CBL comparisons. These data show that needle gauge effects buckling behavior significantly and that needle brand is less influential overall, particularly for smaller needles.

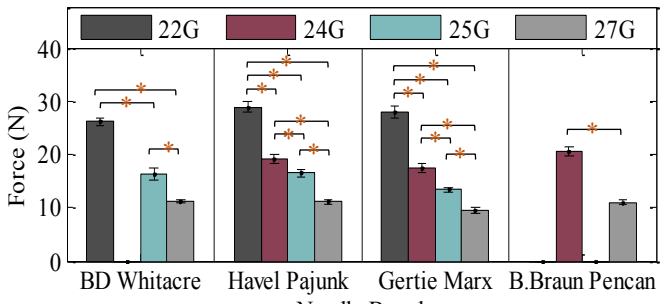

Figure 3. CBL Results Collected in 50mm Tissue. * = p<0.001. Each bar represents n=8-12 needles tested.

CONCLUSIONS

Our results indicate the use of axial force feedback as the primary metric to detect buckling. Barrier contact may be challenging to detect before buckling occurs, but the large stiffness increase that occurs during needle axial loading may be used to prevent permanent needle damage. To choose a needle best equipped to resist buckling complications, special consideration for needle gauge should be taken. Needle brand should also be considered, especially if a larger gauge needle is appropriate. We expect the results of this study and further analyses of spinal needle yield and failure point to help us achieve our long-term goal of improving spinal anesthesia procedure safety.

SAMPLE SIZES OF STATISTICAL MODEL FOR THE ELDERLY

Eunjoo Hwang, Sven Holcombe, Susumu Ejima, Kristen Cunningham and Stewart Wang

University of Michigan Health System, Ann Arbor, MI, USA
email: ejhwang@umich.edu

INTRODUCTION

To prevent serious injury from repetitive low-intensity usage or sudden high-energy impact, various computational models have been developed and used to reveal the injury biomechanics. For injury biomechanics during high-energy impact such as motor vehicle crashes, whole-body-level human body models (HBMs) have been developed and examined under diverse impacting scenarios. As a result, a few commercialized subject-specific HBMs have been presented to represent midsize male, small female, and large male [1, 2].

Recently, HBMs for the elderly, which is a vulnerable and growing population, have been actively studied. With concerns about the representation of subject-specific HBMs and the efficiency of developing procedure, elderly HBMs are developed mainly by a mesh morphing process to fit statistically-determined geometries. However, sample sizes of statistical models for the entire age spectrum were ranged between less than 50 and 350 [3, 4]. These wide variances in sample sizes may have an effect on the statistically-determined geometry. There might be recommendable sample sizes that represent the elderly population properly. Thus, this study was to designed to address these issues by generating multiple thorax-skin statistical models from diverse sample sizes of subjects.

METHODS

Geometries of thorax skin were obtained from CT scans which were collected and processed by a high-throughput in-house program in the International Center for Automotive Medicine/ Morphomic Analysis Group. For the adult thorax skin model, CTs were collected only from subjects older than 18 years of age who had all images between highest thoracic vertebrae (T1) and lowest lumbar vertebrae (known as L5). For each CT, individual vertebral levels between T1 and L5 were divided into four levels, and the circumference of each level was demonstrated as 200 data points. Due to arm posture during CT imaging, gradually fewer data points were extracted from the levels above the T8 vertebrae.

For this study, massive asymmetric data points per subject were processed to be symmetric in sagittal plane and condensed into 1/20 ratio. Data points in left and right body sides were averaged in each vertical level. Among 66 vertical levels, data points in every other vertical level were used. In one vertical level, every tenth data point was used to represent the thorax skin.

The thorax skin statistical models were generated through principal component (PC) analysis and multivariate regression analysis. As predictors, age, body mass index (BMI), and height of the subject were used for separate models for male and female cases. Based on thorax skin data points matrix, the covariance and PC scores were calculated. In all statistical models, the numbers of PC scores cover more than 99% of the variance in each set of sample data. This study tested diverse sample sizes; 100, 200, 300, 500, 800, 1000, 1200, and 1500 subjects per sex. For each sample size, the mean age, BMI, and height for men fell at approximately age 45, BMI 28, height 178 cm, and for women, the mean age was 51, BMI 30, and height 163 cm.

To compare the statistically-determined geometry, individual statistical models predicted 27 different thorax skins. 3 values for age (20, 45, and 70 years), BMI (20, 30, and 40), and height (145, 160, and 175 cm for female; 160, 175, and 190 cm for male) were combined. On all vertebrae levels, the anterior-posterior and lateral-medial distances passing the center of the spinal canal (total 34 values) were obtained. The differences from reference in those 34 measurements were calculated and averaged among individual thorax skins. Reference measurements

were the predicted values by the statistical model using 1500 subjects. The ability to predict thorax skin by the statistical model based on 1500 subjects was previously tested by direct comparison to the 27 subject-specific thorax skins. The averaged differences in both male and female models were less than 1% (0.7 ± 0.2%) which was not strongly related to subjects' age, BMI, and height.

RESULTS AND DISCUSSION

The thorax skin to represent the mid-age, mid-BMI, and mid-height subject was not as varied as thorax skin representing subjects at both the lower and upper ends of age, BMI, and height, regardless of sex. The smallest difference in the midsize subject among 27 subjects was observed in all of statistical models in this study, even the model with only 100 sample sizes.

The mean and standard deviation of the difference in geometry were decreased with increasing sample sizes in both sexes. In the thorax skin of the subject representing both the lower and upper ends in age, BMI, or height, the benefit of using larger sample sizes for the statistical models was demonstrated. Averaged difference among three female thorax skins representing mid-age, mid-BMI, or mid-height was 5.49, 5.72, 4.25 in 100 sample sizes, and reduced to 0.34, 0.42, 0.29 in 1000 sample sizes. However, averaged difference among three female thorax skins for young, low BMI, or shorter height were 8.97, 9.48, 7.11 in 100 sample sizes reduced to 0.51, 0.65, 0.36 in 1000. The negative relationship between sample sizes and difference in geometry was also observed in the male statistical models.

With specific attention to the elderly, the isolated age factor on the negative relationship was presented in Figure 1. Figure 1 shows that the mean difference in thorax skin geometry was reduced by around 1% when the sample sizes reached 500 for the 45-year-old cases, and 1000 for the 20-year-old and 70-year-old cases. The variations in the difference for 70-year-olds were almost double the variations in the difference for 45-year-olds, especially in the statistical models taking smaller sample sizes than 800. Furthermore, the negative relationship stabilizes when the statistical model is based on more than 1000 sample sizes. Thus, the sample sizes of a robust statistical model for the elderly were recommended to be greater than 1000.

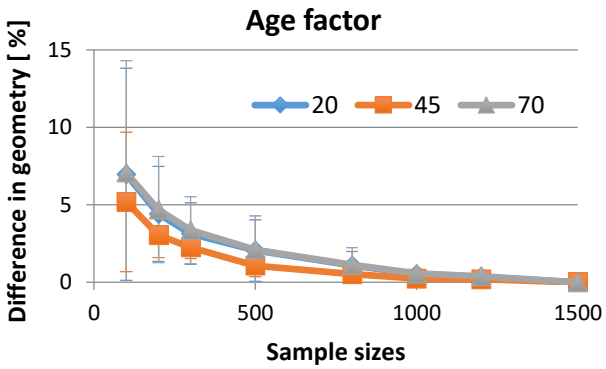

Figure 1: The mean and standard deviation of the difference in geometry as a function of sample sizes in each age group.

This study tested only for the thorax skin. The skin was defined by the soft tissues, so that more variation may be presented than in the geometry defined by the bone tissues. The current study sampled subjects across the adult age population (18 years and above). For the elderly HBMs, the sample could be selected from a more limited age group; smaller sample sizes then might capture the variations.

CONCLUSIONS

This study generated thorax skins by statistical models based on different numbers of subjects. The thorax skin representing a midsize subject experienced the minimum influence based on sample size among individual sets of 27 thorax skins. However, the difference in the statistically-determined thorax skin from the reference for subjects who are not mid value in age, BMI, or height significantly decreased with increasing sample size. Thus, this study suggests more than 1000 for each sex as the sample size for the robust statistical thorax skin model.

RADIOULNAR WRIST COMPRESSION FOR CARPAL TUNNEL SYNDROME TREATMENT: A PRELIMINARY CLINICAL STUDY

[1]Lenicia N. Jenkins, [1]Emily Grandy, [1]Carli Norman, [2]Peter J. Evans, [3]Juliet Hou, [2]William H. Seitz, Jr., [1,2,3]Zong-Ming Li

email: liz4@ccf.org web: http://handlab.org/

INTRODUCTION

Carpal Tunnel Syndrome (CTS) is the most common compressive neuropathy, causing pain, paresthesia, numbness, and tingling in median nerve innervated digits. Routine treatment for CTS involves surgically transecting the transverse carpal ligament, however this procedure is associated with several complications. Conservative treatment methods such as physical therapy, corticosteroid injection, and splinting are also commonly used as a first line of defense, but lack scientific and clinical efficacy. As an alternative, we have developed a method to enlarge the carpal arch using radioulnar wrist compression (RWC) as a means to decompress the median nerve [1, 2]. The purpose of this study was to evaluate the RWC treatment efficacy in relieving hand symptoms and improving hand function in CTS patients. It was hypothesized that daily RWC intervention would alleviate CTS symptoms and improve hand function.

METHODS

Nine patients (6 females, 3 males; 53.67 ± 16.46 years old) were recruited for this study. Individuals were eligible if they were over age 18, clinically diagnosed with CTS, experienced nocturnal pain, numbness or tingling, demonstrated one positive provocative maneuver (Tinel's sign, Phalen's test, or carpal compression test) and/or abnormal nerve conduction finding for the median nerve at wrist. Patients were excluded for any systemic disease (i.e. rheumatoid arthritis, diabetes, osteoarthritis), history of major injury to the wrist or hand, BMI over 30, or were currently pregnant.

The RWC was implemented by an intervention device (Fig. 1) consisting of a thermoformable Exos Wrist Brace with Boa (DJO, Vista, CA), inflatable bladder, and aneroid sphygmomanometer dial and bulb assembly. The brace was molded to stabilize the patient's wrist in an anatomically neutral position. The air bladder, measuring 50mm x 50mm when deflated, was attached with Velcro to the inside of the brace. The bladder was centered on the medial side of the wrist and at the level of hook of hamate to apply radial-ulnar wrist compression, achieving compression forces similar to that implemented in our previous experimental studies [1, 2].

Fig. 1: RWC bracing device worn on the hand (A) and inside view with inflated bladder (*) (B)

Patients performed three RWC bracing sessions daily. Each bracing session consisted of three 5-minute pressurized intervals, with a 1-minute rest between each application. To apply pressure, subjects were instructed to inflate the bladder and maintain the pressure at 140 mmHg. Patients participated over an 8 week period which was subdivided into three phases: pre-intervention (Week 0), intervention (Weeks 0-4), and follow-up (Week 8). Laboratory data collection was performed at weeks 0, 2, 4, and 8. Primary outcome measures used to evaluate intervention effectiveness included (a) Boston Carpal Tunnel Syndrome Questionnaire (BCTQ) [3] including Symptom Severity Score (SSS), Functional Severity Score

(FSS), and Overall Score (OS), and (b) pain, numbness, and tingling intensity using a 0-10 visual analog scale (VAS).

One-way repeated measures ANOVAs or the non-parametric equivalent were performed to determine differences in FSS, SSS, OS and individual VAS scores across intervention time points. Post-hoc Tukey's tests were used for all pairwise comparisons. A significance level of $\alpha = 0.05$ was used for statistical comparisons.

RESULTS

Outcome scores (mean ± SD) are summarized in Table 1. By the second week of intervention, patients' numbness and tingling had significantly decreased ($p<0.05$), as had SSS and OS ($p<0.05$), however pain and FSS had not improved significantly. At Week 4, patients' SSS and OS had decreased by 0.52 ($p<0.05$) and 0.40 ($p<0.01$), respectively, compared to pre-intervention, however FSS reduction (by 0.25) was not significant. Similarly, worst pain ($p<0.05$), numbness ($p<0.001$) and tingling ($p<0.05$) improved between baseline and Week 4. At Week-8 follow-up, SSS remained 0.39 lower compared to pre-intervention, as did FSS and OS (0.1 and 0.26 points lower, respectively), however these BCTQ score changes relative to the baseline were not statistically significant. Worst pain ($p<0.05$), numbness ($p<0.05$), and tingling ($p<0.01$) had all significantly decreased at Week-8 follow-up in comparison to pre-intervention.

Table 1: Clinical outcome scores (mean ± SD) at individual assessment time points

Outcome	Week 0	Week 2	Week 4	Week 8
BCTQ OS	2.50 ± 0.46	2.11 ± 0.50	2.10 ± 0.56	2.24 ± 0.95
BCTQ SSS	2.83 ± 0.45	2.29 ± 0.70	2.31 ± 0.62	2.44 ± 1.03
BCTQ FSS	2.06 ± 0.52	1.86 ± 0.46	1.81 ± 0.52	1.96 ± 0.88
Worst Pain	6.33 ± 3.84	4.44 ± 3.06	4.22 ± 3.27	3.89 ± 3.86
Worst Numbness	7.56 ± 2.19	4.89 ± 1.45	4.56 ± 2.07	3.78 ± 2.91
Worst Tingling	6.44 ± 3.17	4.00 ± 2.00	3.89 ± 2.62	3.33 ± 2.69

DISCUSSION & CONCLUSION

In this study, we utilized radioulnar wrist compression to alleviate symptoms and improve functional performance in patients suffering from CTS. After two and four weeks of 3x daily treatment consisting of 15 minutes of bracing, subjects noted marked symptom improvement. When compared to 8 hours of nightly splinting over a similar time period (1 month), our treatment, 45 min of daily wear, achieved comparable reductions in functional severity (compression -0.25 ± 0.52 vs splinting -0.21 ± 0.34) , and achieved even greater improvements in symptom severity (-0.52 ± 0.53 vs -0.38 ± 0.47) and overall scores (-0.40 ± 0.49 vs -0.29 ± 0.35) [4]. Compared to surgical intervention, in which a BCTQ raw score decrease of 0.47 is considered clinically significant [5], our non-surgical, biomechanical intervention demonstrated comparable overall score reductions between baseline and the end of intervention, indicative of active symptom relief and functional improvement. These results were further supported by patients' diminished worst pain, numbness and tingling after four weeks of intervention. Although BCTQ scores increased between Weeks 4 and 8, follow-up scores did not return to baseline measures, suggesting positive lasting effects of our treatment even after four weeks of no device use. In addition to our objective outcomes, we also received favorable written feedback from participating patients. Several months post follow-up, one patient contacted us to report her CTS symptoms remained 'greatly relieved'. Another subject appreciated that a non-surgical treatment for CTS was in development. One limitation of this study is the relatively short intervention phase and low daily dosage. A long-term intervention with a higher daily dosage may provide added benefits of radioulnar compression for CTS symptom relief. Based on these findings, we can conclude that radioulnar wrist compression may be an effective means to relieve symptoms associated with CTS.

BIOMECHANICAL RESPONSE TO ACUTE PATELLOFEMORAL PAIN IN RUNNING

[1] Carl Jewell, [1]Joseph Hamill and [1] Katherine A. Boyer

[1] University of Massachusetts, Amherst, MA, USA
email: cjewell@kin.umass.edu, web: people.umass.edu/mobl, twitter: @carlmjewell

INTRODUCTION

Patellofemoral pain syndrome (PFPS) is the most common lower limb injury in runners, comprising 20 percent of all running injuries [1]. PFPS is marked by persistence and frequent reoccurrence [2]. Despite our current depth of knowledge of PFPS and its resulting impairments in muscle function and gait mechanics, PFPS treatment often remains ineffective. Altered gait and muscular function may contribute to PFPS but may also result from PFPS-related pain. Thus, there is a need to understand the relationship between pain and altered gait and muscular function with PFPS in order to improve treatment efficacy and patient outcomes. The aim of this study was to examine the impact of a 21-minute treadmill run on self-reported pain, frontal and sagittal plane knee mechanics, and muscle activation intensity in both healthy runners and runners with PFPS.

METHODS

Twenty-two active individuals (11 healthy, 11 PFPS) completed a 21-minute moderate, self-selected paced treadmill run. Rating of perceived exertion (RPE) on a modified Borg scale and knee pain on a Verbal Numeric Rating Scale were measured every two minutes of the run.

Kinematic data were collected unilaterally at 200 Hz. Ground reaction forces were measured using an instrumented treadmill at 1000 Hz. Electromyograms (EMG) were collected from six muscles (medial and lateral gastrocnemii, biceps femoris, lateral and medial vastii and gluteus medius) using a wireless Delsys Trigno system at 2000 Hz. Data for all measures were collected on the same computer for 30 seconds one minute into the run, and during the final 30 seconds.

Angle and moment data were filtered using an 8 Hz low pass, second-order Butterworth Filter. Joint moments presented are internally referenced to the proximal segment. EMG data were wavelet-transformed using 13 non-linearly spaced wavelets and the activation intensity was calculated as the sum of all wavelets for each muscle for each time sample. The net activation intensity (sum of activation intensity over time) was determined for three time windows: pre-contact (50 ms before foot strike), weight acceptance (first 50% of stance), and propulsion (final 50% of stance).

Two-way repeated measures ANOVAs were used to test for differences in the knee angles and moments and in the EMG intensity of each time window at the beginning of the run and in the change over time between PFPS and healthy controls. For kinematic and kinetic measures, testing was performed on waveforms using one-dimensional Statistical Parametric Mapping [3]. Across all outcomes, significance was defined as $p \leq 0.05$.

RESULTS AND DISCUSSION

An increase in pain was found for the PFPS group (2.2±1.8) but not the healthy group with the 21-minute run. Eight out of the 11 participants with PFPS had a clinically significant increase in pain (> 1 point). Each group had a mean change in RPE of 3.1. The healthy group ran at a faster speed (3.30 vs 2.97 $m \cdot s^{-1}$, $p = 0.04$) compared to the PFPS group.

Kinematics

A significant main effect for group was found in knee flexion angle between 34-64% of stance ($p = 0.006$). The PFPS group had a lessor knee flexion angle in this window compared to the healthy group. This may be due to an avoidance strategy to prevent further increases in pain as an increased knee flexion angle can lead to increased patellofemoral joint stress [4]. A significant main effect for run time was found in the knee adduction angle from 20-64% stance ($p =$

0.002). This indicates that over the course of the 21-minute run, knee adduction angles decreased in both groups. No group*time interactions were present in either plane.

Kinetics

For joint moments, there was a significant main effect for group in the sagittal plane between 0-5% stance ($p = 0.043$) and 20-44% stance ($p < 0.001$). This indicated a greater initial knee flexion moment at footstrike and a larger extension moment in midstance in the PFPS group relative to healthy controls. This result is in contrast to previous work investigating healthy individuals' response to experimental knee pain that found decreased knee extension moments with greater pain severity [5]. The PFPS group, despite an increase in pain, showed no adjustment in knee extension moment. It is possible that some form of long term adaptation to unsuccessful pain reduction blunted this response.

There was much greater variance for the PFPS group relative to healthy in the frontal plane moments, with a significant main effect for group in the final 10% of stance (p=0.034). This was marked by a small adduction moment in the healthy group and a small abduction moment in the PFPS group. This increased variance in this moment could be due to a lack of control in frontal plane loading due to PFPS. No group*time interactions were present in either plane.

Electromyography

There were no significant group differences found in EMG. There were also no significant differences found for time in the pre-contact window. During weight acceptance, there was a significant main effect for time (p=0.002) indicating a decrease in total gluteus medius activity between the beginning and end of the run. During propulsion, there was also a main effect for time (p=0.024), indicating a decrease in total biceps femoris activation between the beginning and end of the run. These results indicate that despite differences in kinematics and kinetics between healthy runners and those with PFPS, the muscles included in this investigation showed no difference in net activation intensity. It is possible that other metrics of EMG, such as timing or duration of activity, may uncover differences between groups related to a pain response.

CONCLUSIONS

Individuals with PFPS have different kinematic and kinetic patterns at the knee at baseline compared to healthy runners. Those with PFPS do not appear to adapt their mechanics in response to an acute change in pain, suggesting that the gait differences observed may arise in part from an adaptation to chronic pain or that the abnormal mechanics are what leads to the observed pain increase.

GAIT PERFORMANCE IN BIPOLAR DISORDER: A 6-MONTH PILOT LONGITUDINAL STUDY

[1*] Gu Eon Kang, [2] Brian J. Mickey, [1] Melvin G. McInnis, [1] Barry S. Krembs and [1] M. Melissa Gross

[1] University of Michigan, Ann Arbor, MI, USA
[2] University of Utah, Salt Lake City, UT, USA
[*]email: guekang@umich.edu

INTRODUCTION

Bipolar disorder is a severe mood disorder that is characterized by periods of (hypo)mania and depression, with euthymia, a relatively normal mood state [1], for which objective biomarkers have not been developed yet. In the United States, lifetime prevalence of bipolar disorder is 4.4% among adults [2]. Diagnoses of bipolar disorder are based on evaluating clinical criteria such as abnormal motor behavior [1]. However, the evaluation of the behavioral symptoms depends on qualitative self-report only and lacks objective basis, resulting in subjective assessments with limited reliability.

Gait performance can be measured quantitatively and expresses emotional state [3]. In addition, gait performance can be easily tested in clinics, thus may have potential as objective clinical criteria; however, too little information about gait performance and bipolar disorder has been established until now. Therefore, the purpose of this study was to investigate gait variables in bipolar patients (BP) across mood states and healthy controls (HC) over the course of a 6-month period.

METHODS

BP and HC were recruited from the Heinz C. Prechter Longitudinal Study of Bipolar Disorder Cohort [4]. BP had no history of neurological or orthopedic conditions. HC had no history of psychiatric, neurological or orthopedic conditions. Participants completed baseline (31 BP; 14 HC) and 6-month follow-up sessions (24 BP; 13 HC). Manic and depressive symptoms were assessed using the 5-item Altman Self Rating Mania Scale (ASRM; total score of 20; on a score of 0-4 per item) [5] and the 9-item Patient Health Questionnaire (PHQ-9; total score of 27; on a score of 0-3 per item) [6]. Baseline mood symptoms for BP were categorized into hypomania (n=5; ASRM≥6; PHQ-9<6), euthymia (n=14; ASRM<6; PHQ-9<6) and depression (n=12; ASRM<6; PHQ-9≥6).

Participants performed gait trials on an 8-meter walkway five times at each of comfortable, slow and fast speeds. Preliminary analyses revealed gait performances were similar in slow or fast speeds in BP and HC [7], thus this study included only data from comfortable speed. Data from marker and ground reaction forces (GRFs) were collected at 120 and 1200 Hz, respectively, using a 16-camera motion capture system (Motion Analysis, Santa Rosa, CA) and two force plates (AMTI, Watertown, MA), and were low-pass filtered at 6 and 50 Hz, respectively. Visual3D (C-Motion, Germantown, MD) was used to compute gait speed during one gait cycle, and peak anterior-posterior and vertical GRFs in the first half of stance. Mean values for baseline anthropometric and gait data were compared among BP-hypomania, BP-euthymia, BP-depression and HC using one-way ANOVA with Tukey correction. Correlations between baseline mood scores and gait data were determined for BP using coefficient of determination (R^2). Changes in anthropometric and gait data between baseline and 6-month follow-up sessions were compared between BP and HC using independent t-test. Correlations between changes in mood scores and gait data between baseline and 6-month follow-up sessions were determined using coefficient of determination. A $p<0.05$ value was used to detect significant differences among means.

RESULTS AND DISCUSSION

Baseline results showed that age and body mass index were not significantly different among BP-hypomania (45.2±15.1 years; 26.5±5.5 kg/m^2), BP-euthymia (38.7±10.5 years; 26.5±4.1 kg/m^2), BP-depression (38.4±9.3 years; 27.0±6.9 kg/m^2) and HC (42.2±12.6 years; 25.6±5.1 kg/m^2) (all $p>0.05$).

Mean gait speed was greater for BP-hypomania (1.48±0.21 m/s) than for BP-euthymia (1.21±0.15 m/s), BP-depression (1.14±0.26 m/s) and HC (1.22±0.12 m/s) (all $p<0.05$). Mean values in peak anterior-posterior and vertical GRFs in the first half of stance (fraction of body weight) were greater for BP-hypomania (0.25±0.07 and 1.22±0.18, respectively) than for BP-euthymia (0.18±0.03 and 1.09±0.09, respectively), BP-depression (0.16±0.05 and 1.06±0.09, respectively) and HC (0.18±0.03 and 1.07±0.06, respectively) (all $p<0.05$). Within BP, gait speed and peak anterior-posterior and vertical GRFs were significantly correlated with manic scores (R^2=0.247, 0.347 and 0.333, respectively) (all $p<0.05$), but not with depressive scores (R^2=0.034, 0.069 and 0.037, respectively) (all $p>0.05$).

For both BP and HC, body mass index was not significantly different between baseline and 6-month follow-up sessions (all $p>0.05$). Changes in gait speed (m/s), and peak anterior-posterior and vertical GRFs were not significantly different between BP (-0.02±0.17, 0.00±0.04 and -0.01±0.12, respectively) and HC (-0.03±0.16, 0.01±0.03 and 0.03±0.09, respectively) (all $p>0.05$). Within BP, changes in peak vertical GRFs between baseline and 6-month follow-up sessions showed significant negative correlation with changes in depressive scores (R^2=0.180) ($p<0.05$) but not with changes in manic scores (R^2=0.047) ($p>0.05$). Changes in mood scores, and gait speed and peak anterior-posterior GRFs were not significantly correlated with manic (R^2=0.001 and 0.082, respectively) and depressive scores (R^2=0.098 and 0.018, respectively) (all $p>0.05$).

CONCLUSIONS

Results suggest that gait speed and peak GRFs may reflect mood symptoms in BP. Changes in GRFs were associated with changes in mood symptoms over the longitudinal course. Monitoring speed and GRF-related variables (i.e., foot contact pressure) in the community and clinic using wearable equipment could help detect and predict mood symptoms. In conclusion, gait variables may have potential as behavioral biomarkers for BP

Wearable Sensors for Assessment of Varus Thrust in Knee Osteoarthritis: A Proof of Concept

[1] Deepak Kumar, PT, PhD; [1]Victoria Brus; [1]Chun Jui Lin; [1]Julie Osipow, BA; [1]Alex Geronimo, MS; [2]Jim Richards, PhD

INTRODUCTION

Knee osteoarthritis (OA) affects 12% of American adults over the age of 55 years, and is the leading cause of disability in the US. There is no available treatment to slow the progression of knee OA. Up to 50% of people with knee OA exhibit a varus (adduction) thrust during walking. Varus thrust is associated with knee pain and stiffness,[1] measures of knee loading including KAM,[2] and most importantly, a 4x greater risk of medial knee OA progression.[3] It may be possible to reduce the varus thrust by means of devices (braces), exercises (gait retraining, neuromuscular exercise), or surgery. However, previous research has been based on either visual determination of presence/absence of varus thrust, or quantification of angular knee kinematics in an expensive gait lab. An inexpensive technique to quantify the presence and magnitude of varus thrust is acutely needed for clinical research on interventions to reduce varus thrust.

The objective of this study was to evaluate the feasibility of using gyroscopes within wearable inertial sensors for assessment of the angular knee velocity in the frontal plane,[4] a known biomechanical marker of varus thrust, in people with medial knee OA.

METHODS

So far, data from 10 participants (Age = 65.8±7.1 years; BMI = 28.7±4 kg/m^2; 5 men, 5 women) are included in these analyses. The participants were recruited from the community using advertisements. The inclusion criteria were age between 45 and 80 years, BMI ≤ 35 kg/m^2, frequent knee pain, and radiographic medial knee OA. Exclusion criteria were use of walking aid, inflammatory arthritis, total knee replacement, neurological disorders, and other conditions that could affect gait. All participants underwent weight-bearing fixed flexion radiographs for Kellgren-Lawrence Grading (KLG) and joint space width measurements and long-limb radiographs for measurement of alignment. All participants also completed the Knee injury and Osteoarthritis Outcome Score (KOOS).

All participants completed 3D gait analyses while walking at their self-selected pace and their fastest pace. Kinematic data were collected with a 12 camera passive motion capture system @ 250 Hz and ground reaction forces were collected using floor-imbedded force platforms @ 2000 Hz. A cluster-based marker set was used and high-resolution 2D color video was also recorded during all trials. Marker and GRF data were processed to calculated knee joint angles, angular velocities, and moments. Additionally, inertial sensors (@ 148 Hz, upsampled to 2000 Hz) were placed on the shank and thigh clusters, and distal lateral tibia. The sensors included tri-axial accelerometer (± 16g), triaxial gyroscope (± 2000 deg/s) and triaxial magnetometer (± 1000 μT)(Delsys Inc, Natick, MA, USA). For these analyses, only the gyroscope signal was used. Peak knee angular adduction velocity was calculated from motion capture data, as well as, the three gyroscopes, during loading response phase (initial contact to peak knee flexion). Correlations were assessed between the gyroscope and motion capture data across all participants.

RESULTS AND DISCUSSION

There was 1 participant with KLG2, 6 with KLG3 and 3 with KLG4. Mean medial joint space width was 2.3±1.2 mm and mean alignment was

175.3±3.3° (<180° = varus). KOOS scores for the participants were as follows – Pain = 66.8±10.6, Symptoms = 57.8±9.4, Activities of Daily Living = 66.2±16.3, Sports/Recreation = 46±17.1, and Quality of Life = 41.9±11.8.

Correlations between knee angular velocity from motion capture and gyroscope data during the two tasks are shown in Table 1. Lateral tibia gyro accounted for 53% and 73% of the variability in knee angular velocity during the self-selected and fast pace conditions.

CONCLUSIONS

These preliminary findings suggest that a single inexpensive gyroscope sensor on the distal lateral shank may allow for assessment of varus thrust during walking in people with medial knee OA. This approach could allow for clinical identification of the presence and magnitude of varus thrust without reliance on 2D video or expensive gait labs. Hence, this technology could be used in future clinical trials to evaluate the efficacy of interventions to reduce varus thrust and slow the progression of knee OA.

INTRODUCTION

Breast cancer survivors (BCS) may encounter upper limb morbidities post-surgery. Impairments such as reduced range of motion, reduced strength, pain, and lymphedema are commonly reported post-treatment [1]. BCS have a higher occurrence of other secondary morbidities, including rotator cuff disorders (RCD). It is currently unclear how these impairments affect arm kinematics, particularly during functional task performance, and how possible changes affect future injury risk or RCD development.

Limited documentation of BCS shoulder kinematics suggests conflicting results for scapular motion. In the first year after treatment, increased protraction and decreased anterior tilt have been reported, but there is no indication that these alterations remain longer term [2]. Past the first year of treatment, BCS with no indication of RCD may have higher scapular upward rotation than controls during arm elevation [3], but it is unknown if these alterations affect functional tasks performance.

The purpose of this investigation was to examine upper body kinematics during a waist to overhead lift for BCS and an age matched control group.

METHODS

Breast cancer survivors between the ages of 35 and 65, who had undergone mastectomy at least six months prior to participation, and were able to lift their arms above shoulder height were recruited from community advertisements. A control group of women in the same age range with no known upper limb impairments also participated.

Prior to task performance, all participants completed consent forms and the Quick Disability of Arm Shoulder and Hand (QuickDASH) questionnaire and were evaluated with three impingement tests (Neer, Hawkins-Kennedy, and empty can). A positive on any test warranted exclusion from the control group. For the waist to overhead lift, a shelves set at approximate waist and forehead heights. Participants lifted a weighted standard size milk crate (total load: 6.2 kg) between these two shelves 5 times in row. After a rest period, this was repeated twice. Motion of the torso and upper limbs was tracked with 10 VICON MX-T40 (Vicon Motion Systems, Oxford, UK) optoelectronic infrared cameras and reflective markers were placed on the skin near anatomical landmarks per ISB standards.

Torso, scapular, and thoracohumeral angles were calculated for all trials and split into cycles. A cycle was defined from the first upward movement of the hands to when the hands reached maximum height. Mean and maximum angles were calculated for each cycle and averaged within each participant. Torso and upper arm angles were compared between groups and to normative values from young, healthy adults performing the same lift [4]. Differences between the three groups were determined via one-way ANOVAs ($p<0.05$) and confirmed with Tukey HSD. For scapular angular kinematics, BCS were split into 2 groups based on pain in impingement tests and compared to age-matched controls with one-way ANOVAs ($p<0.05$).

RESULTS AND DISCUSSION

BCS reported significantly higher QuickDASH scores. Out of 16 BCS, 11 reported pain on at least one impingement test (Table 1).

Compared to younger controls, BCS presented with higher average torso flexion (-5.0 compared to 4.9, $p = .037$) and less peak arm abduction during the waist

to overhead lift (126.1 compared to 137.0, p = .027). Age-matched controls did not differ from either group. However, both BCS and age-matched controls had more horizontal flexion than the younger group (Figure 1).

While trends indicated BCS and age-matched controls differences, i.e. humeral abduction and axial rotation, none were significant. However, dividing BCS by impingement test status identified lower peak scapular upward rotation for BCS with pain than controls (-27.8 vs -35.8, p = .016) (Figure 2).

Kinematic alterations of BCS suggest impingement pathways. Increased torso flexion throughout the lift may reflect a kyphotic thorax commonly observed in BCS [5]. This torso position combined with decreased humeral abduction and scapular upward reduction may decrease available subacromial space, thereby raising rotator cuff tendon impingement risk [6]. Further, an average decrease of peak humeral external rotation of 7 degrees existed in BCS with impingement pain, which is also associated with RCD. The collective effects of BCS and RCD status indicate important pathological kinematics existed during functional task performance.

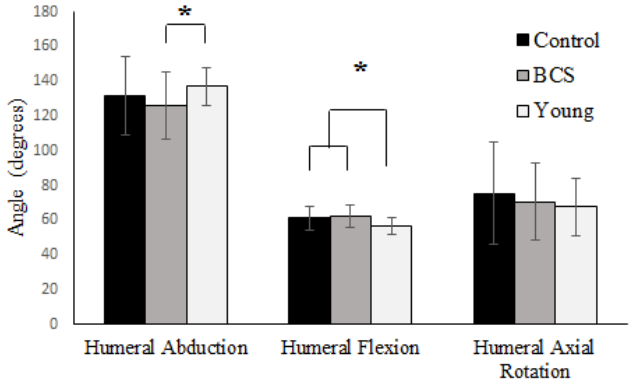

Figure 1: Peak humeral angles for BCS, age-matched controls, and young controls (+ve values for axial rotation represent external rotation).

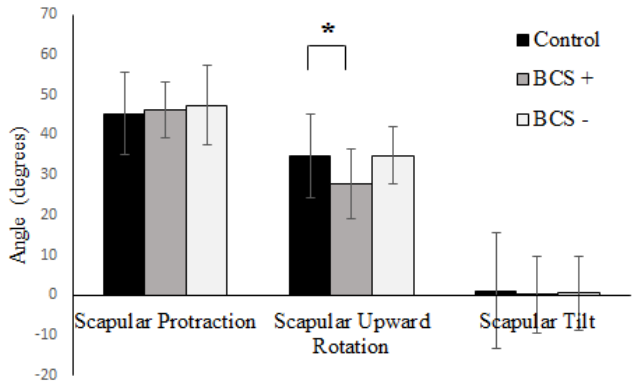

Figure 2: **Peak scapular angles with impingement test results (+ve vales represent protraction, upward rotation and anterior tilt, respectively). BCS + = 1+ positive impingement test; BCS – = 0 positive tests; Control = age-matched.**

CONCLUSIONS

Breast cancer survivors past the initial recovery stage demonstrated kinematic alterations in overhead lift performance. However, these alterations appear to be more strongly influenced by presence of RCD in BCS. It is not currently clear if these alterations are the cause or result of the pain.

INTRODUCTION

In the clinic, it can be useful to measure gait kinematics and kinetics to determine the outcome measures and effectiveness of treatment. Maintaining and operating a research-grade gait analysis system, however, can be time consuming and cost-prohibitive. A low-cost gait analysis system would allow higher reliability of quantitative assessment that could be more broadly utilized in clinical settings to promote evidenced based outcomes (Rathinam et al, 2012).

Our objective was to validate the performance of a portable gait analysis system that utilizes widely available, affordable technology. We hypothesized that a low-cost system could perform comparably to a popular laboratory grade gold standard system in terms of forces (within ±5% bodyweight) and kinematics (within ±3°).

METHODS

Five healthy, recreationally fit subjects (163.9±11.9 cm, 62.7±19.2 kg, 2 males) gave informed consent prior to participating in this Georgia Tech IRB approved protocol.

The low-cost gait analysis system consisted of four major parts. A Wii Balance Board (WBB, Nintendo, Kyoto) provided ground reaction force (GRF) data and was embedded within a custom wooden walkway (731.5 cm x78.7 cm). We obtained sagittal plane video data (60 Hz) using a portable camera (GearPro GDV285, New York). We performed kinematics analysis using an open source motion-tracking software (Kinovea.org). The total cost of this system was under $300.

The research grade system consisted of a force platform (AMTI, Watertown, MA) and a six-camera motion analysis system (Vicon, Oxford) sampled at 1080 Hz and 120 Hz, respectively. The WBB was mounted on top of the force platform within the walkway to allow simultaneous collection of all data for a given trial. Only vertical ground reaction forces were compared since the WBB only measures this one component of force.

We performed static calibration trials with known weights (25-126 lbs) and a rigid phantom with a known angle (90^{o}) to record and compare the two systems. We also collected data from both systems simultaneously as subjects walked on the walkway. We used high contrast 2D markers for the low-cost system and retroreflective spherical markers for the Vicon system. Ground reaction forces (GRF) and sagittal plane segment angles were collected and analyzed.

We used custom MATLAB software to analyze the GRF and segment angle data from the laboratory grade system. We used standard spreadsheet software (Microsoft Excel) to analyze the data from our low-cost system and compared the two systems with percent error and absolute error metrics using a paired t-test (alpha=0.05). Bland-Altman plots were used to visualize the means and differences between the two systems.

RESULTS AND DISCUSSION

In static validation trials, the WBB measured weights to be 2.0-3.7% heavier than the force plate. Human walking trials showed similar GRF trajectories across the two systems (Figure 1). Across subjects, the difference in vertical GRF at the first peak GRF was non-significant, with the average difference across trials being ≤3.04%BW.

Maximum GRF errors measured across the gait cycle for each subject were between 25-53%BW, which largely occurred at the end of stance phase.

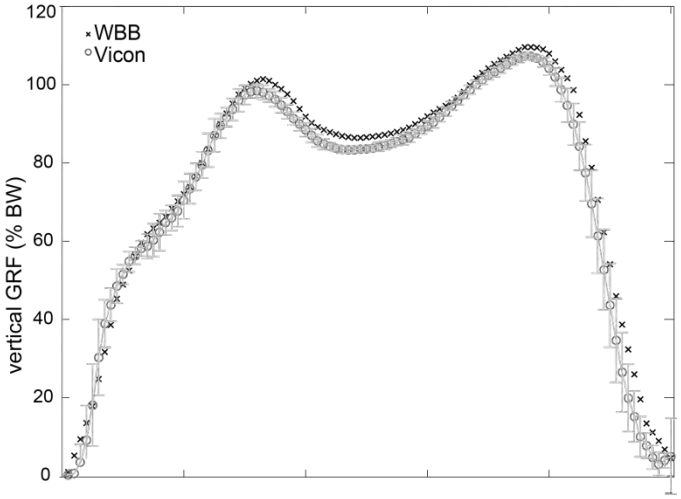

Figure 1: Vertical ground reaction forces from a representative trial measured with WBB (x's) and AMTI force plate (circles).

We accepted our hypothesis that the WBB could measure peak GRF during gait within 5% of a research-grade force plate. The greatest errors in GRF data occurred at times when force values changed rapidly but were consistent with previous studies [2]. The larger errors in GRF during highly dynamic periods of stance suggest an inconsistent sampling rate of the WBB as the cause rather than inaccurate force measurement.

Segment angles measured in Kinovea were similar to Vicon-measured angles for the shank, thigh, and, to a lesser extent, the foot (Figure 2). For the foot, the largest average difference between systems for any subject was 3.2° while the largest differences for the shank and thigh were 2.8° and 2.2°, respectively. The pelvis exhibited the largest errors, with maximum differences between 4.8° and 11.0°. The foot, thigh, and shank angles were more accurate than the pelvis angle for both individual subjects and the group average.

The hypothesis that the Kinovea/GearPro system could measure segment angles within 3° of the Vicon system was partially supported. The higher errors of the pelvis and foot segment angles were likely due to placement of the Vicon pelvic and toe markers relative to the low-cost markers. The high contrast markers taped to the skin for Kinovea (e.g. over the ASIS) were not as clearly visible in the sagittal plane view of the video camera.

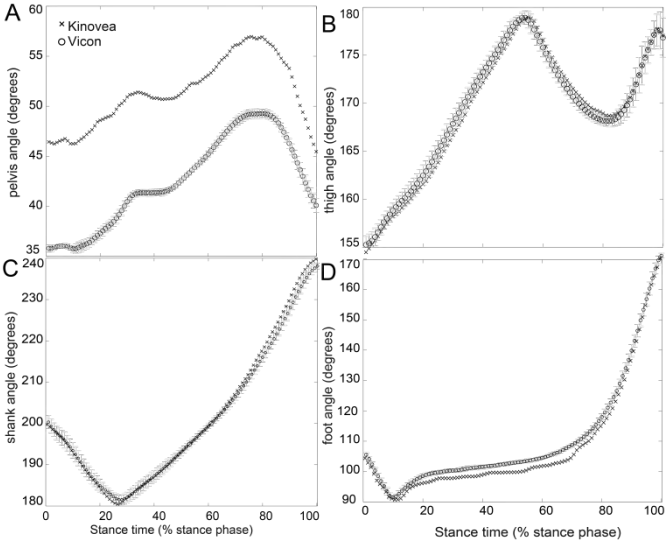

Figure 2: Sagittal plane segment angles for the pelvis (A), thigh (B), shank (C), and foot (D) from a representative walking trial measured by the low-cost system (x's) and by the Vicon system (circles).

CONCLUSIONS

The proposed system has the potential to provide a low-cost, quantitative gait analysis system to inexpensively measure gait kinetics and kinematics. The system was particularly accurate for key parameters such as peak force during gait and thigh and shank segment angles. It can be used to aid in determining effectiveness of various clinical approaches in prosthetics and orthotics without the need for a costly laboratory grade motion analysis system. This system could also provide an affordable solution for classrooms and outreach.

INTRODUCTION

Musculoskeletal neck pain is a significant healthcare problem. One-year prevalence rates for neck pain are between 20-40% and nearly two-thirds of the general population will experience some form of neck pain in their lifetime [1]. Muscle strength and endurance are common targets for neck pain rehabilitation and deficits may be contributory risk factors for its development. Indeed, reduced cervical muscle endurance was a significant predictor of first-time onset of neck pain in a prospective study of office workers [2]. Additional loads, such as military helmet attachments (i.e. night vision goggles) create higher cervical muscle activity to accommodate the increased head mass and altered center of mass [3], thereby potentially elevating the risks of developing neck pain.

Unfortunately, it is unclear what level of neck strength is needed to reduce risk levels. Further to predict high-risk levels of neck torque during functional tasks, high quality normative neck strength data is required. However, relatively few studies of normative strength are available in the literature for the cervical spine compared to other joints, and none assessing 3 planes of motion, considering multiple isometric angles and isokinetic velocities. This information is important for predicting strength requirements for functional tasks, ergonomic applications, or helmet design.

Thus, the primary goals of this project were to 1) comprehensively assess cervical strength for each cardinal plane of cervical spine motion, considering multiple angles and velocities in healthy men and women and 2) develop normative mathematical models to represent cervical strength. Secondarily, we aimed to differentiate capital neck strength (i.e., head on neck caption) from full cervical neck strength in the sagittal plane (i.e., flexion and extension).

METHODS

56 participants (28M, 28F) completed 2 visits assessing peak neck strength. All subjects provided written informed consent, as approved by the Western Institutional Review Board. Isometric and isokinetic neck peak torque (Nm) was assessed using the Biodex System 3 Isokinetic Dynamometer (Biodex Medical Systems, Shirley, New York) in the sagittal (flexion/extension, FE), frontal (side-bending, SB), and transverse (rotation, RO) planes of motion. Custom attachments were built for each test, and secured to the head with Velcro straps. For the FE and SB testing, participants were seated and securely strapped into a chair to minimize unwanted movement. RO testing was performed supine on a plinth. For each plane, isometric strength was assessed prior to isokinetic strength (**Table 1**). During capital FE, only isokinetic strength was tested.

Table 1: *Neck strength protocol.*

	Angle (deg)	Velocity (deg/s)
Cervical FE	-25, -15, 0, 15, 30	30, 60, 90, 120
Capitol FE	-15, 0, 15	60, 75, 90, 120
Lateral SB	-25, -15, 0, 15, 25	30, 60, 90, 120
RO	-30, -15, 0, 15, 30	30, 60, 90, 120

Note: +/- angles represent flexion/extension for FE and left/right for SB and RO, respectively.

Mean peak torques for each angle and velocity combination (4 velocities, 3 to 5 angles), for each test plane were determined for men and women separately. These mean data were plotted as 3D strength surfaces, with peak torque as a function of joint angle and movement velocity. Mathematical models of the 3D strength surfaces were curve fit using logistic regression (TableCurve 3D, SYSTAT) [4].

RESULTS AND DISCUSSION

Normative neck strength models were fit for male and female cervical and capitol FE, SB, and RO. Only cervical flexion and extension are shown in **Figures 1 and 2** due to space constraints. Extension stre[illegible] me[illegible] vel[illegible]
